Abstract: Face recognition ability is important for social interaction. In our previous studies, we have shown that face-responsive neurons in the temporal cortex of macaque monkeys represented information about a global category of stimuli, namely, human vs. monkey vs. shapes earlier than information about more detailed categories associated with facial expression and identity (Sugase et al., 1999; Sugase-Miyamoto et al., 2014). In this study, we further investigated the correlation between receptive-field characteristics of face-responsive neurons and the temporal processing stages. Neuronal activities were recorded in area TE of one rhesus monkey (*Macaca mulatta*) performing a fixation task. Test stimuli were colored pictures of monkey faces, human faces (three models with three expressions, respectively) and geometric shapes. The size of the stimuli was within 6° x 6°. To identify the receptive field of each neuron, a stimulus that evoked the strongest response was presented at one of 15 positions (in a 5 x 3 grid located in the center of the monitor, the size of each cell was 6° x 6°), while the monkey fixated a central fixation point. To determine the dependence of each neuron on the stimulus position, the responses to the stimulus at each position were averaged in a window 50-450 ms after the stimulus onset, and the baseline activity (the average response during 400 ms before the stimulus onset) was subtracted, and the responses were normalized. To visualize the dependence on the stimulus position across 25 face-responsive neurons, principal component analysis was applied on the normalized responses across 25 face-responsive neurons. It revealed that the receptive fields can be classified into three groups according to the scores for the first principal component: central visual field type (n = 12), wide field type (n = 7) and others (n = 6). Mutual information was calculated for the neuronal responses of each type when the test stimulus was presented at the center of the screen. The neurons of the central visual field type represented information about both the global category of the stimuli (monkey faces, human faces or shapes) and the more detailed facial category items (individuals and expressions). The neurons of the wide field type represented information about the global category. Together with our previous findings, these results suggest that the global information is rapidly processed by both the central and wide visual field types of face-responsive neurons, while the information about the facial identity and expression is relatively slowly processed by the central visual field type.

Title: Evaluating approaches for reconstructing face images from distributed patterns of fMRI activity

Authors: *M. L. DRASCHER[1], H. LEE[2], B. A. KUHL[1]
[1]Psychology, Univ. of Oregon, Eugene, OR; [2]New York Univ., New York, NY

Abstract: Reconstruction of visual stimuli from neural data has been a valuable tool for understanding how stimuli are represented in the brain, and further, how these representations both vary across cortical regions and change in response to task demands. Previous efforts to reconstruct stimuli from neural data have run the gamut from simple line gratings (e.g. Serences et al., 2009; Kamitani & Tong, 2005) to complex, dynamic stimuli such as movies (e.g. Nishimoto et al., 2011). Here, we consider reconstruction of face images—a stimulus class of particular interest because (a) faces can be readily dimensionalized and (b) humans are highly skilled at perceiving and remembering faces.

We have recently demonstrated that face images can be successfully reconstructed from human fMRI data utilizing an unsupervised approach in which face images are first dimensionalized using the Eigenface model and face dimensions are then mapped to fMRI activity patterns (Cowen, Chun, & Kuhl, 2014; Lee & Kuhl, 2016). More recently, Chang & Tsao (2017) achieved high-fidelity reconstructions of faces from electrophysiological recordings of macaque monkeys. They found that an alternative model for dimensionalizing face stimuli—the Active Appearance Model (AAM)—yielded significantly more accurate reconstructions than an Eigenface model. The AAM also has the added benefit of dissociating shape and non-shape dimensions of face stimuli, which allows for potential dissociation of face processing regions that code for shape vs. non-shape face features.

Here, we replicate and extend the findings of Chang & Tsao (2017) by applying a similar AAM-based reconstruction approach to human fMRI data. In the scanner, participants completed a continuous recognition memory task with 432 unique face images. Consistent with the findings by Chang and Tsao, we found reliable face reconstructions using the AAM approach and that this model performed better than the Eigenface model. Above-chance reconstructions were obtained from voxels widely distributed across visual cortical areas as well as from regions outside of visual cortex. Additionally, successful reconstructions were obtained both for the shape and non-shape dimensions of faces with partially distinct populations of voxels representing shape vs. non-shape dimensions.

Finally, we consider potential applications of AAM-based face reconstructions for measuring and characterizing the representations of stimuli in visual perception and memory.

Title: MEG decoding reveals early representations of face identity, age and gender that are enhanced by familiarity

Authors: *K. DOBS, L. ISIK, D. PANTAZIS, N. KANWISHER
MIT, Cambridge, MA

Abstract: From a brief glimpse of a face, we extract not just the presence of a person, but many different kinds of information about that person, such as their gender, age, familiarity and specific identity. Here we ask two questions. First, how quickly are these specific dimensions of face information extracted, and do some arise before others? Second, given the considerable evidence that familiar faces are processed differently than unfamiliar faces, which of these dimensions are affected by familiarity, and how early in processing do these effects occur?
To answer these questions, we used Magnetoencephalography (MEG) and representational similarity analysis (RSA) to measure the time course of extraction of each of these dimensions of face information and their modulation by familiarity. Subjects (n = 16) viewed 80 different face images (five images of each of 16 different celebrities), while monitoring for consecutive repetitions of identical images (one-back task). Each of the 80 images was presented 28 times upright and 28 times inverted in separate sessions (in counterbalanced order). Half the celebrities were familiar (US actors) versus unfamiliar (German actors), young (< 36 years) versus old (> 59 years), and female versus male.
RSA analyses showed that we could decode identity, gender and age of face images within 130 ms after stimulus onset, significantly later than image decoding (i.e. discriminating any pair of stimulus images; $p < 0.05$, peak analysis), which occurred ~100 ms after stimulus onset. To further exclude the contribution of low-level stimulus features, we computed correlations between representational dissimilarity matrices derived from candidate models (identity, gender and age) and MEG neural data, while partialing out the correlation between similarity patterns based on physical stimulus features (e.g. image pixels or early layers of a face deep neural network). All model correlations remained significant ($p < 0.05$, sign permutation test) suggesting that this decoding is unlikely to be accounted for by low-level image properties, a

conclusion further supported by the fact that decoding accuracy was significantly reduced by face inversion ($p < 0.05$, peak analysis). Importantly, familiarity significantly enhanced the decoding accuracy of all three face dimensions (age, gender, and identity), and did so at similar latencies for each dimension (~120 ms after stimulus onset).
Overall, our results indicate that different kinds of face information become available extremely rapidly, within 130 ms of stimulus onset, and that familiarity enhances representations of face dimensions already at this early stage.

Title: Selectivity for individual body parts within body selective visual cortex

Authors: *A. BRATCH[1], L. VIZIOLI[2], E. YACOUB[2], S. A. ENGEL[1], P. C. BURTON[3], D. J. KERSTEN[1]
[1]Dept. of Psychology, [2]Dept. of Radiology, [3]Office of the Associate Dean for Research, Col. of Liberal Arts, Univ. of Minnesota, Minneapolis, MN

Abstract: Spatially localized patches of cortex containing neurons selective for specific features are a major characteristic of sensory cortices. Such organization has been well demonstrated for simple visual features in primary visual cortex (e.g., orientation, ocular dominance, etc.) using electrophysiology in primates. In recent years, ultra-high field (7T) fMRI has afforded the ability to investigate these organizational principles non-invasively in humans. While these methods have revealed the same organization in primary visual cortex, it remains unclear the extent to which similar organization is present for higher level visual features represented in later visual areas. Here, we tested for the spatial organization of responses to images of individual body parts in the extrastriate body area (EBA), a cortical region that responds selectively to images containing the human body (Downing et al., 2001). Using 7 Tesla fMRI with a gradient echo pulse sequence (0.8 mm isotropic resolution, TR = 2.2 s, TE = 26.4 ms, 84 slices, iPat = 3, multiband = 2), we measured neural activity in 3 human subjects. Subjects viewed images of 5 different body parts (hands, arms, feet, legs, and torsos) in a blocked design. Functional localizers for object, motion, and body selective cortex were run in separate scans. We found that

the right EBA is actually comprised of three areas surrounding motion selective area MT, replicating the results of Weiner and Grill-Spector (2011). We then implemented a winner-take-all procedure, based on the response amplitude to each body part on a voxel-by-voxel basis, to create voxel preference maps. Cross validation on an independent portion of the data was used to assess the consistency of these maps and to establish tuning curves for each subject. Statistical significance was inferred using 95% bootstrap CIs. In all 3 subjects, this analysis revealed patches of voxels in the left and right EBA showing reliable tuning for all 5 individual body parts, with the strongest tuning found in patches selective for hands and torsos. These data not only reveal a distinct organization of body selective visual cortex but demonstrate spatial organization of high level visual features in human visual cortex. Furthermore, this work provides the foundation for assessing whether these patches are arranged topographically and whether they extend uniformly through cortex.

Title: Face coding in the macaque perirhinal face patch

Authors: *L. SHE, D. Y. TSAO
Caltech, Pasadena, CA

Abstract: Face-selective regions in inferior temporal cortex encode the identity of visually perceived faces, but how this code interfaces with memory remains unclear: how is a new face remembered, and how is this memory re-activated during perception? To address this, we recorded in a face patch located in perirhinal cortex, a region that has been strongly implicated in processes related to visual memory. We used fMRI to locate the perirhinal face patch (PR). Single-unit recordings targeted to this region revealed a high concentration of face-selective cells. Measurement of responses to human faces, monkey faces, and objects, at different views and levels of familiarity (personally familiar, pictorially familiar, and unfamiliar), revealed that most cells were view tolerant and modulated by both identity and familiarity. Measurement of responses of each cell to thousands of human and monkey faces revealed that many cells inherit

the previously described “axis code” of IT face patches (Chang and Tsao, Cell 2017). A subset of these were also modulated by familiarity, and some cells were even ‘grandmother cell’-like, responding only to a few faces, often personally familiar. In addition, we found that PR cells are strongly modulated by scene context, often showing a nonlinear interaction between face and context. Together these results suggest that PR cells implement a critical stage in the process of face memory storage and retrieval.

Title: Reflexive gaze following in common marmoset monkeys

Authors: *S. SPADACENTA, P. DICKE, P. THIER
Hertie Inst. for Clin. Brain Res., Tübingen, Germany

Abstract: The ability to follow the gaze of a conspecific to an object of interest to the other allows human observers to shift the attention to the same object, i.e. to establish joint attention. The observer may develop a concept of the other's desires, beliefs and intentions, in short a theory of mind (ToM), by attributing his own assessment of the object significance to the other. Although old world monkeys such as macaques may lack a full-fledged ToM, they are able to deploy gaze following and joint attention, essential social skills, orchestrated by a generic gaze following network with a central node in the superior temporal sulcus, likely shared with humans. The common marmoset is a highly social species of new world monkey which separated from the old world line about 30 million years ago. Casual observations indicate that marmosets are interested in the other´s face and that they may follow the gaze. Yet, it has been unclear if they establish joint attention, which features of the other one may be relevant for gaze following and joint attention and if the underlying brain circuitry is similar and eventually homologous to those of old world primates. As a first step to address these and related questions we embarked on quantitative behavioral experiments deployed in a well controlled experimental environment. We trained 3 marmosets to voluntarily enter a monkey chair and accept immobilizing their heads by permanently implanted head holders to measure eye movements using video eye tracking. Our animals were then studied in a free choice task. This started with the presentation of a central dot which had to be fixated for 500 msec. If fixation was acquired, at the end of the 500 msec a portrait of a marmoset face looking either to the left or the right

appeared in the center of the screen. After a viewing time of 100 to 600 ms, varied at random from trial to trial, during which the animal was allowed to freely explore the portrait, the face disappeared while at the same time two peripheral targets popped up. The monkey was rewarded with a small amount of marshmallow or fruit juice if it executed a saccade to either one of the two targets within 500 ms. Both choices were equally rewarded, independently of facial orientation. We found that when the face viewing time was 200, 300, 400 or 500 ms the animal's choice was significantly biased towards the target congruent with the face´s orientation, while staying at chance level for the shortest and the longest times. Our results clearly show that marmosets follow the gaze of conspecifics in a reflex-like manner, very similar to old world primates, supporting the hypothesis of a phylogenetically old faculty shared by both old and new world primates.

Title: Investigating fine-scale functional diversity in face-processing network with 7T MRI and correlation-based clustering analysis

Authors: *J. ZHANG[1], Y. WANG[1], S. HE[1,2]
[1]Inst. of Biophysics, Chinese Acad. of Sci., Beijing, China; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Many functional magnetic resonance imaging (fMRI) studies revealed the existence of face-processing areas with strong selective responses to faces. However, it is difficult to address the functional diversity within these areas by only investigating their sensitivity to different visual features. Here we used dynamic visual stimuli and data driven analysis to explore this issue. In particular, movies depicting various natural and social activities were presented to human participants while they were scanned in 7T and 3T MRI scanner to obtain the time courses of neural activity in face-processing areas (7T) and through the whole brain (3T). Correlation maps between voxels in face areas and in other brain regions were calculated based on the neural activities driven by the same movies. Then principal components analysis and

clustering algorithm was applied to such maps for separating face-selective voxels into different clusters. Results showed multiple clusters in the right fusiform face area and occipital face area and each cluster demonstrated different strength of correlation to the brain regions outside the face-selective regions. Our data indicate the feasibility of using dynamic visual stimuli to examine the fine-scale functional diversity across voxels in a visual processing network. The multiple clusters of voxel within face selective region suggest that they have different visual feature sensitivities and warrant further investigation in future studies.

Title: The top-down processing of faces in occipital-temporal cortex

Authors: *X. FAN[1], H. SHAO[1], F. WANG[1], S. HE[1,2]
[1]Inst. of Biophysics, Chinese Acad. of Sci., Beijing City, China; [2]Departments of Psychology, Univ. of Minnesota, Minneapolis, MN

Abstract: The processing of face information involves a distributed network of face-sensitive areas in the occipitotemporal cortex and beyond. Both hierarchical and non-hierarchical models have been proposed to understand the neural mechanisms of face perception. To explore the temporal dynamics of bottom-up processing and top-down modulation of face processing, we analyzed the activation timing of the face-selective areas in "core face processing system" using fMRI and Magnetoencephalograpy (MEG).Subjects were presented with various pictures including normal faces and two-tone Mooney faces (containing little facial features) while MEG signals were recorded. From the MEG sensor data, we reconstructed the cortical responses to faces using the beamforming approach; and in conjunction with information from fMRI localizer, we extracted the time courses of face-selective areas in each individual subjects. First, the feedforward processing sequence along ventral occipitotemporal cortex was revealed in their responses to normal face pictures. The top-down operation in face processing was highlighted in their responses to the two-tone Mooney faces. Our results showed that when processing Mooney faces for which top-down modulation is critical, the right Occipital Face Area (rOFA) was activated later than both hemispheres' posterior Fusiform Face Area (pFFA) and the direction of

information flow is from pFFA to rOFA. Together, these findings indicate that both bottom-up and top-down processing are involved in the occipital-temporal face network and the processing sequence in the rOFA and r/lpFFA depends on the stimuli and task demand.

Title: Effects of experience on face and body selective neurons in macaque IT

Authors: *P. F. SCHADE, M. J. ARCARO, M. S. LIVINGSTONE
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: The primate visual system is a hierarchically structured network of increasingly abstract feature detectors. It culminates with cells in inferotemporal cortex (IT) that are selective for particular image categories, such as faces, bodies, text, and places. Recent work in our lab has shown that the domain organization of IT is malleable by early experience. Here, we report that face and body-selective neurons in lab-raised non-human primates are often selective for human faces or bodies wearing personal protective equipment (PPE; e.g. face masks, lab coats). We targeted face and body domains and recorded single unit and multiunit activity in posterior and central IT while macaques passively viewed thousands of different images. We found clusters of cells and sites that were selective for human faces and/or bodies wearing PPE. These clusters were intermixed with cells that were selective for monkey faces and bodies. Our results emphasize the importance of experience in molding the selectivity of IT neurons.

Title: Effect of electrical microstimulation of the anterior Superior Temporal Sulcus body patch on visual categorization tasks

Authors: *S. KUMAR, E. MERGAN, R. VOGELS
KU Leuven, Leuven, Belgium

Abstract: fMRI studies in primates show patches in the temporal cortex that are more strongly activated by images of bodies compared to other visual categories (objects and faces). Single unit studies in macaques have shown that in at least two of these fMRI defined body patches neurons respond on average stronger to bodies, including bodies of humans, monkeys, and other four-legged mammals, compared to images of objects and faces (Popivanov et al., J.Neurosci., 2014; Kumar et al., Cerebral Cortex, 2017). The body patch spiking activity contains sufficient information to categorize bodies vs. objects (including faces). Here we examine the contribution to categorization behavior of the anterior Superior Temporal Sulcus body patch, ASB, which is located rostrally in the lower bank of the Superior Temporal Sulcus (Kumar et al., Cerebral Cortex, 2017). In a first experiment, we trained two monkeys to categorize a broad set of images of four-legged mammals versus images of objects (excluding houses), with each category being associated with a saccadic choice target and using saccades as operants. Images were shown centrally (maximum image extent 4 deg) and were partially occluded by white noise at various signal to noise ratios. In both animals, unilateral electrical microstimulation (EM; 150 uA) of ASB increased the overall proportion of mammal target responses without affecting the slope of the psychometric function. In one monkey, EM did not affect body categorization at another location (1mm further but still inside ASB), which may suggest a heterogeneity of ASB in its contribution to body categorization behavior. Both monkeys were tested on faces vs. objects categorization where faces were paired with the same choice target as for the mammals. EM of ASB increased also the overall proportion of face choices. To dissociate face from mammal targets and evaluate the stimulus selectivity of EM, we associated each of 4 categories, i.e., mammals, human faces, objects, and houses, with each of 4 saccadic choice targets. EM (50 uA) during the performance of this 4-alternative categorization task affected mammal and house category choices but not faces and objects. In one monkey, EM increased mammal choices, while in the second animal, the opposite effect was present. In each animal, this effect of EM was absent in a site of the STS that was not body category selective (3-5 mm away from ASB stimulation site). Subsequent pairwise testing of the mammal category with objects also showed increased or decreased mammal target choices, depending on the monkey, with EM of ASB. These data suggest that low current EM of a body patch affects choice biases during categorization of complex visual images.

Title: Binocular rivalry in macaque without active report

Authors: *J. K. HESSE, D. Y. TSAO
Biol., Caltech, Pasadena, CA

Abstract: When two incongruent stimuli are presented to the two eyes, the conscious percept alternates between the two stimuli, even though the physical input stays constant. This paradigm, also known as binocular rivalry, offers an entry point to study how switches between conscious interpretations of ambiguous stimuli are represented and broadcasted across the brain. Logothetis et al. (e.g. 1989) measured for different brain regions how much neural activity was modulated by reported switching. However, Fraessle et al. (2014) found that during active report, modulation by conscious percept is confounded with the act of reporting and introspection itself, and that when active report is stopped, modulation vanishes in most parts of the human brain. We thus set out to identify a brain region with broad connectivity whose activity reflects perceptual switching that could be used to "trigger" analysis of neural activity across the brain during binocular rivalry without any active report. We performed multi-channel population recordings from a number of areas including the amygdala, claustrum, and face and body patches in inferotemporal and prefrontal cortex, while monkeys fixated: (1) a perceptually switching binocular rivalry stimulus, (2) an unambiguous non-switching monocular stimulus, or (3) a physically switching stimulus. We analyzed time courses and correlations of simultaneously recorded neurons across these areas as well as pupil data to determine how activity is coordinated in these regions, in an effort to understand the extent to which population dynamics during the rivalry condition resembles that during the physically switching condition.

Title: A framework of robust sensory processing

Authors: *R. RAJ, D. DAHLEN, K. DUYCK, C. YU
Yu Lab., Stowers Inst. for Med. Res., Kansas City, MO

Abstract: Brain is remarkably effective in creating consistent internal representations of perceptual objects present around us. These representations allow for recognition and discrimination of stimuli and are formed even in situations when input is corrupted or incomplete. It has been theorized that, to construct such consistent representations, brain should be able to extract statistical dependencies present in the stimulus space. However, the elemental rules that may guide brain to extract these dependencies remain unclear and how consistent perceptual experiences arise from incomplete input is unknown.We reason that individual objects are independent sources of perceptual experience whereas individual features that define an object are mutually dependent. Following this rationale, we developed a computational framework that captures the structural dependence among the stimuli features, which allows individual objects to be encoded as sparse, statistically independent representations. The framework, which relies on sparse, non-negative matrix blind source separation, is effective in extracting various linear and non-linear dependencies present in the stimulus space. Moreover, we introduce a novel decoding process that is similar to sparse recovery. When the two elements of the framework are used together, the coding scheme allows for robust sparse representations of stimuli that are resistant to corruption due to noise and occlusion. We show that in the mouse olfactory system, it is possible to recover odor identity accurately and robustly from the responses of small numbers of randomly selected olfactory glomeruli, and in the presence of high levels of noise. We also show that when used in facial recognition, faces that are learned in a single shot can be precisely identified even when corrupted or occluded. We suggest that framework can be used to understand how the nervous system may employ a robust neural code.

Title: The representation of orientation and identity in human ventral face processing areas as measured by intracranial electroencephalography

Authors: *A. ALREJA[1], M. J. WARD[2], M. RICHARDSON[2], A. S. GHUMAN[2]
[1]Ctr. for Neural Cognition, Carnegie Mellon Univ., Pittsburgh, PA; [2]Neurolog. Surgery, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Faces can be recognized across a remarkable degree of transformations, including viewpoint, which greatly shifts the position and orientation of facial features. Primate electrophysiology studies provide evidence that identity and facial orientation representations evolve along a three level hierarchy across the monkey face patch system. These levels proceed from viewpoint dependence at the lowest level, mirror-symmetry at the mid-level, and viewpoint invariance at the highest levels. In the human brain, face identity processing is thought to involve a distributed network of several brain areas including the occipital face area (OFA) and fusiform face area (FFA). FMRI studies in humans have begun to shed light as to how the levels of face viewpoint coding are reflected in the human face processing system, however many questions still remain.

To help resolve these questions, we recorded intracranial electroencephalography (iEEG) data from 13 patients with a combined total of 43 electrodes in the OFA andor FFA. The stimulus set is composed of 40 unique identities (20 male + 20 female), each with 5 different emotional expressions, presented either straight, facing away (left or right) 90 degrees, or facing tilted (right or left) 45 degrees. Using nearest centroid classifiers, we can reliably predict face orientation in 11 out of the 13 patients. Evidence for mirror symmetric coding (confusion between left and right facing away faces and significant classification between straight, away, and tilted in a 3-way classifier) was seen in 6 out of 13 patients. Significant identity classification was seen when all orientations are present in trainingtest data in all 13 subjects. However, when a viewpoint was left out of the training sample for the classifier identity classification fell to chance for that viewpoint, suggesting the identity code was viewpoint dependent.

These results suggest that the OFA and FFA code for both viewpoint and identity, however the identity representation was viewpoint dependent despite some broad mirror generalization for faces. Further analyses will examine how these effects spatially distribute across these face processing areas and how they evolve over time.

Title: Whole-brain fMRI analysis of face-selective neurons in cortex and thalamus

Authors: *S. PARK[1], K. W. KOYANO[1], B. E. RUSS[1,2], A. P. MURPHY[1], R. A. BERMAN[1], D. A. LEOPOLD[1,3]
[1]SCNI, Lab. of Neuropsychology, NIMH, NIH, Bethesda, MD; [2]Nathan S. Kline Inst. for Psychiatric Res., Orangeburg, NY; [3]Neurophysiol. Imaging Facility, NIMH / NINDS / NEI, NIH, Bethesda, MD

Abstract: Face-selective neurons are found clustered in the macaque temporal cortex, forming multiple isolated "patches." Recently we compared spiking responses within the anterior fundus (AF) patch to fMRI signals throughout the brain in monkeys viewing natural video stimuli. We found diverse correlation maps from neurons occupying a few hundred microns, indicating that neighboring neurons bear markedly different relationships to activity throughout the whole brain (Park et al., 2017). Here, we extended this whole-brain mapping method to the middle lateral (ML) and anterior medial (AM) face patches, as well as the thalamic pulvinar, to gain new insights into the functional differences among face-selective neurons in the different regions. Whole-brain fMRI responses were measured separately in two rhesus macaque monkeys, and electrophysiological recording of single neurons in the ML, AF, and AM face patches and the pulvinar were conducted in seven other monkeys viewing the same video. For all isolated neurons, we created single-unit fMRI maps by computing the Spearman's rank correlation coefficients between the spiking time course, convolved with the hemodynamic response function, and the fMRI time course of each voxel throughout the brain. Among the three face patches, we found partially overlapping populations of neurons, as characterized and categorized by their fMRI correlation maps. One common motif in all three areas was a selective and positive correlation restricted to the face patches, with the proportion of such neurons varying across recordings in ML, AF, and AM. Other categories of whole-brain maps were observed in only a subset of face patches. For example, positive correlation with caudal STS motion areas was prominent in AF but entirely absent in ML and AM. On the other hand, neurons in ML and AM, but not AF, exhibited positive correlation with foveal region of V1 and V2. Initial analysis of pulvinar neurons indicate significantly less consistency across trials during video watching and less robust whole-brain correlations. In summary, we found a dense, local mixture of

complex neural responses to the video, as well as a sharing of similar responses across distant regions in the face network. Together, these results present a new perspective on cortical pathways carrying visual information in the face patch system, posing challenges for theories of brain organization that hinge on strict spatial segregation.

Title: What is the contribution of faces to the representations of animate and inanimate objects in the ventral temporal cortex?

Authors: *D. PROKLOVA[1], M. A. GOODALE[2]
[1]Psychology, The Brain and Mind Institute, Western Univ., London, ON, Canada; [2]The Brain and Mind Inst., The Univ. of Western Ontario, London, ON, Canada

Abstract: Animate and inanimate objects elicit distinct response patterns in the human ventral temporal cortex (VTC), but the exact features driving this distinction are still being investigated. In a recent fMRI study, we showed that the animate/inanimate distinction in VTC was still present even after controlling for visual (shape) similarity of the stimuli. Another prominent feature that distinguishes most familiar animals from inanimate objects and that could potentially explain the animate-inanimate distinction in the VTC is the presence of a face. In the current fMRI study we investigated the role of faces in the animate/inanimate distinction of VTC representations. To address this question, we created a stimulus set that consisted of eighteen unique stimuli, divided into six subsets of three stimuli. Within each subset, all three objects shared a similar shape, with one inanimate and two animate objects per set (e.g, rope-snake-worm). Critically, the two animals within each shape subset were selected so that one of them had a distinct face and the other did not. This stimulus selection was confirmed in a separate behavioral experiment, in which participants rated the degree to which a given animal is perceived as having a face (e.g., a snake received significantly higher “faceness” ratings than a worm). To test whether the presence of a face can explain the animate-inanimate distinction in the VTC, we estimated the response patterns to all stimuli within this region and computed pairwise pattern correlations between them. We found that within-category pattern similarity was significantly higher than between-category similarity, consistent with the animate-inanimate

distinction. Interestingly, this was true even after all the animals with faces were removed from the analysis, showing that even the animals without a distinct face are represented differently than inanimate objects in the VTC. Furthermore, the results stayed the same even when the analysis was restricted only to stimuli from the same shape cluster, suggesting that animate/inanimate distinction is still present in VTC even for stimuli that are closely matched for shape, both for animals with or without a distinct face. These results suggest that the presence of a face is not a defining feature driving the distinction between representations of animate and inanimate objects in the ventral temporal cortex.

Title: Predictive coding account of action perception: Evidence from effective connectivity

Authors: *A. P. SAYGIN[1,2], B. A. URGEN[1,3]
[1]Dept. of Cognitive Sci., Univ. of California San Diego, La Jolla, CA; [2]Neurosciences Program, UCSD, La Jolla, CA; [3]Dept. of Neurosci., Univ. of Parma, Parma, Italy

Abstract: Visual perception of actions is supported by a network of regions in the occipito-temporal, parietal, and premotor cortex in the primate brain, known as the Action Observation Network (AON). Although significant progress has been made in understanding the neural correlates of action perception, one open question is how the nodes of this network communicate. According to the predictive coding account of action perception (Kilner et al. 2007), this network is not a purely feedforward system but rather has feedback connections through which prediction error signals are communicated between the regions of the AON. In the present study, we investigated the effective connectivity of the AON in an experimental setting where the human subjects' predictions about the observed agent were violated (via a mismatch between appearance and motion), using fMRI and Dynamical Causal Modeling (DCM). We specifically examined the influence of the lowest and highest nodes in the AON hierarchy (pSTS and ventral premotor cortex, respectively), over the middle node (inferior parietal lobe) during prediction violation. To this end, we constructed three specific models that differ in the connection that is modulated by the mismatch condition: 1) connection from pSTS to parietal cortex, 2) connection from the premotor cortex to the parietal cortex, and 3) both connections. In

all models, parietal node has reciprocal intrinsic connections with pSTS and premotor cortex, and action information modulates all intrinsic connections. Our results show that the most likely model that explains data is one in which the connection from premotor cortex to parietal cortex was modulated by mismatch, which indicates a top-down influence. Examination of the parameter estimates of the optimal model shows that all of the intrinsic connections were significant, confirming the well-known anatomy between these regions. In addition, all of the intrinsic connections were modulated significantly by the observation of actions suggesting that action-related information is processed via both feedforward and feedback connections in the AON. In sum, our DCM results provide empirical support for the predictive coding account of action perception.

Title: Not movement duration but movement velocity is altered by implicit adaptation to movement-amplitude perturbation in self-paced reaching task

Authors: *T. HAYASHI, K. TAKIYAMA
Engin., Tokyo Univ. of Agr. and Technol., Koganei-Shi, Japan

Abstract: When reaching for a cup of coffee, the motor system must determine a movement time and trajectory from an infinite number of repertoires. For instance, you can make a reaching movement towards an explicit target (e.g., a cup) with low velocity and long duration or with high velocity and short duration. This indicates that movement velocity (MV) and movement duration (MD) are redundant parameters, which would be determined by optimizing several cost functions (Haith et al., J Neurosci, 2012; Shadmehr et al., Curr Biol, 2016). Similarly, when a movement amplitude is altered by implicit motor adaptation, the motor system needs to solve the redundancy. Previous studies have just focused on how movement amplitude is altered to minimize a sensory prediction error (Krakauer et al., J Neurosci, 2000; Pearson et al., J Neurophysiol, 2010), while It is still unknown whether the motor system operates the same optimization during identical movements generated by implicit motor adaptation and directed towards an explicit target. To clarify it, in this explement, we investigated how the redundant parameters, namely MV and MD, are altered during implicit motor adaptation as those aiming an

explicit target. Eight participants made self-paced reaching movements while holding a manipulandum to land a cursor on a target on the screen. The cursor was not visible during a movement, but only the final position was fed back. Consistent with the previous studies (Gordon et al., Exp Brain Res, 1994a, b), both of the MV and MD were systematically altered when the explicit target extents were varied from 6 to 14 cm. Then, while reaching towards the target located at 10 cm, the participants adapted to cursor shifting perturbations in which the cursor was gradually shifted up or down to 3 cm. Statistical analyses revealed that the participants implicitly but successfully altered their movement amplitude to approximately 7 or 13 cm. Surprisingly, although the MV was correspondingly altered with changes in the movement amplitude, the MD remained unchanged. The result illustrated that the resultant of MV and MD altered by implicit motor adaptation were clearly different from those directed towards explicit target extent, suggesting that the motor system may solve the redundancy for MV and MD differently between implicit motor adaptation and explicit movement control.

Title: Different eye-hand coordination forms distinct motor memories in visuomotor adaptation

Authors: *N. ABEKAWA, H. GOMI
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: Recent theories of motor control emphasize the role of behavioral context in learning multiple motor skills that could interfere with each other. Human can simultaneously adapt two opposing novel environments (e.g. CW or CCW force-filed) when each environment is associated with distinct reaching movements. More recent study (Sheahan et al. Neuron, 2016) further suggested that motor planning rather than execution is crucial for such context-dependent learning. Meanwhile, it is still unclear whether the hand-eye coordination can be used as a context for distinct motor learning while gaze direction relative to the reaching target is crucial information in reaching planning. Here, we examine whether distinct motor memories can be formed and retrieved depending on different coordination between gaze and hand movement. Participants (n=6) moved hand on a digitizing tablet, and the hand position was presented by a cursor on a monitor. They moved the cursor toward a reaching target while looking at a fixation point. For each trial, locations of the target and the fixation point were independently selected

from three possible locations. Nine possible combinations of the reaching targets and the fixation points were categorized into two types of reaching: foveal-reaching and peripheral-reaching. Visuomotor rotation was applied to the hand cursor, and its rotation angle gradually increased from 0 to 30 deg throughout the training session (40 blocks of 12 trials). Importantly, the direction of rotation (CW or CCW) was randomly selected trial by trial, but uniquely specified by foveal or peripheral reaching. The result showed clear decrease in the initial direction error of reaching in each rotation. When the rotation was removed after the training, we observed strong aftereffect in the direction opposite of each rotation corresponding to the foveal and peripheral-reaching. Error-decrease and aftereffects did not differ between both rotations, indicating that two opposing rotations can be simultaneously adapted with less interference. In control experiments, the direction of rotation was associated with blue or red background color (n=6), or with visual cue presented in the foveal or peripheral field (n=6), instead of with gaze-reach coordination. In both groups, clear direction error decrease was not observed. These results suggest that, unlike weak association with external visual information such as color or spatial cue, distinct motor memory would be clearly formed and retrieved associated with the state of eye-hand coordination.

Title: Effect of offline transcranial alternating current stimulation at alpha and beta frequencies on visuomotor learning task

Authors: *T. HARADA[1], M. HARA[3], K. MATSUSHITA[4], K. KAWAKAMI[2], H. SUGATA[2]
[2]Fac. of Welfare and Hlth. Sci., [1]Oita Univ., Oita, Japan; [3]Grad. Sch. of Sci. and Engin., Saitama Univ., Saitama, Japan; [4]Dept. of Mechanical Engin., Gifu Univ., Gifu, Japan

Abstract: The number of studies on transcranial alternating current stimulation (tACS) has been growing exponentially. The behavioral effects of tACS have been related to the entrainment of ongoing oscillatory neural activity by stimulation frequency, and such interaction between an externally applied stimulation and brain oscillations has been shown to manipulate brain functions by promoting neural activity to resonate at the stimulation frequency. In particular, online tACS has been reported to be associated with the modulation of motor learning and

memory. However, there have been few reports on the effect of offline tACS on the modulation of motor learning. The aim of the present study was thus to investigate the effect of offline tACS targeted at motor-cortical alpha (10 Hz) and beta (20 Hz) frequencies on the acquisition of motor learning. Twenty-seven right-handed healthy participants were randomly assigned to 10-Hz tACS (n = 10), 20-Hz tACS (n = 9), and sham (n = 8) groups. The participants underwent a visuomotor learning task before (baseline task,BT) and after (training task,TT) tACS. Each visuomotor learning task consisted of 40 blocks. In each block, five targets were randomly presented and the subjects controlled a lever-type controller to reach the target with the cursor (center-out reaching task). In the TT, 30° clockwise or counterclockwise transformation was applied to evaluate the effect of tACS on the modulation of motor learning. The angular transformation was counterbalanced in each group. tACS was delivered by a DC stimulator plus (NeuroConn) via a sponge electrode (5 × 7 cm). tACS at 10 and 20 Hz containing sham stimulation was performed between the BT and the TT over the left primary motor cortex for 10 min at 1 mA. The average angular error in each block of 10 in the TT was defined as the learning index. The average angular errors were compared between the groups using ANOVA. The results showed a significant difference in angular error in the initial average block (block 1-10) ($F = 5.20$, $p < 0.05$). Post hoc analysis showed that the average angular error in the 10-Hz tACS group was significantly smaller than that in the sham and 20-Hz tACS groups (sham vs. 10 Hz, $p < 0.05$; 10 Hz vs. 20 Hz, $p < 0.05$). The present study demonstrates the effect of offline 10-Hz tACS over M1 on the acquisition of motor learning. Previous studies have shown that motor learning was improved by applying 10-Hz offline tACS. Additionally, the aftereffect of 10-Hz tACS has been shown to persist for at least 30 min in the alpha band. Thus, our results support these previous studies. Therefore, offline tACS can be a useful conditioning tool for the brain before rehabilitation for various diseases.

Title: The effects of subjective value for meta-learning in visuomotor transformation

Authors: *T. SUGIYAMA[1], N. SCHWEIGHOFER[3], J. IZAWA[2]
[1]Univ. of Tsukuba, Tsukuba-Shi, Japan; [2]Univ. of Tsukuba, Tsukuba/Ibaraki, Japan; [3]USC, Los Angeles, CA

Abstract: The rate of motor learning is often altered by various types of information such as statistics of the environment (Herzfeld, 2014) and motivational feedback (Galea, 2015). In theory, an ultimate goal of motor learning is to maximize future performance by updating motor memory after observing sensory prediction error. Thus, modulation of memory update, which is manifestied as an altered learning rate, may follow reinforcement learning because its goal is indeed maximizing performance. If memory update at a certain step is expected to improve performance (e.g., amount of reward) at the next step, the brain should upregulate sensitivity to prediction error (i.e., learning rate) to facilitate future learning. In contrast, if memory update degrades performance, the brain should suppress the learning rate. Thus, it is beneficial to optimize the rate of learning proactively by forming a subjective value of the rate of memory update and evaluating it. Here, we hypothesize that there is a meta-learning architecture in human motor learning that optimizes the learning rate for different reward structures. To test this hypothesis, we have devised a novel visuomotor meta-learning task that involves a gain/loss of numerical score (i.e., reward/punishment). In the task, people have to adjust their adaptation rate to maximize performance because a better performance is achieved with more adaptation in one condition and less in another condition. The results confirm our hypothesis, showing that the participants successfully adjust learning rate in such a way that increases the performance (repeated measure-ANOVA, the effect of group, $p = .01$). This suggests that neither the statistics of the environment or the motivational feedback but the trial-to-trial structure of reward is the fundamental cause of the learning rate modulation. In addition, a post hoc analysis on the later phase of learning reveals a marginally significant effect of the valence (type of numerical score feedback) that sensitivity is higher when training is accompanied by loss of score than gain (two-way ANOVA, $p = .07$). Interestingly, this trend is opposite to the one found in motivational decision-making task (e.g., Go/Nogo task), where taking action is easier to learn with gain than loss (Dolan, 2012). We speculate that the decision-making task involves the cortico-basal circuit that is sensitive to rewarding information, whereas motor adaptation involves the cerebellar circuit that is sensitive to aversive information.

Title: Select changes in the fast and slow adaptive processes based on learning context

Authors: *S. K. COLTMAN[1], J. G. CASHABACK[2], P. L. GRIBBLE[3]
[1]Neurosci., Univ. of Western Ontario, London, ON, Canada; [2]Hotchkiss Brain Institute, Fac. of Kinesiology, Univ. of Calgary, Calgary, AB, Canada; [3]Brain and Mind Institute, Dept. Psychology, Western University, Canada, London, ON, Canada

Abstract: By analysing properties of movement errors, we aim to uncover underlying mechanisms of motor adaptation such as learning and retention. Short-term motor adaptation is believed to be supported by two separate processes, each with distinct timescales that operate simultaneously. Characteristically, the fast process learns quickly, but has poor retention; while the slow process has better retention but learns more slowly. We tested the hypothesis that repetition of the same motor task influences properties of the fast and slow processes (fast & slow learning rates and retention rates) differently than when switching to a novel motor learning task. Healthy adult participants grasped the handle of a robotic manipulandum and performed reaches to virtual visual targets while the hand/arm were occluded. Participants completed one of two experiments, each of which was divided into two sessions, separated by a 5 minute break. In the first session participants adapted their reaches to a viscous (velocity-dependent) force field (FF). In the second session participants reached in the same FF as the first session (Experiment 1, n=54) or in the opposite FF (Experiment 2, n=46). The experimental sequence was null field (no force) trials, FF adaptation, FF reversal, and finally a series of channel trials. During FF adaptation we probed learning using randomly interspersed channel trials in which the path of the robot handle was constrained to a straight line. In Experiment 1, in which participants experienced repetition of the same perturbation, we found an increase in learning rate both in the fast and slow processes that resulted in savings. In Experiment 2, in which participants experienced a novel perturbation in the second session, we observed a statistically reliable difference in the fast process retention parameter. Given that the sequence of trials within a session included a brief FF reversal, the FF in session 2 was not completely novel and this difference could reflect spontaneous recovery. Our work suggests that the well-known phenomena of savings and spontaneous recovery can be linked to select changes in the two-state model. Further demonstrating that the underlying mechanisms of short-term motor adaptation are not fixed, but malleable based on learning context.

Title: Adaptation and de novo learning can be distinguished by the presence of aftereffects: A system identification approach

Authors: *C. YANG[1], N. J. COWAN[3], A. HAITH[2]
[1]Neurosci., [2]Neurol., Johns Hopkins Sch. of Med., Baltimore, MD; [3]Dept. of Mechanical Engin., Johns Hopkins Univ. Dept. of Mechanical Engin., Baltimore, MD

Abstract: It has been proposed that new motor tasks can be learned through two different mechanisms (Telgen et al., 2014): 1) Adaptation: parametric adjustment of an existing controller, or 2) De novo learning: building a new controller from scratch. Although the difference between these two types of learning is conceptually clear, it can be difficult to determine which learning mechanism is engaged to counter an imposed perturbation. We propose that the existence of aftereffects provides a means of dissociating the two learning mechanisms. De novo learning results in the formation of a new controller, and when the perturbation is removed, one may expect quick reinstatement of the baseline controller (i.e., zero or transient aftereffect). On the other hand, adaptation to a perturbation results in modifying one's baseline controller, thus removing a perturbation results in the slow restoration of this controller to its baseline state (i.e., persistent aftereffect). Here, we tested whether different perturbations might be solved through different learning mechanisms and thus might exhibit different patterns of aftereffects. Human participants made point-to-point movements under one of two perturbations: 1) 90 degree visuomotor rotation (presumably learned through adaptation) 2) mirror reversal about an oblique 45 degree axis (presumably learned through de novo learning). In order to precisely examine participants' ability to counter the perturbation at different points during learning, including possible aftereffects, we employed a system identification approach: Periodically during learning, participants were asked to track a target moving along a sum-of-sinusoids trajectory. Assaying the strength, direction, and timing of the tracking responses at different frequencies allowed us to comprehensively characterize each participants' controller. We found that compensation was more successful at low frequencies of target motion than high frequencies, likely due to greater influence of feedback control. Across all frequencies, however, participants in the rotation group exhibited strong aftereffects while mirror-reversal subjects did not, consistent with our hypothesis that these two perturbations are learned through distinct mechanisms.

Title: The influences of a switching cue on aftereffects in visuomotor adaptation

Authors: *Y. ITAGUCHI[1], C. YAMADA[2], K. FUKUZAWA[2]
[1]Dept. of Syst. Design and Engin., Keio Univ., Kanagawa, Japan; [2]Waseda Univ., Tokyo, Japan

Abstract: The present study investigated the influences of a switching cue on aftereffects in visuomotor rotation task by multiple measurements. Previous studies have used aftereffects as a measure reflecting the degree of acquisition of a new internal model; if aftereffects are observed in a catch trial, one is regarded to successfully adapt a new visuomotor environment. Considering our daily activities where we retain multiple internal models at the same time and voluntarily switch them for an upcoming situation, aftereffects may reflect not only the achievement of acquisition but also switching efficiency. To address this question, we measured aftereffects multiple times in the time course of visuomotor adaptation with or without a switching cue. In the experiment, participants carried out a visuomotor rotation task, in which they continuously followed a randomly moving dot with a mouse cursor as accurately as possible. In adaptation trials, visual feedback of the mouse cursor was rotated by 150 degrees. We manipulated the measurement times as an independent variable; in the time course of the adaptation task, catch trials were introduced four times with or without a switching cue. A two-way ANOVA found main effects of group and phase in the tracking error and the initial directional error. The aftereffects in the group without a switching cue were consistently larger than those in the group with the cue. Aftereffects in the group with a switching cue turned to decrease from the 3rd evaluation. These results suggest that aftereffects with a switching cue would be a good indicator for an explicit strategy for visuomotor rotation tasks.

Title: Distinct effects of motor adaptation and proprioceptive recalibration in visual error clamp tasks

Authors: *E. POH, J. A. TAYLOR
Psychology, Princeton Univ., Princeton, NJ

Abstract: The idea that we predict the consequences of our motor commands has emerged as an important theoretical concept for accurate motor control. When an initial motor command is

generated but the observed sensory feedback does not match the predicted sensory consequences, the next movement will be updated to reduce the occurrence of similar errors. This prediction error is thought to be the dominant signal driving learning during visuomotor adaptation tasks and is responsible for the presence of aftereffects. However, some studies have shown that aftereffects can also arise when the hand is passively moved and there is a mismatch between the visual feedback and hand location. Because passive movements should not produce prediction errors and, thus, not updated a forward model, these results have been attributed to proprioceptive recalibration. Indeed, separate tests of perceived hand location have shown a systematic shift in the direction of the mismatched visual feedback. This presents a complication for the prediction error account since aftereffects may be largely attributed to a shift in state estimation rather than an updated forward model. A potential counterargument could be that passive movements still generate prediction errors reflexively and, perhaps, both processes are occurring. Here, we set out to test if aftereffects are primarily driven by sensory prediction errors or proprioceptive recalibration. In three experiments, subjects performed either active or passive movements toward a training target, while visual feedback was fixed in a direction angled 15° away. In this visual error clamp task, significant aftereffects emerge through passive movements. The size of aftereffects was similar irrespective of whether the target was present or absent, suggesting that the aftereffects could not have emerge from prediction errors due to latent motor commands that are reflexively generated when a target is presented. In a second study, we showed that linking conflicting visual error clamps to active and passive movements allows concurrent adaptation in opposing directions. This suggests different mechanisms for aftereffects that emerge from active and passive training. In the third study, we quantify the degree of proprioceptive recalibration in both passive and active error clamps task. Preliminary results show significant proprioceptive recalibration for active movements in the error clamp task, suggesting that a portion of the aftereffects might be derive from the change in localization of the hand. Taken together these results underscore the multiplicity of processes that contribute to learning and aftereffects in visuomotor adaptation tasks.

Title: Transfer of implicit and explicit learning components of sensorimotor adaptation

Authors: *X. XING, J. SAUNDERS
Dept. of Psychology, The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Sensorimotor adaptation can involve two types of learning: implicit learning driven by sensory prediction error that accumulates slowly, and explicit learning driven by target error that can occur quickly. In this study, we tested how implicit and explicit components of learning transfer across tasks, and the specificity of transfer. Experiment 1 tested adaptation and transfer between pointing and stepping toward a target, using virtual reality to perturb visual feedback. Experiments 2 and 3 tested transfer between these tasks and a novel hand locomotion task, in which subjects used pointing movement to simulate self-motion. The hand locomotion task used the same physical movement as pointing, but performed the same function as stepping. During an experimental block, subjects performed adaptation trials with perturbed feedback and interspersing test trials with no feedback. The test trials were either the same task to measure adaptation, or a different task to measure transfer. Perturbations on adaptation trials varied over time as a sum of sinusoids with different frequencies. Fast explicit learning would be expected to produce equal responses to these components, while slower implicit learning would dampen the higher frequency component. Subjects were not aware of the smoothly varying perturbations, but showed detectable adaptation for all three tasks. Only pointing produced significantly different responses to high and low frequency components, consistent with slow implicit learning. Pointing adaptation produced more transfer to hand locomotion, which shared the same effector and physical movement, than to stepping. The other tasks showed little or no implicit learning, and equal transfer to tasks with different effector or function. Our results suggest that the slower implicit components of sensorimotor adaptation are more movement specific, while explicit learning is more generalizable.

Title: Handedness influences how limb motion is used to compensate for arbitrary dynamical perturbations

Authors: *W. ZHOU[1], M. DICKERSON[1], C. DENNIS[1], S. KELLY[2], W. M. JOINER[1]
[1]Bioengineering Dept., [2]Psychology Dept., George Mason Univ., Fairfax, VA

Abstract: Previous work (Sing et al. 2013) has shown that adaptive responses to non-motion dependent perturbations during reaching movements are based on limb motion state (e.g., position, velocity, and acceleration of the limb). Additionally, prior work suggests handedness reflects a differentiation of control processes focused on either limb dynamics or position (Sainburg 2005). Here, based on these previous studies, we examined single-trial adaptive responses to non-motion dependent dynamics (force-pulse perturbations, FP). We trained two groups of subjects (right-handed and left-handed individuals, N=14 in both groups) to perform 10 cm point-to-point reaching arm movements using a robotic manipulandum. All subjects performed two experimental sessions (counterbalanced across subjects), one limb on the first day, and the other on day two. Following an initial baseline block, subjects completed 15 experimental blocks with the FP perturbation (18N in magnitude). We randomized (1) the movement direction the FP was applied (towards or away from the body), (2) the FP direction (right or left), and (3) when the FP was applied (either 2, 5 or 8 cm into the movement). We used an error clamp triplet (EC-FP-EC) to determine the single trial response and 5 null-field trials to washout the learning. The single-trial adaptation was well-characterized by a linear combination of the velocity, position, and acceleration profiles associated with movement (R^2>0.9). For the 2 cm perturbation, for both subject groups, the adaptive responses were more velocity dependent and there was no significant difference between the dominant and nondominant limb (P>0.64). However, when the FP was applied later in the movement (8 cm), the adaptive responses were more position dependent (greater position gain) with no significant difference between the two limbs (P>0.6). When the perturbation was applied in the center of the movement (5 cm) the motion state dependence was significantly different based on handedness (P<0.013); left-handed subjects applied greater position gain in the adaptive response, while right-handed subjects applied a greater velocity gain. These results suggest that subjects adjust the motion state the FP perturbations are associated with based on when the manipulation occurs (early versus late). However, when the perturbation is arbitrary, handedness significantly influences the motion state emphasized in the adaptive response.

Title: M1 beta oscillation control over learning rates in sensorimotor adaptation

Authors: *J. M. FINE[1], K. UEHARA[2], M. SANTELLO[1]
[1]Sch. of Biol. and Hlth. Systems Engin., [2]Neural Control of Movement laboratory, Sch. of Biol. and Hlth. Systems, Arizona State Univ., Tempe, AZ

Abstract: When there is a divergence between expected and actual sensory outcomes of a movement, people readily adapt their subsequent movements to these prediction errors. Predominant computational models have presumed adaptation rates are error-size invariant. This has led studies of neural mechanisms underlying sensorimotor learning to focus mainly on encoding of prediction errors. However, recent evidence from human and animal models suggests that adaptation rates are flexible and depend both on the error size and history. This raises the question of whether there are distinguishable neural markers for prediction errors versus adaptation rates. Our previous work has demonstrated EEG oscillatory frequencies occurring in the motor (M1), somatosensory, and medial prefrontal cortex may encode prediction-error signals and learning rates at different task stages (Fine et al., 2017). Motor cortex beta (15-30 Hz) rebounds occurring post-movement (PMBR) could potentially be a neural marker of prediction error as they tend to increase as motor error decreases. However, extant results are mixed, suggesting PMBR may respond to errors independent of learning rate, or may index inhibition of an action. To address this gap, we ran two experiments on 27 subjects to examine whether M1 PMBR is solely related to error size independent of learning, or whether its relation to error size is also modulated by the history of errors. Both studies required subjects to produce fast planar reaching movements to a target 10 cm ahead. Adaptation was examined by perturbing reaches with a force field on random trials. In Experiment 1, we examined the relation of PMBR to error history by clamping the error to zero on 50% of trials before a perturbation trial. This manipulation revealed that (1) error sizes were the same for a given force-field size across trial sets with or without preceding clamps, and (2) that adaptation rates were lower when preceded by a clamp trial compared to trials without a clamp. EEG source analysis revealed that M1 PMBR magnitude was sensitive to this manipulation, with PMBR being lowest for large errors without a leading clamp trial. This result suggests that the M1 PMBR indexed changes in adaptation rate. We further tested the relation of PMBR to adaptation rate in Experiment 2 by using the same behavioral paradigm while applying 5 pulses of 20 Hz (beta) rhythmic transcranial magnetic stimulation (rhTMS) over M1 after movement cessation. During rhTMS trials, we found ~12% decrease in learning rate. These findings offer the first causal evidence that M1 PMBR is directly involved in scaling learning rates in short-term sensorimotor adaptation.

Title: Task practice intensity estimation in individuals with traumatic brain injury

Authors: *S. K. SUBRAMANIAN[1], J. J. BARELA[1], L. A. LANDRY[1], B. D. SHEFFIELD[1], P. A. RIVERA[5], E. A. KOYLE[5], J. W. NEELEY[5,2], K. AULTMAN[3], R. GRANDHI[4,6]
[1]Physical Therapy, [2]Rehabil. Med., [3]Sch. of Hlth. Professions, [4]Neurosurg., UT Hlth. San Antonio, San Antonio, TX; [5]Reeves Rehabil. Ctr., [6]Univ. Hosp. - Univ. Hlth. Syst., San Antonio, TX

Abstract: Traumatic Brain Injury (TBI) is one the leading causes of mortality and morbidity in the United States. Individuals sustaining a TBI often have motor impairments involving the lower (LL) and upper limbs (UL), with lower levels of improvement seen in the UL compared to the LL. These factors may continue to limit UL involvement in performance of functional activities of daily living, well after cessation of rehabilitation. UL motor improvement after a TBI is attributable in part to adaptive neuroplasticity and motor learning, with the intensity of task-practice representing a key influence. Intensity of task-practice has many definitions, including the time spent in therapy and the number of repetitions employed in a single session. There is a growing consensus that the numbers of repetitions used in a session may be the better choice. The minimum number of repetitions per session of therapy for optimal levels of UL motor improvement in people with TBI is currently unknown. One potential solution, used previously in individuals who sustained a stroke, is to estimate the number of repetitions necessary to achieve a plateau in the performance of a motor task (pointing to a target) using kinematic analysis. Our study objective was to estimate the minimal number of repetitions to achieve an asymptote in a UL pointing task in individuals with TBI. We recruited TBI patients with UL hemiparesis along with age-matched controls. The TBI group was further sub-divided into participants having mild and moderate severity of injuries (based upon 12-hour post-injury Glasgow Coma Scale scores). Both groups of participants were seated. They pointed repeatedly to a target placed in front of them at a distance equal to their UL length. We aligned the target to their sternal notch and placed it at a height of 90° of shoulder flexion. The trial duration was 3-5 seconds and recording frequency was 100 Hz. The primary outcome was the number of trials necessary to achieve an asymptote in the endpoint error during pointing movements. The root mean squared error between the endpoint position and the center of the target at the end of the movement quantified the endpoint error. Secondary outcomes included movement speed and ranges of motion of UL joints (elbow, shoulder) and trunk. Preliminary results indicate that compared to controls, individuals with TBI needed more trials to reach an asymptote in the performance of the pointing movement. In addition, the TBI group had slower movements and used less shoulder horizontal adduction range of motion. Results of this study will help in providing information on the minimal number of repetitions necessary to achieve optimal UL motor improvement in individuals with TBI.

Title: Short-term structural change in fractional anisotropy correlates rapid performance improvement

Authors: *M. KODAMA[1], T. ONO[3], F. YAMASHITA[4], H. EBATA[3], M. LIU[5], S. KASUGA[6], J. USHIBA[2]

Hosp., Yokohama, Japan; [4]Inst. for Biomed. Sci., Iwate Med. Univ., Iwate, Japan; [5]Dept. of Rehabil. Med., Keio Univ. Sch. of Med., Tokyo, Japan; [6]Ctr. for Neurosci. Studies, Queen's Univ., Ontario, ON, Canada

Abstract: Researches on human brain imaging during skill acquisition have revealed structural changes in task-relevant areas. A recent study demonstrated that short-term changes were detected after only 2 h of training, pointing to a rapid timescale of structural plasticity (Sagi et al., 2012). Another study (Wenger et al., 2017) proposed expansion-renormalization model that explains the process of human brain plasticity detected by MRI. According to the expansion-renormalization model, learning-related neural processes often follow a sequence of expansion, selection, and renormalization of neurobiological candidates (e.g., neurons, synapses, astrocytes, and glia cells). However, how such process drives the subsequent behavioral improvement remains unknown. In the current study, we shed light on the short-term (i.e., hour-to-day) plasticity that would reflect the expansion processes and investigated the relationships between short-term plasticity and subsequent motor learning with a longitudinal study.
Fifteen healthy, right-handed participants performed an upper-arm reaching task under left-right mirror-reversal for 5 consecutive days, using KINARM Exoskeleton lab (BKIN Technologies, Canada). To investigate the process of motor learning (i.e., learning speed and final error level), endpoint errors of the participants during the training period (i.e., 1-5 days) were fitted with a

simple exponential function. Participants were scanned with diffusion tensor imaging, an MRI framework which is sensitive to tissue microstructure, before, after the first and fifth days, and 1 week and 1 month after training. Track-based spatial statistics was used to conduct a voxel-wise analysis of fractional anisotropy (FA). In left primary sensorimotor area (SM1), we set region of interest where gray matter increase occurred in the first day of training detected by voxel-based morphometry, which had previously been reported. The ratio of FA decrease after the first day of training in the region of interest was correlated with learning speed of endpoint error ($r = 0.604$, $p < 0.05$ (FDR)), and learning rate from day 1 to day 2 ($r = 0.657$, $p < 0.05$ (FDR)). Considering that FA quantifies the directional dependence of water diffusion and depends on features such as axonal integrity, myelination, axon diameter and density, it is reasonable to assume that FA decreases occurred due to expansion process of Wenger's model (e.g., dendritic branching and axon sprouting). These results suggest that the experience-dependent short-term plasticity drives the subsequent motor learning rapidly.

Title: Gradual and abrupt virtual surgeries elicit two different muscle activation adaptation strategies

Authors: *V. BARRADAS PATINO[1], T. KAWASE[3], Y. KOIKE[4], N. SCHWEIGHOFER[2]
[1]Biomed. Engin., [2]USC, Los Angeles, CA; [3]Inst. of Biomaterials and Bioengineering, Tokyo Med. and Dent. Univ., Tokyo, Japan; [4]Tokyo Inst. Tech., Yokohama, Japan

Abstract: Individuals post-stroke often exhibit "abnormal synergies", pathological patterns of upper limb muscle co-activation that lead to a compromised ability to perform daily life activities. Reducing abnormal muscle co-activation via a myoelectric computer interface has been shown to be feasible for a small set of muscles using arbitrary muscle-to-cursor mappings (Wright et al. 2013). Our long-term goal is to investigate whether abnormal synergies can be reduced by gradually normalizing the activity of multiple muscles via "virtual surgeries". A virtual surgery is a type of unintuitive myocontrol task in which participants control the position of a cursor on a screen using EMG signals collected from multiple upper limb muscles while isometrically producing forces at the wrist (Berger et al. 2013). Here, we investigated how non-

disabled participants learn a virtual surgery task that mimics the abnormal synergies observed post-stroke. Because such surgeries generate low controllability for some directions, and are consequently hard to learn (Berger et al. 2013), we compared learning virtual surgeries abruptly to gradually. In addition, we investigated whether learning such a task exhibits savings following a washed-out task. During the baseline phase of the myocontrol task, the mapping from EMG signals to cursor position corresponds to the direction and magnitude of the forces generated at the wrist on the horizontal plane. Afterwards the virtual surgery is introduced: the mapping is modified, and participants must learn to complete the task under the new mapping. We quantified task performance as the error in cursor initial direction. Preliminary results show that subjects learned how to decrease initial angular error to baseline levels, and exhibited similar levels of washout in the two conditions. We analyzed EMG patterns during the learning, washout, and re-learning phases using methods developed by Golub et al. (2018) and found that while abrupt surgery leads to rescaling of baseline EMG activity, gradual surgeries lead to re-association. Our results suggest that gradual virtual surgery training could be effectively applied in a post-stroke rehabilitation protocol comprised of multiple short bouts of training.

Title: Interlimb transfer of newly learned motor skills

Authors: *G. YADAV, P. MUTHA
Indian Inst. of Technol., Gandhinagar, India

Abstract: Motor learning is beneficial when it transfers to unpracticed conditions. Transfer of learning within and across limbs has been widely investigated in motor adaptation, where people learn to modify motor output while moving under novel conditions. However, whether and how learning of new motor skills, in which subjects overcome performance-limiting relationships, and which is presumably mediated by distinct neural mechanisms, transfers across limbs has not been well studied. We investigated interlimb transfer of newly acquired motor skills in order to understand whether such transfer has features similar to motor adaptation. 58 healthy right-handed individuals learned a new motor task in which they were required to accurately move their hand to one of 8 randomly presented targets within 550 msec. Subjects were divided into

two groups: 1) RL, who practiced with the right arm first followed by the left arm, and 2) LR, who practiced in the reverse order. We assessed transfer by comparing naïve performance of an arm with its performance after the other arm had undergone learning (e.g., the right arm of the RL and LR groups was compared). Based on these findings, we recruited two more groups who practiced the same task, except that they moved only to 1 target instead of 8. We found significant interlimb transfer in both the 8-target and the 1-target cases. Further, unlike adaptation, this transfer was symmetric, i.e. occurred from the left to the right arm and vice-versa. Additionally, we found that in the 8-target condition, subjects learned the new skill consistently faster with their left arm compared to the right. We hypothesized that this might be due to a previously suggested left arm-right hemisphere advantage for control of actions under variable task environment. We confirmed this using the 1-target condition; when task variability was removed by using single target, subjects learned at the same rate with the two arms. In line with prior suggestions, the current study demonstrates a left arm-right hemisphere advantage for motor control under variable task conditions which enables the left arm to learn faster than the right arm. Our study also reveals, perhaps for the first time, that learning a new motor skill in different task conditions can transfer to the untrained arm; and this can have implications for rehabilitation. Such transfer could occur because learning leads to neuroplastic changes in both the hemispheres; or because the untrained arm/hemisphere system has access to neuroplastic changes that occur only in the trained hemisphere. Future studies could help disambiguate these possibilities.

Title: Functional coupling between the basal ganglia and cerebellum during visuomotor adaptation learning

Authors: *C. ARESHENKOFF[1], J. Y. NASHED[2], D. STANDAGE[3], J. P. GALLIVAN[3]
[1]Queens Univ., Kingston, ON, Canada; [2]Ctr. for Neurosci. Studies, [3]Queen's Univ., Kingston, ON, Canada

Abstract: Converging evidence suggests that sensorimotor learning can be decomposed into multiple distinct mechanisms; an implicit process, driven by sensory prediction errors, and an explicit process, driven by a deliberate, strategic process. Work in cerebellar ataxic patients and neurophysiological recording studies heavily implicate the cerebellum in implicit, error-based adaptation, with recent evidence of direct functional connections between the cerebellum and

basal ganglia providing a possible source for the error signals used by the cerebellum during such adaptation. Here, using functional MRI, we examined functional connectivity between the cerebellum (CB), basal ganglia (BG), and cortical motor structures in 34 subjects during the learning and subsequent re-learning of a visuomotor rotation task on two separate days. We found increased coupling between the CB and BG coinciding with the onset of visuomotor rotation learning, which was gradually reduced throughout learning in subjects who exhibited rapid adaptation to the rotation (rapid learners), but which was relatively sustained in subjects who only managed to reduce their errors gradually (slow learners). Further, a subset of slow learners, who displayed rapid learning during the second session, exhibited network profiles remarkably similar to the fast learning subjects during the first session. This suggests that the initial recruitment and timecourse dissolution of a CB-BG subnetwork is linked to individual differences in rates of learning and relearning, and that such subnetwork integration reflects reliance on implicit learning processes.

Title: Muscle-based perturbation using electrical stimulation revealed sensorimotor coordination in multiple muscles during motor adaptation

Authors: *S. HAGIO[1,2], D. NOZAKI[1]
[1]The Univ. of Tokyo, Tokyo, Japan; [2]Res. Fellow of the Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Human sensorimotor system can flexibly modify motor commands to relevant muscles in order to adapt movements to a novel condition resulting from usage of new tool, fatigue, or injury. A lot of researchers have tried to investigate the characteristics of the sensorimotor adaptation using experiments in which the interaction between internal and external states in the motor system was modified with novel force fields or visuomotor rotation during reaching movements (Shadmehr et al., 1994; Krakauer et al. 2000). However, the sensorimotor coordination in multiple muscles during the adaptation has not been fully elucidated. To approach to this problem, in the present study, we proposed the adaptation paradigm to the alteration of the mechanical output in a single muscle; we built the system for inducing fatigue to

a target muscle using high-frequency electrical muscle stimulation (EMS). Participants sat in a chair and held a handle attached to six-axis force transducer by their right hand. A cursor was displayed in a screen located in front of their body, the xy-coordinates of which represented the vectors of horizontal isometric force, F_x and F_y, produced against the handle. The experimental session consisted of baseline and EMS blocks. In the baseline block, the subjects were instructed to move the cursor from a start position to one of the 8 equally placed targets by 45° as straight as possible and maintain the cursor position at the target for 1.5 seconds. The magnitude of force was determined based on the force during maximal voluntary isometric contraction (MVC). In the EMS blocks, a triceps brachii muscle (TrBrac) was electrically stimulated through surface electrodes. Trains of rectangular, balanced, biphasic and asymmetric pulses were applied at fixed frequency (80 Hz), fixed duration (1 msec), and the amplitude was adjusted to produce approximately 20 % level of MVC at the beginning of the EMS trial. The continuous high-frequency EMS rapidly reduced the force induced by the EMS up to 2 minutes (Bigland-Ritchie et al. 1979). To measure the learning response, we randomly interleaved the cursor-clamp trials, with which the trajectory of the cursor was constrained to a straight path from the start position to the target. After the EMS to TrBrac, the produced force was deviated to the lateral direction from the straight path to the target, which was opposite to the force direction produced by TrBrac stimulation. However, the participants rapidly reduced the errors to adapt to the change of the dynamics in the motor system due to muscle fatigue. The EMS for muscle-based perturbation enabled us to unravel the sensorimotor coordination in multiple muscles during the adaptation.

Title: Age-related decline in motor cortical GABA promotes retention of sensorimotor adaptation

Authors: *G. SPITZ[1,2], P. PETITET[1], H. JOHANSEN-BERG[1], J. O'SHEA[1,3]
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Monash Inst. of Cognitive and Clin.

Neurosciences, Monash Univ., Melbourne, Australia; [3]Donders Inst. for Brain, Cognition and Behaviour, Radbound Univ., Nijmegen, Netherlands

Abstract: Sensorimotor cortex mediates the early consolidation of motor memories. Using a prism adaptation task, we have shown that individual differences in retention are causally related to the neurochemical balance of excitation/inhibition (GABA/Glutamate) in sensorimotor cortex. In young adults, lower levels of GABA are associated with greater retention. Here we investigated whether this relationship between sensorimotor cortex neurochemistry and retention is preserved with age. We predicted that: 1) individuals with lower GABA would show greater retention; 2) individuals with higher GABA concentration would be more responsive to brain stimulation that lowers GABA—resulting in increased retention. We recruited 32 men (mean age of 67.5 years, SD = 8.1). To test prediction 1, participants underwent magnetic resonance spectroscopy (MRS) and a single session of prism adaptation. Participants adapted to a 10-degree rightward optical shift. Retention of the leftward prism after-effect was assessed after 10 minutes and 24 hours. MRS data quantified the concentration of GABA and Glutamate/Glutamine (Glx) in sensorimotor cortex (2 cm^3 isotropic VOI) and occipital cortex (control). To test prediction 2, participants underwent two further sessions of prism adaptation, combined with real or sham anodal transcranial direct current stimulation (TDCS; 1mA, 20minutes, 7 x 5 cm electrodes) of sensorimotor cortex. Prediction 1 was confirmed. Participants adapted to prisms and showed short (10 minutes) (t = -11.2, p<.001) and long-term retention (24 hours) (t = -2.70, p < .01). We observed three inter-related correlations: 1) older individuals showed greater long-term retention (r = -.50, p <.05); 2) older individuals had lower GABA levels in sensorimotor cortex (r = -.52, p = 0.012); 3) individuals with lower GABA levels in sensorimotor cortex showed greater 24-hour retention (r = .73, p < 0.001). We performed mediation analysis: GABA concentration explained the relationship between age and retention (66% variance). Prediction 2 was confirmed. At the group mean level, there was no significant overall increase in retention with anodal stimulation compared to sham. However, across individuals, higher basal GABA levels correlated with stimulation-increased long-term retention (anodal>sham; r = .52, p < .05). This relationship was temporally, neurochemically and anatomically specific. We observed similar findings in the elderly to our earlier work in young adults. Individual differences in the balance of neurochemical excitation/inhibition in sensorimotor cortex is causally related to individual differences in behavioural retention of sensorimotor adaptation.

Title: The effect of task-irrelevant outcome on implicit sensorimotor adaptation

Authors: *G. AVRAHAM[1,2], D. E. PARVIN[1,2], H. E. KIM[1,2], R. IVRY[1,2]
[1]Psychology, [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: When performing motor tasks, humans adapt to variations in the environment and changes in their body state. This learning process can be driven by both error and reward signals. How these signals interact has been the subject of considerable research. We recently addressed this question, using a visual error clamp in which the spatial trajectory of a feedback cursor is independent of the movement path; this method allows us to measure error-based adaptation when the error signal remains invariant and is not influenced by behavioral changes (Morehead et al. 2017; Kim et al., 2018). By varying the size of the target, the cursor could land consistently inside or outside of the target. The learning rate and aftereffect are smaller in the former compared to the latter case (Kim et al., in prep). Based on a series of control experiments, we concluded that, even though participants are aware that they do not control the path of the cursor, an "intrinsic reward" signal is generated when the cursor lands inside the target, and this signal attenuates the error-based learning process that underlies sensorimotor adaptation.
In the current study, we explored whether an "intrinsic reward" would occur even when the cursor hit a task-irrelevant landmark. On each trial, a ring of grey landmarks was presented, one of which turned blue to indicate the target location. The participant made a rapid reaching movement, attempting to intersect the target. After a baseline session in which the cursor feedback was veridical, the clamp manipulation was described, with the instructions emphasizing that the path of the cursor was independent of their hand movement. The clamped feedback followed a path that deviated from the target by 15^0. For one group of participants, the landmarks were spaced by 15^0; thus, the clamped cursor always terminated inside a landmark adjacent to the target. For the other group, the landmarks were spaced by 22.5^0; here, the clamped cursor always landed between the target and adjacent landmark. In this manner, we sought to test the hypothesis that "reward signals" are generated in an implicit and automatic manner if a feedback cursor lands within an object, even if that object is not part of the task goal. Preliminary results indicate that the size of the aftereffect is attenuated when the cursor lands inside a landmark. However, the learning functions in this condition are highly variable, with some participants showing a marked non-monotonicity and a corresponding increase in reaction time during the clamped feedback session. These results suggest that hitting a task-irrelevant landmark can alter behavior through a change in strategy, rather than modulating adaptation directly.

Title: Learning of kinematic and dynamic transformations after spinal cord injury

Authors: *Y. LEI[1,2], M. A. PEREZ[1,2]
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Bruce W. Carter Dept. of Veterans Affairs Med. Ctr., Miami, FL

Abstract: A critical component of motor learning is the ability to form internal models for sensorimotor transformations, which largely rely on afferent inputs from the periphery. Spinal cord injury (SCI) often disrupts the integrity of afferent axons projecting through the spinal cord dorsal columns to the brain. The aim of our study was to examine adaptations to kinematic (visuomotor rotation) and dynamic (velocity-dependent force) transformations in humans with cervical SCI and uninjured controls. We found that individuals with SCI showed slower adaptation rates to kinematic but not dynamic errors compared with controls participants. Individuals with SCI with greater deficits in limb position sense exhibited slower adaptation rate to kinematic but not dynamic errors. SCI participants showed a weaker kinematic internal model compared with controls, as exhibited by weaker after-effects. These findings suggest that spinal cord integrity is critical for learning kinematic models. We propose that enhancing sensory function can be used for improving learning of kinematic errors after human SCI.

Title: Individual patterns of sensorimotor adaptation to novel mechanical loads and visuomotor rotations

Authors: *R. T. MOORE, T. CLUFF
Fac. of Kinesiology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Humans can perform a range of motor actions, from playing piano to throwing a baseball, but vary in how well they learn to perform these skills. It has been challenging to understand individual patterns of motor adaptation because studies have focused on the average behaviour of groups of subjects when adapting their arm movements to counter visual or mechanical disturbances. It is unclear if, and to what extent, individual patterns of motor adaptation are preserved when exposed to diverse visual or mechanical disturbances. Here we examine how individual participants adapt their reaching movements when exposed to novel mechanical environments and visual transformations. Experiments were performed using a planar robotic exoskeleton (BKIN Technologies, Kingston, ON). Subjects completed 15 cm reaching movements within 500 ms of leaving the start position (diameter = 2 cm). The goal target (diameter = 2 cm) turned green if the participant completed their movement on time and blue if they did not. We first exposed subjects (n=20) to novel velocity- and position-dependent force fields. We then examined how a separate group of subjects (n=20) adapted to a visuomotor rotation (30° CCW) and velocity-dependent force field. After a baseline period (50 trials), we introduced a novel visual or mechanical disturbance (200 trials). Adaptation was washed out (50 trials) before subjects performed the second task. We generated adaptation profiles for each subject by measuring peak perpendicular (mechanical loads) or angular (visuomotor rotation) deviations between their hand path and a straight line joining the start and end targets for each movement. We also calculated the amount of adaptation participants attained over the last 25 trials they performed in each condition. We found participants attained similar amounts of adaptation when exposed to position and velocity-dependent forces ($p > 0.1$), but adapted faster to the position-dependent forces. Interestingly, we observed a moderate correlation between the amount of adaptation participants attained when learning to counter position- and velocity-based forces ($r = 0.51$, $p < 0.05$). In the second experiment, participants adapted faster ($p < 0.05$) but to similar amounts ($p > 0.1$) when exposed to velocity-based forces compared to the visuomotor rotation. The amount participants adapted did not correlate across visual rotation and mechanical load tasks. Our results reveal commonalities in the amount individual participants adapt to mechanical disturbances, despite marked differences in the shape of their adaptation profiles. Adaptation patterns were not conserved when exposed to novel visual and mechanical disturbances.

Title: Reaching movements in force-fields simulated by a motor control-learning model without desired trajectory

Authors: *H. KAMBARA, H. SHIMIZU, T. KAWASE, A. TAKAGI, N. YOSHIMURA, Y. KOIKE
Tokyo Inst. Technol., Yokohama-shi, Japan

Abstract: Arm reaching is one of the motor tasks that has been studied a lot to clarify mechanism underlying neural motor control. Force-fields adaptation task is one of the motor task frequently used to investigate the process of motor learning (or motor adaptation) when normal reaching movement is disturbed by the force imposed to the hand.
Several computational models have been proposed to explain how the brain adapts reaching skill to compensate perturbing force and to became able to generate accurate and smooth reaching motion. Some of them assume the existence of desired trajectory, and claim that the brain is learning set of motor command signal that can move the hand along with the desired trajectory under the force. On the other hand, Izawa et al. (2008) observed that the movement trajectories after adapting to the force became different from the ones in baseline condition. And they suggested that the movements are re-optimized to behave optimally under force perturbation rather than canceling the force to trace same trajectory as baseline movement. Although optimal feedback controlled based models have succeeded in reconstructing kinematic features of force adaptation task, all of them simplified the dynamics of the arm to a point-mass model.
Here we apply our motor control-learning model to force-fields adaptation task in which arm is driven by nonlinear musculoskeletal dynamics. An advantages of our model is that it does not require prior knowledge about the dynamics of controlled object and. As results of simulation, we show that kinematic features during before and after adaptation to velocity-dependent force-field can be reproduced without assuming desired trajectory. In addition, we show that muscle activation pattern found in divergent force-field experiment can also by reproduced by our model.

Title: Implicit adaptation is sensitive to relevance of multiple cursors

Authors: *D. E. PARVIN[1], J. R. MOREHEAD[2], K. V. DANG[3], A. R. STOVER[3], R. B. IVRY[1]
[1]UC Berkeley, Berkeley, CA; [2]Sch. of Engin. and Applied Sci., Harvard Univ., Cambridge, MA; [3]Univ. of California, Berkeley, Berkeley, CA

Abstract: Implicit sensorimotor adaptation is thought to be driven by discrepancies between 'predicted' and 'actual' feedback, or sensory prediction errors (SPEs). It has been suggested that this process is automatic and obligatory, even when detrimental to task success (Srimal et al., 2008; Mazzoni & Krakauer, 2006). To explore whether implicit adaptation is truly insensitive to the task conditions, we manipulated the relevance of the sensory feedback. Specifically, using a center-out reaching task, multiple feedback cursors with different rotations were presented simultaneously (Kasuga, Hirashima & Nozaki, 2013). By using redundant feedback signals, the movements and feedback could be held constant while instructions were used to manipulate the task relevance of the feedback signals.

In experiment 1, three cursors were simultaneously presented as participants reached towards a target located at one of three locations. In the baseline phase, the cursor rotations were -45º, 0º and 45º with respect to hand position and participants were instructed to hit the target with the middle, 0º cursor. Three conditions in the training phase were compared. For each condition we varied the mean rotation of all three cursors, and the "task-relevant" cursor, defined by the one they were instructed to hit the target with. The other two cursors were irrelevant distractors. If adaptation was insensitive to task relevance, adaptation should be driven by the mean rotation of all three cursors. If on the other hand, adaptation was sensitive to task relevance, adaptation should be driven specifically by the rotation of the task-relevant cursor with respect to the hand. In all groups, participant's performance and aftereffects were consistent with them effectively ignoring the irrelevant cursors.

In experiment 2 we assess the strength of the effect of relevance by contrasting it to another manipulation known to affect the strength of implicit adaptation - delaying feedback. In the training phase, two cursors are presented: The first cursor is rotated by 45º and is presented immediately with online feedback. The second cursor follows the veridical trajectory of the hand, but is presented after a delay of two second after the completion of the reach. Participants are instructed to hit the target with the delayed and non-rotated cursor, and to ignore the

immediate and rotated cursor. If using delayed cursor feedback is sufficient to attenuate adaptation from irrelevant cursors, we would expect no adaptation, whereas if it is not sufficient, we would expect to see adaptation.

Title: Neural substrates of reward and sensory error based reach adaptation

Authors: *D. PALIDIS[1], P. L. GRIBBLE[2]
[1]Psychology, Univ. of Western Ontario, London, ON, Canada; [2]Brain and Mind Institute, Dept. Psychology, Western University, Canada, London, ON, Canada

Abstract: Adaptation of motor output to changing environments occurs by multiple distinct processes. In sensory error based learning, it is thought that the nervous system predicts the sensory outcomes of motor commands, and that sensory prediction error drives learning when sensory input differs from these predictions. In reinforcement learning, it is thought that the brain predicts the subjective value of actions, and that reward prediction error, signaled by midbrain dopamine neurons, drives learning when outcomes differ in value from these predictions. Actions that produce better than expected outcomes are reinforced, while actions that produce worse than expected outcomes are deterred. We recorded EEG activity to identify and dissociate the neural correlates of reward and sensory prediction error elicited by feedback in two different sensorimotor learning tasks designed to isolate each response. We observed sensory error based learning in a visuomotor rotation task, in which feedback was provided in the form of a cursor that indicated movement endpoint. During randomly selected trials, the cursor was rotated around the starting position of the reach to induce sensory prediction error. Participants adapted their reaches on a trial by trial basis to compensate for these perturbations. In a reward learning task, binary reward feedback indicated whether each reach was successful or unsuccessful without revealing hand position at movement endpoint. Reward was delivered probabilistically according to reach angle, and participants adapted their reaches to produce reach angles that resulted in higher reward probability. We administered levodopa, a dopamine agonist, and placebo in a repeated measures double blind randomized controlled design to test the role of

dopamine signaling in neural and behavioural responses to reward and sensory error processing. We found that a fronto-central event related potential called the feedback related negativity specifically encoded reward prediction error during reward based learning, but did not occur during the sensory error based learning task. These findings suggest that the feedback related negativity is specific to processing reward prediction error, as opposed to general error processing. Furthermore, distinct patterns of event related spectral modulation were evoked by sensory error feedback and reward feedback. We evaluate the effect of dopaminergic manipulation on behavioral learning and neural responses to feedback. Our results reveal a dissociation between EEG signatures of error and reward processing in two distinct motor learning processes.

Title: Value of segmental kinematic information for learning external locomotor dynamics

Authors: P. F. JALILI[1], S. E. GOODMAN[2], *C. J. HASSON[2]
[2]Dept. of Physical Therapy, Movement and Rehabil. Sci., [1]Northeastern Univ., Boston, MA

Abstract: In the field of human sensorimotor control, there is significant evidence that proprioception plays a key role in learning novel dynamics. There is also evidence that vision can make meaningful contributions in more complex dynamical situations; however, this is less well-understood. The role of vision in learning dynamics is an important practical question, particularly in rehabilitation. In manual gait training, therapists need to effectively control the complex locomotor dynamics of patients. However, the segmental kinematics of a locomoting patient, which influence the mapping between joint torques and end-point forces, cannot be directly sensed through proprioception. Thus, vision of segmental kinematics should be important when learning external locomotor dynamics. This study tests the hypothesis that seeing the segmental kinematics of a patient's leg improves the ability to manipulate locomotor patterns, and is associated with a stronger internal representation of patient locomotor dynamics. Because this study focuses on the learning of the caregiver (e.g., therapist) instead of the patient, variability on the patient-end was controlled with a newly developed interactive locomotor simulator. This consists of an impedance-based model of stroke patient locomotor dynamics, called a virtual patient (VP), which subjects interact with through a small robotic manipulandum. Subjects were asked to use their dominant hand to practice moving the VP into a healthy gait pattern; the point of interaction was the VP's ankle. To accomplish this, subjects had to

compensate for the resistive force field created by the VP, which attempted to walk in an asymmetrical, non-healthy, locomotor pattern. Random catch trials were used to probe the presence of aftereffects and the degree of generalization was used to assess internal representations. One group of subjects saw a stick-figure representation of the VP's leg during training; a second group only saw a point representing the VP's ankle. Early results support the hypothesis that seeing stick-figure segmental kinematics aids subject manipulation performance by reducing kinematic errors, and this is associated with a stronger internal representation of locomotor dynamics (i.e., larger aftereffects/improved generalization). If supported with further data, this would highlight the importance of visual information when interacting with complex dynamics external to the body. It may also open the door for augmentation of therapist visual feedback to improve care delivery and patient rehabilitation outcomes.

Title: Quantification of active phase corticosterone during baseline, oral nicotine, and withdrawal conditions

Authors: *A. ALVARADO, H. MATTHEWS, J. STITZEL
Univ. of Colorado Boulder, Boulder, CO

Abstract: In spite of heightened education and prevention strategies, cigarette smoking remains a major health risk. As nicotine is the major psychoactive component in tobacco, it is of interest to understand the behavioral and physiological effects of nicotine and nicotine withdrawal that could contribute to ongoing tobacco use. One physiological effect of nicotine use and withdrawal from chronic nicotine is a disruption in the hypothalamic-pituitary-adrenal (HPA) axis. This drug-induced disruption in HPA function is thought to be important for drug dependence. The present study aimed to assess disruption of the HPA axis via the observation of corticosterone levels during baseline, oral nicotine, and withdrawal conditions. Adult female C57BL/6J mice were individually housed and maintained on a 12 hr light/12 hr dark cycle with ad libitum access to food and a 0.2% saccharin drinking solution. Pre-nicotine baseline (BL) blood samples were collected at ZT12 one week after placement in individual cages. To establish nicotine dependence, 200µg/ml nicotine was added to the 0.2% saccharin water. After 14 days of nicotine exposure, withdrawal was induced by excluding the nicotine from the water. Animals served as

their own control, and blood samples were collected at ZT12 on nicotine day 8 (N8) and withdrawal day 1 (WD1). Compared to BL, corticosterone levels were significantly decreased for both N8 and WD1 suggesting a blunted HPA axis activity in the animals. No significant difference was observed between N8 and WD1 time points. These data are consistent with human literature, yet it remains unclear whether the WD1 response is a consequence of abstinence or whether it is a symptom of the disruptive effect of exposure on the HPA axis that persists during withdrawal. Samples will be collected for WD5 to see if blunted corticosterone levels persist throughout withdrawal. In addition, samples will be collected at ZT0 to determine if there is diurnal variation and to explore whether this physiological measure is time-of-day dependent. These data could elucidate long-term disruptions in the HPA axis that make smoking cessation increasingly difficult.

Title: Thalamus modulates cortical gamma oscillations via a chain of phase coupling and phase amplitude coupling

Authors: *S. NIKETEGHAD[1], M. MALEKMOHAMMADI[2], E. TSOLAKI[3], H. SPARKS[2], N. POURATIAN[3]
[1]Bioengineering, Univ. of California Los Angeles, Panorama City, CA; [3]Neurosurg., [2]Univ. of California Los Angeles, Los Angeles, CA

Abstract: Objective We have previously shown thalamo-cortical α and low-β oscillations are dampened during voluntary movement. This change in oscillatory power in both thalamus and cortex is accompanied by a suppression in thalamo-cortical phase coupling as well as thalamo-cortical/cortico-cortical Phase Amplitude Coupling (PAC) between phase of α /low-β and amplitude of γ oscillations. Investigating the causal relationship among these measures is a crucial step towards understanding the oscillatory mechanism of the thalamo-cortical network and its role in regulating voluntary movement. **Method** Local Field Potentials (LFPs) from Ventral Intermediate (ViM) nucleus of the thalamus were recorded from Essential Tremor (ET) patients during Deep Brain Stimulation surgeries. Simultaneously, we recorded LFPs from sensory-motor cortex via a subdural ECoG strip. Causality analysis was performed using Directed Transfer Function (DTF) method between Thalamic and cortical signals. Phase

Amplitude Coupling (PAC) among all possible contacts in the thalamo-cortical network was measured using Modulation Index (MI) method. The phase lag likelihood was measured between ViM and cortex and was compared against the difference between preferred phase of the thalamo-cortical and cortico-cortical PAC. **Results** In subjects with significant resting state thalamo-cortical phase coupling and PAC, the phase lag likelihood matched the difference between thalamo-cortical and cortico-cortical PAC in alpha/low-beta band. Moreover, causality analysis showed that ViM leads the thalamo-cortical coupling. **Conclusion** Our findings indicate that γ oscillations which are associated with the execution of voluntary movement may be modulated by ViM via a chain of thalamo-cortical α /low-β phase coupling and cortico-cortical PAC. This provides a basic understanding of subcortico-cortical communications through phase and cross frequency coupling and may be extended to other brain areas during different functions.

Title: The relationship between implicit and explicit visuomotor task learning in hippocampus and parietal cortex

Authors: *R. LIENKÄMPER, M. SAIF-UR-REHMAN, Y. PARPALEY, J. WELLMER, C. KLAES
KlaesLab, Knappschaftskrankenhaus Bochum, Bochum, Germany

Abstract: It has been shown that different brain structures are active while learning an explicit or implicit task. The structure mostly associated with explicit learning is the hippocampus, while implicit learning is believed to mainly rely on frontal areas, basal ganglia and the parietal cortex. However, both types of learning can interact with each other depending on the task instructions. Furthermore, tasks that have been learned explicitly can be transformed into an implicit representation after overlearning.
Apart from the tasks explicitness, the involvement of hippocampus and parietal cortex has also been shown to vary depending on the difficulty of a task and its novelty. However, transitions from the involvement of one structure to the other are not yet understood. Using state-of-the-art virtual reality technology and EEG as well as ECoG recordings, we are investigating the changing involvement of hippocampus and parietal cortex during a centerout reaching task under three conditions: Visuomotor adaptation, visuomotor transformation and visuomotor association.

For the visuomotor adaptation, we are introducing a misalignment between visual input (the observed movement of the arm in virtual reality) and the motor output (the movement of the subject's arm in reality). During visuomotor transformation, the subject is instructed to move his / her arm towards, for example reach to the clockwise neighbour of the visual cue. The concept is similar to the adaptation condition but relies on an explicit rule instead of a misalignment. Visuomotor association represents the most explicit condition in our experiment. In this condition, a non-spatial cue (a number word, e.g. "three") is shown and must be associated with one of the possible targets (which are labeled with numbers, e.g. "3").
These three conditions form a transition from implicit (visuomotor adaptation) to explicit learning (association). By altering the strength of the misalignment during the adaptation, using more complex transformation rules ("reach to opposite direction of the cued target") and different association cues (e.g. "Five minus two" instead of "three"), we can alter the difficulty of the task as well. Finally, the amount of training spent on a specific condition of the task is a gradual change in the tasks novelty.
Preliminary results shows that the strength of misalignment in adaptation condition significantly impacts the path length and completion time, indicating that it is indeed a change in the task difficulty.

Title: Effects of distance control practice of lower limb on motor skill learning and transfer in patients with cerebellar disease

Authors: *J.-H. PARK
Korea Univ., Seoul, Korea, Republic of

Abstract: Cerebellar disorders are characterized by irregular steps, difficulties with inter- and intra-limb coordination, and reduced postural stability. In particular, impaired control of lower limb movement are often major causes of functional disturbances that affect patient's independent activities in daily living. At present, there is a lack of studies on how repeated practice of lower limb movement influences motor learning and transfer in patients with cerebellar disease. The aim of this study was to investigate the effect of distance control practice using lower limb on motor skill learning and generalization to different task conditions in patients with cerebellar disease. Twelve individuals with cerebellar disease (CD) and age- and

sex-matched 12 normal controls participated in the study. Both group practiced reaching to the targets with their right lower limb presented at three distances (5, 10, 15cm) while sitting. Kinematic data were measured to determine scaling of movement accuracy from start to target position. Performance was tested pre- and post-training for retention effect and two learning transfer conditions (horizontal & vertical directions). The results demonstrated that both groups showed significant improvements in 5cm, 10cm and 15cm distances while distance errors of CD patients were higher than normal controls. In addition, there were significant learning transfer effects to new task conditions, but less evident improvement was observed in vertical direction transfer condition in CD group. Taken together, the results from this study suggest that even though the cerebellum is damaged, task-specific motor training is a promising intervention for improving skill learning for distance control of lower limb and motor generalization in patients with cerebellar ataxia.

Title: Interlimb generalization of learned bayesian prior occurs in extrinsic coordinates

Authors: C. L. HEWITSON[1,2], P. F. SOWMAN[1,2], *D. M. KAPLAN[1,2]
[1]Dept. of Cognitive Sci., [2]ARC Ctr. of Excellence in Cognition and its Disorders, Macquarie Univ., Sydney, Australia

Abstract: Recent work suggests that the brain represents probability distributions and performs Bayesian integration during sensorimotor learning. However, our understanding of the neural representation of this learning remains limited. To begin to address this, we performed two experiments. In the first experiment, we replicated the key behavioral findings of Körding and Wolpert (2004), demonstrating that subjects can perform in a Bayes-optimal manner by combining information about their own sensory uncertainty and a statistical distribution of lateral shifts encountered in a visuomotor adaptation task. In the second experiment, we extended these findings by testing whether visuomotor learning occurring during the same task generalizes from one limb to the other, and relatedly, whether this learning is represented in an extrinsic or intrinsic reference frame. We found that the learned mean of the distribution of visuomotor shifts generalizes to the opposite limb only when the perturbation is congruent in extrinsic coordinates,

indicating that the underlying representation of learning acquired during training is available to the untrained limb and is coded in an extrinsic reference frame.

Title: Perception and visuomotor adaptation share the same psychological space

Authors: *C. CAMPAGNOLI, J. A. TAYLOR
Princeton Univ., Princeton, NJ

Abstract: Several features of a visual scene can potentially serve as feedback for movement planning. One compelling example of such mechanism is motor adaptation in an error clamp paradigm: in it, participants aim a series of reaching movements at an instructed location, while receiving endpoint feedback at a different location regardless of the actual movement direction. Even though they are told to ignore the feedback, participants gradually bias their reaching movements in opposite direction to that specified by the clamp, as if trying to compensate for an error. This subconscious behavior is commonly referred to as implicit adaptation.
When studying the spatiotemporal unfolding of visuomotor implicit adaptation, it is commonly assumed that the magnitude of the error signal (i.e., the simulated size of the clamp) is somehow accurately estimated by the visuomotor system. However, this statement contrasts with many psychophysical studies showing that spatial perception is often inaccurate. In this study we investigated whether the same visual feature is retrieved from different psychological spaces for motor adaptation and for perception.
We started exploring this problem using a Virtual Reality setup, where we instructed our participants to perform reaching-in-depth movements towards a target. At the beginning of each trial, they viewed a 42 cm wide circular target at a distance of 2 meters, in the middle of the visual field. Participants were asked to throw a virtual cursor at the center of the target, but to ignore the clamped endpoint feedback: regardless of the actual hand's direction, the cursor always hit off the target by a fixed horizontal offset. In a blocked design, two different groups saw the target either alone (No-depth condition) or embedded in a 3D scene (Depth condition). As expected, overall participants showed implicit adaptation in response to a task-irrelevant error clamp. Importantly, the size of the motor compensation was smaller in the Depth condition, although in principle the movement could be planned using only retinal information in both

conditions. Furthermore, these results mirrored those of a perceptual task, which showed that, in the Depth condition, the target appeared overall smaller than in the No-Depth condition. Taken together, these findings suggest that the size of the error clamp was estimated differently depending on the presence or absence of depth information, irrespective of the task. This suggests that perception and adaptation share a common psychological space.

Title: Searching for sensitization to visuomotor errors with task-irrelevant clamped feedback

Authors: *J. R. MOREHEAD[1], H. E. KIM[3], D. E. PARVIN[4], R. IVRY[5], M. A. SMITH[2]
[1]Sch. of Engin. and Applied Sci., [2]Sch. Engin., Harvard Univ., Cambridge, MA; [3]Dept. of Psychology, Univ. of California, Berkeley, Berkeley, CA; [4]UC Berkeley, Berkeley, CA; [5]Univ. California, Berkeley, CA

Abstract: Visuomotor adaptation is thought to be driven by errors. Much work has proposed that the motor system may alter its sensitivity to errors over time (Burge, Ernst & Banks, 2008; Zarahn et al.; 2008; Herzfeld et al., 2014). However, the experiments inspiring these proposals did not control explicit aiming strategies, leaving the possibility that the observed behavior may not reflect the implicit recalibration of a visuomotor map. Recent work that did control cognitive aiming strategies has shown that the initial rate of learning increases linearly for errors smaller than 4.5°, before becoming saturated for error sizes larger than 4.5° (Kim et al., 2018). However, after prolonged training, this study showed that asymptotic learning from all error sizes reached a similar magnitude. This conflicts with the predictions of state-space learning models featuring a fixed learning and forgetting rate (Thoroughman & Shadmehr, 2000). For these models, large early differences in learning rate across error sizes would cause substantial differences in the magnitude of asymptotic learning. A way that the motor system could have different early learning rates but also similar asymptotic learning magnitudes across error sizes is that the it becomes sensitized to small errors (< 4.5°) over repeated exposures, eventually delivering the same response that errors larger than 4.5° would evoke, causing asymptotic learning state to be similar across error sizes.
We tested this hypothesis by comparing the asymptotic magnitude of learning between two groups. After a baseline of 40 cycles, the Sensitized group (n=15) had extended exposure (480

cycles) of clamped visual feedback offset by ±2.5° from the reach target. The Unsensitized group (n=20) was first exposed to 320 cycles of clamped feedback offset by ±7.5°, which then changed to ±2.5° for the remaining 160 cycles (counter-balancing offset sign). This afforded comparison of the magnitude of asymptotic learning from a 2.5° error, for a group that was allowed sufficient exposure to become sensitized to the 2.5° error and one that was not. The prediction of the sensitization hypothesis is that the mean hand angle of the Unsensitized group will drop below that of the Sensitized group during the final 160 cycles of the perturbation because the Unsensitized group will have a smaller learning rate. The Unsensitized group dropped to 3.2° below the Sensitized group, but this was not significantly different (p=.31, 95% CIs = [-3.2°,9.6°]). This lack of a difference could indicate that sensitization is not taking place, but our results were underpowered to detect a difference. Therefore, further work is needed to assess the sensitization hypothesis.

Title: Suppression of lateral prefrontal cortex impairs somatosensory working memory

Authors: *A. SIDARTA[1], N. KUMAR[2,1], T. F. MANNING[1], D. J. OSTRY[1,3]
[1]Dept. of Psychology, McGill Univ., Montreal, QC, Canada; [2]Indian Inst. of Technol. Gandhinagar, Gandhinagar, India; [3]Haskins Labs., New Haven, CT

Abstract: The capacity to maintain in working memory previously performed movements, and their success or failure, presumably plays a substantial role in human motor learning. Indirect evidence in support of this idea comes from a recent study in which we found that motor learning is associated with changes in functional connectivity between second somatosensory cortex (SII) and right BA 9/46 (lateral prefrontal cortex), the latter presumably is important for somatosensory working memory. In the current study, we directly tested the hypothesis that lateral prefrontal cortex is the neural substrate of somatosensory working memory. We used a variant of an *N*-back procedure to assess working memory. On each trial a robotic device displaced the participants arm (without vision of the arm) in a number of different directions (memory set), and this was followed by a test displacement (also without vision) that was used to assess working memory. On half of the trials, the test direction was one of the items in the

memory set, and in the other half it was not. Participants had to indicate whether or not the test movement was from the memory set. Performance was estimated using hits and false alarms. We observed a reduction in the working memory performance following a cTBS protocol to the right lateral prefrontal cortex (BA 9/46). To assess the specificity of the finding, we recruited a control group that received sham cTBS to the same cortical region. The sham stimulation involved similar tactile and auditory effects without the actual stimulation pulses. Given that somatosensory working memory is necessary for reinforcement-based motor learning, our future plan is to test the effect of cTBS directly on motor learning.

Title: Somatosensory but not primary motor cortex is involved in the consolidation of motor memory

Authors: *N. KUMAR[1,2], T. F. MANNING[2], A. SIDARTA[2], D. J. OSTRY[2,3]
[1]Indian Inst. of Technol. Gandhinagar, Gandhinagar, India; [2]Dept. of Psychology, McGill Univ., Montreal, QC, Canada; [3]Haskins Labs., New Haven, CT

Abstract: There has been recent interest in the idea that motor learning does not occur in isolation but rather that motor learning involves changes to sensory systems and sensory networks in the brain as well. As an example, previous studies of sensorimotor adaptation have shown that motor learning is associated with a systematic change in the sensed position of the limbs. Consistent with this finding, neuroimaging studies have found learning related changes in both sensory and motor areas of the brain. The neuroplasticity that is seen in sensory systems following motor learning could be driven by corticocortical connections between motor and somatosensory cortex such that motor outflow during learning causes the changes in somatosensory cortex. Another possibility comes from motor learning studies in rats which suggest that plasticity in somatosensory cortex could be a result of its role in processing sensory error information during motor learning. However, it is unknown whether these learning related changes in somatosensory cortex play any role in the consolidation of motor memories developed through motor learning. We test the hypothesis that somatosensory cortex contributes directly to the consolidation of motor memory by using inhibitory transcranial magnetic

stimulation. Participants perform a motor learning task which involved force-field adaptation. Immediately following adaptation, we applied continuous theta-burst transcranial magnetic stimulation (cTBS) to suppress activity in primary somatosensory cortex (S1) with the goal of blocking motor memory consolidation. Subjects returned to the laboratory 24 hours later to test for memory retention. It was seen that stimulation of somatosensory cortex following adaptation greatly reduces retention. Sham TMS to S1 does not interfere with retention, nor is the interference following stimulation of S1 due to the spread of current from S1 to motor cortex (M1). This is shown by applying cTBS stimulation directly to M1. Suppression of M1 does not interfere with retention of motor learning and participants' performance was similar to that of the sham control group. These results suggest that primary somatosensory cortex is involved in the initial consolidation of motor memories developed during sensorimotor adaptation.

Title: Environmental compliance modulates the rate of motor learning

Authors: *L. ALHUSSEIN[1], A. E. BRENNAN[2], M. A. SMITH[3]
[1]Sch. of Engin. and Applied Sci., [3]Sch. Engin., [2]Harvard Univ., Cambridge, MA

Abstract: The motor system has the ability to update subsequent actions based on the error resulting from the current action. The ability to learn from errors in our movements is crucial for motor skill acquisition, and allows for an automatic adjustment, for example, of subsequent saccadic gain following an eye saccade that falls short of its target. While our motor systems have the remarkable ability to not only correct for motor errors by adapting motor output, it can also modulate the rate at which this error-dependent motor adaptation occurs. However, although the relationship between the size of error and the subsequent adaptive response has been extensively studied, less is known about the mechanisms governing how this relationship changes. A greater understanding of these mechanisms may offer deeper insight into the underlying organization of the motor system itself. We have previously reported that the motor system can modulate its learning rate based on environmental consistency. Here we demonstrate that an internal estimate of the physical compliance of an environment is another critical determinant for the learning rate. We used a reaching task where participants were asked to move towards a straight-ahead target, where we dramatically increased the compliance of the

environment by guiding participants' movements through virtual force-channels (FC) in directions that varied from the target direction. These FC trials were implemented as a high-stiffness one-dimensional spring that resisted lateral deviations from a pre-defined straight-line path but had no effect on longitudinal movement. We also introduced a controlled pattern of errors by varying the FC directions in a manner that reflects baseline movement variability. Specifically, the FC directions were drawn from a normal distribution with a standard deviation of 2.6 degrees. Surprisingly, we found a nearly one-to-one relationship between the compliance of the environment and rate of learning from error with a ~12-fold decrease in compliance leading to a ~12-fold increase in the adaptive response. These results suggest that the rate of error-dependent adaptation strongly depends on internal estimates of environmental compliance.

Title: Force production during holding suggests presence of a neural integrator for reaching

Authors: *S. T. ALBERT, R. SHADMEHR
Biomed. Engin., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: "Posture follows movement like a shadow" - Sir Charles Sherrington. As noted by Sherrington, the movements we make are linked to the postures we hold at the end of movement. Although these processes are separated in time, changes in the motor commands that move the limb may affect perception and control of posture. In terms of perception, adaptation to an externally imposed force field leads to a shift in our belief of where our arm is in space. And in terms of control, forces related to movement adaptation linger into holding - curiously, after adapting to a force field, subjects produce unnecessary postural forces at the end of movement. These observations raise the following question: are the processes of moving and holding coupled to one another in pre-motor circuits? To test this idea, we performed a series of force field adaptation experiments. In these tasks, subjects held the handle of a robotic arm and made reaches to peripheral targets. We gradually imposed a force field to perturb reaching movements. However, at the end of movement, the robot clamped the hand at its final position. In this way,

we perturbed the moving system but removed errors related to holding posture. These experimental conditions unmasked a striking relationship between moving and holding: the postural forces at the end of the reach were almost perfectly predicted by the integral of the moving forces that preceded holding ($R^2 = 0.95$). In other words, the motor commands generated to counteract the force field appeared to be integrated into the postural signal that held the arm in place. In a series of tasks where the perturbation conflicted across consecutive movements, we found that these postural forces were specific to the moving forces of the current movement, not the history of prior movements. Moreover, the relationship between postural force and moving force, was independent of the direction, amplitude, and duration of the reach. But was the relationship between moving and holding really captured by mathematical integration? We considered a task where subjects adapted to a force field that had an integral of zero, differing in sign during the first and second halves of the movement. We found that as subjects learned to produce forces during reaching, bringing the integral of their moving forces close to zero, the postural forces vanished. These results demonstrate that the postural system for the arm acts as a mathematical integrator of the forces that the limb produces during movement. Analogous to the brainstem neural integrator of the oculomotor system, there may exist a neural integrator that uses an efference copy of the motor commands during reaching to form the motor commands during holding.

Title: Movement history biases action planning more than action execution

Authors: *H. E. KIM[1], D. E. PARVIN[2], R. IVRY[3]
[1]Dept. of Psychology, Univ. of California, Berkeley, Berkeley, CA; [2]UC Berkeley, Berkeley, CA; [3]Univ. California, Berkeley, CA

Abstract: Repeating a specific movement is thought to bias future movements towards the repeated one, a phenomenon referred to as use-dependent learning (UDL). In center-out reaching, UDL is thought to reduce variability at the most frequently practiced target location, but at the cost of a bias towards this location when attempting to reach elsewhere. Here we attempt to determine whether these effects are primarily due to action selection or action

execution biases. Furthermore, given a recent report that reward-based learning may interact with UDL during isometric tasks, we addressed the issue of whether reward modulates UDL during reaching. In experiment 1, we used a reaching task similar to the seminal study on UDL by Verstynen and Sabes (2011). Participants (n=10) were presented with the repeated target location on 88% of trials, with interleaved probes ±30°, ±60°, and ±90° distal to this location for the remaining trials. Online visual feedback of hand position was provided only during reaches to the repeated target. Initial heading angles revealed mean biases towards the repeated target, comparable in size to those reported by Verstynen and Sabes (~15° maximum). However, a finer grained analysis revealed a wide range of reaches during the probe trials, including some directly towards the repeated target. Despite there being no constraints on participants' reaction time (RT), there was a strong inverse relationship between the size of the bias and RT. This suggests that participants initially selected a default movement plan towards the repeated target prior to completion of planning to the probe, eliciting the biased responses, especially when RT was short. In a second experiment, we removed the RT-dependent effects of action selection biases by enforcing a delay of 500 ms before the response, allowing us to examine the effects of reward on the 'pure' UDL execution bias. One group (n=16/group) received rewarding feedback for accurate reaches to the repeated location; the second group never received performance-based feedback. For both groups, no feedback was given for reaches to probe locations. Despite the rewarded group exhibiting a reduced variance around the repeated target, the bias was similar for both groups, a modest 3°-4° across all probes. Thus, these studies point to a much larger role for action selection biases in use-dependent reaching paradigms than previously reported, and also to a negligible effect of rewards on the small UDL execution bias.

Abstract: The nervous system translates new knowledge into long-lasting plastic changes that lead to the formation of memories. To date, the timescale of structural remodelling that accompanies functional neuroplasticity is largely unknown. Magnetic resonance neuroimaging provides us with non-invasive tools to explore structural neuroplasticity in humans. There is wide evidence of changes in grey and white matter structure in the healthy human brain following extensive motor training (< 1 week, Dragansky et al., 2004; Landi et al., 2011; Scholz et al., 2009; Sampaio-Baptista et al., 2014). Animal experiments, however, suggest that structural remodelling due to motor learning is a rapid, dynamic process that can be detected over much shorter timescales (1-3 hours; Fu and Zuo, 2011; Xiao et al., 2016). A recent Diffusion Weighted Imaging (DWI) study has shown that training on a spatial memory task induces a decrease in mean diffusivity (MD) that correlates with N-methyl-D-aspartate (NMDA) dependent astrocyte hypertrophy in the hippocampus (Sagi et. al., 2012; Assaf, 2017). Here, we used DWI to investigate the emergence of early cortical plasticity elicited by a short session of motor learning. To this end, we trained 21 healthy subjects [11 female; age (mean ± SD): 23,6±3,1 years old] in two well-characterized motor tasks, tapping on different neural substrates: motor sequence learning (MSL) and visuomotor adaptation (VMA). DWI images (2×2×2 mm^3, 30 gradient directions, b-value = 1000 s/mm^2, TR=5208 ms, TE=89 ms, FOV=240x240 mm^2) were obtained before, 30 min and 24 hours after training to asymptotic performance (~15 min for MSL and ~25 min for VMA). Prior to the tensor and MD estimation, DWI images were corrected for geometric distortions (Andersson et al., 2003), head motion, eddy currents and b-vector correction (Andersson and Sotiropoulos, 2015). MD maps were non-linearly transformed to MNI152 T1 using ANTs (Avants et al., 2011), and longitudinal MD changes were statistically assessed using the threshold-free cluster enhancement (TFCE) approach of Randomise (Smith and Nichols, 2009; Smith et al., 2004). Learning the MSL task was associated with a significant reduction of MD in the left hippocampus 30 minutes post-learning that returns to baseline levels at 24 hrs. MSL also lowered MD in the fronto-parietal network 30 min post-learning, but this decrement persisted overnight. No significant changes in microstructure were found after learning a VMA task. Our results suggest that acquiring a new motor policy -as in MSL- may involve changes in synaptic efficacy that are not triggered when learning is associated with recalibration of an existing motor policy.

Title: Role of attention in motor performance on a novel functional upper extremity task: Evidence from aging and implications for motor learning

Authors: P. WANG[1], D. S. PETERSON[2], *S. Y. SCHAEFER[1]
[1]SBHSE, [2]Nutr. and Hlth. Promotion, Arizona State Univ., Tempe, AZ

Abstract: Theories of motor skill learning have long suggested that performing novel tasks requires high levels of attention. We have developed a functional upper extremity motor task that involves reaching, grasping, and object manipulation to study the process of learning more complex, real-world movement, and have validated it against more established upper extremity tasks (i.e., point-to-point reaching). The extent to which this novel motor task involves attentional control has, however, not been established. Thus, the purpose of this study was to test whether participants' performance on a novel functional upper extremity task was related to their dual-task ability. Participants with advancing age were used in this study to maximize the variance in dual-task interference as well as upper extremity motor performance. To minimize any confounds of upper extremity sensorimotor impairment or limitation that may be present in older populations, dual-task ability was measured using the amount of interference in Timed-Up-and-Go test (TUG) under dual-task conditions (i.e., while performing serial subtraction); this assessment has no upper extremity involvement and has been related to cognitive impairment and fall risk in older adults. We hypothesized that more dual-task interference on the TUG would be associated with worse performance on the upper extremity task, even when the upper extremity task was performed without any distraction. Forty-nine community-dwelling adults aged 65 and older performed the functional upper extremity task with both the dominant and nondominant hand as quickly as possible. In the same session, they also completed the TUG under single- and dual-task conditions. Dual-task interference was calculated as the percent difference in time to complete the TUG under single- and dual-task conditions, normalized to the single-task condition. Linear regression indicated that only the nondominant feeding task performance was correlated with dual-task interference (R^2=0.13; p<.05), such that the greater the interference, the worse the performance on the upper extremity task. No relationship was observed when using the dominant hand, suggesting that the task is not novel when performed with the dominant hand and therefore not appropriate for studying skill learning. When performed with the nondominant hand, however, the task has a substantial attentional load and

may be learned with repetitive practice (see Schaefer et al. 2015), validating it as a method for studying motor learning in older adults.

Title: Visuomotor adaptation increases the number of spindles associated with slow oscillation during NREM sleep

Authors: A. SOLANO, L. A. RIQUELME, *V. M. DELLA MAGGIORE
IFIBIO Houssay, Sch. of Medicine, UBA, Ciudad Autonoma Buenos Aires, Argentina

Abstract: It has been suggested that during nocturnal consolidation of hippocampal memories, slow oscillations (SO) facilitate the emergence of sleep spindles, which in turn recruit hippocampal ripples (Staresina et al, 2015). Convergent experimental evidence from human and non-human animals suggests in fact that long-term hippocampal memory measured overnight is associated with an increase in the level of coupling between sleep spindles and slow oscillations (~1Hz) during Non-Rapid Eye Movement (NREM) sleep. Little is known, however, about the presence and relevance of this SO-spindle coupling in non-hippocampal motor memories. To address this issue, we carried out a study in which polisomnographic recordings were obtained from 10 healthy right-handed participants during a night of sleep after performing a visuomotor adaptation task with the right hand. Participants came to the sleep lab three times (familiarization, experimental and control sessions), each separated by one week, and performed the task before and after a full night of sleep. During the experimental session subjects learned to adapt to a 45 deg rotation; during the control session, subjects performed the same task without the perturbation. Sleep recordings were staged according to standard criteria. Spindles and Slow Oscillations were identified using standard detection algorithms in artifact-free NREM sleep segments (Mölle et al, 2011). SO (0.5-1.25Hz) and Spindle (10-16Hz) density and the coupling between Spindles and SO was computed. No differences were found in the sleep architecture across experimental conditions. There were no significant differences in the frequency and duration of spindles across conditions. Yet, we found a significant increase in the density of Spindles in the experimental compared to the control session (Session: $F(1,8)=3.539$, $p=.097$;

Channel: F(10,80)=5.068, p=.001; Session*Chan: F(10,80)=2.164, p=.028). This increment detected in the frontal (FC1) and central (C3, C4) electrodes was associated with the occurrence of SO (RM-ANOVA. Session: F(1,8)=2.410, p=0.159; Channel: F(10,80)=6.673, p=0.001; Session*Chan interaction: F(10,80)=2.310, p=0.019). Our results suggest that the SO-Spindle interaction may not be privative of hippocampal memories, but may reflect a non-specific process underlying consolidation in different memory systems.

Title: The effects of limb-based visual feedback on human's reaching movements

Authors: *F. ZAHED, M. BERNIKER
Univ. of Illinois at Chicago, Chicago, IL

Abstract: Subjects in experimental settings have a strong tendency to move their hand along a straight path. Even when large forces are applied to the hand, subjects adapt to the forces by returning to straight stereotyped movements. In standard reaching experiments subjects are seated in front of a monitor where their hand is displayed as a cursor on the screen and the targets are depicted as circles. The persistence for moving the cursor on a straight path made us think that the cursor is bias for straight reaches. We tested this by changing the standard visual feedback to "limb-based" visual feedback, displaying the posture of the subject's arm, and targets as desired limb-postures. Subjects made roughly 25 cm point-to-point reaching movements on the edges of a right triangle. We found that when limb-based visual feedback is provided reaches become curved relative to the standard cursor feedback, suggesting a new control strategy for movements. This suggests that the type of visual feedback used can affect the control strategy for movements.

Abstract: The importance of cortical coherence during the rehabilitation of motor tasks is still poorly understood. To study this process in healthy subjects, tasks requiring motor adaptation are often used. Here, we evaluated the modulations in the cortical activity associated with a slow or rapid motor adaptation to an altered visual feedback. Healthy participants were asked to perform a three-dimensional, robotic-assisted center-out reaching task, with an inversion of the visual feedback. Initially, among all the possible directions of the workspace only a subset of target directions were presented to the participants. An algorithm running continuously assessed their motor improvement and replaced the targets by new reaching directions when the improvement exceeded a specific threshold. The EEG activity of the participants was recorded before and during the task execution, and we computed the band-specific power and coherence in and between key motor and visual areas. The rate of adaptation to the altered visual feedback, defined as the number of new inserted targets along the practice, distinctively clustered the participants into slow and fast learners. While the fast learners displayed a significant modulation of the beta-band coherence, this phenomenon was not observable in the slow learners. This result highlights the implication of visuomotor correlation in the motor adaptation to an altered visual feedback.

Title: Generalization of visuomotor skill learning across movement directions

Authors: *P. N. PARMAR[1], J. L. PATTON[2]
[2]Arms + Hands Lab., [1]Shirley Ryan Ability Lab., Chicago, IL

Abstract: Error-feedback plays an important role in the acquisition of motor skills for goal directed movements by facilitating learning of internal models. When error is perceived consecutively across different movement directions during training, it is unclear whether the brain learns an independent internal model for each movement direction or a generalized internal model spanning all movement directions. Our study focused on evaluating how errors perceived across different movement directions facilitate learning. We trained 15 healthy human subjects to reach in six directions in various nonlinear visuomotor distortions. We then tested their learning data against three most probable models: movement-direction-specific model where errors across directions are not shared, generalizing model where the current error is shared across all directions, and mixed model, which was a weighted sum. Our results indicate that the subjects learned 6.25 times more from the error that was observed at a movement direction than neighboring directions. Also, the generalization effect of learning from one movement direction to neighboring directions reduced nearly to zero by 60 degrees away.

Title: Neural basis for learning novel sensorimotor maps

Authors: *F. T. VAN VUGT[1], Y. ZENG[2], D. J. OSTRY[2]
[1]Psychology, [2]McGill Univ., Montreal, QC, Canada

Abstract: One of the challenges in a new learning environment is to determine the correspondence between movements and sensory effects: a sensorimotor map. Map acquisition can be studied by monitoring participants as they learn an unknown mapping between previously largely unlinked modalities such as movements and sounds. Several studies have characterised this acquisition process behaviourally but it remains unclear how learning is implemented in the brain. In particular, once a map is acquired, this knowledge then needs to be maintained when the subject no longer engages in the task. In the present work participants learned an audiomotor map in the scanner by making movements to auditory targets using a joystick while their brain activity was measured using functional magnetic resonance imaging (fMRI). Before and after learning resting state brain activity was assessed to track the persistence of information learned during the task. Behaviourally it was observed that participants initially moved at random and then progressively improved their reaching performance, indicating that they were able to learn the mapping. Neural structures involved in the task were defined as those having larger or smaller signal during task than during inter-trial rest and these formed a distributed network comprising cortical primary sensorimotor regions, supplementary motor area, superior parietal lobule, several foci in cerebellum, thalamus and the striatum. Frontal and parahippocampal regions showed lower activity during task than during rest. Changes in functional connectivity between these areas was assessed in subsequent resting state scans in relation to the amount of learning. Taken together, these findings characterise the brain areas that are involved in the earliest stages of learning novel sensorimotor maps and provide a first glimpse into how learned information is maintained when the task is no longer being performed.

Title: Impact of baseline reaching performance on motor adaptation across age

Authors: *K. VANDEVOORDE, J.-J. ORBAN DE XIVRY
Kinesiology, KU Leuven, Leuven, Belgium

Abstract: While the contribution of cognition to motor adaptation is reduced with aging, older adults usually rely more on cognitive control for motor tasks. At the brain level, this higher reliance on cognitive control is reflected by an age-related over-activation of frontal areas. In the current study, we aimed for reconciling these two opposing findings, the decline of the cognitive component of motor adaptation and the increased cognitive control found in motor tasks. We hypothesized that reaching without visual perturbation (i.e. baseline trials) requires more cognitive control in older adults than in younger ones. As a result, the availability of further cognitive control for the adaptation process is further reduced in older adults, which limits the contribution of cognition to motor adaptation in this population.
To investigate the extent to which the availability of cognitive resources influenced performance in unperturbed reaches, a pre-registered dual-task paradigm was implemented during the baseline of a visuomotor rotation task. In this dual-task paradigm, participants were instructed to perform a reaching task, a cognitive task (Eriksen flanker task), or both tasks concurrently. The difference between performances in the single- and dual-task conditions are used as an indicator of the cognitive cost of reaching during baseline and as predictor for the extent of the cognitive component in the ensuing adaptation period. The cognitive component of adaptation was quantified with a cued motor adaptation experiment (Morehead et al. 2015; Vandevoorde and Orban de Xivry, 2018). We tested 31 young (23 ± 4 years) and 31 older adults (67 ± 4 years). Contrary to our prediction, we did not find a correlation between baseline dual task cost and contribution of cognition to motor adaptation. In older adults, we found a link between baseline reaching accuracy during the single reaching task and visuospatial working memory capacity (WMC) (exploratory analysis).
Our study provides little evidence for the limited resources hypothesis. This may be due to the choice of cognitive task and the fact that both tasks are not really performed in parallel but in series. Yet, given the observed link between unperturbed reaching accuracy and adaptation performance, the theory needs to be tested further with additional experiments.

Title: Implicit adaptation does not decline with aging as revealed by measures of spontaneous recovery

Authors: *P. HERMANS, Y. LAM, K. VANDEVOORDE, J.-J. ORBAN DE XIVRY
KU Leuven, Leuven, Belgium

Abstract: In motor adaptation, learning is thought to rely on a combination of several processes. Two of these are implicit learning (incidental updating of the sensory prediction error) and explicit learning (intentional to reduce target error). The explicit component is thought to be fast adapting, while the implicit one is slow (McDougle et al, 2015). The dynamic integration of these components can lead to an adaptation rebound, called spontaneous recovery (Smith et al, 2006): the trace of a first, longer learned adaptation reappears after it is extinguished by a shorter period of de-adaptation. The explicit process decays quickly to baseline during the short de-adaptation period, not contributing to the behavior seen afterwards, while the slow implicit process is still decaying from the first adaptation, resulting in the before mentioned adaptation rebound. Trewartha et al. (2014) found that older adults show less spontaneous recovery than their younger controls, indicating impairments in implicit learning. This is in disagreement with evidence suggesting that the implicit component does not decline with aging (Vandevoorde and Orban de Xivry, 2018). In order to clarify this discrepancy, we replicated the force-field adaptation paradigm designed by Smith et al (2006). Twenty-one healthy young (23.4 ± 2.4 years) and thirteen healthy older adults (64.7 ± 4.2 years) completed a long perturbation phase, followed by a short counter-perturbation phase and an error clamp phase, in which feedback was fixed to zero error to elicit spontaneous recovery. Throughout the perturbation phases we interspersed catch trials, which were color cued, to assess the implicit component of adaptation (Morehead et al, 2015). Both groups adapted equally well to the perturbation. Implicit adaptation of the older subjects was indistinguishable from their younger counterparts (young: 5.01 ± 1.47cm, old: 4.21 ± 1.65cm). In addition, the extent of spontaneous recovery was also similar across groups (young: -0.99 ± 0.86 N, old: -1.08 ± 1.47 N). Implicit adaptation and spontaneous recovery were found to be correlated (Pearson r= 0.53; p=0.0006). Our results reconcile previous studies by showing that both spontaneous recovery and implicit adaptation are unaffected by aging.

Title: Motor practice under transcranially induced variable brain states improves the retention of motor memories

Authors: *M. TAKEMI, D. NOZAKI
Grad. Sch. of Educ., The Univ. of Tokyo, Tokyo, Japan

Abstract: Humans can learn new motor skills through trial and error, producing a memory that will be recalled the next time. However, this memory is temporary, and the skill gets close to the baseline with the passage of time. Thus, a fundamental issue in motor learning is how to better retain the memories. Previous studies that examined familiar tasks such as ball throws revealed the advantage of variable practice over constant practice in retention of motor memory (Kerr and Booth 1978; Shea and Kohl 1991), but its neural underpinnings remain unclear mostly due to the complexity of the learning processes. Here, using an arm-reaching task in a velocity-dependent force field (FF) and transcranial direct current stimulation (TDCS), we indicated that the benefit of variable motor practice stems from the variability of sensorimotor cortical activities during learning period.

36 participants were assigned to one of the three conditions. One condition applied four different TDCSs to the sensorimotor cortex in which current flowed anterior-to-posterior, posterior-to-anterior, medial-to-lateral, and lateral-to-medial directions relative to the central sulcus during FF learning. The others used one or two of the four TDCSs throughout the learning period. Following the FF learning, all participants performed reaching movements in a channel in which errors were absent with sham TDCS. The results showed that the decay of motor memories, quantified using the force exerted against the channel in the last 10 trials, was less in the participants who were exposed to FF with multi-pattern TDCS than those exposed with single- and double-pattern TDCS. The task performance at the end of the learning period and the learning rate were not different between the conditions. Moreover, a follow-up experiment, which tested the effects of the four TDCSs on the recollection of motor memories with 20 participants, demonstrated that the memory was most reinstated when TDCS intervention during FF learning and the channel test was matched. The amount of the memory reinstatement was not associated with TDCS-induced changes in the corticomotor excitability, assessed using electromyographic responses of transcranial magnetic stimulation.

The present results provided causal evidence that the TDCSs targeting sensorimotor cortex manipulated brain states involved in the formation of motor memories and thus enabled to tag a motor memory to multiple cortical activation patterns. Variable brain states motor practice, mediated by externally applied electric fields, may help to compose a more robust representation of the task, resulting in facilitation of the memory stability.

Title: Variety of target position in force-field reaching task affects retention of the motor skill

Authors: *T. OGASAWARA, M. TAKEMI, D. NOZAKI
Grad. Sch. of Education, Univ. of Tokyo, Tokyo, Japan

Abstract: Movement variability is widely thought of the inevitable consequence of stochastic nervous system function (Churchland et al., Neuron 2006) and often deemed as an unwanted characteristic of motor performance. However, a recent study has shown that higher levels of task-relevant intrinsic movement variability related to faster error-based learning to adapt movements in novel physical environments (Wu et al., Nat Neurosci 2014). We inferred from this study that artificial manipulation of the task-relevant variability may benefit motor learning. Yet no one has systematically tested how the extrinsically imposed movement variability affects different aspects of motor learning, such as learning rate, the amount to be learned, and retention of the motor memory.
In this experiment, 50 participants performed 110 reaching movements under a velocity-dependent curl force field (FF) while holding a robotic manipulandum. They were divided into five experimental groups. One group had a single visual target to be reached, which was shown 10 cm forward from the start of the movements. In the other groups, 11 visual targets uniformly distributed in the range of ±2.5°, 5°, 10°, or 20° from the front target were used for the training (10 reaches for each target). The targets distributed within different ranges enabled to artificially manipulate the task-relevant movement variability. Following the FF learning, all participants performed 50 reaching movements to the front target in a channel in which errors were absent. The results showed that motor memories, quantified using the intercept of the exponential curve that was fitted to the peak force in the last 50 channel trials, remained well when the target position varied within ±5°. The amount of memory at the end of FF learning and the learning rate was not different between the groups.
Why did the target variability facilitate retention of the motor memory?Neurons are recruited differently every trial even when one intended to repeat a constant motor act(Churchland et al., Neuron 2006). The variability of reaching targets may further increase the variety of the firing neurons, some of which are hardly activated during a constant motor act. We speculated that optimal level of the additional variability in targets allows to involve residual neurons in motor learning and thus to compose redundant neural representation of the learned skills.

Title: Looking for a sign of failures: Reaching error triggered by slowing down of movement in the preceding trials

Authors: *T. KOBAYASHI, M. TAKEMI, D. NOZAKI
Grad. Sch. of Educ., Univ. of Tokyo, Tokyo, Japan

Abstract: Even in well-practiced motor skill, we cannot repeatedly perform the movement without variability that sometimes makes unexpected motor errors. For example, a professional baseball player who can pitch with high repeatability and precision often threw the ball to the location to which he did not aim (Chaisanguanthum et al., 2014). Previous studies have suggested that movement variability is associated with the neural activities during the preparatory period in dorsal premotor cortex and primary motor cortex (Churchland et al., 2006; Haar et al., 2017). These findings lead to the possibility that we can predict the occurrence of failures from neural activity. In fact, specific patterns of the electroencephalographic activity were observed 100−1000 ms before the movement onset only in the failure trials (Babiloni et al., 2008; Bediou et al., 2012). However, it has not been fully investigated how and why such a failure action and the associated brain activity pattern arise. Do they suddenly arise or is there any sign beforehand? In the present study, we examined this question using a reaching movement adaptation paradigm. 15 healthy adults were trained to reach toward a forward target (movement distance: 10 cm) under the presence of rightward velocity-dependent force field. They performed 440 trials consisting of baseline phase without the force field (trials 1−20), adaptation phase with the force field (trials 21−420) and washout phase removing the force field. We evaluated a lateral deviation (LD) from the straight path between the target and the starting position at the peak hand velocity as a performance index and found that, even for the final 300 trials in the adaptation phase in which the sufficient practice had been completed, the LD varied among trial-to-trial and sometimes exhibited greater magnitude. Failure trials (FTs) were defined as the trials in which the top 5% of the LD was observed. The state space model for motor adaptation (Thoroughman & Shadmehr, 2000) predicts greater LD (i.e., failure trials) should follow smaller LD, but there was no significant change in the LD in the up to 5 trials before the FT. Neither a significant change in the reaction time was observed. The only behavioral sign associated with the FTs was the peak velocity, which gradually decreased from 2 trials before the

FT. These results were substantially unaffected if the definition of FT was changed (e.g., top 3 and 10%). Our results suggest that movement failures do not suddenly happen and there is a sign of the failure observed in the prior trials. Our approach may pave the way to investigate how failures happen and the underlying neuronal mechanisms.

Title: Do movement sequences and consequences facilitate dual adaptation to opposing visuomotor rotations?

Authors: *M. N. AYALA[1], D. Y. HENRIQUES[2]
[1]Psychology, York Univ., Toronto, ON, Canada; [2]Dept Kinesiol & Hlth. Sci., York Univ., North York, ON, Canada

Abstract: When planning movements, the human central nervous system (CNS) can actively compensate and adapt to two or more distinct perturbations simultaneously ("dual adaptation") though this process only occurs when each visuomotor map is associated with a sufficient contextual cue. Not all contextual cues are effective at facilitating dual learning and only more "intrinsic" or motor-based cues tend to be integrated by the CNS. More recently It has been shown that lead-ins, follow-throughs, or even a sequence including both, can facilitate learning of opposing force-field perturbations. Here, we investigate whether movement sequences require an active component or if a visual consequence is sufficient in facilitating dual adaptation of opposing visuomotor rotations. Using a virtual reality paradigm, participants manipulated a projected hand-cursor using a digitizing tablet in a semi-dark room with an opaque board occluding visual feedback of the hand. In the sequence experiment, participants experienced opposing rotations (30° clockwise (CW) or 30° counter-clockwise (CCW)) within the same experimental block, each associated with a distinct sequence (i.e. hand reaches to the left or right of the primary target to a secondary target). To explore whether a passive visual consequence was sufficient, in the follow-up experiment each rotation was associated with a target consequence (i.e. target moves to the left or right secondary target). In the final experiment, the secondary target cued the perturbations but no action was required to achieve it. To compare the extent of dual learning, two more groups each learned a single rotation with the same previous

sequence-rotation association. Lastly, in a secondary task immediately following training, all groups received additional training where we brought awareness to the cursor-movement discrepancy. In these tasks, participants were instructed to include or exclude any strategy they formed to compensate for the perturbed hand-cursor. Across all experiments, in the training condition, participants either completed CW trials only, CCW trials only, or both interleaved within the same block ("dual group"). We find that both movement sequences and consequences sufficiently but weakly facilitate dual adaptation showing small reach aftereffects in the expected directions. Static visual cues did not lead to dual learning. Together these findings show whether active movement sequences and passive consequences are incorporated into motor planning and execution, and can thus facilitate dual learning of opposing visuomotor rotations.

Title: The fast and slow process differ with feedback but not age

Authors: *J. E. RUTTLE[1], B. M. 'T HART[2], A. STÄUBLE[3], T. EGGERT[4], D. Y. HENRIQUES[5]
[1]York Univ., North York, ON, Canada; [2]Ctr. for Vision Res., York Univ., Toronto, ON, Canada; [3]Brain Res. Inst., Univ. of Zurich, Zurich, Switzerland; [4]Ludwig-Maximilians Univ. München/ Dept. of Neurol., Muenchen, Germany; [5]Dept. of Kinesiology and Hlth. Sci., York Univserity, North York, ON, Canada

Abstract: Motor control is integral for quality of life. Importantly, the motor system can adapt to alterations in visual feedback, to ensure consistent, accurate movements. One prominent model, the two-rate model (Smith et al., 2006), proposes that a fast and slow process, which respond differently to errors in movement, combine to create changes in motor output, including those seen during rotated visual feedback training (McDougle et al., 2016). Specifically, the two-rate model can explain a "rebound" effect observed in error-clamp trials in some perturbation schedules. However, how these two processes contribute to motor adaptation with different visual feedback and in different age groups is still unclear. First we change how errors are shown to participants who learned to reach with a visuomotor rotation of 45º by giving them either terminal or continuous feedback. In continuous feedback the cursor was shown throughout, but

in terminal feedback it only appeared at the end of the reach. The same participants completed both feedback conditions with different rotations in separate areas of the work space and in counterbalanced order to prevent interference. As expected, reaches with continuous feedback were best modeled with a two-rate model of motor learning. On the other hand, we found that terminal feedback reaches were best modeled with a single process, which follows from the lack of a rebound. We also tested if age affects visuomotor adaptation when the rotation is introduced abruptly or gradually over the course of 60 trials, by testing a group of younger (under 35 yrs.) and older (over 55 yrs.) participants. We found no effect of either speed of rotation introduction or age with no interaction between measures; the magnitude of the rebound was similar. In other words, it appears the balance of fast and slow processes is comparable in abrupt and gradual rotation introduction paradigms regardless of age. Simulations suggest that changing the perturbation schedule could lead to larger differences in reach deviations in the error clamp phase between abrupt and gradual conditions, or different age groups, but this remains to be tested. Our results highlight the viability and benefits of within-subject paradigms for testing models of motor learning and may improve the design of motor-learning experiments.

Title: Proprioception and prediction do not optimally integrate in hand localization

Authors: *B. M. 'T HART[1], M. N. AYALA[2], D. Y. HENRIQUES[3]
[1]Ctr. for Vision Res., [2]Psychology, York Univ., Toronto, ON, Canada; [3]Dept Kinesiol & Hlth. Sci., York Univ., North York, ON, Canada

Abstract: Knowing where your limbs are, is important for planning and controlling movements. Limb position also takes a central role in optimal feedback control paradigms when evaluating movements to update internal models. When people are asked to localize their unseen hand after a movement, they have two non-visual signals available: predicted sensory consequences, based on an efference copy of the motor command, and felt hand position, or proprioception. People could combine these two signals in a maximum likelihood estimate which would have higher reliability than each signal individually, evident as a lower variance. While we can’t measure

hand location estimates based on predicted sensory consequences in isolation, we can measure hand location estimates based on the two signals combined (lower variance) and based on proprioception alone (higher variance). In a previous paper (’t Hart & Henriques, 2016) we found no evidence of maximum likelihood estimation as the variance of the responses was approximately equal. However, there were very few trials, and a relatively small group of participants, potentially obscuring effects. Here we have almost triple the data per participant in 84 younger participants. In this larger dataset there is again no evidence of maximum likelihood estimation: the variance of responses in the two hand localization tasks is equal. In sum, it seems that the brain does not create a maximum likelihood estimate integrating predicted sensory consequences with actual sensory information the same way it would integrate two sensory signals. Perhaps it is optimal to either keep both predicted and actual sensory information separately available, or combine the signals in a different way.
We use this larger dataset to explore some other issues as well. In a group of older participants (N=24, age: 55+) we can test if proprioceptive acuity decreases with age. Furthermore, we can probe if weaker proprioceptive priors lead to larger training-induced recalibration of proprioception, or if the variance of pre-training no-cursor reach directions can better predict training-induced changes on any measures.

Title: Adaptations of motor cortex activity in the planning and execution of sensory selection

Authors: K. ARULJOTHI, *E. ZAGHA
Dept. of Psychology, Univ. of California Riverside, Riverside, CA

Abstract: What neural mechanisms enable us to respond to certain stimuli while ignoring others? To address this question, we developed a lateralized whisker detection task, in which mice are trained to respond to stimuli in one whisker field (target) and ignore stimuli in the opposite whisker field (distractor). In expert mice, we used widefield GCaMP6 Ca2+-sensor imaging to observe activity in target and distractor, sensory and motor cortices simultaneously. For both target and distractor stimuli, sensory responses rapidly emerged in primary somatosensory cortex. On hit trials (responses to target), we observed rapid and robust propagation of activity into motor cortex preceding the response, which was significantly

stronger in the target-aligned versus distractor-aligned motor regions. Additional evidence suggests that asymmetric motor cortex activity is a task-dependent adaptation for sensory selection. First, stronger activation of target-aligned motor cortices was also observed preceding spontaneous responses and responses to the distractor, and therefore is not dependent on sensory inputs. Second, stronger activity in the target-aligned motor cortices was present during the inter-trial even before stimulus onset. These data contrast with recordings in naïve or anesthetized mice, in which activity is highly symmetric across hemispheres. Overall, these recordings demonstrate task-dependent adaptations of motor cortex activity in the planning and execution of goal-directed behavior.

Title: Functional plasticity of motor cortex in a lateralized whisker detection task

Authors: *B. ZAREIAN[1], Z. ZHANG[2], E. ZAGHA[1,2]
[1]Dept. of Psychology, Univ. of California Riverside, Riverside, CA; [2]Neurosci. Grad. Program, Univ. of California, Riverside, Riverside, CA

Abstract: Recent studies have reported diverse and contradictory roles for motor cortex in motor control, including motor learning, execution, initiation and inhibition. One possible explanation for these discrepancies is that the function of motor cortex may differ under different task conditions. We wanted to test the extent to which motor cortex function is task-dependent, even within the same individual. Therefore, we developed a Go/NoGo whisker detection task, in which mice were trained to respond to stimuli in one whisker field (target) and ignore stimuli in the opposite whisker field (distractor). In expert mice, we used optogenetic methods to test the functional output of motor cortices aligned either to the target or distractor representations. Additionally, we tested two major types of layer V pyramidal neurons, within both whisking and licking motor regions. We observed significant differences in the functional outputs of target-aligned and distractor-aligned motor regions. Notably, in the distractor-aligned motor cortices, we observed on-off responses, which was not observed in target-aligned motor cortices or naïve animals. Our results highlight the capacity for motor cortex to undergo extensive and asymmetric functional plasticity with task learning. Furthermore, these findings argue that motor cortex may mediate multiple aspects of motor control, depending on the contingencies of the task.

Title: Investigating kinesthesia in the primate somatosensory cortex

Authors: *R. DARIE[1], D. A. BORTON[2,3,4]
[1]Sch. of Engin., [2]Brown Univ., Providence, RI; [3]Carney Inst. for Brain Sci., Providence, RI; [4]Dept. of Veterans Affairs, Providence Med. Center, Ctr. for Neurorestoration and Neurotechnology, Providence, RI

Abstract: Motor control is a dynamic feat that humans perform seamlessly across diverse and changing environments. Rich kinesthetic feedback concerning the state of one's limbs is a necessary condition for fluid motor function. Understanding the neural code for kinesthesia could inform the design of afferent prosthetic interfaces that communicate such feedback to the nervous system. However, efforts in this direction have been restricted to the upper limb representation and the problem remains unsolved. We propose to close this knowledge gap by recording broadband neural signals from the hindlimb area of primary somatosensory cortex (S1) in an awake, behaving, nonhuman primate engaged in a kinesthetic categorization task.
We have trained a nonhuman primate to sit in a standard primate chair while its foot is secured to a motorized manipulandum with one circular degree of freedom. On each trial, the manipulandum displaces the foot to a predetermined target position. By pressing one of two buttons (two alternative, forced choice) the animal indicates whether the displacement was greater than 90 degrees in magnitude. As expected, the animal's performance is proportional to the difference between the target angle and the reference. In the case of touch perception, somatosensory cortical spike timing and cortical spike rate carry complementary information. We hypothesize that similar mechanisms are at play for kinesthesia. To test this hypothesis, we have recorded and analyzed the activity of neural features (i.e. changes the firing rate and timing of cortical action potentials) evoked by the hindlimb displacements during the task at a single neuron level and at a population level. Simultaneously, we have measured the positions of anatomical landmarks using a motion capture system. We hypothesize that it is possible to decode kinematics from the firing rate of somatosensory cortical neurons. Furthermore, information about a stimulus might be present in the response of a neural population, but not

used by higher order regions to drive behavior. Therefore, our analysis seeks to identify the sensory responses relevant to the behavioral outcomes: we have constructed neurometric curves based on rate and timing neural features and compared them to psychometric response curves.

Abstract: Humans have the remarkable ability of walking without cognitive effort, yet can smoothly and quickly adjust the trajectory of their legs in response to environmental cues, such as obstacles along one's path. It has been shown in animal models that the spinal cord is capable of generating the base muscle activation patterns necessary to perform locomotion through central pattern generators; however supraspinal regions are still required to carry out precise, volitional limb movements. Primary motor cortex (M1) is one such region, yet how M1 seamlessly weaves voluntary limb movements into the ongoing locomotor rhythm during walking in primates is still an open question. Here, we employed an obstacle avoidance paradigm using rhesus macaques to investigate the role of motor cortex in voluntary control during locomotion. Animals were trained to perform three different movement tasks inside a treadmill enclosure. First, they were trained to walk on a treadmill at 2.5km/h. Next, animals were trained to step over an obstacle (3"x2"x17") moving toward them at a speed of 2.5km/h from a stationary, standing position. These two tasks were designed to decouple the neural correlates of autonomous and voluntary movements. Finally, animals were trained to step over the moving obstacle while walking on the treadmill at 2.5km/h. This task integrates the voluntary motion into the underlying locomotion movements. Animals were then implanted with 96-channel Utah-type arrays (Blackrock Microsystems, Utah) in M1 which were connected to a wireless neural recording headstage streaming extracellular activity from untethered animals as they performed the above tasks. Simultaneously, joint kinematics of the hindlimb were obtained using a video tracking system (Simi Motion, Germany). Animals carried out similar movement strategies to avoid the obstacle while stationary compared to while walking. Here, we discuss preliminary

results elucidating the role of motor cortex during primate locomotion. These results could also have implications for the development of hind-limb brain-machine interfaces.

Title: The supplementary motor area, but not motor cortex, produces neural trajectories consistent with a network that can autonomously generate long-timescale sequences

Authors: *A. A. RUSSO[1], R. KHAJEH[1], S. R. BITTNER[1], S. PERKINS[2], J. CUNNINGHAM[1], L. ABBOTT[3], M. M. CHURCHLAND[3]
[2]Biomed. Engin., [3]Neurosci., [1]Columbia Univ., New York, NY

Abstract: It has been hypothesized that the supplementary motor area (SMA) contributes to motor sequence generation while motor cortex (M1) is primarily concerned with the current motor output. We translated this hypothesis into a dynamical systems framework and examined its predictions. We defined a 'sequence-generating network' as one able to autonomously generate long-duration outputs based on minimal guiding inputs. In contrast, we defined a 'pattern-generating' network as producing outputs more complex than its inputs, while still relying on inputs for timing information. We considered data recorded from monkeys trained to produce rhythmic sequences: 1,2,4, or 7 revolutions of a hand-pedal.
Networks were trained to produce 4- and 7-cycle outputs – a simplified version of the empirical task. A sequence-generating network received a pulse input (different for 4- vs. 7-cycles) and generated the desired output, stopping at the appropriate time, with no further inputs. Network trajectories resembled a spiral, with 4- and 7-cycle sequences involving separated trajectories. These features allowed the network to 'know' whether it was on a 4- or 7-cycle trajectory, and where it was within each trajectory. We trained a pattern-generating network to produce the same output, but with a 'go-pulse' and a 'stop-pulse' 4 or 7 cycles later. This network produced a

limit-cycle that repeated, almost identically, until terminated by the stop-pulse. Thus, the pattern-generating network did not, on its own, retain knowledge regarding which sequence it was generating or where it was within that sequence. We refer to this lack of information as 'trajectory confusion'.
SMA and M1 population trajectories resembled, respectively, sequence- and pattern-generating networks. SMA trajectories avoided trajectory confusion: different sequences and different cycles within each sequence were distinct. M1 showed considerable trajectory confusion: trajectories followed a repeating orbit until the sequence was terminated. We quantified trajectory confusion via an index that is high when two trajectory segments are similar yet lead to dissimilar future trajectories. Trajectory confusion was much lower in SMA.
To further explore computational implications of the differences between SMA and M1, we trained networks to internally follow the empirical neural trajectories, with no aid from guiding inputs. In the presence of noise, networks were stable only when generating the low-confusion SMA trajectories. Thus, SMA neural trajectories, but not M1 trajectories, are consistent with a network that can generate long time-scale sequences with minimal reliance on guiding inputs.

Title: Preparation of movement sequences in motor cortex

Authors: *A. J. ZIMNIK[1], M. M. CHURCHLAND[2]
[1]Dept. of Neurosci., Columbia Univ., New York City, NY; [2]Neurosci., Columbia Univ., New York, NY

Abstract: Before movement, population activity within motor cortex establishes a preparatory state from which movement-related dynamics evolve. Converging evidence argues that this

preparatory process is essential and universally present. Yet our understanding of preparatory activity derives largely from the study of solitary point-to-point movements while most real-world movements occur within sequences. Are sequences prepared as a single 'chunk', or does preparation for subsequent movements occur as the current movement unfolds?
We trained a monkey to perform individual reaches and sequences of two reaches. We recorded from 140 single neurons in motor cortex. We considered two hypotheses: first, sequences might be prepared as a single 'chunk'. Second, reaches might be prepared sequentially, with preparation of the second occurring during execution of the first. These hypotheses make divergent predictions. Consider neural activity when reaching to target A alone, versus A then B. If preparation is chunked, sequence AB should be prepared differently from A alone. If preparation is sequential, there should be little difference in preparation before A begins. Instead, during sequence AB, there should then be a second epoch of preparation during reach A, in anticipation of reach B.
Behavior suggested use of a chunking strategy: sequences were highly practiced and unfolded rapidly and accurately. However, the neural data strongly supported sequential preparation. To isolate preparatory activity, we defined a five-dimensional 'preparatory subspace' based on neural activity during a delay-period. This subspace became strongly occupied once the target(s) were presented. Activity within this subspace depended primarily on the first target, regardless of the presence or direction of a second reach. Among conditions that shared the same first movement, the mean Euclidean distance was 13% of that between conditions with different first movements.
The sequential preparation hypothesis predicts that preparation for the second movement must occur during the first. This was indeed the case. For conditions with only one reach, preparatory subspace occupancy rose following target onset, remained high during the delay, fell as the movement began, and remained low. For sequences, the same pattern was observed, but preparatory occupancy did not stay low. Instead, occupancy re-emerged ~30 ms after initiation of the first movement, reaching a peak 67% as large as during the delay. These results do not rule out chunking in regions upstream of motor cortex, but demonstrate that even rapid and well-learned sequences are subserved by sequential preparation in motor cortex.

Title: LFP signature of an optimal preparatory subspace in primate reaching and grasping motor networks

Authors: *J. B. HYNES, C. E. VARGAS-IRWIN, J. P. DONOGHUE
Neurosci., Brown, Providence, RI

Abstract: Emerging views in systems neuroscience regard motor cortical circuits as dynamical systems that combine sensory information with internally generated signals in order to compute activity patterns that drive spinal motor circuits. In this view, each behaviorally-relevant movement is associated with a specific preparatory neural 'state' (a collective pattern of activity across neurons) that represents the initial phase in a cascade of states (or a neural trajectory (NT)) that ultimately generates movement (Shenoy, 2013). However, little is known about the computations that might drive a neural population to a given preparatory state. Here we examine the relationship between local field potentials (LFPs) and single unit ensemble activity during movement preparation to gain insight into the network computations underlying preparatory state dynamics. We used a state-space analysis framework (Vargas-Irwin, 2015) to examine neural activity in macaque primary motor and dorsal/ventral premotor cortex recorded during the preparation of reach-and-grasp actions cued using a set of instructions (one of two objects and a colored light indicating grip-type) followed by a go signal. The instructions were presented in two different temporal orders (sequential or simultaneous) in order to generate different sets of neural dynamics during the movement planning phase. Analysis of the two experimental conditions revealed distinct NTs associated with the different cue presentation orders. However, activity patterns for both conditions tended to converge to a common preparatory state prior to movement onset. For the sequential condition, the common state was reached around 400ms after the onset of the final instruction cue (1.6 s before the go signal). The simultaneous trials converged onto the same state at a wider range of latencies, reflecting variations in reaction time. In both conditions, the common neural preparatory state coincided with a large negative deflection in the LFP resembling the macroscopic n400 signal observed in frontal and parietal EEG during the semantic integration of representations into working context. We argue that the n400 observed in our data reflects computational processes associated with integrating cue information into the working motor plan at the neural population level. Our results provide support for the 'optimal subspace' hypothesis and suggest that the evolution of population activity to a final preparatory state for a given movement is associated with a general principle of network computation announced by an n400-like field potential.

Title: Stability of single-unit and ensemble-level tuning in primate primary motor and premotor cortex through extensive practice of a motor skill

Authors: *K. PAROO[1], C. E. VARGAS-IRWIN[1], L. FRANQUEMONT[1], J. P. DONOGHUE[1,2]
[1]Neurosci., Brown Univ., Providence, RI; [2]Wyss Ctr. for Bio and Neuro Engin., Geneva, Switzerland

Abstract: Brain networks underlying the formation of a conditional arbitrary association ndergo substantial changes early in learning, when behavior is erratic yet rapidly improving. Research in sensory learning has found that activity distributed across many neurons becomes consolidated into a smaller subset of more highly specialized cells. Neurons that carry low levels of stimulus information bifurcate into a small subset with high information and a larger subset with little to no information. However, little research has been done test whether these same changes occur in motor cortex in response to skill learning. Additionally, a skill can continue to be practiced after one has achieved a high level of behavioral performance. It is an open question whether networks underlying the skill continue to evolve more compact and efficient representations as practice continues. Here, we test whether motor cortex evolves into a sparse network with few highly selective neurons following extensive practice of a motor skill. Two rhesus macaque monkeys were trained to reach and grasp objects with two possible grips. A colored light cued the grip for each trial, and another light subsequently cued the monkey to move. We recorded neural activity of populations of neurons in MI, PMd, and PMv using microelectrode arrays (Blackrock Microsystems). Each monkey learned this core task for at least one year before we introduced variations such as reversing the order of cues or delivering both cues simultaneously. All data presented here come from trials of the core task that were interspersed with variation trials during a period of three to four months after the year in which the monkeys achieved proficiency at the core task. After the year of training, nearly half of all MI neurons, and a third of premotor neurons, exhibited selective firing for grip-object combinations during the task. Nearly all neurons in all three areas exhibited some kind of task response. Population analyses reveal that while information in MI is more broadly distributed than in premotor areas, significant decoding is still only achieved with ensembles of dozens of neurons. These results suggest that primary and premotor areas of primate cortex do not evolve toward a compact or sparse representation of task features, despite a lengthy training period and high behavioral

accuracy. This may be an intrinsic feature of a learning function in motor cortex, or it may be due to the learning of novel tasks that occurred contemporaneously with the continued practice of the well-learned task.

Title: Premotor cortex contributes to the planning of visually-guided gait modifications in the cat

Authors: *T. NAKAJIMA[1], N. FORTIER-LEBEL[2], N. YAHIAOUI[2], T. DREW[2]
[1]The Res. Ctr. for Brain Function and Med. Engin., Asahikawa Med. Univ., Asahikawa, Japan; [2]Univ. Montreal, Montreal, QC, Canada

Abstract: We have tested the hypothesis that the cat premotor cortex (PMC) contributes to the visuomotor transformations implicated in the planning of gait modifications. We recorded single unit activity from 136 cells localized within areas 6iffu and 4δ of the ventral bank of the cruciate sulcus, lying caudal and medial to the primary motor cortex (area 4ɤ), while cats walked on a treadmill and stepped over an obstacle that advanced towards them. We found a rich variety of discharge patterns including limb-independent cells that discharged several steps in front of the obstacle regardless of whether the limb contralateral or ipsilateral to the recording site was the first to step over the obstacle. Other cells showed step-related changes in discharge patterns related to the contralateral limb when it was the first (lead) limb to step over the obstacle. Such cells discharged either in the steps leading up to the step over the obstacle or during the step over the obstacle. Another class of neurons discharged only, or primarily, when the contralateral limb was placed in front of the obstacle prior to the step over the obstacle by the ipsilateral limb. We also found a mediolateral gradient in the characteristics of neuronal activity within the ventral bank in which a majority of neurons in the medial portion of the PMC were limb-independent while step-related cells were more prevalent in the lateral portion. We propose that the population of cells within the PMC in the ventral bank of the cruciate sulcus contributes to the temporal evolution of a planning process that transforms global information of the presence of an obstacle into the precise spatio-temporal limb adjustment required to negotiate that obstacle.

Title: Long trains of stimulation applied to the cat's premotor cortex during locomotion modify gait

Authors: *N. FORTIER LEBEL, T. DREW
Dept. de neurosciences, Univ. Montreal, Montreal, QC, Canada

Abstract: The premotor cortex is known to play a significant role in the planning and execution of visually-guided movements. However, in the context of natural locomotion, the contribution of this area remains poorly understood. In the current study, we used long trains of intracortical microstimulation (ICMS; 200 ms trains of 0.2 ms pulses at 330Hz) to examine the influence of several regions of the cat's premotor cortex to the structure of the locomotor cycle during treadmill walking. Using glass-insulated tungsten microelectrodes, a total of 120 sites were stimulated at 1.5-2 times the threshold for movement in one chronically-instrumented, unrestrained animal. ICMS was applied both at rest and during all phases of the step cycle in areas 6aα/β, and 6aγ, as well as in area 4γ (the cat's primary motor cortex). We identified stimulation effects by recording both movement kinematics and the electromyographic activity evoked in multiple muscles of the fore- and hindlimbs. Stimulation in area 4γ evoked responses primarily in the contralateral forelimb or hindlimb, depending on the site of the stimulation (forelimb or hindlimb representation). The most common effect was an increase in swing duration and amplitude (for stimulation during swing) with or without a reset of the step cycle (for stimulation during stance). Stimulation in different sites produced different limb geometries during swing. Similar effects were observed upon stimulation of area 6aγ, although often accompanied by movements of the head. In contrast, stimulation of area 6aα/β evoked more complex patterns that frequently involved all four limbs, and often included a curtailment of the contralateral forelimb swing phase. While the stimulation responses were generally incorporated into the gait, some sites produced strong bilateral hindlimb responses that interrupted locomotion. The results show that the premotor cortex of the cat can exert a strong influence on locomotion and that some areas may make an important contribution to interlimb coordination. Such effects may be particularly important for coordinating limb activity when walking over uneven terrain.

Title: Neural activity during corrective, precise arm movements displays cyclic dynamics

Authors: *A. G. ROUSE
Neuroscience, Del Monte Inst. for Neurosci., Univ. of Rochester, Rochester, NY

Abstract: Many voluntary movements have been shown to have common neural population activity that is cyclic. This cyclic activity appears as a condition-independent, circular trajectory in the neural space. This cyclic activity has been observed in not only inherently cyclic movements like locomotion but also single, point-to-point reaching movements. Most reaching studies, however, have focused on consistent, overlearned movements with few errors or corrective movements.

To examine the common neural activity during corrective movements, monkeys were trained to use a joystick to reach to 8 peripheral targets of varying sizes in a precision center-out task. The smaller targets required significant precision, often with corrective movements. The subjects were required to acquire and hold the final target for 500-600ms. If the subjects left the target during the final hold, they were allowed to make a corrective movement (without going back to the center) to re-enter and successfully hold the target and complete the trial.

In initial analysis, firing rates were averaged separately for both initial as well as corrective movements. These condition-independent averages were computed for all trials regardless of target or movement direction. jPCA was performed on both the initial movements and corrective movements to identify the two neural dimensions with the most rotational activity. We observed that the initial and corrective jPC subspaces were largely overlapping. Additionally, the neural trajectories of both the initial and corrective movements followed a similar circular path and aligned to the onset and offset of movement.

The phase of the jPCs was next examined for its relationship to the corrective movements. We observed consistent phase alignment of the neural activity with the corrective movement back to the target. In some cases, corrective movements involved multiple peaks in speed and we observed that each was typically accompanied by additional cycles of neural jPCs. In each of the 1st, 2nd, and 3rd cycles of corrective movements, there was a significant relationship between the jPC phase and the peak speed of movement. Finally, we found evidence that the brain state at the time of target exit as defined by jPC phase was predictive of how long the subject took to

make the corrective movement back to the target.
These results suggest that the corrective movements were not performed using a continuously updating model where feedback is used to constantly adjust the hand towards the target. Rather, the results support a pulsatile or cyclic model where discrete submovements are made toward the target.

Title: Neurons in somatosensory and motor cortices encode hand postures, not joint velocities

Authors: *J. GOODMAN, JR, A. S. LEE, E. V. OKOROKOVA, A. K. SURESH, N. G. HATSOPOULOS, S. J. BENSMAIA
Univ. of Chicago, Chicago, IL

Abstract: Despite the remarkable complexity of our hands, we effortlessly use them to grasp and manipulate objects. To achieve dexterous object manipulation requires not only a sophisticated motor system to move the hand but also a sensory system to provide sensory feedback - proprioceptive and tactile - about the consequences of those movements. While some progress has been made to understand the neural basis of touch in somatosensory cortex, much less is known about the neural basis of hand proprioception. To fill this gap, we simultaneously record time-varying joint kinematics of the hand - measured using a camera-based motion tracking system - and neural activity from somatosensory and motor cortices of rhesus macaques - using chronically implanted electrode arrays - as they perform natural grasping movements and are subjected to passive hand movements. We find that somatosensory representations of kinematics are very similar to their motor counterparts, with spiking activity preferentially encoding the postures (not the velocities) of multiple joints spanning the entire hand. Preferential encoding of hand posture stands in stark contrast to models of kinematic encoding of the shoulder and elbow, where velocities are preferentially encoded. Moreover, we observe similar response properties in somatosensory and motor cortices during both active and passive movements of the wrist and digits. We conclude that hand shaping via movements of the digits and wrist relies on different neural mechanisms than does hand transport via movements of the arm.

Title: Parallel motor pathways in the neocortex of tree shrews and monkeys

Authors: *M. K. BALDWIN[1], L. A. KRUBITZER[2]
[1]Ctr. for Neurosci., Univ. of California Davis, Davis, CA; [2]UC Davis, Davis, CA

Abstract: The current study is part of an ongoing project focused on understanding the organization and function of frontoparietal networks in mammals and how these pathways were elaborated in primates. Previous work from our lab, using long duration intracortical stimulation techniques, has shown that evoked movements can be elicited from both frontal motor cortical areas (i.e. primary motor and premotor cortex), posterior parietal cortex (PPC), as well as somatosensory cortical areas in both tree shrews (Baldwin et al., 2017) and macaque monkeys (Baldwin et al., 2018). Other studies in primates have shown that evoked movements from stimulation within PPC rely on the integrity of M1 (Stepniewksa et al., 2014; Cooke et al., 2015). Thus, when M1 is inactivated, movements from PPC cannot be evoked suggesting that M1 serves as a gateway for motor commands from PPC. However, little is known about how primary somatosensory cortex functions in the frontoparietal network. In the current set of studies, primary motor cortex was reversibly inactivated using cooling techniques while stimulating somatosensory and posterior parietal cortical areas in both New World titi monkeys, and tree shrews, one of the closest living relatives to primates. When M1 was inactivated, evoked movements could not be elicited from matched movement domains within PPC; similar to previous findings in New World monkeys and prosimians. However, evoked movements from stimulation of the primary somatosensory area (3b) were unaffected by M1 inactivation in both titi monkeys and tree shrews. These findings suggest that 3b is part of a parallel pathway from which movements can be generated; and this pathway does not rely on the integrity of M1. Therefore, primary somatosensory cortex does not simply provide sensory feedback for the frontoparietal motor network, but has the capacity to be involved in the generation of motor movements independent of motor cortex.

Title: Decoding hand kinematics from neuronal populations in primary motor and somatosensory cortices during grasping

Authors: *E. OKOROKOVA[1], J. GOODMAN[1], S. LEE[1], G. TABOT[2], A. RAJAN[4], N. G. HATSOPOULOS[1], S. J. BENSMAIA[3]
[2]Organismal Biol. and Anat., [3]Dept. of Organismal Biol. and Anat., [1]Univ. of Chicago, Chicago, IL; [4]Epigenetics, Quadrant Biosci., Syracuse, NY

Abstract: The hand, a complex effector comprising dozens of degrees of freedom of movement, endows us with the ability to flexibly, precisely, and effortlessly interact with objects. The neural circuits that mediate manual dexterity in primary motor (M1) and somatosensory (S1) cortices have received comparatively less attention than have those that mediate proximal limb control. The goal of this project is to assess the degree to which hand kinematics can be reconstructed from the activity of neural populations in M1 and S1. To this end, we measure time-varying hand kinematics using a camera-based motion tracking system and simultaneously record the responses evoked in M1 and S1 using chronically implanted electrode arrays while a monkey grasps objects that vary widely in shape and size. We then evaluate our ability to decode hand kinematics from M1 and S1 responses. We find that both neuronal populations yield high decoding performance. Interestingly, hand postures (joint angles) are better decoded than are hand movements (joint angular velocities) from both M1 and S1, in contrast to what has been observed for proximal limb kinematics. Results from this decoding analysis suggest differences between the neural representations of the proximal and distal limb. Furthermore, we show that signals from sensorimotor cortex can support the dexterous control of an anthropomorphic robotic hand using a brain-machine interface.

Title: Size of the spatial correlation between ECoG and fMRI activity

Authors: *G. PIANTONI[1], D. HERMES[1,3], N. F. RAMSEY[1], N. PETRIDOU[2]
[1]Brain Ctr. Rudolf Magnus, [2]Ctr. of Image Sci., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [3]Stanford Univ., Stanford, CA

Abstract: Electrocorticography (ECoG) is widely employed to accurately identify the seizure focus as well as the location of brain functions to be spared during subsequent surgical resection in patients with drug-resistant epilepsy. Increasingly, this technique has become a valuable tool to investigate the detailed neurophysiology of human brain functions. Functional MRI (fMRI) is used for similar purposes at a much larger scale but the neural underpinnings of the measured Blood-Oxygen Level Dependent (BOLD) signal are not well understood. ECoG can be used to elucidate this, but since the different modalities exhibit different spatial and temporal features, research would benefit from being able to correlate across modalities. A major issue complicating this is the unknown spatial extent of BOLD signal generated by neuronally active foci. Each grid electrode is thought to record from the cortical area directly underneath the contact but the size of a corresponding BOLD response is unknown. An estimate of this measure would be highly beneficial to cross-modal research (eg neurovascular coupling).
We compared the high-frequency broadband (HFB) activity recorded with ECoG while patients (n=8) performed a motor task (quantified as r-squared), with the activity maps measured with fMRI at 3 Tesla for the same task prior to surgery. For both the preoperative fMRI and ECoG sessions, patients were asked to flex and extend their thumb or all the fingers of one hand for 30 seconds, followed by a rest period of 30 seconds, four or five times. Electrodes covered large parts of one hemisphere and were spaced 1 cm apart. The research was approved by the local institutional review board.
Channels exhibiting low signal or artifacts were rejected and signals from remaining electrodes were referenced to the common average. Subsequently we computed HFB activity in the range between 65 and 95 Hz and compared it between the task periods and the rest periods for each electrode. The fMRI pipeline consisted of realignment, gray-matter segmentation, and general linear model regression . No smoothing was applied. We correlated HFB power change measured with ECoG with the fMRI BOLD percent signal change in the area around each electrode. This latter measure was quantified by applying a 3D Gaussian kernel of varying width

(sigma between 1 mm and 12 mm) to the fMRI maps including only gray-matter.
We confirmed previous reports that HFB activity can explain up to 40% of the BOLD percent change at 3T. Further, we found that the best kernel size across subjects was between 6 and 8 mm. These results suggest that ECoG electrodes are best compared to 3T fMRI with a kernel width of 6-8 mm for crossmodal research.

Title: Changes in corticospinal excitability reflect hand preferences for reaching during whole-body motion

Authors: L. OOSTWOUD WIJDENES[1], S. C. WYNN[1], B. ROESINK[1], D. J. L. G. SCHUTTER[1], L. P. SELEN[1], *W. MEDENDORP[2]

Abstract: An important aspect in the planning of a reaching movement is deciding which hand to use. While this decision is affected by various factors (incl. handedness, task demands, distance to the reach goal), we recently showed that this decision also depends on whether the body is stationary or in motion (Bakker et al. 2017). More specifically, we showed that acceleration of the body, but not velocity, affects the decisions of hand choice. The neural correlate underlying this observation is not known. Here, using single-pulse TMS, we investigated the excitability of left M1 during a hand selection task under sinusoidal whole-body translations, imposed by a vestibular sled. At eight possible motion phases, subjects had to reach, freely choosing either their left or right hand, to a target presented at one of 35 possible directions (reach trials) or received a short magnetic pulse to their left M1, in the absence of a target and reach (TMS trials). While experiments are still underway, we have now collected data in 8 subjects. As a measure of hand selection bias in the reach trials, we determined the target direction that resulted in equiprobable right/left hand choices, using an adaptive approach. While hand choice was biased towards the dominant hand, this choice bias was modulated by the acceleration signal, replicating our earlier findings. During the TMS trials, we measured MEP amplitudes from the lateral triceps of the right arm as an indicator of corticospinal excitability. We found that MEP amplitudes were dependent on the phase of the motion, following a similar

modulation of the behavioral choice bias. Our findings so far suggest that whole-body motion affects corticospinal excitability, thereby biasing upcoming hand choices in an acceleration dependent manner.

Title: Delineation of effector-specific representations in M1 using ultra-high resolution (7T) imaging

Authors: *J. GOOIJERS[1], A. KAAS[2], A. ROEBROECK[2], S. P. SWINNEN[1]
[1]KU Leuven, Leuven, Belgium; [2]Cognitive Neurosci., Maastricht Univ., Maastricht, Netherlands

Abstract: It is generally accepted that a coarse topographical representation of body parts is present in the primary sensorimotor cortex (M1-S1)**[1]**. As to finer-grained representations, i.e. single digits, there is less consensus. Although separate center-of-mass coordinates per digit have been observed, these representations also show overlap**[2]**. Considering these ambiguous findings, the spatial resolution at which the topography is studied might be key. Using ultra-high field (7T) MR scanning, our goal is to determine if increased spatial resolution allows us to more finely delineate digit representations in M1-S1.
Right-handed participants (N=16, age ~24 yrs, 7 male) performed a finger-tapping task. They were instructed to tap one of ten fingers for 20-sec at 1.5Hz. These 20-sec tapping trials were repeated 6 times per finger across 4 runs. Tapping performance was recorded by MR compatible force sensors. Functional images were acquired using a 7T Siemens scanner (32-channel head coil; 1.25 mm isotropic resolution). Functional data were analyzed using GLM with a separate regressor for each finger convolved with a HRF (BV 20.6). Estimates were used to calculate distance measures.
See *Fig.1* for finger representations in M1-S1 superimposed on high-resolution anatomical images. Differential activations are shown, i.e., one finger against other fingers of the same hand.Note that an increased spatial resolution reveals significant peak voxels using differential contrasts (i.e. increased sensitivity to pick-up finger-specific activations). Regarding the thumb, activations are found laterally in M1-S1 (influence of draining veins to be explored). Regarding

all fingers of the left hand, the differential contrast maps of some of the participants show a medial to lateral order for the little/ring, middle/index and thumb. The dissimilarity between activation patterns, measured for each finger pair (Mahalanobis distance), should confirm these results. ROI-based analyses will be performed to separate M1 & S1.
Acknowledgements: We thank J Diedrichsen for assistance with apparatus design

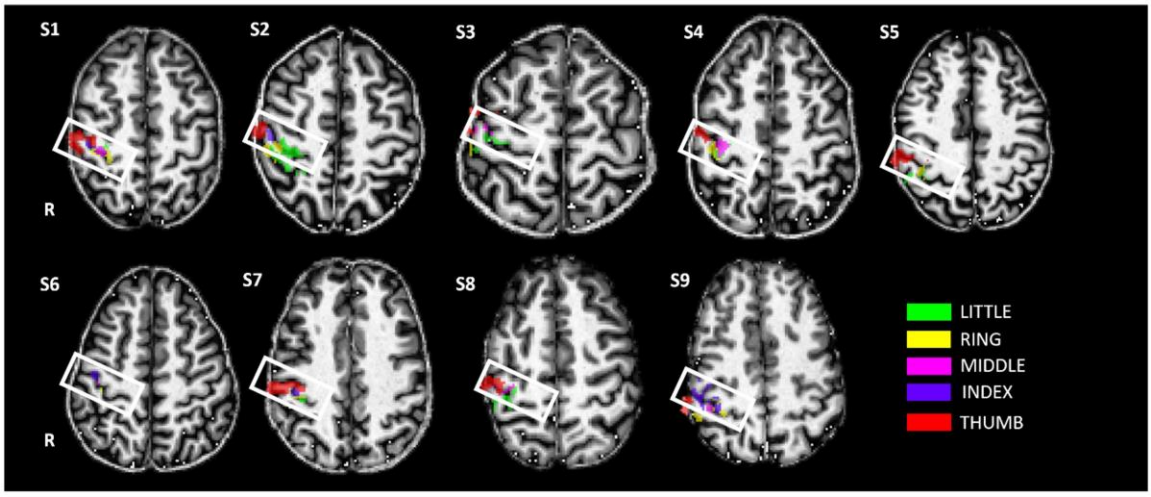

Figure 1. *Individual finger representations in sensorimotor cortex in right hemisphere for left hand tapping. Example subjects are presented. Red: activation in response to tapping of the thumb. Purple: activation in response to tapping of the index finger. Pink: activation in response to tapping of the middle finger. Yellow: activation in response to tapping of the ring finger. Green: activation in response to tapping of the little finger. Activations within the white rectangle largely represent sensorimotor cortex (M1/S1).*

Title: Cognitive-motor integration performance and its association with white matter integrity in females

Authors: J. M. HURTUBISE[1], *D. J. GORBET[2], L. E. SERGIO[3]
[1]York Univ., Toronto, ON, Canada; [2]Ctr. for Vision Res., York Univ., North York, ON, Canada; [3]Sch. Kinesiol & Hlth. Sci., York Univ., Toronto, ON, Canada

Abstract: In everyday reaching tasks we often look towards the target we are reaching for. This type of visuomotor transformation is considered "standard" visuomotor mapping. However, reaching movements where the eye and hand are incongruent - "non-standard" mapping - are also common in our daily life. These decoupled eye-hand coordination tasks require cognitive-motor integration (CMI), where rules dictate the relationship between perception and action[1,2]. Previous work has shown an association between poor performance on CMI tasks and decreased white matter integrity in individuals at risk for dementia[3]. The aim of this study is to examine whether such a relationship also exists in individuals with post-concussion syndrome (PCS) [4]. **Methods:** Twenty-six female participants are included in this study; 13 with PCS, with symptoms persisting for 6 months or greater at the time of examination, and 13 age-matched healthy control participants with no self-reported history of concussion. Participants completed 2 visuomotor transformation tasks; one requiring standard mapping (reaching directly to visual targets) and one requiring non-standard mapping (reaching on a different spatial plane relative to visual targets and with 180° rotated visual feedback). In addition diffusion weighted images were acquired. Fractional anisotropy (FA) values were extracted from white matter tracts for analysis of correlation with composite scores of movement timing, trajectory, and corrective movement production. **Results:** No significant differences were detected between the two groups of participants on either performance or white matter integrity. However, there was a significant overall relationship between white matter integrity and CMI task performance. In the non-standard condition, there was a significant relationship between the trajectory performance score and the FA of the inferior longitudinal fasciculus (ILF) and the inferior fronto-occipital fasciculus (IFOF). Furthermore, there was a significant association between the corrective movement score and FA of the IFL, IFOF, superior longitudinal fasciculus (SLF), and corticospinal tract (CST). In all regions, worse performance was associated with decreased FA. There were no associations between FA in any tract and any of the performance scores in the standard condition. **Conclusions:** The results of this study suggest that decreases in white matter integrity may underlie impaired performance in cognitive-motor integration. Title: Exploring changes in motor network physiology and complexity with HD-tDCS and fMRI

Authors: *S. LEFEBVRE[1], K. JANN[2], A. SCHMIESING[1], K. ITO[1], M. JOG[2], N. SCHWEIGHOFER[3], D. J. J. WANG[2], S.-L. LIEW[1]
[1]Neural Plasticity and Neurorehabilitation Lab., [2]Lab. of FMRI Technology, USC Stevens Inst. for Neuroimaging and Informatics, USC, Los Angeles, CA; [3]Computat. Neuro-Rehabilitation Lab., USC, Los Angeles, CO

Abstract: ***Introduction*** Transcranial direct current stimulation (tDCS) applied to the primary motor cortex (M1) may be an effective tool to modulate motor cortex excitability. However, recent studies have demonstrated significant inter-individual variability in behavioral and neurophysiological changes following M1 tDCS. We hypothesized that stimulating another target, (dorsal premotor cortex; PMd) with high-definition tDCS (HD-tDCS) might modulate brain excitability and motor network complexity more reliably than M1 tDCS.
Methods 46 healthy participants were randomized into 3 groups (left M1, left PMd or sham) in this double-blind study. A 7-minute resting-state fMRI scan was acquired before and after a 7 min HD-tDCS (1mA) session to explore changes in network complexity using a multiscale entropy (MSE) measure, which examines the regularity of biological signals across a range of temporal scales. Changes in cortical excitability were measured before and after tDCS using motor evoked potentials (MEP). fMRI data were linear-drift detrended and noise-corrected using white-matter, CSF, and motion-parameters as regressors. MSE computations used a pattern matching threshold of 0.5 and a pattern length of 2. In total 20 coarse-sampled scales and four regions of interest (L M1, R M1, L PMd, R PMd) were investigated.
Results No significant differences in cortical excitability were found between PMd and M1 groups, which were then combined into one "active stim" group for excitability analyses. A two-way RM-ANOVA, with factors group (active stim, sham) and time (pre, post), showed a marginal increase in cortical excitability (measured by peak-to-peak MEP amplitude) following HD-tDCS (group*time $F(1,43)=2.6$, $p=0.11$; post-hoc tests: *active stim post > sham post* $t(43)=2.3$, $p=0.03$. The weak significance of these results reflects the strong inter-individual variability in groups; only 50% of participants responded to M1 tDCS, versus 73.3% to PMd tDCS.
The MSE analysis showed significant changes after tDCS. In the PMd group, MSE increased in the L PMd (group*time $F(2,43)=7.5$, $p=0.002$, post-hoc tests *PMd post > PMd pre* $t(43)=4.1$, $p>0.001$) and in the R PMd (group*time $F(2,43)=3$, $p=0.06$, post-hoc tests *PMd post > PMd pre* $t(43)=2.2$, $p=0.03$). In the M1 group, MSE showed a marginally-significant increase in the L M1 (group*time $F(2,43)=2.5$, $p=0.09$; post-hoc tests *M1 post > M1 pre* $t(43)=1.68$, $p=0.09$). Overall, MSE changes were stronger in the PMd than M1 group.
Conclusion PMd HD-tDCS may modulate motor network neurophysiology and complexity more robustly than M1 HD-tDCS. In addition, multiscale entropy may be a sensitive marker of changes following noninvasive brain stimulation.

Title: Effect of the viewpoint on motor learning and brain activity

Authors: *H. KADOTA, S. SAWADA
Kochi Univ. of Technol., Kochi, Japan

Abstract: Humans can perform appropriate behavior under conditions different from their own viewpoint, such as remote operation, through engineering innovation. In this study, we investigated the effect that different view point environments had on motor memory and brain activity. First, participants performed reaching task with force field learning. This task was carried out from a frontal viewpoint or a right viewpoint. The viewpoints were counterbalanced between participants. The first (from the frontal/right viewpoint) and the second (from the right/frontal viewpoint) blocks were set as the baseline. The third block (the frontal/right viewpoint) had a clockwise velocity-dependent force field. This block was set as learning. The fourth (the right/frontal viewpoint) and fifth (the frontal/right) blocks were set as washout (null force field) to verify the presence of an after-effect and to cause participants to forget the memories that they had learned. The results indicate that motor learning occurred regardless of the viewpoint. Moreover, after-effects were shown at the washout when a viewpoint was converted. This result suggests that the two viewpoints have both a shared motor memory and independent motor memories. Next, we conducted fMRI experiment to identify the neural correlates of the different process from the frontal and the right viewpoint. The participants performed reaching tasks with MRI compatible joystick from either the frontal viewpoint or the right viewpoint. Each participant participated in ten sessions, each consisting of six 20-s blocks. Each session was composed of two resting blocks (the first and the last) and two frontal and two right viewpoints blocks (the order of viewpoint was counterbalanced between participants). The fMRI result showed that the posterior parietal cortex activated during the right viewpoint compared with the frontal viewpoint, whereas there was no significant activation during the frontal viewpoint compared with the right viewpoint. This area appears to be involved to the transformation of visual information from right viewpoint to motor output for reaching movements. The difference of brain activity may contribute to the motor memory depending on the viewpoint.

Title: Receptor architecture of the macaque monkey superior parietal lobule

Authors: D. IMPIERI[1], K. ZILLES[2], M. NIU[2], L. JANKOVIC-RAPAN[2], C. GALLETTI[1], *N. PALOMERO-GALLAGHER[2]
[1]Dept. of Biomed. and Neuromotor Sci., Univ. of Bologna, Bologna, Italy; [2]Res. Ctr. Juelich, Juelich, Germany

Abstract: The macaque monkey superior parietal lobule (SPL) is part of a neuronal network involved in the integration of information from visual and somatosensory cortices for execution of reaching and grasping movements. The cytoarchitecture of areas V6, V6Ad, V6Av, PE, PEc, PEci and PGm of the SPL has been described, but little is known about their receptor architectonic organization, although receptor analyses not only provide information concerning brain structure, but also crucial insights into its functional organization.
We applied quantitative in vitro receptor autoradiography to analyze the distribution patterns of 15 different receptors for glutamate, GABA, acetylcholine serotonin, dopamine and adenosine in the SPL and adjoining cortex, as well as in the primary visual, somatosensory and motor areas of four adult male *Macaca fascicularis* monkeys. For each area, mean (averaged over all cortical layers) receptor densities were visualized as a receptor fingerprint of each area. Multivariate analyses were conducted to detect clusters of areas according to the degree of (dis)similarity of their receptor organization.
Differences in regional and laminar receptor distribution patterns confirm the location and extent of areas V6, V6Ad, V6Av, PE, PEc, PEci and PGm as found in cytoarchitectonical and functional studies. Receptor densities are higher in supra- than in infragranular layers of SPL areas, with the exception of kainate, M_2 and adenosine receptors, which reach highest values in layers V-VI. The hierarchical cluster analysis (Figure 1) shows a principal segregation of SPL areas from the primary sensory cortices. Areas PE, PEc, PEci and PGm cluster with posterior cingulate area 31. Area V6Av clusters with visual V6, and V6Ad with MIP and somatosensory area 2. These results are in accordance with the fact that V6Av contains more cells responsive to visual stimuli than does V6Ad, whereas the opposite holds true for cells responsive to

somatosensory stimuli. They further emphasize the special receptor architecture of posterior parietal areas involved in reaching and grasping.

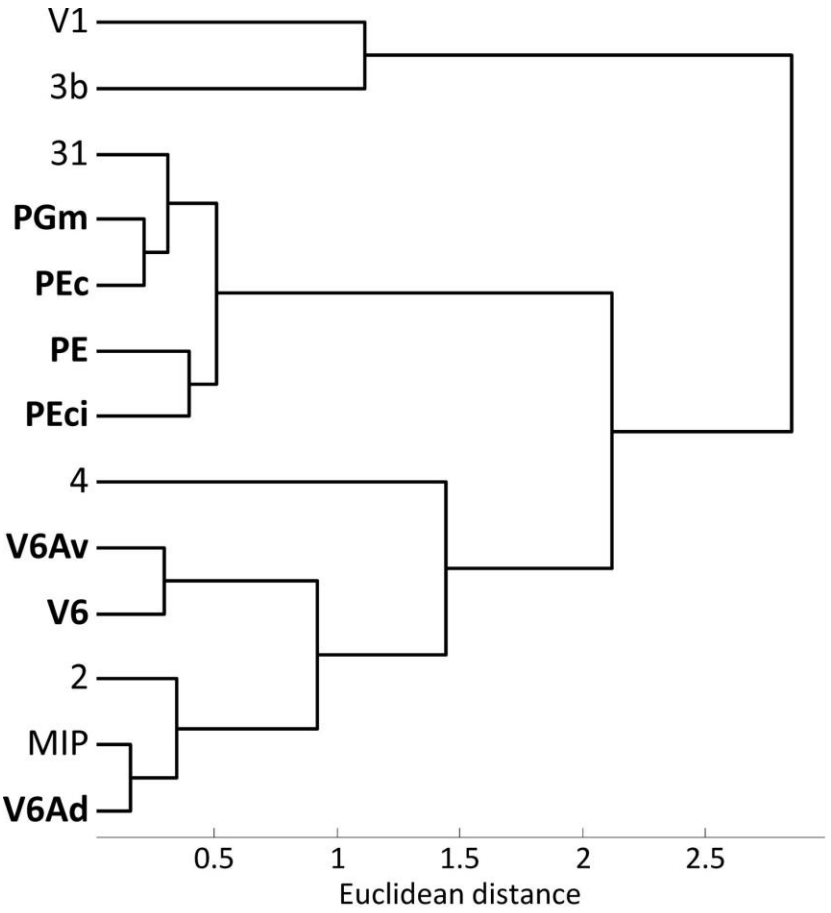

Figure 1: Hierarchical cluster analysis of the receptor fingerprints of areas of the macaque superior parietal lobule (bold font), as well as of the primary visual (V1), somatosensory (3b), and motor (4) areas, and of somatosensory area 2, cingulate area 31 and intraparietal area MIP.

Title: Test-retest reliability of corticospinal tract integrity in chronic stroke

Authors: *A. F. LEWIS, M. K. MYERS, J. HEISER, M. B. KOLAR, J. C. STEWART
Univ. of South Carolina, Columbia, SC

Abstract: Stroke often results in damage to the corticospinal tract (CST) that correlates with motor deficits. Fractional anisotropy (FA) of CST is often used to quantify the extent of damage to the motor system, predict motor outcomes, and investigate response to intervention. However, the stability of FA is unknown. The purpose of this study was to examine the test-retest reliability of corticospinal tract FA using two different methods. Eighteen participants with chronic stroke (mean age 59.2 years, months post-stroke 45.4, UE FM score 42.9) underwent diffusion tensor imaging (DTI) on the same MRI scanner 4 days apart. All images were preprocessed in FSL. Two methods for determining CST FA were analyzed. In the manual-based method, a single researcher hand drew masks of the CST at the level of the cerebral peduncle (3 slices). In the template-based method, a standard sensorimotor area tract template (S-MATT) of the CST was transformed into native space. Investigators were blinded to participant and day of data collection in both methods. FA was extracted and reliability was determined by calculating an intraclass correlation (ICC) and minimal detectable change (MDC). As expected, mean FA was significantly lower in the ipsilesional CST compared the contralesional CST ($p<0.02$) and FA ratio (ipsilesional/contralesional FA) values were <0.93 across days. For the manual-based method, FA on Day 1 correlated with FA on Day 4 in both the ipsilesional CST ($r=.698$; $p=.012$) and contralesional CST ($r=.730$; $p=.007$). Moderate reliability was found for ipsilesional CST FA (ICC=.696; MDC=.072) and contralesional CST FA (ICC=.707; MDC=.069); FA ratio was slightly more reliable (ICC=.773; MDC=.101). For the template-based method, FA on Day 1 correlated with FA on Day 4 in both the ipsilesional CST ($r=.967$; $p<.001$) and contralesional CST ($r=.910$; $p<.001$). Excellent reliability was found for ipsilesional CST FA (ICC=.966; MDC=.013) and contralesional CST FA (ICC=.910; MDC=.014); FA ratio was slightly more reliable (ICC= .986; MDC=.015)). FA correlated with UE FM in the manual-based method ($r=.868$; $p<.001$) but not the template-based method ($r=.380$; $p=.180$). The results of this study indicate that both a manual-based and template-based approach are reliable measures of CST FA across days. The template-based approach showed higher reliability than the manual-based approach; however, the validity of this method in capturing CST accurately is unclear (FA did not correlate with motor impairment). The ICCs and MDCs reported here may be useful for future research that aims to predict motor outcomes using CST FA values or report changes in CST FA values over time or in response to intervention.

Title: Dissociation of neural substrates for motor planning and execution in learning multiple visuomotor mappings

Authors: *S. KIM, K. LIM
Neurosci., Inst. of Basic Sci., Suwon, Korea, Republic of

Abstract: Previous behavioral studies have shown that humans can simultaneously adapt movements to multiple visuomotor mappings after extensive practice. Motor planning, not motor execution, has been known to play a critical role in separating multiple interfering motor tasks and motor memory formation. However, it remains unclear how the human brain represents distinct motor planning and execution for multiple visuomotor mappings. To address this issue, we designed a fMRI experiment in which motor planning and execution can be dissociated during learning multiple visuomotor mappings. Specifically, subjects first adapt to two conflicting visuomotor rotations with different movements and then later with identical movements but different plannings. Finally, subjects make different movements without rotations, by which we can control the effect of motor execution. We reported distinct neural substrates revealed by multivoxel activity pattern analysis (MVPA) for motor planning and execution in learning multiple visuomotor mappings. We also discuss how the pattern separation can account for experienced interference between the mappings, which decreases as a course of learning.

Title: Interactions between auditory and motor networks during command-driven actions

Authors: *D. GALE[1], C. H. HONDA[1], I. S. JOHNSRUDE[2], J. R. FLANAGAN[1], J. P. GALLIVAN[1]
[1]Queen's Univ., Kingston, ON, Canada; [2]Psychology / Comm Sci. Disorders, Univ. of Western Ontario, London, ON, Canada

Abstract: While following verbal commands seems effortless in everyday tasks, this belies the complexity of multisensory and motor-related processing occurring in underlying neural systems. Research in rodents and primates has provided critical insights into how the brain transforms visual information into motor-related commands, yet remarkably little is known at the neural level about how incoming auditory commands are similarly used to guide goal-directed behaviour. Here, using functional magnetic resonance imaging (fMRI) and a verbal command-following task that guided different hand movements, we examined neural interactions between human auditory and motor systems. Participants learned to map two nonsense verbal commands to either a right- or left-handed reach-to-grasp movement; the mapping of which switched throughout the experiment, allowing us to disentangle neural activity related to the verbal command from the motor response associated with that command. We hypothesized that representations of the verbal commands in auditory regions might be flexibly shaped by the motor responses cued by those commands. To explore this hypothesis at a network level, we performed task-based functional connectivity analyses between several auditory and motor regions during the task, which showed that the functional coupling of auditory and motor regions increased within the hemisphere guiding the upcoming grasping action. Within auditory regions, multivoxel pattern analysis and dimension reduction techniques were used to reveal time-varying changes in pattern information and low-dimensional neural states, respectively, influenced by the motor effector used. Together, this study provides a first glimpse into the highly dynamic and intertwined nature of auditory and motor networks during natural communicative behaviour, while offering promising avenues for future work examining interactions cognitive and motor systems.

Title: Stability of cortical muscle representations: TMS motor mapping test-retest study

Authors: *V. MOISEEVA[1], M. NAZAROVA[1], P. NOVIKOV[1], E. IVANINA[1], K. KOZLOVA[1], V. NIKULIN[1,2]
[1]HSE, Moskva, Russian Federation; [2]Max Planck Inst., Leipzig, Germany

Abstract: Cortical mapping with transcranial magnetic stimulation (TMS) is a promising approach for non-invasive investigation of the motor cortex in humans. However, apart from the parameters reflecting general corticospinal excitability, e.g., resting motor threshold (RMT) and mean amplitude of the motor evoked potentials, the reproducibility of other TMS motor maps metrics remains controversial or unknown. We studied a test-retest reliability of TMS cortical maps corresponding to multiple hand muscles. We took into account both standard size parameters such as map`s areas as well as novel parameters such as intricate muscle-specific excitability profiles.
The study included 18 young healthy right-handed male volunteers. We used MRI-navigated TMS to stimulate left motor cortex in two mapping sessions separated by 5-10 days. For the mapping we used a grid of 53-58 points each being stimulated in a pseudo-random order five times. Second day TMS session was an exact repetition of the first day session. An analysis was performed using custom-made software TMSmap (http://tmsmap.ru/). We used intra-class correlation coefficient (ICC) to assess reliability of map areas, volumes and the extent of the different muscles overlap. For the quantative comparison of the cortical excitability profiles of individual muscles we utilized earth mover's distance metrics (EMD).
We found that RMT remained the same across two testing sessions in all but two subjects in whom it changed by one percent. ICC for the same muscle representation could be considered as good (0.73-0.85) for areas, moderate for the extent of the different muscles maps overlap (0.7) and poor (0.45-0.49) for volumes. An average shift for hotspots was ~10 mm and for centers of gravity it was ~3 mm. When assessing individual excitability profiles, we found significantly smaller normalized EMD (higher reproducibility) for the same muscle representations across days than for the different muscle representations across days ($P<0,0001$).
The obtained results provide evidence that not only general excitability but also other specific features including standard characteristics (areas, volume) and even excitability profiles of the cortical muscle representation can be reliably traced with TMS motor mapping. This in turn indicates that the existence of the complex TMS cortical representations doesn't simply indicate stochastic fluctuations in the corticospinal excitability during TMS mapping procedure but rather demonstrates a possibility to probe with TMS cortical organization reflecting intricate descending projections relating to specific muscles.

Title: The role of the interaction between action generation and hand identity in self-other distinction

Authors: *L. UHLMANN, M. PAZEN, B. VAN KEMENADE, T. KIRCHER, B. STRAUBE
Dept. for Psychiatry and Psychotherapy, Philipps Univ. Marburg, Marburg, Germany

Abstract: The feeling that a seen hand movement can be attributed to one's own action is in part based on a match between the incoming sensory information and predictions about the sensory consequences of the action. Matches should occur if the hand movement was self-generated (i.e., active) and if the moving hand was recognized as one's own hand. It has been shown that sensory consequences caused by active movements are attenuated perceptually and neurally. It is still unclear, however, how predictive processes interact with afferent signals relaying the identity of a seen hand in order to coordinate self-other distinction. Thus, we conducted an fMRI study in which we investigated whether the sensory consequences of active and passive hand movements are processed differently depending on whether one's own or someone else's hand is seen. In the experiment, 24 healthy participants (14 female, aged 20-35 years) were instructed to detect temporal delays between active or passive hand movements and a visual feedback displaying a correspondingly moving hand on a computer screen. To execute a hand movement, participants had to grab the handle of a custom-made movement device while performing an extension and a flexion of their right wrist. In passive trials, the movement device moved automatically so that the participant's hand was moved passively. Furthermore, either the participant's own or someone else's hand was displayed as feedback. Importantly, the movement trajectories of the seen hand always corresponded with the actual hand movement. These manipulations allowed us to disentangle movement-related effects (e.g., who is triggering the movement) from effects due to visual characteristics (e.g., whose hand is moving), which both contribute to self-other distinction. On the neural level, passive movements elicited a stronger BOLD-response in parietal and frontal areas than active movements. Moreover, an interaction between action generation and hand identity was found in the precuneus and the angular gyri, suggesting that self-referred processing was modulated by sensory predictions accompanying active movements. In addition, taking the precuneus as seed region, a stronger functional

connectivity (PPI) with the middle occipital lobe as well as the left precentral and postcentral gyrus was found for passive movements, as compared to active movements, indicating that a loss of self-agency is processed in a wide network including motor and sensory areas. We assume that efferent signals involved in action generation processes and afferent signals relaying the identity of the seen hand interact in order to differentiate between self and other.

Title: Single trial investigation of flash-cued hand clenching through scalp EEG and source localization

Authors: *Y. ZHANG[1], T. T. NGUYEN[2], T. POTTER[1], R. G. GROSSMAN[3]
[2]Biomed. Engin., [1]Univ. of Houston, Houston, TX; [3]Neurosurg., Houston Methodist Hosp., Houston, TX

Abstract: Voluntary motor activity is a complex task that been a focus of study for many decades. Of particular interest are the cortical dynamics that support motor reactions and the role of the readiness potential, which appears before subjects report the decision to move.
In this experiment 5 healthy subjects were recruited to perform a visually-cued hand clenching. Subjects were seated in a comfortable chair in front of a laptop computer and a 64 EEG cap was placed on their head, with the FT10 channel sacrificed to measure EMG. Participants were asked to squeeze their hand for ~10 seconds whenever the screen flashed white, without straining or counting the time. Under the experimental paradigm, the screen displayed a green background screen with white flashes occurring every ~25 seconds. Data were collected across 30 total trials at a 1 kHz sampling rate. Signals were band-pass filtered from 0.5-50 Hz and ICA was applied to remove ocular and motion artifacts. T1 structural MRI data was also collected from each subject and Freesurfer software was used to create subject-specific models. Source imaging was then performed using the sLORETA algorithm and signals were analyzed at the scalp and electrode layers. Single trial results were examined at the supplementary motor area (SMA) and motor cortex (MCx), along with their associated EEG channels (Cz and C3).
Scalp EEG at the Cz location showed an increase in alpha activity that began ~50 ms after the

flash and ended ~50 ms before hand squeezing. This activity was comprised of two peaks: one exclusive to the alpha band and a broader activation spanning from ~0.5-10 Hz. A gradually increasing positive potential can be seen to peak ~350 ms after stimulus flash, which deflects to a negative peak at the time of hand squeezing. Cortical activity showed a spike of activity that aligned with stimulus perception, followed by a quiescent period and a second peak ~50ms before hand clenching. EEG activity at the C3 electrode showed a negative peak (3-12 Hz) occurring ~100 ms after stimulus onset, with a positive deflection occurring ~250 ms before hand clenching. Source imaging revealed a peak in activity immediately after stimulus onset that matched with EEG (0.5-12 Hz), with a second peak rising largely in the alpha band ~100 ms after clenching. Despite maintaining the clenching, no further peaks in activity remarkable peaks were observed after the initial response.
Results revealed activity in the SMA and MCx that was associated with the readiness potential and motor response. While EEG responses were generally seen as broad, slow waves, cortical responses instead showed distinct spiking activity that related to both stimulus perception and movement.

Title: Mesoscopic imaging of the mouse cerebral cortical network dynamics during spontaneous behavior

Authors: *S. WEST[1], L. S. POPA[1], R. E. CARTER[1], G. CHEN[1], J. D. ARONSON[1], L. GHANBARI[2], S. B. KODANDARAMAIAH[2], T. J. EBNER[1]

Abstract: The brain performs complex computations involving large networks that span across multiple cortical and subcortical structures. However, study of these processes is difficult, as the recording of neuronal activity is often limited spatially or temporally. Using CAD design and 3D

printing, we fabricated optically clear, geometrically conformant cranial prostheses that chronically replace a large portion of the dorsal mouse cranium without inducing tissue deformation of the cerebral cortex. These prosthetic windows allow for wide field-of-view (approximately 4 x 4 mm) for optical imaging of the majority of the dorsal cerebral cortex at 1x magnification. By implanting these windows in Thy1-GCaMP6f mice expressing the Ca^{2+} indicator GCaMP6f in Layer II/III and Layer V pyramidal neurons, we imaged cerebral cortical Ca^{2+} activity in awake animals (50 Hz acquisition) with high spatial resolution (35 x 35 µm pixel size). After recovery from surgery and acclimatization to experimental setup, the animals were recorded during multiple sessions, typically 10 trials each 50 s in duration, over several months. During imaging sessions, the mice were head-fixed under a single-photon fluorescent microscope (Nikon AZ-100), on a low friction, disk treadmill. Simultaneously with imaging, motor behaviors including locomotion, grooming, and whisking were recorded using-high speed cameras at either 50 Hz or 200 Hz. Behavioral motion was tracked using a computer vision segmentation and SURF tracking algorithm. Additionally, locomotion distance and speed were monitored by sensors on the treadmill. Mesoscopic Ca^{2+} imaging of the dorsal cerebral cortex revealed a widespread and dynamic nature of neuronal activity even during quiescent periods. During a trial, different regions of the cerebral cortex are active at various times with a strong tendency for homotopic cortical regions to be active bilaterally. These complex spatial and temporal activity patterns were analyzed using spatial independent component analysis (ICA), segmenting the cortical surface into spatially distinct cortical domains. Typically, 10-20 independent components were identified in a trial that, in aggregate, cover the entire dorsal cortex. Individual components tend to reflect functional domains (i.e. barrel or motor cortex) and are consistent across trials and days. Several of the components are present at all times, while others depend on the behavioral state of the animal. We are able to quantify cortical activity as patterns of activation that occur on a mesoscopic scale across the brain. These patterns are dynamic over time and reflect the variation in cortical function with behavioral states.

Abstract: Over the last decade, a plethora of tools have been developed for neuroscientists to interface with the brain. Implementing these tools requires precise removal of sections of the skull to access the brain. These delicate cranial microsurgical procedures need to be performed on sub-millimeter thick bone without damaging the underlying tissue and therefore, require significant training. Automating some of these procedures would not only enable more precise microsurgical operations, but also democratize use of advanced neurotechnologies. We have developed the Craniobot, a cranial microsurgery platform that combines automated skull surface profiling with a computer numerical controlled (CNC) milling machine to perform a variety of cranial microsurgical procedures in mice. The Craniobot utilizes a low force contact sensor to profile the skull surface and uses this information to perform micrometer-scale precise milling operations within minutes. The Craniobot's custom contact sensor was able to detect the surface of the mouse's skull precise to 6 μm for 97.4% of measurements (n = 6 mice, 192 points each mouse). Data acquired from surface profiling was successfully used to perform microsurgical procedures for demonstration purposes, including skull thinning and polishing for optical access, skull excisions for glass coverslip implantations, and pilot holes for skull anchors. The Craniobot is built using off-the-shelf components for under $1000 and is controlled using open-source CNC programming software.

Title: Functional interactions within the mouse cerebral cortical network during spontaneous behavior

Authors: *L. S. POPA, Mr[1], S. WEST[1], R. E. CARTER[1], G. CHEN[1], J. D. ARONSON[1], L. GHANBARI[2], S. B. KODANDARAMAIAH[2], T. J. EBNER[1]

Abstract: Understanding both brain function and pathology at a system level rests on understanding the multitude of interactions between structures defined by specific behavioral roles. However, the sheer complexity of the brain as well as the dynamic nature of the functional interactions require new investigative approaches. One of these experimental paradigms is longitudinal mesoscopic imaging of cellular Ca^{2+} signals. We deployed this approach in the dorsal cerebral cortex of behaving mice, using chronic implants of morphologically conformant, optically clear, 3D printed skull prostheses in Thy1-GCaMP6f mice expressing a Ca^{2+} indicator in neurons. This method allows repeated imaging of large cortical areas (~16 mm^2) at 50 Hz during 50 s trials over months simultaneously with high-speed imaging of behavior. We used independent component analysis (ICA) to functionally segment the imaged cerebral cortical area, obtaining on average 13 ± 3 spatial independent components, excluding movement artifacts. We used a second ICA step to extract six independent time courses for each spatial independent component that characterize their temporal evolution. For further analyses, we retained only the time courses with a relative high stability score (iq > 0.75). Within a trial, the population of stable time courses cluster in groups with high similarity (correlation coefficient > 0.7). The clustering of time courses is highly dependent on the behavioral state of the mouse (preparing to walk, walking, or resting after walk). To better understand the functional interactions between the spatial independent components, we used conditional, multi-variate Granger causality. This allowed us to measure the directed interactions between selected groups of time courses, conditional on the presence of the rest of the time courses extracted within the same trial. The interacting groups were selected based on being extracted from one spatial component. To determine the interaction timing, the target time courses were shifted relative to the rest of the time courses in 20 ms steps over a ±5 s time window. The Granger analysis was repeated at each time shift. We determined that the interactions between independent components are highly dependent on the behavior state of the mouse. We also determined that long range interactions between independent components over extended time spans (up to ± 5s) are very common, even during fast motor behavior epochs. One of the more intriguing findings is that the interaction between the same independent components can be repeated at multiple times, spanning the whole ± 5s time window investigated.

Title: Therapeutic and neurophysiological effect of combining physical and mental practice in breast cancer survivors

Authors: *S. H. SALEH[1], D. ALLEXANDRE[1], A. HOXHA[1], G. H. YUE[1,2]
[1]Kessler Fndn., West Orange, NJ; [2]Rutgers Univ., Newark, NJ

Abstract: Breast cancer survivors often experience physical weakness due to the effect of treatment, which limits their ability to participate in high effort physical training. We hypothesize that combining submaximal physical practice with motor imagery (MI) at maximum voluntary contraction (MVC) can have significant therapeutic and neurophysiological effect on cancer weakness without inducing fatigue. This was tested on the right hand (High Mental Effort, HME) in breast cancer survivors by evaluating its effect on muscle strength, and cortical activation during an MVC and a submaximal (20% of MVC) task. Effect of HME was compared to a control group who received physical training only (Low Mental Effort, LME) and another who received no training (CTR). To date, 6, 5 and 5 female cancer survivors were randomly assigned to the HME, LME and CTR group respectively. The HME and LME group participants completed 5 weekly training sessions for 5 weeks. Baseline measures included MVC of right hand and fMRI cortical brain activation measures. An MRI-compatible Biopac force transducer was used to acquire and provide real-time visual feedback of the handgrip force in the scanner. In scan 1, subjects were provided with visual cues to squeeze a handgrip sensor up to the 20% MVC target (PercMVC). In scan 2, subjects were instructed to perform a MVC. 10 trials were acquired for each task (10 seconds each with 12 to 16 seconds of rest in between). fMRI data were preprocessed using conventional methods in FSL. Neural correlates of each experiment task were analyzed using simple regression analysis, and between sessions comparison was performed using mixed-effects ANOVA. Results show changes in neural correlates of percMVC and MVC tasks in the HME and LME groups and no changes in the CTR group. In the HME group, results show increased activation in contralateral sensorimotor cortex during MVC task after training and more focal activation during percMVC task. Similar changes in sensorimotor activation were shown for both the LME and HME groups during the percMVC task while no significant activation change was observed during the MVC task. The percent change in MVC after training is similar in all groups. In conclusion, these preliminary data show that even though no difference in strength improvement could be observed, combining MI and physical training

resulted in higher neuromodulatory effect than performing physical training alone. Future effort will include additional analyses of connectivity and muscular activity and additional data from newly enrolled participants to increase statistical power and help better understand the therapeutic and neurophysiological effect of HME versus LME and CTR.

Title: EEG source-space connectivity during motor imagery versus motor practice in breast cancer survivors

Authors: *D. ALLEXANDRE, A. HOXHA, V. SHENOY, S. H. SALEH, G. H. YUE
Kessler Fndn., West Orange, NJ

Abstract: Background: The underlying premise for the therapeutic benefit of motor imagery is that it engages the same motor-related cortical regions than those during the actual motor task. This study examines the potential benefit of combining motor imagery with submaximal motor contraction in breast cancer survivors with muscle weakness by investigating its neural correlates using an EEG source-space connectivity analysis. Method: In a randomized mixed design, 10 right handed breast cancer patients were asked to (1) perform series of actual submaximal right hand handgrip contractions (Squeeze Exercise; SE) at 20% of their maximal voluntary force (MVF), or (2) imagine contracting their handgrip at their MVF (Imagine Exercise; IE) or (3) combine SE and IE conditions by performing handgrip contractions at 20% MVF while imagining and urging the handgrip muscles to contract maximally (Squeeze+Imagine Exercise; SIE). After computing EEG source localization time series from 22 motor related region of interests using the sLORETA inverse modeling technique, connectivity was estimated using the imaginary coherence in the alpha band (8-12Hz) during the initial and static phase of each handgrip contraction trial. Results/Discussion: Motor execution shows strong brain connectivity across all regions in the initiation phase; most evident in the premotor and sensorimotor regions. This connectivity subsequently diminished during the static phase suggesting that maintaining a steady state contraction does not require strong interregional interactions. Although connectivity was lower in IE than SE during the initiation phase, it intensified and consequently became greater than SE during the static phase, thus keeping the regions strongly engaged without physical exertion. Stronger connectivity was also observed in SIE during the sustained phase but

to a lesser extent than SE, possibly due to challenges in engaging in a dual task. In summary, SE and SIE showed strong brain connectivity in the visuo-motor network, providing support for their benefit as low exertion therapeutic approaches.

Title: Understanding the neural dynamics of Traumatic Brain Injury participants during the lower limb balance dysfunction task: An EEG source-space connectivity study

Authors: *V. SHENOY HANDIRU[1,2], A. HOXHA[3], S. SALEH[3], G. YUE[3,2], D. ALLEXANDRE[3]
[1]Kessler Fndn., West Orange, NJ; [2]Physical Med. and Rehabil., Rutgers Biomed. Hlth. Sci., Newark, NJ; [3]KESSLER FOUNDATION, West Orange, NJ

Abstract: Background: Traumatic brain injury (TBI) patients often suffer from long term balance problems, the cause of which remains poorly understood. To elucidate the underlying mechanism of the deficit, an EEG based connectivity analysis was performed on the neural

response to balance perturbation. **Method:** Brain activity (64 ch Brainvision EEG system), lower limbs muscle activity (EMG) and center of pressure (COP) were collected from 4 TBI and 4 age-matched healthy control (HC) participants while they stood on a balance platform (NeuroCom Inc). The platform was subjected to ~100 unpredictable forward or backward 4s long perturbations at low (1cm) and high (4cm) amplitude sinusoidal displacements at 0.5Hz. After computing EEG source-space time series using sLORETA, imaginary coherence based functional connectivity (FC) between motor-related regions of interest (ROIs) was estimated in the alpha band (8-12Hz) during the first 1.5s of the perturbation. Weighted node degree (WND) values defined for a given ROI as the sum of its coherence values with other ROIs were then compared between groups and conditions using ranksum test. **Results:** The TBI group had balance deficit compared to HC (mean Berg Balance test score of 49 vs 56, p=0.02). As shown in the figure, there was an overall increase in WND-based FC for HC group for the high (vs. low) backward perturbations reaching significance (or trend toward) for the superior occipital gyrus (**, p<0.05), and post- and pre-central right gyri (*, p<0.1). Surprisingly the TBI group shows an opposite trend, leading to significantly greater (or trend toward) FC in postcentral and superior occipital gyri (**, p<0.05) and precentral gyrus (*, p<0.1) in HC compared to TBI for the high backward perturbation. **Conclusions:** The inability for the TBI group to increase brain connectivity in response to a more challenging high perturbation task (as the HC group do), may be a contributor to the balance deficit. Future efforts will include more participants and study the correlation of COP and muscle response with connectivity results to further interpret our results.

Title: Expanding the reach of upper-limb prosthetics: Restoring sensorimotor function after complex regional pain syndrome, long-term hand disuse and an elective transradial amputation

Authors: ***J. A. GEORGE**[1], M. R. BRINTON[1], T. S. DAVIS[2], M. D. PASKETT[1], D. T. KLUGER[1], C. C. DUNCAN[3], D. T. HUTCHINSON[4], G. A. CLARK[1]

Abstract: The long-term goal of these studies is to provide intuitive, dexterous motor control of, and biomimetic sensory feedback from, an advanced prosthetic hand after prior amputation in humans. Here we report on a unique case-study in which an individual with Complex Regional Pain Syndrome (CRPS) and multi-year disuse of their intact hand underwent an elective transradial amputation, received neural and intramuscular electromyographic (iEMG) implants simultaneously, and then subsequently controlled an advanced prosthesis (e.g., DEKA LUKE arm; HANDi Hand). During amputation, three Utah Slanted Electrode Arrays (USEAs; Blackrock Microsystems) were implanted into the residual nerves (distal median, proximal median and ulnar) and 32 iEMG recording electrodes (Ripple, LLC) were implanted into the residual forearm muscles. Sensory percepts were evoked by passing current through USEA electrodes (biphasic, 100-200 μs, 1-18 μA pulses at 5-50 Hz), triggered by the experimenter or by sensors on the prosthetic hand. Motor intent was decoded from neural and iEMG recordings using two different motor-decode algorithms: a modified Kalman filter (mKF) and a convolutional neural network (CNN). Despite prior multi-year hand disuse, during the first post-amputation assessment, the participant successfully achieved 8-degree-of-freedom (DOF) proportional control via the mKF with modest, tolerable pain. In contrast, a pre-amputation study with surface EMG was limited to 3 DOFs and involved debilitating pain. USEA-evoked sensory percepts had low detection thresholds (e.g., 4-7 μA) and provided the participant with the first functional, non-painful sensory hand experience since CRPS onset. EMG signal and motor-

decode capabilities improved over time. Motor-decode performance was also increased with a novel training paradigm involving extended hold-times at the end point of each DOF. The relative performance of the two motor-decode algorithms varied according to the performance metric: the CNN had fewer unintended movements ($p < 0.05$), whereas the mKF provided significantly better control over intended movements ($p < 0.05$). Altogether, this work highlights progress in motor-decode algorithms and provides novel insights from a unique case-study. Future investigations using selective USEA stimulation to generate well-controlled afferent activity may help elucidate the underlying mechanisms of CRPS. Ultimately, the ability to restore non-painful sensorimotor function demonstrates that neuromyoelectric prostheses can also benefit CRPS individuals after hand amputation.

Abstract: Modern actuated prostheses for upper-limb loss patients provide many degrees of freedom (DOF) and mimic natural limbs well, but robust, multi-DOF control of such devices has not yet been achieved. Electromyography (EMG) signals based on patients' intact muscle activity may be used as control signals, but most available algorithms employ very simple encoding and mapping of EMG features to actuation of few DOFs. Modern machine learning methods can be used to classify gestures and movements from EMG features, but their accuracy is degraded by variance in signal properties due to changing electrode placement, arm position, and other contextual variations.

We present an end-to-end system for classifying finger/wrist movements and gestures using EMG recordings from a flexible, printed, high-density electrode array. Raw signals are digitized right at the electrode array and wirelessly transmitted to a base-station. They are then encoded and classified using a brain-inspired hyper-dimensional computing algorithm operating on 10,000-element random vectors. Because of the high-dimensionality of the vectors, classification performance is very robust to noise and context changes. Hyper-dimensional computing also offers fast, incremental learning, allowing for a minimal initial training dataset and quick model updates for learning new contexts. We achieve ~95% accuracy in classifying 25 common finger/wrist movements and gestures, with little accuracy degradation between different arm positions and wear sessions.
The classified gestures are wirelessly sent as a set of commands to be actuated on a 3D-printed prosthetic arm. The arm is based on HACKberry open-source bionic hand design with some modifications in order to accommodate more DOFs. Two servomotors for wrist (elevation and azimuth), one for thumb, one for index, and one for the rest of the fingers are used to mimic flexion, extension, and combination movements on the prosthesis.

Abstract: This work documents the first portable neuromyoelectric prosthetic interface capable of providing intuitive, dexterous, high degree-of-freedom, motor control to amputees, with potential expansion to include neural stimulation for sensory feedback. A mobile processing unit

(Nomad; Ripple, LLC) was used to record 96 neural and 496 differential, electromyographic (EMG) channels (from 32 single-ended electrodes); perform optimal channel selection; estimate user intent using a modified Kalman filter; and communicate that intent to an advanced six degree-of-freedom prosthetic arm (DEKA LUKE arm). Participants in the study included (a) two healthy volunteers with 32 surface EMG electrodes applied to the skin near forearm muscles and a bypass-socket to support the DEKA arm; and (b) a recent upper-limb amputee with prior complex region pain syndrome (CRPS) and long-term hand disuse (George et al., SFN 2018). To begin the decode training, the users simply pressed a button and then mimicked preprogrammed movements of the DEKA arm with their own phantom or intact hand while the Nomad recorded neural and EMG signals. In less than 15 minutes, the decode training was complete and control of the prosthetic was automatically transferred to the participant. Intact participants used the system to complete dexterity tasks in the lab (e.g., Box and Block Test, SHAP). In preparation for future take-home trials, lab personnel successfully operated the system at home to perform activities of daily living (e.g., don a sock, use scissors, open jars, sweep floor, fold towel). The amputee participant used both EMG and neural inputs (median nerve) to control the arm in a laboratory setting. The system can acquire neural and EMG signals, calculate differential EMG pairs, decode motor intent and communicate with the DEKA arm in less than 2ms, faster than the threshold for perceived delay. The system can be programmed to provide position or velocity control of the wrist and digits. For post-hoc analysis of a take-home trial, the DEKA arm stores the length of time each degree of freedom moved, the velocities at which they moved and the amount of compliance experienced. This work represents a major step toward the development and commercialization of advanced neuromyoelectric prostheses.

Title: Representation and performance of multiple effectors in closed-loop cortical control recorded from a single array in human posterior parietal cortex

Abstract: Recently, our lab has found "partially mixed selectivity" in human posterior parietal cortex (PPC), a method of encoding information enabling multiple variables to be represented in a shared substrate (Zhang et al., 2017). Here, we study this structure and how it behaves in a closed-loop cortical brain-machine interface (BMI). Recordings were made from a 4x4 mm electrode array implanted in the anterior intraparietal area (AIP) of a human tetraplegic patient. We examined the representations of imagined or attempted movements of the left or right hand, comparing how the structure of the representations are preserved between BMI calibration (training) and closed-loop control (online). We also assessed the control performance of the different movement conditions in a one dimensional cursor control task. We found that all four movement conditions were feasible for BMI control. The structure of the representations was largely preserved between training and online control, generalizing from training to online control and vice versa. Furthermore, of the four tested movement conditions, attempted movements of the right (contralateral) hand performed best in online BMI control, with the relative performance differences predictable from offline analyses. Our results demonstrate that the overlapping mixed representations previously found in offline analysis are still meaningful and accessible during BMI control. This result indicates that the large number of variables found in the partially mixed encoding structure of a small patch of human PPC can be still decoded and used for BMI control.

Title: Separability of neural population structures in human motor cortex during gross and fine upper limb movements

Authors: *D. A. ROYSTON[1,5,2], A. P. BATISTA[1,5], E. C. TYLER-KABARA[2,3,1,4], M. L. BONINGER[2,1,6,4], R. A. GAUNT[2,1], J. L. COLLINGER[2,1,5,6]

Abstract: A fundamental question in neuroscience is how neural activity in the primary motor cortex (M1) drives ongoing movements. Recent evidence suggests that populations of neurons produce coordinated activity patterns in order to generate arm movements, but it remains unclear how these population structures behave to drive selective movement in different parts of the arm and hand. Here we examined whether gross and fine upper limb movement tasks are driven by similar structures of population-wide activity patterns in human sensorimotor cortex.
We conducted intracortical recordings from two 88-channel microelectrode arrays, implanted in medial/lateral areas of M1 in a human participant with a C5-motor/C6-sensory incomplete spinal cord injury (limited arm use, paralyzed hand), while the participant viewed and engaged with cyclic movement tasks. Gross (shoulder, elbow, wrist, whole hand) and fine (five individual finger) movements were presented on a computer monitor in separate task-specific blocks, and the participant was instructed to attempt to perform each movement in time with the viewed actions (0.5 Hz). We defined a neural state space by performing principal component analysis (PCA) on binned firing rates, and examined the trajectory of the population's trial-averaged time-series activity through this space during different movements.
We found that the neural state oscillated rhythmically between separate regions of neural space during the two phases of each movement (e.g. flexion/extension). In the space defined with activity from both arrays together, the general shape and location of these trajectories varied significantly between movements, with gross movements spread out and fine movements closer together. Analyzing each array separately revealed that neural trajectories from the medial and lateral array were more separable during gross and fine movements respectively, as predicted by somatotopy. Despite this bias, each array's activity also displayed similar dynamics during both movement types. This provides preliminary evidence of a common neural mechanism for encoding gross and fine movements.
We found that the coordinated activity of neural populations in M1 produced highly structured trajectories through neural space. Within each movement, neural activity moved cyclically between different neural states which varied with the movements' phases. The similarity in population structures across cortical areas and movement types suggests that population activity in M1 may be coordinated at a large spatial scale, acting less as a set of spatially distinct representations and more as a unified dynamical system.

Abstract: The lack of sensory feedback during grasping is a very important limitation of current hand prostheses, which affects their everyday usability. In the last years several research groups have demonstrated that nerve stimulation by implantable peripheral nerve interfaces can be reliably used to restore sensory feedback to upper limb amputees. They have shown that direct neural stimulation of peripheral nerves can effectively provide tactile information to the amputees, controlling the sensation intensity by modulating either the amplitude or the frequency of the injected stimuli. However, efforts are still necessary to identify encoding strategies converting tactile information into neural stimulation patterns capable of eliciting percepts that are both felt as natural and effective for prosthesis control. In this study, we compared the naturalness and efficacy of a set of encoding strategies based on biomimetic (model-driven) frequency modulation, amplitude modulation, or combinations of both. Such strategies were used to deliver neural stimulation to a trans-radial amputee implanted with intraneural electrodes (*TIMEs*). Frequency modulation was based on a biomimetic model (*TouchSim*) able to reproduce nerve activation patterns of the multifaceted mechanics of the skin and mechano-transduction. It was perceived as more natural, while amplitude modulation enabled better performance in tasks requiring fine identification of the applied force. Notably, hybrid encoding strategies involving both amplitude and frequency modulation were able to convey at least as much information as the amplitude modulation (for the completion of tasks), and were perceived at least as natural as the frequency modulation. The hybrid strategies improved the gross manual dexterity of the subjects during functional tasks while maintaining high manual accuracy. They also improved

the level of prosthesis embodiment and reduced abnormal body perceptions of the phantom limb ("telescoping"). Encoding strategies based on the combination of biomimetic frequency modulation and amplitude modulation are able to provide highly sensitive and natural percepts and should be preferred in bidirectional prosthesis use.

Title: Modeling neural ensemble dynamics in motor cortex leads to improved EMG decoding of multiple muscles in goal-directed reaching tasks

Authors: *L. N. WIMALASENA[1], A. CHERIAN[2], L. E. MILLER[2], C. PANDARINATH[1,3]

Abstract: Mounting evidence demonstrates that the activity of large ensembles of neurons in primary motor cortex (M1) reflects network level phenomena: lawful "dynamics" that dictate how activity evolves over time. We recently demonstrated a deep learning tool, Latent Factor Analysis via Dynamical Systems (LFADS), that uses artificial neural networks to uncover dynamics from neural ensemble activity on a single-trial, moment-by-moment basis. We previously found that LFADS is able to uncover dynamics from ensemble activity in M1 during structured motor tasks (highly stereotyped reaches, consistent task timing, a single starting position), and further, that modeling dynamics dramatically improved our ability to decode reaching kinematics. Here we aimed to test the extent to which uncovering ensemble dynamics in M1 might also improve decoding the more dynamically complex EMG activity underlying reaching, and whether M1 dynamics could also be modeled during tasks that lacked consistent structure. We analyzed simultaneously recorded spiking activity of ~90 neurons and electromyographic (EMG) activity from 10 muscles, from a monkey performing two separate tasks: (a) a center out task with a single starting position and 8 fixed target locations and (b) a random target task with variable starting positions and rapid sequential movements to capture a series of targets in random locations spanning the workspace. First, we analyzed activity during the center-out task, testing whether, by modeling ensemble dynamics, LFADS could infer neural firing rates that were more informative about EMG activity than a standard method (Gaussian

smoothing of the spiking activity). We compared the methods by using simple, cross-validated, least-squares linear regression to map firing rates onto EMG activity. We used small bin sizes (4ms) and no temporal history to determine how predictive the inferred rates were about EMG activity on a moment-by-moment basis. LFADS produced firing rate estimates that improved EMG decoding accuracy over Gaussian-smoothed spiking for all recorded muscles (quantified via R^2; improvements ranged from 7-32%). Next we analyzed neural activity from the random target task. Its less structured design ensured a large variety of movements and pacing, with no repeating sequences of movements. Despite the lack of task structure, LFADS uncovered dynamics from the M1 ensemble activity, allowing it to infer firing rates that improved (6-42%) decoding accuracy for all recorded muscles. Our results offer more evidence of the critical role of M1 ensemble dynamics in commanding movement, and may provide important new insights into the generation of muscle activity.

Title: Neural control strategies of a kinematically redundant brain-machine interface

Authors: *A. YOU[1], V. ATHALYE[2], S. GOWDA[3], H. G. MOORMAN[4], J. M. CARMENA[5]
[1]Bioengineering, The UC Berkeley - UCSF Grad. Program in Bioengi, Berkeley, CA; [2]Neurosci., Columbia Univ., New York, NY; [3]Electrical Engin. and Computer Sci., [4]Helen Wills Neurosci. Inst., [5]UC Berkeley, Berkeley, CA

Abstract: Natural learning of motor skills involves the coordination of our body's numerous, redundant degrees of freedom (DOF) to achieve goals such as controlling joints in our arm to reach an endpoint target**.** Some motor control studies have shown that while this control is reliable, the reach trajectories are variable, with inconsistent joint angle combinations. This suggests that there may be an optimal control policy where goal-relevant dimension errors are corrected while task-irrelevant dimensions are tolerated. However, how motor cortex generates and refines these neural commands for kinematically redundant control is not well-understood. Understanding how the brain controls these high degrees of freedom may be important in designing neuroprostheses with multiple actuators. To examine this question, we previously

studied how subjects learned to control a 4-DOF virtual limb using BMI. Neural activity was recorded from motor cortex of two rhesus macaques and decoded into joint angle velocity commands for each of the four joints. Subjects were instructed to complete a center-out task to eight different targets, and movements were constrained to a 2D plane, thereby creating the kinematic redundancy. Over training, the reach times for both animals decreased with joint angle variability increasing over sessions. In this study, we find neural correlates of refined control that improve the subjects' performance. Using linear regression, we find that in both animals, past state space information drives future neural commands to the decoder. In particular, the performance in both animals was highly correlated with how representative neural activity reflected past joint angle velocities. Interestingly however, the joint angle velocities were not the most predictive states for the neural activity, but only acted as performance correlates. Our results indicate that while neural activity became increasingly more decoder-relevant (i.e. pertaining to joint angle velocities), both subjects seemed to generate more neural patterns correlated to other task-relevant variables (e.g. endpoint position, joint angle, etc). This suggests that even if the control variables imposed by the BMI are not analogous to natural reaching, embodiment of a multi-DOF prosthesis might still occur over sessions, with joint angle velocities become represented in the neural activity in addition to the endpoint kinematics. Future work will elucidate how control of kinematically redundant neuroprostheses can be generalized or embodied by subjects.

Abstract: Electromyographic (EMG) signals from residual extrinsic hand muscles can be used to control prosthetic hands. Clinically available systems typically use one of two algorithms for control: pattern recognition, in which predetermined prosthetic movements or states are commanded based on recognizing patterns of activity across multiple EMG sensors, or direct control, in which EMG activity directly controls output for a given degree of freedom (DOF). Both approaches face challenges in taking full advantage of modern prosthetic hands that can control individual fingers.In order to address some of the challenges of existing control schemes, we have created a biomimetically inspired, dynamic model of the hand with Hill-type muscle actuators, that estimates joint torques and solves forward dynamics of the hand to generate movement. Here we describe an optimization approach to determine the impact of different intramuscular EMG to muscle activation signal transformations to drive the model and use the same approach to test the effect of different model joint stiffnesses, for which experimental data are lacking.In 14 able-bodied subjects, intramuscular electrodes were acutely placed in the extrinsic hand muscles, including individual compartments of the finger muscles. Subjects performed single and multi-DOF movements of the fingers and wrist while EMG activity and hand kinematics were recorded. The contribution of muscle activity to total finger and wrist joint torques were estimated using inverse dynamics in MuJoCo simulation software using recorded kinematics as input and assuming internal finger joint stiffnesses ranging from 0.01 to 0.1 N/rad. EMG activity was converted to activation using a high-pass filter at 100 Hz, rectification, and then low-pass filtering with cutoff frequencies ranging from 1-10 Hz. This set of activation signals were passed to the musculoskeletal model to calculate simulated joint torques. Summed root-mean-square error between the stimulated torques and inverse torques was minimized using an optimizer that varied a per-channel activation scaling term. In preliminary results for a single subject, we found that using a low-pass filter at 8 Hz and setting the joint stiffness to 0.01 N/rad reduced total torque error by 34% compared to our previously used values of 0.1 N/rad and a 10 Hz. We plan to continue this approach to further test feature extraction and processing to create a robust model-based controller for prosthetic hands.Funding: Research was sponsored by the U.S. Army Research Office and the Defense Advanced Research Projects Agency (DARPA) and was accomplished under Cooperative Agreement Number W911NF-15-2-0016.

Title: Clinical training platform for ECoG-based motor BCI control of multi-degrees of freedom effectors

Authors: *G. CHARVET[1], S. COKGUNGOR[1], T. AKSENOVA[1], A. ELISEYEV[1], A. VERNEY[2], T. COSTECALDE[1], A.-L. BENABID[1]
[1]Univ. Grenoble Alpes, CEA, LETI, CLINATEC, MINATEC, Grenoble Cedex 9, France; [2]Univ. Grenoble Alpes, CEA, LIST, CLINATEC, MINATEC, Grenoble Cedex 9, France

Abstract: In the field of neuroprosthetics, one of the major challenges is the development of a Brain Computer Interface (BCI) system for a chronic use in clinical applications with high performance of decoding to control a large number degrees of freedom. The challenge of chronic recording of the brain activities was addressed by the CEA/LETI/CLINATEC with the development of a wireless 64-channels ECoG recording implant WIMAGINE [1]. Moreover, innovative ECoG signal decoding algorithms (tensor-based multimodal algorithms [2] and multi-state hybrid algorithms [3]) was achieved to perform the decoding, by the subject's brain activity, of complex effectors such as a 4-limbs exoskeleton.
One other challenge is the training of patients to perform mental tasks of upper or lower limbs movements. To do that, a BCI training platform has been developed to allow the training of patients whether in a clinical environment or at home. This BCI training platform is composed of a software dedicated to record ECoG signal from WIMAGINE implants and a real-time BCI decoding software and an another software to control the 4-limbs exoskeleton or virtual effectors (such as 3D avatar and serious games). Several virtual environments with different levels of difficulties was developed to allow a gradual training of the patient to control each degrees of freedom necessary to pilot, ultimately, a 4-limbs exoskeleton.
Finally, to allowing the model creation in real time (calibration step), a dedicated software based on adaptive algorithms [4] was performed.
In conclusion, this BCI training platform was achieved to be used during a clinical trial [5] whose the goal is to demonstrated that a tetraplegic patient can control, after training, a 4-limbs exoskeleton thanks to his brain activity monitoring and decoding.

Abstract: Rehabilitation studies leveraging brain-machine interface (BMI) technology have demonstrated clinical improvements with systems where changes in decoded brain activity coincide with peripheral feedback through the movement of an orthosis. In these systems, the decoded movement intention from brain signals is translated into movement of the peripheral orthosis, giving patients feedback about their brain activity. This allows them first to refine their neural activity patterns to be more specific for a given movement, and second leverages the endogenous sensorimotor learning system to link these neural signals and the activation of the peripheral nervous system. So far, studies have been limited to linking patterns from non-invasively acquired brain signals to single movements such as only grasping or only reaching. One challenge with using non-invasive brain signals in these systems is the low number of movements that can be reliably decoded on a single-trial basis. This restriction limits the

feedback available to the patient about how to refine their neural activity patterns, as well as the number of trained movements these systems can reinforce. Thus, one way to improve upon current state-of-the-art is to use a neural recording modality that allows for accurate, single-trial decoding of greater number of movements, and deliver feedback of these decoded movement intention signals through an orthosis with multiple degrees of freedom.
Hemiplegic stroke patients may not exhibit overt movements, but some patients have subthreshold muscular activations during intended movements that can be detected with surface electromyography (EMG). Such activity can be used to discriminate differing movement intentions.
In this work, we present a novel brain-machine interface rehabilitation system for hemiplegic chronic stroke patients that leverages a temporarily implanted intracortical multi-electrode array and a seven degree-of-freedom arm and hand orthosis. Previous work has demonstrated successful use of neural signals acquired from implanted multi-electrode arrays for closed-loop control of multi degree-of-freedom robotic arms. Further, we introduce a novel method of shared control of the orthosis where decoded neural activity signals are fused with decoded movement intention signals from surface EMG. This fusion is hypothesized to accelerate the formation of the neuro-muscular link by reinforcing the co-activation of motor-related neural circuits and target muscles. We demonstrate the usability of this system with a severely paralyzed chronic stroke patient.

Abstract: Brain computer interfaces (BCI) bypass spinal cord injuries (SCI) by translating motor cortical signals into command signals for computer cursors or robotic arms. After cervical SCI, overt movement is retained above the level of the injury. Ideally in these cases, people could successfully coordinate both overt and BCI movements. In moving towards this goal, we investigated whether the neural representation for overt movement overlapped with BCI movement such that it would interfere with BCI performance. We found that arm movements both ipsilateral and contralateral to the array interfered with BCI performance, with contralateral arm movements causing more interference.

We recorded neural activity from motor cortex (M1) using intracortical arrays in a 31-year-old human male participant with tetraplegia who retained some bilateral arm movement. While at rest, he observed a 1D cursor moving towards left and right targets. After observation, we trained an optimal linear estimator decoder to translate neural activity into horizontal cursor velocity. We then tested his BCI cursor performance (1) with his arms at rest or (2) while he made ipsilateral or contralateral arm movements to the right or left. Arm movements were performed in alternating order for each successive target so that the movements were not associated with the randomized target order.

While his arms were at rest, the BCI cursor's initial movement was towards the target in 95% of trials. However, both ipsilateral and contralateral arm movements interfered with BCI decoding performance. Initial cursor movement was towards the target in 47% of contralateral arm trials and 80% of ipsilateral arm trials. To determine if the neural activity reflected these performance results, we grouped the overt movement trials in two ways, either by BCI target direction or by overt movement direction. A Naïve Bayes neural classifier correctly predicted the movement direction for 100% of contralateral movements and 98.7% of ipsilateral arm movements. However, the classifier predicted the BCI target direction better during ipsilateral arm movements (92.9%) than during contralateral arm movements (57.8%). These classification results are consistent with the performance results. Taken together, these results indicate that contralateral, and to a lesser extent, ipsilateral arm movements overlap with the neural representation of BCI movements.

For future work, we will investigate whether changes to BCI calibration and decoding can minimize the impact of overt movements on BCI control. This will further propel research towards a BCI that can augment overt movements to jointly achieve a motor goal.

Abstract: Our goal is to restore voluntary control of forelimb function after spinal cord injury (SCI) via an artificial connection from the brain to spinal cord. This approach includes recording from multi-channel intracortical electrodes and using a computational model to extract the intention to move the forelimb. This intention to move can then be used to control stimulation of electrodes on the spinal cord. To accelerate clinical translation, we deliberately selected both recording and stimulation methods with potential for near-term use in human subjects. This included intracortical Local Field Potentials (LFP) that provide more stable movement-related information and require less power for hardware implementation compared to single unit spike sorting and decoding. We also selected epidural stimulation of the spinal cord surface as it evokes natural fatigue resistant contractions and synergistic movement similar to intraspinal stimulation. Animals were trained to press a lever for liquid reward. We used a Canonical Correlation Analysis (CCA) filter to predict the animals' movement intention from 16-channel LFP recorded from forelimb region of primary motor cortex. After several weeks of cortical recording, the animals received a lateralized contusion on the right side of spinal segment C4 and an epidural implant on the right side of spinal segment C6. We then decoded motor command

from recorded LFPs after SCI to continually control the amplitude of epidural stimulation delivered to the spinal cord below the injury. LFP-controlled epidural stimulation produced significantly larger lever displacements when the stimulation was on compared to trials with no stimulation. Here we demonstrate the effectiveness of closed-loop continuous control of epidural spinal cord stimulation based on LFP signals recorded from motor areas of the brain after spinal contusion injury, with substantial advantages as a platform for clinical translation.

Abstract: Cortical neural prosthetics decode intention related activity from populations of cortical neurons to enable direct neural control of external assistive devices. This study aims to understand how different cortical areas encode planning and execution related intention activity across four brain areas recorded in two human subjects with tetraplegia implanted with chronic arrays as part of a neural prosthetic clinical trial. Recordings were made in the region of ventral premotor cortex (PMv), supramarginal gyrus (SMG), and primary somatosensory cortex (S1) in subject FG and the anterior intraparietal cortex (AIP) of subject NS. We used a delayed-reach paradigm in which we systematically varied hand, eye and target position in order to determine the reference frame encoding of reach intentions during planning and execution epochs. A trial consisted of the subject fixating their gaze and imagining their hand at one of four possible locations, followed by target presentation with a delay, and a subsequent imagined reach to the cued target. We used gradient analysis (Pesaran et al., 2006) to determine the relationship between neural firing and behavioral variables. This design allowed us to characterize whether the target of a reach is coded, as a function of brain area and task epoch: relative to the direction of gaze (eye-centered), the position of the hand (hand-centered), relative to the position of eye, hand, and target specifying the differences in locations (relative), or body/world centered. We recorded from 441 (PMv), 982 (SMG), 654 (S1), and 421 (AIP) units across 4-6 sessions. We found 27%, 24%, 20%, and 7% of units tuned during the delay and 6%, 15%, 17%, 17% during the go epoch for PMv, SMG, S1, and AIP ($p < 0.05$, FDR corrected), respectively. Population level gradient analyses during the delay epoch showed a relative reference frame coding in SMG and S1, PMv showed tuning to hand relative to target, and AIP had a very small proportion of tuned units to hand relative to gaze and hand relative to target. These coordinate frames shifted during the execution epoch with all brain areas coding mostly for hand relative to the target (hand-centered). These results demonstrate that: 1) reference frame encoding for some areas vary across epochs, 2) S1 displays significant levels of tuning during the delay and execution epochs, and 3) during the execution phase all areas code the intended movement in hand-centered coordinates.

Title: Temporal stabilized arm movement for efficient neuroprosthetic control by individuals with tetraplegia

Authors: *I. IOSSIFIDIS[1], M. A. HUSSAIN[2], C. KLAES[3]
[1]Computer Sci., Ruhr West Univ. of Applied Sci., Müelheim an der Ruhr, Germany; [2]Ruhr West Univ. of Applied Sci., Mülheim an der Ruhr, Germany; [3]Biol., Ruhr Univ. Bochum, Pasadena, CA

Abstract: The generation of discrete movement with distinct and stable time courses characterizes each human movement and reflect the need to perform catching and interception tasks and for timed action sequences, incorporating dynamically changing environmental constraints. Several lines of evidence suggest neuronal mechanism for the initiation of movements i.e. in the supplementary motor area (SMA) and the premotor cortex and for movement planning mechanism generating velocity profiles satisfying time constraints.
In order to meet the requirements of on-line evolving trajectories we propose a model, based on dynamical systems which describes goal directed trajectories in humans and generates trajectories for redundant anthropomorphic robotic arms. The analysis of the attractor dynamics based on the qualitative comparison with measurements of resulting trajectories taken from arm movement experiments with humans created a framework able to reproduce and to generate naturalistic human like arm trajectories.
This framework for robust incorporation of fluctuating sensor information, but control of movement time is usually restricted to rhythmic motion and realized through stable limit cycles. The present work uses a Hopf oscillator to produce discrete motion and formulates an on-line adaptation rule to stabilize total movement time against a wide range of disturbances. This is integrated into a dynamical systems framework for the sequencing of movement phases and for directional navigation. With only three parameters the presented framework is able to generate temporal stabilized (timed) discrete movements, dealing with disturbances and maintaining an approximately constant movement time.
The approach is demonstrated within a simulation task in a virtual reality environment as well as with a real anthropomorphic robotic arm (KUKA Lbr aiwa). In addition we aim to replace the robotic manipulator by an exoskeleton for the upper body which will enable the patients to move his or hers own limbs, which would complete the development of a real neuroprosthetic device

for every day use.
In the current study we will implant two 96-channel intracortical microelectrode arrays in the primary motor and the posterior parietal cortex (PPC) of an individual with tetraplegia. In the training phase the parameters of the dynamical systems will be tuned and optimized by machine learning algorithms. Rather controlling directly the arm movement and adjusting continuously parameters, the patient adjust by his or hers thoughts the three parameters of the dynamics, which will remain almost constant during the movement.

Abstract: Recent progress in Brain Machine Interface (BMI) research using signals from subdural electrocorticographical (ECoG) arrays implanted over primary motor cortex has demonstrated the potential for successful decoding of participant's arm or hand movement. Concurrent advances in wireless implantable electrode technology are further shortening the gap between existing systems and real functioning rehabilitative neural prosthetics for use by patients with motor system disorders. However the long-term stability and effectiveness of BMI technologies depends crucially on the stability and effectiveness of the feature extraction and decoding algorithms used to translate the neural signals into behavioral commands. Given the limited density and coverage of ECoG channel arrays, it is critical to reliably extract as much of the available information as possible. While some success has been achieved using channel-based features, we have recently shown that improvement may be gained by first applying the Independent Component Analysis (ICA) method to the ECoG channel data to separate and isolate relevant cortical signals. We present results of application of ICA to ECoG data for the derivation of features for BMI applications and comparison to standard approaches. We discuss the interpretation of the ICA features and suggest directions for future improvements.

Title: Networking properties of primary motor cortical neurons can predict decoding performance of upper limb movements in advance

Authors: *M.-K. KIM[1], J.-W. SOHN[2], S.-P. KIM[3]

Abstract: Brain-machine interfaces (BMIs) for upper limb movement restoration rely on motor cortical circuits coordinating complex arm movements. As BMI decoding performance can vary across days or sessions due to the variation of the recordings of motor cortical neurons, it is important to understand how decoding performance changes with certain properties of the ensemble of neurons. Generally, it is plausible to predict decoding performance by assessing how well neuronal activities encode kinematic information, which requires both neuronal and kinematic data. Yet, it is desirable to estimate decoding performance even before a session starts with no kinematic information so that one can flexibly adjust decoder types or the amount of training in advance. To this end, we examined the networking properties of primary motor cortical (M1) neurons during a pre-session period, where the subject did not begin an arm movement task, to find if these could provide predictive information about decoding performance on the same day (or session). We analyzed networking patterns within M1 neurons of a primate (a Rhesus macaque) during the pre-session periods of seventeen different sessions. The linear Kalman filter was used to decode M1 ensemble firing rates into 3D velocity, and decoding accuracy was calculated as correlation coefficient between predicted and actual movements. We adopted the graph theory to quantitatively assess networking properties. As a result, we found that M1 networking properties could predict across-session performance of 3D velocity decoding. Specifically, an increase in the global clustering coefficient of M1 network led an increase in decoding performance. The result suggests that the M1 networking properties before the session starts can predict decoding performance in BMIs to restore upper limb control.

Title: Neural features of intrinsic error recognition in human motor cortex during intracortical brain-computer interface use

Authors: C. DUNLAP[1], N. SKOMROCK[2], H. TRIVEDI[2], N. ANNETTA[2], M. SCHWEMMER[2], S. COLACHIS IV[2], G. SHARMA[2], D. FRIEDENBERG[2], P. D. GANZER[2], *M. A. BOCKBRADER[3]

Abstract: Introduction: Brain-computer interface (BCI) performance may be improved by using task-outcome related cerebral activity as input to neural decoding algorithms. Our group has recently shown detectable changes in neural firing rates in the motor cortex of a tetraplegic participant using a BCI coupled with a functional electrical stimulation (FES) orthotic following mismatches between motor intent and muscle activation. In this subsequent study, our objective is to determine if a similar error signal is present while the participant plays a guitar video game without audio or visual feedback. Methods: A 27-year-old man with C5 ASIA Impairment Scale category A traumatic spinal cord injury was recruited from the Reanimation in Tetraplegia clinical trial (ClinicalTrials.gov NCT01997125), an ongoing Phase I/II study for an investigational, intracortical BCI interfaced with an 130-electrode, transcutaneous, forearm FES orthotic. The intracortical microelectrode array implanted in his left primary motor cortex allowed for online recording of neural activity and decoding with machine-learning algorithms. The participant was instructed via a visual cue at specified time intervals to think about flexing his index, middle, or ring finger to press the buttons of a guitar game controller. Single unit activity during the cueing intervals was categorized to one of four groups based on neural decoder performance: correct, incorrect, or no movements, and a class for movements that were not sustained long enough to meet the criteria for any other class. Spikes were binned at 100ms intervals aligned by the start of the cueing window, summed across all channels of the array, and averaged across trials of the same classification. Results: Of 159 trials analyzed, the participant's performance is as follows: 25.2% correct, 8.0% incorrect, 35.2% no movement, and 31.4 % where erratic decoder behavior could not sustain movement. Average firing rates for all classes peaked between 1 and 1.5 seconds after the cue was presented to the participant. The missed cue class had the lowest average firing rate following the initial peak, and the incorrect class had an

additional peak in firing approximately 2 seconds after the start of the cue which was not observed for any other class. Conclusion: These preliminary results suggest that in the absence of performance feedback, intrinsic error recognition during a guitar video game is sufficient to elicit an error signal in the primary motor cortex. Future work aims to increase the sample size and to determine if an increasingly distinctive error signal is present when real-time feedback is given to the participant.

Abstract: Brain-computer interfaces (BCIs) allow people with severe motor deficits to control a variety of end effectors using only their neural signals. However, a major obstacle to the clinical adoption of BCI technologies is neural recording instabilities (Downey et al., 2018), which degrade performance until recalibration is performed. This places a burden on the user by requiring them to stop using the BCI in order to perform a recalibration procedure. Here, we show that by extracting a stable representation of neural activity from unstable neural recordings, human BCI control can be sustained across days without the need for recalibration.

We stabilize neural activity by extracting a consistent low-dimensional representation of population activity from different sets of neurons. Previous work in non-human primates (NHP) has found that neural population activity resides in a low-dimensional space (Sadtler et al., 2014). Given recordings from neural populations that are different but have some neurons in common, this space can be identified in a consistent manner (Bishop et al., 2014). Neural activity represented in this stable space can then be used with a fixed decoder that translates neural activity into BCI command signals, eliminating the need for recalibration (Degenhart et al., 2016).

We used neural signal stabilization over a 4-week period while a human participant performed a 2D BCI cursor movement task. Neural signals were recorded from microelectrode arrays implanted in the motor cortex of a 31-year old male participant with tetraplegia. On the first day of the experiment, we determined the initial parameters of the stabilizer and fixed parameters of the decoder using a standard calibration procedure. The neural signal stabilizer was then turned on and run continuously. Parameters of the stabilizer were updated every 16 trials to compensate for recording instabilities. On subsequent sessions, BCI control began with the final stabilized BCI from the previous session. At the end of each session, we retested the fixed decoder estimated on the first day. For each of 9 test sessions, we compared BCI performance using the final stabilizer update to that of the fixed decoder. Across experiments, trial completion times and angular error obtained with stabilization were significantly better than those obtained with the fixed decoder.

Our results provide a preliminary demonstration that neural signal stabilization allows BCI performance to be maintained across multiple weeks. Future work will explore the robustness of the stabilized BCI during both higher dimensional tasks, such as prosthetic arm control, and across different control contexts during human BCI use.

Title: Neural modulation in other cortical areas while a BCI is controlled with M1 units

Authors: *Z. LIU[1], M. H. SCHIEBER[2]
[1]Biomed. Engin., [2]Neurol. and Neurosci., Univ. of Rochester, Rochester, NY

Abstract: The development of brain-computer interfaces (BCI) that use spike recordings for input has made use primarily of neural recordings from the primary motor cortex (M1). Previous work has revealed that the firing rates of many M1 units not directly involved in controlling the BCI (non-BCI units) nevertheless vary in relation to BCI performance. We investigated whether non-BCI units in cortical areas other than M1 also modulate while a BCI is controlled with M1 units.

We trained two monkeys (*Macaca mulatta*) to perform an 8-target center-out task using a joystick to control a cursor. In each trial, the monkey first acquired a center target and then one of the 8 peripheral targets shown on a computer screen. Each monkey then learned to perform the same task with a BCI that drove cursor velocity through linear decoders using the firing rates of 4 M1 units, each acting in one of four cardinal directions (left, right, up, and down). Once subjects achieved stable BCI performance, we recorded the spike activity of non-BCI units simultaneously in 6 cortical areas—M1, dorsal premotor cortex (PMd), ventral premotor cortex (PMv), primary somatosensory cortex (S1), the anterior intraparietal area (AIP), and dorsal posterior parietal cortex (dPPC)—as the monkey first performed the center-out task using the joystick and then performed the same task using the BCI.

Off-line, modulation depth during BCI performance was calculated for each single- or multi-unit with significant cosine tuning ($p<0.05$). More than 80% of non-BCI units in M1 and in PMd but less than 50% of units in PMv and in AIP were modulated significantly during the BCI task. Meanwhile, 60% to 80% of units in S1 and in dPPC were modulated significantly. The modulation depth of such units also varied among cortical areas (Kruskal-Wallis test, $p<0.05$). Followup tests indicated the modulation depth of non-BCI units in M1 was significantly greater than that of units in PMv, or in AIP; and the modulation depth of units in PMd was significantly greater than that of units in PMv, in AIP, or in dPPC. Interestingly, the modulation depth of units in S1 was significantly greater than that of units in PMv.

Our findings demonstrate that non-BCI units in many cortical areas are modulated significantly while M1 units control a BCI, with the number of modulated units and their modulation depth varying among areas. Whether such modulation outside of M1 reflects responses to visual inputs, efference copy, or causally drives M1 activity during BCI control is as yet unknown. We suggest that control of a BCI using M1 neurons may require a network extending well beyond M1.

Title: Decoding sustained cyclic movements from low-dimensional neural states

Authors: *S. M. PERKINS[1,2], K. E. SCHROEDER[2,3], Q. WANG[1], M. M. CHURCHLAND[2,3,4,5]
[1]Biomed. Engin., [2]Zuckerman Inst., [3]Neurosci., [4]Kavli Inst. for Brain Sci., [5]Grossman Ctr. for the Statistics of Mind, Columbia Univ., New York, NY

Abstract: Decode algorithms for brain-machine interfaces allow impressive two-dimensional cursor control. Successful decode algorithms do not attempt to decode descending commands for muscle activity, but rather exploit the statistically robust covariance of firing rates with hand velocity. However, because that relationship is unlikely to be fundamental, it may not generalize well. Different types of movements may thus require exploitation of different statistical relationships.
Here we focus on decoding rhythmic neural activity during a cycling task where a monkey advances through a virtual environment by rotating a hand-pedal forward or backward. A 96-dimensional vector of firing rates, recorded from motor cortex, was summarized in a low-dimensional neural state space. We previously reported that, in the dominant two dimensions, forward and backward cycling involve trajectories that rotate in the same direction, rather than reversing. Thus, the most robust statistical relationship is not a straightforward covariance of neural activity and hand velocity. Yet other reliable statistical relationships were found. First, movement onset was preceded by a translation of the neural state from a region occupied when stationary to one occupied during cycling. Second, during steady-state cycling the neural state traced roughly circular rhythmic trajectories. Third, circular trajectories occupied different subspaces during forward versus backward cycling.
We leveraged this structure by implementing a hidden Markov model to convert the state translation into a binary move/stop command. We used a Kalman filter (which captured neural

dynamics) to denoise the neural state in the two rotational planes. We computed the difference in angular momentum between the forward and backward planes, leading to commands for the direction and magnitude of motion through the environment.
During online control, the monkey initiated movements via the decoder and stopped on or close to instructed targets in the majority of trials. These decoded movements were in the direction instructed by the task in 89.1%±0.3% (SEM) of individual 1 ms samples from 1933 brain control trials. To better understand the decoder's performance, we performed an offline analysis of 1560 arm control trials. The move/stop command was correctly decoded in 88.6%±0.2% of samples. Peak cross correlation between the decoded velocity and actual velocity on each trial was 0.811±0.004, with a decode lag of 112±5 ms. Thus, although our decode approach bore little resemblance to most prior approaches, it performed well because it was tailored to the statistical regularities within the present application.

Title: Mechanisms of temperature robustness and signatures of animal-to-animal variability in a rhythmic motor circuit

Authors: *H. D. RODGERS, L. M. ALONSO, E. MARDER
Volen Ctr. for Complex Systems and Dept. of Biol., Brandeis Univ., Waltham, MA

Abstract: Temperature affects the rate of biochemical processes including those that regulate neural activity. Previous work has shown that the phase relationships of oscillatory neurons in the crustacean pyloric circuit are maintained over a large temperature range (Tang et al, 2010, PLoS Biol). Strikingly, these networks produce similar activity despite a large variation in the number of ion channels across animals (Schulz et al, 2006, Nat Neurosci). Because individual ion channels possess different temperature sensitivities, the mechanism of temperature compensation is nontrivial. Here, we build on previous work in our lab (Tang et al, 2012, J Neurosci; Caplan et al, 2014, J Neurosci; O'Leary and Marder, 2016, Curr Biol) to further investigate these phenomena using the *C. borealis* stomatogastric ganglion (STG). We made

extracellular recordings of the STG during slow temperature ramps and found signatures of animal-to-animal variability in the duty cycle of pyloric units. The distribution of duty cycles of individual neurons changes with temperature in a structured way that differs across animals. Above a critical temperature, the rhythm deteriorates giving rise to aperiodic activity with long timescales. To gain further insight, we built temperature-sensitive models of the pyloric network that capture broad features of our data. In our models, the duty cycles remain approximately constant over the working range, and their precise distribution depends on temperature in a way that closely resembles our data. Near the critical temperatures, our models display complex dynamical states characterized by the emergence of timescales much longer than the period of the rhythm. In our models, the maximal conductances of all channels increase monotonically with temperature but the peak current for some ion species may decrease with temperature. Additionally, even though the temperature sensitivities of the channels are the same across cells, we find that the effect of temperature in a given current type can be different across cells.

Title: The dynamics of ionic currents in conductance based models of neural activity during normal function and failure

Authors: *L. M. ALONSO[1], E. MARDER[2]
[1]Volen Ctr. for Complex Systems and Dept. of Biol., Brandeis Univ., Waltham, MA; [2]Volen Ctr. and Biol. Dept., Volen Ctr., Waltham, MA

Abstract: Recent computational studies have demonstrated that neurons and circuits with very similar behaviors can nonetheless have very different values of the conductances that control intrinsic excitability and synaptic strength [Prinz et al. Nat. Neuro. 2004]. While individual healthy animals may appear quite similar under control conditions, in response to extreme perturbations, they become dysfunctional, or "crash", and they appear to do so differently [Tang et al. J. Neuro 2012].
Inspired by this we studied a standard model of the pyloric network of crustaceans subject to temperature perturbations. We explored circuits with different sets of maximal conductances but the same temperature sensitivities, that respond similarly to temperature from 10-25 ˚C (as do crabs), but crash with entirely different dynamics at more extreme temperatures. We introduce a simple visualization of the dynamics of the ionic currents that allows us to represent in a syntactic manner the contribution of each current type to the neural activity. We find that even though the circuits behave similarly over a temperature range, the percent contribution of each current type depends on temperature in a non trivial manner. While the temperature sensitivities in the parameters is the same in all our circuits we find that failure occurs through diverse mechanisms.

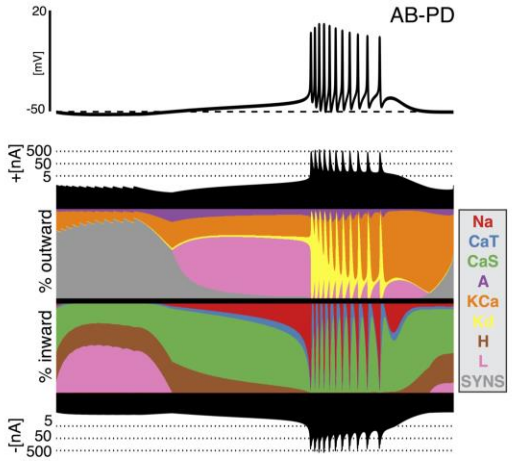

Fig 1: *A novel representation of the contribution of each current type to the neural activity. We compute the total inward and outward currents and represent the percent contribution of each current type in colors.*

Title: Exploring robustness in small circuits of conductance based model neurons using landscape optimization

Authors: *N. GUZMAN[1,2], L. M. ALONSO[2], E. MARDER[2]
[1]Biol., Brandeis Univ., Boston, MA; [2]Biol., Brandeis Univ., Waltham, MA

Abstract: The numerical exploration of conductance-based models of neurons is a common approach to address fundamental questions in neuroscience. Because these models are high-dimensional and contain large numbers of parameters, exploring their solutions can become cumbersome. Here we describe a procedure to find parameters in small networks of model neurons so that the network will produce a specified target behavior. The procedure consists of optimizing a landscape function that scores the models' solutions according to a set of measures that encode the target or desired behaviors [Ben-Shalom et al. J. Neuro. Methods]. We show that this approach is an efficient tool to explore the solution space of these models.
We explored the solutions of a model of the crustacean's pyloric network which consists of three cells with eight ionic currents and seven inhibitory synapses [Prinz et al. 2004]. Previous work by our lab showed that these models are highly degenerate: there are many sets of parameters (e.g. maximal conductances) that result in similar activity. Theoretical studies by our group and others suggest that this degeneracy plays an important role in providing these circuits with robustness to perturbations [Caplan et al. 2014].
We employed landscape optimization to explore the solution space of the model. We generated 20000 circuits that produce pyloric rhythms between 1-4 Hz. Inspired by the effect of temperature in these circuits, we asked if it was possible to perturb all the kinetic variables and still obtain rhythms with similar properties. Mathematically, this amounts to finding paths in parameter space that interpolate regions where the models solutions correspond to the target pyloric rhythm. We found that there are multiple paths in parameter space where the models produce the pyloric rhythm. In many cases this is achieved by visiting attractors that satisfy the target behavior via distinct dynamical mechanisms. Thus in our models, the same perturbation at different temperatures may elicit qualitatively different responses.

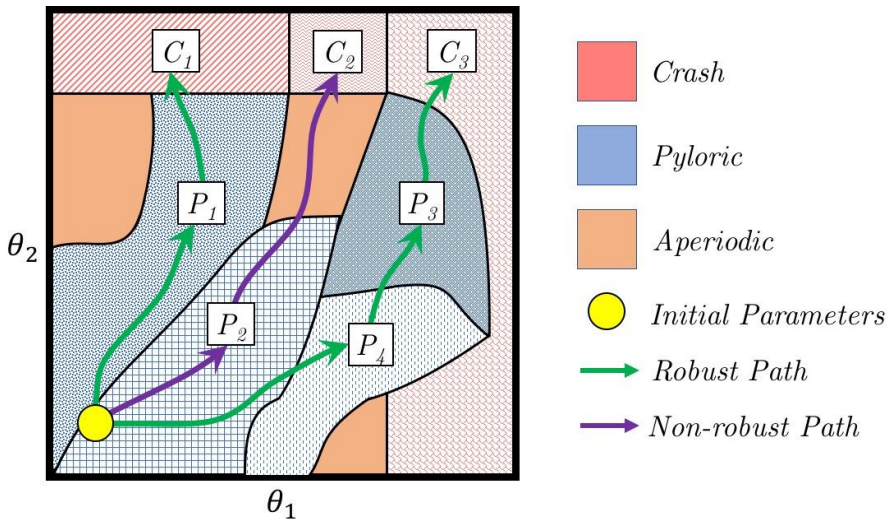

Fig. 1. A conceptual visualization of the parameter space. Bounded regions in the space represent unique attractor states with similar activity but different dynamical mechanisms. Robust paths through the space maintain pyloric rhythms until the point of crash by passing only through pyloric attractors, while non-robust paths pass through aperiodic states.

Title: Network degeneracy and dynamics of task switching in the feeding circuit in *Aplysia*

Authors: *Y. WANG, K. R. WEISS, E. C. CROPPER
Dept. of Neuroscience, Friedman Brain Inst., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Degeneracy is observed in neural networks in that particular patterns of motor activity are not necessarily encoded as a unique set of cellular and synaptic properties. Although this phenomenon is ubiquitous, its functional significance is poorly understood. We address this issue utilizing a multi-tasking network-the feeding circuit in *Aplysia*. The feeding circuit generates egestive and ingestive motor programs.

Previous data have shown that egestive activity can be triggered in the feeding circuit of *Aplysia* using two paradigms, egestive repetition priming and positive biasing. We hypothesized that circuit parameters (i.e., the properties of neurons and synapses) differ in the two situations. To generate egestive motor programs, there is an increase in the firing frequency of an identified protraction phase motor neuron, B8. In principle, this could happen either by a change in B8 excitability or by alterations in B8 synaptic input. Using voltage clamp techniques we demonstrate that there is a significant increase in phasic (presumably synaptic) input to B8 during both egestive priming and positive biasing. Previous work demonstrated that B65 is essential for positive biasing as measured approximately one minute after task switching. We now show that B20 is not essential at this time point. Previous data suggested that B20 plays an important role during egestive priming. We now demonstrate that egestive priming is not observed if B20 is hyperpolarized. In contrast, egestive priming is observed with B65 hyperpolarized. These results implicate one interneuron, B65, in positive biasing and a second interneuron, B20, in egestive repetition priming. We suggest that this degeneracy in circuit function will have implications for task switching. Consistent with this idea we demonstrate that an immediate return to ingestive activity is not possible after egestive priming but is possible after positive biasing. Taken together, these data suggest that degeneracy in network function is observed in the feeding network. In addition, our results support the idea that the dynamics of task switching can be determined by the nature of the mechanisms that are used to pattern activity.

Title: Dynamic changes in the character of a motor program may be determined by the complement of projection neurons activated

Authors: *C. G. EVANS[1], M. A. BARRY[1], M. H. PERKINS[1], J. JING[1,2], K. R. WEISS[1], E. C. CROPPER[1]
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Nanjing Univ., Nanjing, Jiangsu, China

Abstract: In many motor systems, multiple projection neurons are activated to initiate or maintain a behavior. In principle this may suggest there is redundancy, or alternatively that each

projection neuron has a unique function, contributing to specific parameters of the behavior. Although data are beginning to favor the latter view, little is known about these individual functions. We address this issue in the feeding system of *Aplysia*. *Aplysia*, motor programs can be ingestive, egestive or have intermediate characteristics. A population of about 13 cerebral-buccal interneurons (CBIs) project to the buccal ganglia (Wu et al. 2014). The most extensively characterized is CBI-2, which is activated by food and strongly and reliably drives motor programs. Previous work demonstrated that CBI-2 can trigger ingestive motor programs but that repetition priming is necessary to generate fully ingestive programs. Specifically, cycles of activity are initially intermediate but become ingestive over time (Proekt et al. 2004). We now report that in some preparations repetition priming is not observed, i.e., the conversion to ingestive activity does not occur. An issue we address is, can ingestive activity be triggered in these preparations if a second CBI is coactivated?

We study CBI-3 and CBI-12 (Jing and Weiss 2001, 2005; Hurwitz et al. 1999). Both are activated by food, additionally, CBI-3 is electrically coupled to CBI-2. We first sought to determine whether CBI-3 and CBI-12 are recruited when programs are triggered by CBI-2. We found that CBI-12 fires at a very low frequency and there is no correlation between its firing frequency and whether or not priming is observed. CBI-3 also fires at a low frequency but there is a significant increase in its firing frequency in preparations that undergo priming (i.e., the CBI-3 firing frequency reaches 3 Hz). However, it is unlikely that this change in CBI-3 activity accounts for priming. Intermediate programs triggered by CBI-2 do not become ingestive with bilateral co-activation of CBI-3 at 3 Hz.

Other experiments were conducted in preparations in which CBI-2 failed to induce repetition priming. We asked whether ingestive activity could be triggered by coactivating either CBI-12 or CBI-3. CBI-3 and CBI-12 were stimulated at physiologically relevant frequencies (15 Hz and 10 Hz respectively). Co-activation of CBI-12 failed to convert intermediate programs to ingestive. In contrast, with co-activation of CBI-3, programs were immediately ingestive, i.e., repetition priming was not necessary. Our data suggest that dynamic changes in the character of the motor program induced may be determined by the complement of activated CBIs.

Title: Robustness of neuromechanical model with two layer CPGs and muscle synergies

Authors: A. J. HUNT[1], K. DENG[2], *R. D. QUINN[2]
[1]Mechanical and Materials Engin., Portland State Univ., Portland, OR; [2]Mechanical and Aerospace Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: This work demonstrates a neuromechanical model of rat hindlimb locomotion undergoing nominal walking with perturbations. A synthetic nervous system uses separate rhythm generator and pattern formation layers to activate antagonistic muscle pairs (extensor and flexor) about each joint in the sagittal plane. Two pattern formation groups are used to activate the six muscles in the leg, one activating hip muscles while the other activates knee and ankle muscles. In order to test the stability of the model, different perturbations were applied to the network. These include inhibitory tonic stimuluses to the synthetic nervous system and forces applied to the limb. Results show that the synthetic nervous system with two-layer central pattern generators exhibit more robustness than when individual half-center oscillators are used to control each joint. While any perturbation permanently altered the stepping rhythm of the half-center oscillators, the two-layer CPG often restored walking rhythms and coordination quickly. Some perturbations permanently resulted in an altered gait. For these perturbations, the two-layer CPG has improved stability over the individual half-center oscillators. We also observed another interesting result. For non-resetting deletions, unlike fictive motion which stepping phase immediately returned after perturbation ends. In our simulation, the stepping rhythm reset slowly over time. This difference between our simulation and fictive motion shows the importance of sensory feedback. This multi-layer model of locomotion demonstrates complex interdependencies of mechanics, sensory feedback, and rhythm generation during phase resetting and non-phase resetting deletions of locomotor rhythms. This model also demonstrates how the pattern formation network can activate muscle synergies in a coordinated way to produce stable walking.

Title: Circuit and computational analyses reveal specific contributions of synaptic strengths and noise to motor variability in a feedforward network

Authors: *G. ZHANG[1], K. YU[1], T. WANG[2], T.-T. CHEN[1], W.-D. YUAN[1], F. YANG[2], Z.-W. LE[1], S.-A. CHEN[1], F. LIU[2], E. C. CROPPER[3], K. R. WEISS[3], J. JING[1,3]
[2]Sch. of Physics, [1]Nanjing Univ., Jiangsu, China; [3]Mt Sinai Sch. Med., New York, NY

Abstract: When one repeats a motor act, the executions vary as a result of variable activity of the behavior mediating neurons. Variability must originate partly from mechanisms in the behavior-generating network. Whereas previous work showed that variable outputs are often produced by concurrent excitation and inhibition, we provide a first example where feedforward excitation in conjunction with synaptic noise generates variable motor output in the *Aplysia* feeding system. We identified a command neuron, cerebral-buccal interneuron-10 (CBI-10) that is active during feeding behavior. CBI-10 drives more variable motor programs than programs driven by a previously-identified command neuron, CBI-2. The difference in variability is partly attributable to differences in the strength of synaptic connections between the command-like neurons and B63 and B34 pattern-generating interneurons that excite motoneurons. In particular, B34 receives weaker excitation from CBI-10 than from CBI-2, and fires at lower frequency during CBI-10-elicited programs. B34 subthreshold depolarization decreases the variability of CBI-10 induced motor programs, suggesting an obligatory role of B34, and a role of the weaker synaptic connection between CBI-10 and B34 in generating variability. To determine whether this is the case, we constructed a simplified Aplysia-like feeding network model. Synapses between CBI-2 and CBI-10 and B34 and B63 were modeled using physiological data. We selected a set of parameters that result in network activity resembling the activity of the biological network. Variability is not seen if there is a weak synaptic connection between CBI-10 and B34 but no synaptic noise, suggesting necessity of synaptic noise in generating variable programs. With synaptic noise, activity of the model network is similar to activity of the biological network in several respects, e.g., CBI-10 evoked programs are more variable than CBI-2 induced. We also performed parameter analyses. First, we varied the synaptic conductance from CBI-10 to B34, as conductance increases, the network output shifts from no programs, to programs, to overactivated states. Interestingly, the variability in programs tends to be high near bifurcation points between the three states. Second, we varied the level of synaptic noise and found that moderate, not high, level of synaptic noise promotes more variability. Thus, our studies provide evidence for the joint roles of synaptic conductance and noise in variability generation within a feedforward network. Our findings may be broadly relevant because many neural circuits incorporate feedforward properties and show various degrees of variability.

Title: Cellular switches orchestrate rhythmic circuits

Authors: *A. FRANCI[1], G. DRION[2], R. SEPULCHRE[3]
[1]Dep. Matematicas, Facultad De Ciencias, UNAM, Ciudad DE Mexico, Mexico; [2]Electrical Engin. and Computer Sci., Univ. of Liege, Liege, Belgium; [3]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Small inhibitory neuronal circuits have long been identified as key neuronal motifs to generate and modulate the coexisting rhythms of various motor functions. Our paper highlights the role of a cellular switching mechanism to orchestrate such circuits. The cellular switch makes the circuits reconfigurable, robust, adaptable, and externally controllable. Without this cellular mechanism, the circuits rhythms entirely rely on specific tunings of the synaptic connectivity, which makes them rigid, fragile, and difficult to control externally. We illustrate those properties on the much studied architecture of a small network controlling both the pyloric and gastric rhythms of crabs. The cellular switch is provided by a slow negative conductance often neglected in mathematical modeling of central pattern generators. We propose that this conductance is simple to model and key to computational studies of rhythmic circuit neuromodulation.

Title: Adaptation of neurons in the crab stomatogastric ganglion to changes in extracellular potassium concentrations

Authors: *L. HE, E. MOROZOVA, M. RUE, D. J. POWELL, E. MARDER
Brandeis Univ., Waltham, MA

Abstract: Neural circuits must be robust to various environmental perturbations. This is especially true for central pattern generators (CPGs) that are active throughout an animal's lifetime and that produce essential motor patterns such as breathing, walking, and chewing. Stability over a range of perturbations requires multiple intrinsic and synaptic mechanisms that operate at various timescales in order for the neural network to maintain function. To achieve a better understanding of the regulatory mechanisms underlying the maintenance of robust output of pattern-generating neural circuits, we studied the responses of the pyloric neurons of the Cancer borealis stomatogastric ganglion (STG) to changes in extracellular potassium concentration. A 2.5-fold increase in [K+] in the extracellular bath solution led to membrane potential depolarization by ~15 mV for most pyloric cells. This depolarization coincided with the temporary loss of activity of the pyloric dilator (PD) neurons for up to an hour, followed by recovery of spiking and, in some cases, bursting activity, despite continued perfusion of 2.5x[K+] saline. To better understand whether the adaptation to elevated [K+] is largely due to circuit level, cell-intrinsic, or a combination of the two types of mechanisms, we isolated the pyloric pacemaker kernel (AB/PD) using the synaptic blocker, picrotoxin (PTX). The experiments in 2.5x[K+] with PTX saline revealed a two distinct phenomena. First, PD neurons demonstrated a shorter period of absence of activity than the preparations with intact circuitry, and soon switched to tonic spiking. Secondly, some neuronal firing properties of the pyloric cells changed, with their activity gradually becoming more burst-like over the timescale of hours. Together, these data support the involvement of more than one mechanism. Because the STG is modulated by neurons in the three presynaptic ganglia, we wanted to know if descending inputs play a role in the recovery in response to changes in [K+]. Therefore, we blocked all descending modulatory inputs. In these experiments, the pyloric neurons exhibited activity patterns very similar to the experiments with intact circuitry on a similar timescale. The results of these experiments support the presence of a cell-intrinsic adaptation mechanism. To determine what kinds of cell intrinsic mechanisms could be involved in the adaptation of pyloric neurons to elevated potassium, we measured gene expression changes in STGs exposed to 2.5x[K+] saline. We found that mRNA for the potassium channels IA and the IKD were upregulated. In addition, we found increases in stress-related heat shock proteins in STGs exposed to 2.5x[K+] saline.

Title: Characterizing conductance variations in model crab cardiac ganglion networks

Authors: J. WANG[1], P. SAMARTH[2], T. BANKS[2], D. R. KICK[3], D. J. SCHULZ[3], *S. S. NAIR[2]
[1]Bioengineering, [2]Electrical & Computer Engin., [3]Biol. Sci., Univ. of Missouri Columbia, Columbia, MO

Abstract: The crustacean cardiac ganglion (CG) network coordinates the rhythmic contractions of the heart muscle to control the circulation of blood. The network consists of 9 cells, 5 large motor cells (LCs) and 4 small endogenous pacemaker cells (SCs). Variability in maximal conductances of intrinsic currents have been reported for the five LCs, even within the same animal. Despite this variability, the intact network maintains a synchronous output, but how it does so is unclear. Recent results using perturbations to the system using blockers showed that gap junction conductances provide compensation to restore network function. However, the role of synaptic conductances remain unexplored, although compensatory changes in synaptic conductances has been reported in the literature in other species.
To study the role of intrinsic and synaptic conductances in such compensatory mechanisms in a comprehensive manner, we first developed a new and morphologically realistic 3-compartment single cell model using first-hand recordings of intrinsic currents from LCs of the crab cancer borealis. The three compartments were the soma, neurite and a spike-initiation zone (SIZ). We then performed a modeling study in two steps. We first generated a large number of models, each with a different parameter set and then applied a 3-stage "rejection sampling" procedure to select: (i) isolated LCs that reproduce realistic passive properties and responses to a "stimulus protocol"; (ii) intact LCs that reproduce realistic responses to the same "stimulus protocol"; (iii) CG networks that reproduce realistic responses to a variety of realistic synaptic excitation.
At the next step, we studied the covariations among the currents that preserve model single cell and network outputs, and their relative roles in such compensation. Additionally, we investigated the interesting noise or "jitter" of synaptic input that improves the model performance.

Title: Similarities and distinctions among electroconvulsion- and proconvulsant-induced seizure discharges and native motor patterns during flight and grooming: Quantitative analysis of spike firing patterns in *Drosophila* flight muscles

Authors: *A. IYENGAR, J. LEE, C.-F. WU
Univ. of Iowa, Iowa City, IA

Abstract: In *Drosophila*, high frequency electroconvulsive stimulation across the brain triggers a highly stereotypic repertoire of spasms which are exaggerated in epilepsy gene mutants with a distinct spike discharge patterns known as electroconvulsive seizure (ECS). These seizure discharges manifest across the nervous system and can be conveniently and stably assessed throughout the seizure event in the large, isometric indirect flight muscles, the Dorsal Longitudinal Muscle (DLM). Despite the widespread use of DLM spiking activity to monitor ECS discharges [ref. 1, 2, 3], it is unknown how the ECS firing patterns relate to native motor programs, including courtship song, flight, and grooming which drive DLM activity. We employed quantitative spike pattern analyses to contrast ECS discharges against flight and grooming activity. We quantified: 1) overall spiking activity, 2) short-term alterations in firing regularity, 3) timing relationships among adjacent spikes, and 4) the bilateral coordination of motor patterns. Our results suggest ECS discharges share a number of similarities with spike patterns during sustained flight, including instantaneous firing rate (mean [95% interval]): 7.5 [3-14] vs. 6.7 [3-12] Hz respectively, but were distinct from grooming behavior whose spiking was highly variable (16.6 [0-60] Hz). Further, we constructed Poincare plots (return maps) of adjacent inter-spike intervals, which revealed that ECS discharges and flight generally displayed substantially greater short-term firing regularity compared to grooming-related activity. Finally, we utilized such approaches to examine the impacts of disrupting several critical neurotransmission systems. Picrotoxin (PTX) a known procovulsant that inhibits $GABA_A$ receptors, induced DLM seizure patterns which evolved over time with phases resembling flight but distinct from ECS discharges. A gain-of-function $GABA_A$ receptor mutant, *rdl* also modified flight patterns, without major alterations in ECS. Conversely, mutants affecting cholinergic

transmission, *Cha*, and electrical transmission, *ShakB* modified ECS repertoire more severely, while sparing flight patterning. Together, our results indicate that applications of quantitative techniques may be further explored to reveal further relationships between native and aberrant motor programs that drive the DLM.

Abstract: Rhythmic motor functions like breathing and leech heartbeat require robust yet flexible operation of central pattern generator (CPG) circuits producing appropriate patterns of bursting activity. The interaction of multiple mechanisms supporting bursting at the neuronal level with network mechanisms could be responsible for the robustness and flexibility characteristic living CPGs. We investigate the role of Na^+/K^+ pump, a basic cellular engine maintaining the physiological gradients of Na^+ and K^+ ions across the membrane, for which growing evidence indicates that the Na^+/K^+ pump current plays important roles in the electrical activity of neurons, contributing to functional and dysfunctional dynamics. To understand how the pump dynamics contribute to neuronal activity, the kinetics of Na^+/K^+ pump function has to be quantitatively evaluated versus the dynamical properties of neurons.
The Na^+/K^+ pump contributes to the dynamics of neurons on the time scale of the period of their rhythmic bursting activity (6-10 s). In the leech heartbeat CPG, the basic building blocks are half-center oscillators (HCO), which are pairs of mutually inhibitory HN interneurons producing alternating bursting activity. A definitive role of the Na^+/K^+ pump current in HN bursting dynamics was revealed by using the H^+/Na^+ antiporter monensin, which stimulates the pump by diffusively increasing the intracellular Na^+ concentration. Application of monensin decreases the

period of the heartbeat HCO (Kueh et al. 2016).
To make quantitative analysis possible, we developed a dynamic-clamp implementation of a hybrid system with a living neuron and mathematical model in real time (corresponding to an HN HCO) in each of which we can manipulate pump parameters on the fly. We explored parameter space to fine-tune the real time model to support functional-like dynamics of a hybrid HCO under variation of the key parameters. We show that the interaction of the persistent Na^+ current (I_P) with I_{Pump} constitutes a mechanisms, which is sufficient to support endogenous bursting activity in HN interneurons and that this mechanism reinstates robust bursting activity in isolated living neurons rendered tonic by persistent leak associated with electrode penetration. This mechanism requires appropriate balance in the strength of I_P and pump activity. The functional alternating bursting of the HCO network requires the neurons to be in parametric vicinity of or in the state of the endogenous bursting. By focusing our analysis on a common network motif of an HCO, we generated insights that generalize to less accessible vertebrate nervous systems.

Title: Neuromodulation of component variability and circuit output variability

Authors: *A. C. SCHNEIDER[1], D. M. BUCHER[2], F. NADIM[2]
[1]Biol. Sci., New Jersey Inst. of Technol., Newark, NJ; [2]Federated Dept of Biol. Sciences; Inst. for Brain and Neurosci. Res. (IBNR), NJIT & Rutgers U-Newark, Newark, NJ

Abstract: Ionic currents and their corresponding channel gene mRNA levels can vary substantially in the same neuron type across animals. Yet, neural circuits produce outputs that are readily identifiable and have consistent characteristics. This disparity raises the question of how variable components can lead to consistent circuit outputs.
We address this question using the pyloric circuit of the crab stomatogastric nervous system (STNS), which has large variability in ionic currents of identified neurons, but produces a stable

triphasic rhythm with remarkably constant activity phases across animals. As in all neural circuits, pyloric activity is subject to actions of a variety of neuromodulators. When descending inputs are blocked in vitro to remove neuromodulator inputs (decentralization), the pyloric rhythm becomes less stable or stops altogether. Many of the individual STNS neuromodulators activate a stable identifiable pattern specific to that modulator. A number of these neuromodulators activate a persistent inward current, I_{MI}, albeit at different levels and in different subsets of pyloric neurons. It is therefore reasonable to assume that neuromodulation is necessary for producing the observed consistent output patterns by reducing component variability.
Hence, we compared the consistency of activity phases (circular variance with bootstrapped 95% confidence intervals) in the intact STNS with that of a decentralized STNS and then in the presence of the excitatory neuropeptide proctolin (1μM). Although some activity phases shifted significantly, their circular variance did not change. We also compared the variability (coefficient of variation, CV) of cycle period and ionic current levels in control (decentralized) and proctolin. CVs of all factors remained comparable and were not reduced. The variability of proctolin-induced I_{MI} was similar to that of other ionic currents.
These results show that a single neuromodulator, which rescues rhythmic activity of decentralized, silent STNSs, does not reduce variability at the component level or the circuit output level. We conclude that consistent circuit output does not require a reduction of variability at the component level. Alternatively, variability could be reduced only if more than one neuromodulator is present, which is the always the case in the intact system.

Title: Monitoring fluctuations in brain extracellular estradiol levels in freely-moving female rats

Authors: *S. AJAYI, A. AMER, P. GOLD, D. KOROL
Biol., Syracuse Univ., Syracuse, NY

Abstract: Evidence for estradiol (E_2) synthesis in the brain suggests that the steroid may operate through a combination of neuromodulator and hormonal mechanisms to mediate improvements and impairments across different types of learning and memory tasks. In this study, we used *in vivo* microdialysis in awake, freely-behaving female rats to measure E_2 concentrations in dialysates of hippocampus extracellular fluid across the estrous cycle and in ovariectomized rats with and without hormone replacement. Dialysate samples were collected hourly for 4 hrs and an

additional 2 hrs when systemic E_2 was given during microdialysis. Cycling rats were staged for estrous cycle using 15 days of vaginal smears. On the day of microdialysis measures, rats in proestrus, the estrous cycle stage with the highest levels of circulating E_2, displayed levels of E_2 in the hippocampus samples of 18 ± 4 pg/ml. In contrast, rats at stages with lower levels of circulating E_2, i.e. estrus and diestrus, had significantly lower levels of E_2 in the hippocampus (estrus, 6.5 ± 2.5 pg/ml), diestrus (4.7 ± 1.2 pg/ml). Thus, as seen in blood, extracellular E_2 levels were significantly higher at proestrus than at estrus or diestrus ($ps<0.05$ vs proestrus). Twenty-one days following ovariectomy, rats that received s.c. injections of E_2 (45 µg/kg) 48 and 24 hrs before testing had higher hippocampal E_2 levels (13.9 ± 0.5 pg/ml) than did the oil-treated control (3.8 pg/ml). Thus, the brain levels persisted for 24 hr after the last injection, similar to results observed previously for blood levels. Interestingly, rapid increases in hippocampal E_2 levels after subcutaneous injections were observed in rats at low hormone states but not in those at high hormone states. We are currently evaluating whether the hippocampal increases in E_2 following rises in blood E_2 are the result of E_2 uptake from the blood into the brain, increased release of brain E_2 in response to a signal conveyed by high levels of blood E_2, or both. Finding increased hippocampus-derived E_2 in the absence of increased circulating levels would provide support for the view that E_2 functions as a neuromodulator and would point to brain targets for estrogen therapies that avoid the health risks of peripheral estrogenic stimulation.

Title: Estradiol modulates extracellular hippocampal glucose and lactate during spatial working memory in female rats

Authors: *W. WANG, D. L. KOROL
Dept. of Biol., Syracuse Univ., Syracuse, NY

Abstract: Estrogens given to young adult ovariectomized rats enhance learning and memory on hippocampus-sensitive tasks, including tests of delayed spatial working memory. Using *in vivo* microdialysis with zero-net flux methods, we previously found that cognitively enhancing doses of estradiol, the predominant form of estrogen in young adults, also increased extracellular levels

of glucose and lactate in the hippocampus. The estradiol-induced increase in energy substrates was accompanied by higher glycogen concentrations in the hippocampus that were depleted after 20 minutes on a delayed spatial alternation task. Because glucose can be stored as astroctyic glycogen and astrocytic glycogenolysis produces lactate, estrogens may boost spatial working memory by increasing hippocampal provisions of glucose and lactate prior to or during cognitive activity. To test this hypothesis, we used wireless bioprobes to measure changes in extracellular glucose or lactate in the hippocampus during a four-arm spontaneous alternation task. Young adult ovariectomized rats were treated with estradiol benzoate (EB; 4.5 μg/kg) or oil 48 and 24 hours prior to testing. EB enhanced alternation scores above those of oil-treated controls. Baseline levels of glucose and lactate were elevated in EB-treated rats, supporting our prior findings with microdialysis. Memory testing produced a rapid reduction in glucose that recovered to and subsequently rose above baseline values throughout testing. EB potentiated the initial testing-induced depletion but not the recovery and elevation later in testing. Absolute values of glucose remained higher in EB-treated rats than in oil-treated rats at all times throughout testing. Testing-induced increases in lactate were significantly augmented by EB throughout the working memory task. Together, the results suggest that EB may enhance glucose storage into glycogen, potentiate glucose consumption early in the testing phase, and stimulate the production of astrocytic lactate to support continued memory processing. More generally, these results imply that estradiol effects on learning and memory may be mediated, at least in part, by the hormone's regulation of metabolic substrate availability and utilization in the brain.

Title: The rapid effects of hippocampally-synthesized estrogens on recognition and spatial learning in ovariectomized mice

Authors: T. MARTIN, L. KING, M. KLEMENS, R. ROSE, E. CHOLERIS
Dept. of Psychology and Neurosci. Program, Univ. of Guelph, Guelph, ON, Canada

Abstract: Estrogen is known to play a role in modulating cognition. Specifically, estrogen has been found to facilitate recognition and spatial learning. The female hippocampus is known to synthesize its own estrogens, and to be highly sensitive to estrogenic action (Frick et al., 2015). Local hippocampal administration of 17-β estradiol was found to facilitate recognition and

spatial learning (Phan et al., 2015), whereas a significant decrease in estrogens impaired long-term recognition memory (Tuscher et al., 2016), with spatial memory still being left unexplored at this time. However, whether locally synthesized, physiological estrogens are also involved in the initial processes of learning of spatial and recognition tasks is unknown. Here, 2-3-month-old CD1 mice were ovariectomized, hippocampally cannulated and infused with the estrogenic synthesizing enzyme inhibitor, letrozole (at one of 3 doses: 0.01, 0.05 or 0.1µg/µL), or vehicle (2%-dimethyl-sulfoxide) 15 minutes before a social, object or spatial recognition task. These tasks included three 4-minute learning periods where the same two stimuli were repeatedly introduced, followed by a 4-minute test period where a novel stimulus was either replaced one of the repeated stimuli or moved to a novel location, each separated by 3-minute rest periods where the stimuli were removed. Our hypothesis was that hippocampally-synthesized estrogens are involved in the initial learning of spatial and recognition memories. It was therefore predicted that letrozole at all doses would impair recognition and spatial learning. In partial support of the predictions, groups treated with 0.01 or 0.05µg/µL of letrozole did not show social or object recognition, whereas groups treated with 0.1µg/µL were not impaired in either. In direct contrast, spatial recognition was unimpaired at the 0.01 and 0.05µg/µL doses, but impaired at 0.1µg/µL. These results contribute a greater understanding of the function of hippocampally-synthesized estrogens within the context of learning and memory. This further characterization of estrogenic action and its effects on cognition could aid in the development of safer hormone replacement therapies for women experiencing cognitive deficits as a symptom of menopause.

Title: The role of androgen receptors and hippocampal estradiol synthesis in memory consolidation in male mice

Authors: *W. A. KOSS, R. L. ALF, J. J. TUSCHER, K. M. FRICK
Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: We have previously demonstrated that infusion of 17β-estradiol (E_2) into the dorsal hippocampus (DH) of ovariectomized female, gonadectomized (GDX) male, or sham-

gonadectomized (sham) male mice enhances memory consolidation as tested in object placement (OP) and object recognition (OR) tasks. We have also shown that DH infusion of the aromatase inhibitor letrozole disrupts OR and OP memory memory consolidation in ovariectomized female mice, which suggests that hippocampally-synthesized E_2 is essential for intact memory consolidation in ovariectomized females. In the current study, we examined effects of aromatase inhibition on memory in male mice. Sham and GDX mice were infused with vehicle or letrozole (1.0 μg/hemisphere) bilaterally into the DH immediately after training in OP and OR tasks. Mice were tested twenty-four hours later for OP, and forty-eight hours later for OR. Letrozole blocked OP and OR memory consolidation in GDX, but not sham, male mice, causing us to hypothesize that circulating androgens in sham males may have masked the memory-impairing effects of letrozole. To test this hypothesis, we designed a study to determine if blocking androgen actions with an androgen receptor antagonist could unmask the memory-impairing effects of letrozole in sham males. However, we first needed to determine how androgen receptor antagonism might affect memory consolidation independent of letrozole. Immediately after OP and OR training, sham males received bilateral DH infusion of vehicle or one of three doses of the androgen receptor antagonist, flutamide (0.25 μg/hemisphere, 0.5 μg/hemisphere, or 1.0 μg/hemisphere). In OP, the 0.25 μg and 1.0 μg doses, but not 0.5 μg dose, impaired memory consolidation. In OR, only 1.0 μg /hemisphere impaired memory consolidation. These data suggest that blocking androgen receptor activation can dose-dependently impair memory consolidation in sham male mice. However, to address our hypothesis about how androgen antagonism might influence effects of letrozole, we are currently co-infusing letrozole with 0.5 μg flutamide because this dose of flutamide had no effect on memory on its own. Together, these data will further define the role of hippocampus-synthesized E_2 and androgen signaling in the memory of male mice.

Title: Development of a novel estrogen receptor beta agonist for enhancing memory consolidation in female mice

Authors: *J. KIM[1], A. M. HANSON[2], I. S. PERERA[3], W. A. DONALDSON[3], D. S. SEM[2], K. M. FRICK[1]
[1]Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Dept. of Pharmaceut. Sci.,

Concordia Univ. Wisconsin, Mequon, WI; [3]Dept. of Chem., Marquette Univ., MILWAUKEE, WI

Abstract: Estrogens promote hippocampal synaptic plasticity and memory, and low or fluctuating estrogen levels may contribute to cognitive symptoms in conditions like Alzheimer's disease, anxiety disorders, and depression. These effects are likely mediated by a combination of intracellular (ERα and ERβ) and/or membrane-bound estrogen receptors. Both ERα and ERβ are highly expressed in the hippocampus, and agonists of either receptor can enhance hippocampal-dependent memory consolidation in female mice. However, ERα agonists can be pro-carcinogenic, which has led to considerable interest in developing agonists that are highly selective for ERβ. Recently, we reported a novel ERβ agonist with higher selectivity for ERβ over ERα activation than previously reported drug candidates (McCullough, et al., Bioorg Med Chem. 2014;22(1):303-10). Here, we optimized a related class of molecules comprised of a 4-hydroxymethyl-cyclohexane ring tethered to a phenol ring, making an *A-C estrogen* that closely resembles the naturally occurring estrogen molecule, but lacks the B and D rings. In cell-based assays, our lead compound, ISP358-2, showed >750-fold selectivity for ERβ over ERα, and EC50s of 20-30 nM for ERβ in both cell-based and direct binding assays. Moreover, ISP358-2 showed no off-target activity with other nuclear hormone receptors including androgen and glucocorticoid receptors, nor did it stimulate breast cancer cell growth or affect peripheral pathology. To assess its effects on hippocampal memory consolidation, ISP358-2 was administered to ovariectomized mice immediately after training in object recognition and object placement tasks via 3 routes of administration: dorsal hippocampal infusion (10 pg, 100 pg, 1 ng), intraperitoneal injection, and oral gavage (0.5, 5 mg/kg). Post-training administration of ISP385-2 enhanced memory consolidation in both tasks via all three routes of administration. Overall, these findings suggest that ISP358-2, a highly selective ERβ agonist with no evidence of peripheral toxicity, can safely and effectively facilitate memory formation in ovariectomized females. This compound may be a promising drug candidate for enhancing memory in disorders characterized by memory dysfunction that occurs under low estrogen conditions, such as menopause.

Title: The interplay between gonadal sex hormones and dorsal hippocampus D2-type dopamine receptors in the mediation of social learning in mice

Authors: *N. BASS, J. ANTHONYPILLAI, R. MATTA, E. CHOLERIS
Univ. of Guelph, Guelph, ON, Canada

Abstract: Abstract: Social learning, learning that occurs following social interaction and observation, is evolutionally adaptive and allows a conspecific to avoid or mitigate the consequences of individual trial and error learning (Galef, 1988). Though important to survival, the mechanisms of social learning are poorly understood. Social learning may be investigated using a social transmission of food preference (STFP) paradigm, where a preference for a novel flavored food diet is transferred from a demonstrator (DEM) to an observer (OBS) animal during social interaction. Previous research has demonstrated that the dopamine (DA) system is directly involved in STFP (Choleris et al., 2011) and that there is a sex difference in the role of D2-type DA receptors (Matta et al., 2017). Intra-dorsal hippocampus (HPC) infusions of D2-type DA receptor antagonist raclopride blocked social learning only in female mice (Matta et al., 2017). Furthermore, estrogen treatment enhanced the STFP (Ervin et al., 2015) and regulates the DA system. Similarly, androgen treatments increase HPC DA release (Tucci et al., 2008). Together, these findings suggest an interplay between HPC D2-type DA receptors and male and female sex hormones in the mediation of social learning in mice. In this study, male and female, either gonadectomised or gonadally intact, experimentally naïve CD 1 mice (2-3 months old), are undergoing a STFP paradigm following dorsal HPC infusions (0.5 μL per hemisphere) of a D2-type DA receptor antagonist, raclopride (18 μg/μL, 20 μg/μL) or control physiological saline solution. Researchers are blind to the drug and dose. First, a DEM mouse consumes 1 of 2 novel flavored food diets for 1-hour while an OBS mouse receives dorsal HPC infusions of raclopride or saline. Following a 10-minute delay, a 30-minute social interaction between the DEM and OBS mouse occurs. Finally, an 8-hour OBS choice test is implemented where the OBS is free to consume the 2 novel flavored food diets. Food intakes are taken at 1, 2, 4, 6, and 8 hours. It is predicted that raclopride will block social learning in castrated males, ovariectomized females, and gonadally intact females, but not in gonadally intact male mice. Unlike previous research that has only explored the role of female sex hormones in social learning, this study considers the possibility that *both* male and female sex hormones are involved in the mediation of DA facilitated social learning.

Title: Behavioral effects of 17B-estradiol and progesterone on the OVX female rat response to ketamine

Authors: *C. GAGNE, S. BENKETIRA, V. BOULOS, M. HERON, J. LACASSE, N. TITO, W. BRAKE
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: The NMDA-antagonist ketamine is a novel fast-acting anti-depressant shown to have therapeutic effects on individuals with treatment-resistant depression. Women are twice as likely to suffer from depression yet the majority of research on the effects of ketamine has focused on males. Moreover, little is known of the interaction between female sex hormones and ketamine. This research aimed to investigate the impact of 17β-estradiol (E2) and progesterone (P) on the ovariectomized (OVX) female rats' response to ketamine. Here 91 OVX female Wistar rats were split into three hormonal conditions (low E2, high E2, and high E2 + P) and five ketamine conditions (0, 2.5, 5, 10, & 20 mg/kg) resulting in 15 total groups. All rats were tested in the open field twice; before and 48 hours after ketamine and E2 administration. Between open-field tests rats were tested in the modified forced swim test (FST) 24 hours after ketamine. Early results show that high E2 + P replacement rats spent the most time immobile overall, compared to the other hormone conditions, and responded to ketamine by spending the least time immobile in the 20 mg/kg ketamine condition. The low E2 and high E2 replacement rats paradoxically spent more time immobile in the FST in all ketamine conditions compared to no ketamine. While there was an effect of hormones on the open field test, i.e. the low E2 group spent more time in the middle than the high E2 + P group, there was no effect of ketamine. Continuing this research should elucidate any interaction between female sex hormones and ketamine. Future work will investigate the neurobiological underpinnings of our findings.

Title: The role of APOE genotype, sex, and 17-beta estradiol in a mouse model of Alzheimer's disease

Authors: *L. TAXIER[1], S. M. PHILIPPI[1], J. M. YORK[3], M. LADU[4], K. M. FRICK[2]
[2]Dept. of Psychology, [1]Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [3]Dept. of Anat. and Cell Biol., Univ. of Illinois at Chicago Dept. of Anat. and Cell Biol., Chicago, IL; [4]Anat. and Cell Biol., Univ. of Illinois, Chicago, Chicago, IL

Abstract: In women, the loss of circulating ovarian estrogens at the onset of menopause is correlated with increased risk for development of Alzheimer's disease (AD) relative to men. Additionally, women carriers of the APOE4 genotype, which is the leading genetic risk factor for late-onset AD, are more likely than women who carry other APOE genotypes and men of any APOE genotype to develop AD. APOE4 status, combined with estrogen loss after menopause, places women at greatest risk of developing AD. Our lab and others have previously shown that the potent estrogen 17β-estradiol (E_2) enhances memory in young and aging female mice. However, the interactions among APOE genotype, sex, and E_2 are not well characterized. The goal of this study was to examine the effects of sex and APOE genotype on memory, and to test the extent to which E_2 mediates memory consolidation in a mouse model of AD. First, to examine effects of sex and APOE genotype on memory, 6 month-old gonadally-intact male and female mice expressing 5 familial AD mutations (5xFAD-Tg) and human APOE3 (E3FAD) or APOE4 (E4FAD) were trained on object recognition (OR) and object placement (OP) tasks to test object recognition and spatial memory formation. Next, to test the extent to which E_2 mediates memory consolidation in E3FAD and E4FAD females, ovariectomized female E3FAD and E4FAD mice were trained in the OR and OP tasks. Mice received an immediate post-training infusion of E_2 into the dorsal hippocampus and then memory was tested 4 or 24 hours later. Male E3FAD mice exhibited intact OR and OP memory, whereas E3FAD females and E4FADs of either sex did not, suggesting preserved memory function in E3FAD males relative to females, and impaired memory in E4FAD mice of either sex. Additional data indicate that E_2 enhances OR and OP memory in E3FAD, but not E4FAD, females. These data suggest that APOE genotype and sex influence memory formation and/or the ability of E_2 to enhance memory consolidation in the EFAD mouse model. Future studies will characterize effects of APOE genotype, sex, and E_2 on hippocampal cell signaling and dendritic morphology.

Title: Time-dependent effects of bisphenol A and hop extracts exposure during adolescence on testosterone and corticosterone secretion in male Wistar rats

Authors: *A. MORIN[1], E. L. PERSON[1], L. VAN DE BEECK[1], H. PLAMONDON[2]
[1]Psychology, Univ. of Ottawa, Ottawa, ON, Canada; [2]Dept Psychol, Univ. Ottawa, Ottawa, ON, Canada

Abstract: Bisphenol A (BPA) is a widespread industrial compound found in many plastic containers, which is shown to act as an endocrine disruptor and promote anxiety. The current research aimed to investigate the effects of daily exposure to BPA (40mg/kg) during the juvenile/adolescent period on testosterone and corticosterone secretion measured at adulthood. In parallel, a second objective examined effects of dietary supplementation with hop extracts (HOP), shown to have antioxidant and anxiolytic effects, on hormonal output after a similar administration regimen. Also of interest were synergistic effects between the two compounds. Initially, the study included 41 male Wistar rats randomly separated into four groups: Control (Corn oil), BPA (Corn oil + BPA 40mg/kg), HOP (Corn oil + hop extracts 50mg/kg), and BPA-HOP (Corn oil + BPA 40mg/kg + hop extracts 50mg/kg). Rats were exposed by oral gavage for 20 consecutive days from PND28 to PND48. As part of this research, rats underwent behavioural testing to assess anxiety and depressive-like behaviour. Blood droplets were collected from the tail vein on PND28 (baseline), PND38, PND48, and PND71 (adulthood-endpoint of the study). Corticosterone and testosterone concentrations were measured using ELISA. Due to defects in the paper used to absorb the blood samples, the following groups were analyzed in the ELISA protocol: Control (n=10), BPA (n=9), HOP (n=10), and BPA+HOP (n=10). Although trends were present, our findings showed no significant differences in hormonal secretion between the groups, suggesting that juvenile exposure to BPA and hop extracts may not have enduring consequences on hormonal secretion during adolescence and adulthood in male rats.

Title: Effects of Bisphenol A and hop extract exposure during adolescence on anxiety- and depressive-like behaviors, memory, and social interaction in adult male rats

Authors: *E. L. PERSON[1], A. MORIN[1], L. VAN DE BEECK[1], H. PLAMONDON[2]
[1]Psychology, Univ. of Ottawa, Ottawa, ON, Canada; [2]Dept Psychol, Univ. Ottawa, Ottawa, ON, Canada

Abstract: In recent years, concerns have raised about the exposition to hormone disruptors compounds like Cisphenol A (BPA) because of their potential negative consequences on health. BPA acts as an endocrine disruptor by mimicking estrogens and have been involved in various health problems. On the other hand, hop extract, a constituent of beer, has long been used for its positive health effects, amongst which sedative and antioxidant actions. This study aims to examine the behavioral consequences of BPA and HOP exposition during the critical developmental period of adolescence on adult male rates. Wistar juvenile male rats (N = 41) were either orally administered a daily supplement of BPA (n = 10), HOP (n = 11), BPA and HOP (n = 10), or the vehicule only in the case of the control group (n = 10) each morning from post-natal day 28 (PND28) to post-natal day 48 (PND48). Animals were tested in the elevated plus maze (EPM), the social interaction and preference test (SIT and SP), the object recognition test, and the forced swim test (FST) and blood samples were collected through the experiment to measure the long-term effects of both supplements on testosterone and corticosterone circulatory levels. Adult rats exposed to hop extract spent significantly more time in the open arms of the EPM, less time in the closed arms of the EPM, and showed better long-term memory capabilities in the object recognition test than their peers in the BPA and BPA+HOP groups. These results support the anxiolytic properties of HOP while also suggesting the long-term negative effects of BPA exposure at a juvenile age.

Title: Impact of gonadal hormone exposure on measures of sex differences in impulsivity in adult rats

Authors: *J. S. DARLING[1,2], L. DARTEZ[2], J. TAYLOR[2], A. MEHROTRA[2], W. SMITH[2], J. M. DANIEL[1,2,3]
[1]Neurosci. Program, Tulane Univ., New Orleans, LA; [2]Tulane Brain Inst., New Orleans, LA; [3]Tulane Psychology Dept., New Orleans, LA

Abstract: The goal of the current work was to examine the influence of gonadal hormones on adult sex differences on measures of impulsivity. Experiment One examined the influence of pubertal and adult gonadal hormones on sex differences in impulsive action and choice. Three sets of male and female rats were used in the study. The first set was gonadectomized prior to puberty (at 28 d of age), the second set was gonadectomized in adulthood (at 90 d of age), and the third set underwent sham surgeries and served as gonadally intact controls. Beginning at ~100 d of age, all rats were trained on the 5-choice serial-reaction time task (5-CSRTT), a test for impulsive action. The task requires rats to identify (via nose poke) the location of a brief light stimulus among five possible locations. When training was completed, impulsive action, as measured by premature responding, was assessed during sessions in which the onset of the stimulus was unpredictably lengthened. After testing on the 5-CSRTT was completed, rats were trained on a delayed-based reward task that measures impulsive choice, demonstrated as aversion to delayed reward. The task requires rats to choose between a delayed large food reward and an immediate small food reward. On the 5-CSRTT, adult males made significantly more impulsive (i.e. premature) responses across all hormone treatment conditions indicating that neither gonadal hormone actions during puberty nor during adulthood mediates the observed sex difference in impulsive action. On the delay-based reward task, no sex difference in impulsive choice was observed across all hormone treatment conditions. Experiment Two examined the influence of neonatal gonadal hormones on adult sex differences in impulsive action. Three groups of rats were used in the study. To serve as controls, one male group and one female group received subcutaneous injections of sesame oil vehicle on postnatal days 0 and 1. The third group, an experimental group of females, received 150 μg of testosterone propionate delivered subcutaneously in sesame oil vehicle on postnatal days 0 and 1. All three groups were gonadectomized prior to puberty (at 28 d of age). Under testing conditions, control males and females given neonatal testosterone, indistinguishable from one another, made significantly more impulsive action responses than did control females. Results indicate that 1) a sex difference in impulsive action observed in adult rats is due to organizing actions of testosterone during the neonatal period, and 2) no sex differences are apparent in adult rats in a delayed-based impulsive choice task.

Title: Chronic immobilization stress primes the hippocampal opioid system for oxycodone associated learning in female but not male rats

Authors: B. REICH[1], Y. ZHOU[2], E. GOLDSTEIN[1], S. S. SRIVATS[1], N. H. CONTOREGGI[1], J. F. KOGAN[3], K. T. BEN[2], B. S. MCEWEN[3], M. J. KREEK[2], *T. A. MILNER[1], J. D. GRAY[3]

Abstract: Our recent studies have shown that oxycodone conditioned place preference (CPP) induces sex-dependent changes in the redistribution of the hippocampal opioid receptors in a manner that promotes excitation and drug-related learning processes, particularly in females via increased disinhibition of inhibitory interneurons. We also found that chronic immobilization stress (CIS) "primes" the opioid system in adult female rats in a manner that would promote excitation and learning processes following subsequent exposure to either stress or an opioid ligand (McEwen and Milner, J. Neurosci. Res., 2017). The present study examined the effect of CIS on the opioid system in female and male Sprague Dawley rats following oxycodone CPP. Oxycodone-injected (Oxy) CIS females, but not Oxy-CIS males, acquire oxycodone CPP. By light microscopy, only Oxy-CIS females exhibited decreased Leu-enkephalin-immunoreactivity in the mossy fiber pathway in CA3 relative to saline-injected (Sal) CIS females. By electron microscopy, Sal-CIS females had fewer delta opioid receptor (DOR) silver-intensified gold (SIG) particles in the cytoplasm and in total in CA3b dendrites compared to Sal-CIS males, but there were no sex differences in DOR density following oxycodone CPP. Consistent with previous studies (Mazid et al., Neurobio. Stress, 2016), Sal-CIS females compared to Sal-CIS males had greater DOR-labeling within the dendritic spines of CA3b pyramidal cells, and this sex difference remained following oxycodone CPP. In the hilus of the dentate gyrus, Sal-CIS females compared to Sal-CIS males had greater total levels of DOR-SIG particles and mu opioid receptor (MOR)-SIG particles in GABAergic interneuron dendrites, and this sex difference is seen in Oxy-CIS females and males. Together, these results indicate that CIS primes the hippocampal opioid system in females for oxycodone-associated learning possibly by increasing DORs in mossy fiber-CA3 pyramidal cell synapses.

Title: The effects of continuous and previous estradiol exposure on nuclear and membrane estrogen receptor α in the hippocampus of aging ovariectomized rats

Authors: *N. E. BAUMGARTNER[1,2], M. E. SCHOENBERG[1,2], M. A. MODI[1,2], J. M. DANIEL[1,2,3]
[1]Neurosci. Program, [2]Brain Inst., [3]Psychology Dept., Tulane Univ., New Orleans, LA

Abstract: Work from our lab has demonstrated that previous midlife estradiol treatment improves memory and results in lasting increases in levels of estrogen receptor (ER) α in the hippocampus of aging ovariectomized rats months after hormone exposure has ended. Traditionally, ERα acts as a nuclear transcription factor. However, membrane ERα can also result in non-genomic, rapid acting effects. In an initial experiment, we found that previous midlife estradiol exposure increases ERα specifically in the nuclear compartment of hippocampal cells. However, it is currently unknown how this increase in ERα following previous estradiol exposure compares to that of ongoing estradiol exposure. The goal of the current work is to compare the subcellular localization of ERα after previous and continuous estradiol exposure following ovariectomy. Middle-aged rats were ovariectomized and implanted with capsules containing either estradiol or vehicle. Forty days later, all capsules were replaced. Rats initially receiving vehicle capsules received another vehicle capsule (ovariectomized controls), and rats initially receiving estradiol capsules received either another estradiol capsule (continuous estradiol) or a vehicle capsule (previous estradiol). One month later, hippocampi were dissected and processed for subcellular fractionation. Hippocampal lysate was separated into cytosolic, membrane, and nuclear compartments using a commercially available kit. All compartments were processed for western blotting for ERα. Results indicate that both continuous and previous estradiol treatment significantly increase nuclear levels of classic 66 kDa ERα, but do not alter cytosolic or membrane levels. Additionally, we found that continuous, but not previous estradiol treatment, resulted in increased levels of a novel 52 kDa membrane-bound ERα. These data suggest that the increase in ERα following ongoing and previous estradiol may result in transcriptional changes that impact hippocampal function, and that continuous estradiol

treatment might also result in changes in the non-genomic actions of ERα through a novel membrane-bound receptor.

Title: Determining which estrogen receptor rapidly interacts with oxytocin to mediate social recognition

Authors: *P. PALETTA[1], A. C. COLLINS[2], E. CHOLERIS[1]
[1]Psychology, [2]Biol. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: Estrogens are gonadal hormones that have been found to have a variety of functions throughout the body, including effecting cognitive abilities like learning and memory. One cognitive function that estrogens have been found to affect is social recognition, the ability to distinguish between conspecifics. Previous studies have shown that knocking out the estrogen receptors impairs social recognition, while the administration of 17β-estradiol (E2) or estrogen receptor agonists were able to rapidly facilitate social recognition. Oxytocin is also necessary for social recognition, in the medial amygdala as shown by gene knockout and receptor antagonist studies. These studies as well as the high expression of estrogen receptors in the regions where oxytocin is produced, specifically the paraventricular nucleus (PVN) and supraoptic nucleus of the hypothalamus, led to the idea that estrogens and oxytocin may interact to rapidly mediate social recognition. We tested this by first infusing E2 into the PVN and using a rapid social recognition paradigm where two stimulus mice are presented to ovariectomized experimental mice in two habituation phases followed by a test phase where one of the stimulus mice is replaced with a novel stimulus mouse. We found that E2 in the PVN was able to facilitate social recognition within 40 minutes of administration. We then tested whether this effect occurs through an interaction with oxytocin by administering a subeffective dose of an oxytocin receptor antagonist into the medial amygdala while also administering E2 into the PVN. We found that the oxytocin receptor antagonist blocked the facilitative effect of E2 on social recognition. These results show support for the idea that the rapid effects of estrogens and oxytocin do interact to facilitate social recognition. However, it is not currently known which estrogen receptor is mediating this interaction with oxytocin. Both estrogen receptor β (ERβ) and

the G-protein coupled estrogen receptor (GPER) are highly expressed in the PVN and either one or both receptors could be involved. This is being tested by administering either the ERβ agonist DPN or the GPER agonist G1 into the PVN to determine if they can facilitate social recognition by using the social recognition paradigm that has been described above. This is the first demonstration of the estrogen-oxytocin interplay in regions of the social brain in the mediation of social recognition. Funded by NSERC.

Title: Progestogens impact cognition during the transition to menopause: Dissociation of progestogen- and memory- type

Authors: *V. L. PENA[1,2], S. V. KOEBELE[1,2], S. NORTHUP-SMITH[1,2], V. E. WONER[1,2], R. MELIKIAN[1,2], S. PATEL[1,2], H. L. BULEN[1,2], D. LADWIG[1,2], C. A. DYER[3], L. P. MAYER[3], H. A. BIMONTE-NELSON[1,2]

Abstract: Progestogens, such as progesterone, medroxyprogesterone acetate (MPA), and micronized progesterone (mP4), are given to ovary-intact women during the transition to menopause to attenuate heavy uterine bleeding and other symptoms. Both progesterone and MPA administration have been shown to impair cognition in ovariectomized (Ovx) rats compared to vehicle-treated controls. mP4, however, has yet to be investigated for cognitive effects in a preclinical setting, despite widespread clinical use. Given that preclinical menopause-related progestogen investigations have been limited thus far to models of surgical menopause via Ovx, the goal of this experiment was to investigate the cognitive impact of the three clinically-used progestogens progesterone (P4), MPA, and mP4, in an ovary-intact transitional menopause model using 4-vinylcyclohexene diepoxide (VCD). One group of rats received vehicle injections, and the remainder of the groups received VCD to induce follicular depletion, modeling transitional menopause in women. Vehicle or hormone administration began during

perimenopause to model the time period when women often take progestogens alone. Rats then underwent testing to assess spatial working and reference memory in the water radial-arm maze (WRAM) and Morris water maze (MM). Results indicate that P4 and MPA improved learning for the working memory measure, but only MPA impaired delayed memory retention in the WRAM. mP4 showed no differences compared to vehicle controls for working memory. For the WRAM reference memory measure, rats that had undergone induced transitional menopause plus vehicle showed impaired learning and memory retention compared to vehicle controls with no induced transitional menopause; progestogens did not impact this impairment. No treatment differences were observed on the MM. Peripheral markers of hormone modulation and brain tissues are being analyzed. These findings indicate that while P4 and MPA have been previously shown to impair cognition in an Ovx model, giving these hormones early in an ovary-intact perimenopause model elicits divergent effects, such that these progestogens can improve cognition. Further investigation into progestogens is warranted to fully understand their impact on cognition and to detail parameters with variants of menopause type.

Title: Behavior and brain: Uncovering relationships between 17-beta-estradiol dose, spatial memory performance, and protein expression in the brain of middle-aged ovariectomized rats

Authors: *A. V. PRAKAPENKA[1], R. NEELEY[1,3], C. BERNS-LEONE[1,3], S. NORTHUP-SMITH[1,3], V. L. PEÑA[1,3], A. A. GEORGE[4], R. MELIKIAN[1,3], S. PATEL[1,3], D. S. LADWIG[1,3], R. HIROI[1,3], A. L. MANN[2,3,5,1], M. J. VALENZUELA SANCHEZ[2,3,5,1], R. W. SIRIANNI[4,1], H. A. BIMONTE-NELSON[1,3]
[2]RISE (Research Intensive Scientific Experience) in Psychology, [1]Arizona State Univ., Tempe, AZ; [3]Arizona Alzheimer's Consortium, Phoenix, AZ; [4]Barrow Neurolog. Inst., Phoenix, AZ; [5]Biotech. Program, Red Mountain High Sch., Mesa, AZ

Abstract: The endogenous estrogen 17-beta-estradiol (E2) is involved in cognitive function, as evidenced in human work and in rodent studies. During the perimenopausal period and at menopause, there are alterations in E2 levels, with an eventual decrease in circulating E2 levels, along with other ovarian-derived hormones. E2-containing hormone therapy is commonly used to alleviate many physiological symptoms associated with menopause. Thus, it is critical to understand how E2 impacts not only cognitive performance, but also the putative underlying neuromechanisms involved in cognitive function. Studies indicate that E2 can increase the expression of insulin-like growth factor-1 receptor (IGF1-R) and activated extracellular regulated kinase (Erk) 2 in the dorsal hippocampus, and there is evidence that IGF1-R and activated Erk 2 are required for E2-induced cognitive effects. Here, we examined how two doses of E2 - 0.3 μg/rat for the low dose and 3.0 μg/rat for the high dose - impact IGF1-R expression and activated Erk 1/2 expression in the dorsal hippocampus, ventral CA1/2 hippocampus, perirhinal cortex, and entorhinal cortex in middle-aged, ovariectomized rats. All animals underwent testing on a behavioral battery evaluating spatial working and reference memory simultaneously (water radial-arm maze) and spatial reference memory alone (Morris water maze) prior to brain analyses, allowing us to evaluate how IGF1-R and activated Erk 1/2 expression relate to learning and memory performance. On the water radial arm maze, the low E2 dose improved spatial working memory performance compared to the vehicle and high E2 dose groups. Interestingly, a linear relationship was found between IGF1-R expression in the perirhinal cortex and E2 dose, whereby as E2 dose increased, IGF1-R expression increased linearly. Additional analyses are underway to determine how IGF1-R expression, and how activated Erk1 and Erk2 expression, in each of the brain regions analyzed relate to learning and memory performance. Determining how behavioral and brain outcomes change as a function of E2 dose, and how these measures relate to each other, is a crucial piece of the puzzle that will help elucidate the role E2 plays in cognitive function concurrent with other factors known to impact efficacy, such as variations in menopause status. A more complete understanding of how E2 impacts the brain, and how this relates to behavior, may lead to the design of hormone therapies that capitalize on E2-induced molecular changes in the brain to obtain optimized cognitive outcomes.

Title: Hysterectomy with ovarian conservation uniquely impacts cognition and serum hormone profiles in a rat model

Authors: *S. V. KOEBELE[1,3], J. M. PALMER[1,3], B. HADDER[1,3], R. MELIKIAN[1,3], C. FOX[1,3], I. M. STROUSE[1,3], D. DENARDO[2], C. GEORGE[4], E. DAUNIS[4], H. A. BIMONTE-NELSON[1]
[1]Psychology, [2]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [3]Arizona Alzheimer's Consortium, Phoenix, AZ; [4]Senestech Inc., Flagstaff, AZ

Abstract: Hysterectomy (surgical removal of the uterus) is the most common gynecological surgery following only cesarean section (CDC, 2010; Carlson et al., 1993). The majority of hysterectomies are performed in women prior to age 51 (Wright et al., 2013), which is the average age for natural menopause onset, and prior observations suggest that surgical removal of the ovaries before natural menopause onset may be detrimental to cognition. Thus, ovaries are preserved in about half of hysterectomy procedures. In the last decade, these findings have been extended, such that hysterectomy itself prior to natural menopause onset has also been implicated in an increased relative risk of developing dementia compared to women who did not undergo gynecological surgery (Rocca et al., 2007, 2012; Phung et al., 2010). The factors underlying cognitive and brain changes with variations in surgical menopause remain unclear and warrant further evaluation. Here, we examined spatial memory in a novel rat model of hysterectomy with ovarian conservation. Adult Fischer-344-CDF female rats underwent hysterectomy or sham surgery. Following surgery, subjects were tested on the water radial-arm maze, a spatial working and reference memory task. Results indicate that hysterectomy impaired spatial working memory performance when working memory load was taxed. Serum ovarian hormone profiles were altered in rats with hysterectomy compared to sham-operated rats, while histological analyses of the ovarian tissue suggested that surgical intervention did not alter ovarian morphology itself, at least at the time point assessed. This is the first systematic pre-clinical evaluation of the cognitive effects of hysterectomy. Relationships among cognition, hormonal changes, and ovarian morphology will be discussed. Overall, these data provide important insight into how hysterectomy may alter cognition during aging.

Title: An evaluation of short-term and long-term ovarian hormone deprivation in the APP/PS1 mouse model of Alzheimer's disease

Authors: *V. E. WONER[1,3], J. M. PALMER[1,3], S. V. KOEBELE[1,3], I. M. STROUSE[1,3], M. N. WILLEMAN[1,3,4], V. L. PENA[1,3], W. WINSLOW[3,5], A. CACCAMO[3,5], S. ODDO[2,3,5], H. A. BIMONTE-NELSON[1,3]
[1]Psychology, [2]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [3]Arizona Alzheimer's Consortium, Phoenix, AZ; [4]Translational Genomics Res. Inst., Phoenix, AZ; [5]ASU-Banner Neurodegenerative Dis. Res. Ctr., Biodesign Inst., Tempe, AZ

Abstract: With no known cure, Alzheimer’s disease (AD) is the most common form of dementia, affecting more than 5.7 million Americans. The aged population is not affected by AD equally; women are at a greater risk for developing AD than age-matched men. This disproportionate risk may be associated with changes in the female hormone profile that occur during reproductive senescence. Further, there is evidence that women who undergo surgical menopause (i.e. oophorectomy, or removal of the ovaries) before the onset of natural menopause are at a greater risk for dementia. We used a double transgenic AD mouse model (APP/PS1), with transgenic mice expressing APP and PS1 gene mutations resulting in beta-amyloid pathology development, to evaluate a short-term period (Study 1) and a long-term period (Study 2) of complete ovarian hormone deprivation. The long-term deprivation timepoint was based on prior work using a triple transgenic AD mouse model (Carroll et al., 2007).
At three months of age, wildtype (Wt) mice and APP/PS1 mice underwent either Sham surgery or Ovariectomy (Ovx) surgery, the surgical removal of the ovary in rodents. Study 1 consisted of a short-term cohort that was tested on a battery of behavioral tasks assessing spatial reference memory and spatial working memory one month following surgery and subsequent hormone deprivation. These tasks included the Morris water maze, the delayed match-to-sample (DMS) water maze, and the visible platform control task. Study 2 consisted of a long-term cohort tested three months following surgery and subsequent hormone deprivation on the same behavior battery. DMS results from Study 1 revealed that, in the learning phase of the task, genotype interacted with surgical menopause status, such that after a short-term deprivation, no genotype

effect was present after Sham surgery, while Ovx induced a genotype effect, with APP/PS1 mice showing poorer cognitive scores relative to their Wt counterparts. DMS results from Study 2 showed a similar pattern of effects, with a comparable interaction between genotype and surgical menopause status. However, this effect persisted across all testing days, suggesting a global, more persistent effect with a long-term ovarian hormone deprivation. These preliminary behavioral findings indicate that ovarian hormone deprivation exacerbates cognitive deficits in APP/PS1 mice. Additional behavioral and neuropathological analyses currently underway will allow us to determine relationships between temporal parameters of surgical menopause, cognitive status within varied domains, and AD-like pathology.

Title: Sex differences in olfaction and executive function among young adults

Authors: *A. A. WALF, D. Z. TAYLOR, A. KHAN, L. D. REID
Cognitive Sci. Dept, Rensselaer Polytechnic Inst., Troy, NY

Abstract: Emerging findings suggest the importance of olfactory function for mood/stress as well as cognitive functions among young adults as well as those from other clinical populations. For example, poor olfactory function may be an early symptom of cognitive disorders, such as Alzheimer's Disease (AD) or other diseases of neurodegeneration; brain injury is also a leading cause of loss of smell (Reid, Walf, & Avens, 2017). Considering the modern theory of AD, there are interacting setting conditions for accumulation of amyloid beta in the interstitial fluid of the brain, including poor fluid flow and immune/inflammatory responses. The brain-nasal cavity (B-NC) interface is a target here. Problems at the B-NC are usually manifest as hyposmia and anosmia. In this study, the hypotheses tested were that: 1) there would be associations between poor olfactory function (as measured by olfactory awareness scores) and executive function (including memory, problem and spatial processing), and mood/stress; 2) there would be sex differences in these tasks. Subjects were men and women, 18-24 years of age, with low and high scores on olfactory awareness/perception. Subjects were tested in a battery of tests to assess stress/mood, olfaction (e.g. discrimination, recent loss in), executive function (Mental Rotation Task, Trail-making Task, short-term and long-term verbal memory), and grip strength. There were no differences in olfactory awareness scores, or reported recent losses/difficulties with

olfaction, between men and women. Differences were noted in the Perceived Stress Score with the highest scores in the men with low olfactory awareness. In the Mental Rotation Task and Trail-making Task, men outperformed women, except those men with low olfactory awareness. In both the short-term and long-term verbal memory tests, women with low olfactory awareness had the lowest scores. As predicted, men had higher grip strength than women, especially when using their dominant hand. Together, this study confirms reported sex differences in executive function as well as expands on this literature to provide proof-of-concept about the relationship between olfactory function (measures of qualitative and quantitative sense of smell), mood, and cognitive function of human subjects. The olfactory system is both remarkably plastic and sensitive to damage. Our continued focus is how olfactory abilities may be related to mood, cognitive function, brain plasticity and the individual differences in these effects across the lifespan and how correcting deficits in these areas may restore brain health.

Title: The effects of olfactory deficits on executive function among human subjects

Authors: *D. TAYLOR, A. KHAN, L. REID, A. A. WALF
Rensselaer Polytechnic Inst., Troy, NY

Abstract: Further elucidating a connection between olfaction and cognition has potential implications in maintaining neuronal health among both young and elderly individuals. The hypotheses tested were that olfaction and cognition are correlated and that resolving olfactory deficits may improve cognitive processing. Collaboration with a team of RPI computer scientists allowed for the construction of a testing platform and database to measure subjective and objective olfaction, working memory, attention processing, physical health, psychological profile, along with a number of demographic variables both in person and online. Human subjects have been tested, in the age demographic 18 to 24 to test these hypotheses and validate the novel approach to testing that has been designed. A connection between subjective olfaction and attention processing in the Trail-making Task and spatial processing in the Mental Rotation Task has been determined among young adult participants. Additionally, relationships have been found between subjective and objective olfactory measures in these study participants, validating the in person and online testing approach. Remaining questions being addressed are age differences for these effects and the role of long-term olfactory training. Physicians utilize lost olfaction as a predictor for Alzheimer's Disease; characteristic neural degeneration is initiated at

the olfactory portions of the brain, which may support the claim that amyloid beta (Aβ) contributes to an immune response against invading microbes entering the brain through the Brain-Nasal Cavity interface (B-NC). Aβ plaques may even be the product of aggregating invading pathogens. Investigations into the molecular targets for these effects are ongoing. Research has posited that Cerebrospinal Fluid (CSF), containing the destructive Aβ, clears out of the brain through the lymph vessels protruding from the cribriform plate in the B-NC. Correcting lost olfaction may restore health to this region, thereby, facilitating CSF flow and promoting neuronal health, which is the ultimate goal of this work.

Title: Sex diferences in central activation of protooncogene c-fos after exposition to environmental noise

Authors: D. FERNANDEZ-QUEZADA[1], S. LUQUIN[2], A. GARCÍA-ZAMUDIO[1], J. GARCIA-ESTRADA[2], Y. RUVALCABA-DELGADILLO[2], *J. FERNANDO[2]

Abstract: Noise is an inarticulate auditive stimulus that threats health in different ways. The Central Nervous System (CNS) is essential to respond and process auditive information. Processing of undesired sounds may involve a number of neural circuits outside the auditory system. Immediate early genes have been helpful to identify the central neural circuits that physiologically or behaviorally regulate the adaptation to environmental threats. Then, in this experiment, we analyzed the rat male and female brain to gain knowledge on how a noisy environment affects the expression of the immediate-early gene product c-Fos (marker of neural activation) in both sexes. Male and female wistar rats were exposed to a rats' audiogram-fitted adaptation of a noisy environment and sacrificed at 0, 2, 6 and12 hours for acute effect; and at 7, 14 and 21 days for chronic effect. Immunohistochemistry against c-Fos was performed on 70μm slices belonging to the male and female rat brains. We found differential patterns of c-Fos expression depending on sex, region, and time of exposure. Besides auditory cortex, we found

activity changes in regions that included the hypothalamus, prefrontal cortex, habenular complex, septum, cingulate cortex, nucleus accumbens, insular cortex, and hippocampus. We also found that female rats exhibited less intense c-Fos activation in most of the examined areas. Then, we demonstrated that environmental noise differentially activates brain structures outside the classic auditory circuits and that female rats are less sensible to the activity changes produced by environmental noise.

Title: Stress elicits contrasting effects on astrocytes not only in the hippocampus versus amygdala, but also between neurons and astrocytes within the amygdala

Authors: *S. NASKAR[1], S. CHATTARJI[1,2,3]
[1]Natl. Ctr. For Biol. Sci., Bangalore, India; [2]Ctr. for Brain Develop. and Repair, Inst. for Stem Cell Biol. and Regenerative Med., Bangalore, India; [3]Ctr. for Integrative Physiology, Deanery of Biol. Sciences, Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Stress causes divergent patterns of structural and physiological plasticity in the hippocampus versus amygdala (Chattarji et al., *Nature Neurosci.*, 2015). However, a majority of earlier studies focused primarily on neurons. Despite growing evidence for the importance of glia in health and disease, relatively little is known about how stress affects astrocytes. Hence, we examined the impact of chronic immobilization stress (2h/day, 10 days), on the number and structure of astrocytes in the rat hippocampus and amygdala. We observed a 14.5% reduction in the number of GFAP-positive astrocytes in the basal amygdala (BA) a day after the end of chronic stress (Control: 15997±594; Stress: 13669±465 cells/μm^3). Detailed morphometric analysis of individual dye-filled astrocytes also revealed a 21.9% decrease in the neuropil volume occupied by these astrocytes in the BA (Control: 41238±1715; Stress: 32175±1636 μm^3). By contrast, the same chronic stress had no effect on the number or morphology of astrocytes in hippocampal area CA3. Finally, we confirmed previous reports that chronic stress triggered dendritic growth in BA principal neurons. BA neurons exhibiting dendritic hypertrophy

(Total dendritic length: Control: 1871±97; Stress: 2286±101 µm) were located adjacent to astrocytes that had undergone atrophy, thereby providing striking examples of the opposite effects of the same stress on neurons versus astrocytes. Together, these findings offer new evidence that the morphological effects of stress not only vary with brain regions, but can also cause markedly different effects on neurons versus astrocytes within the same brain area.

Abstract: Stress is a major risk factor for the development of almost all psychiatric disorders. One of the processes interfered by stress and often deregulated in psychiatric disorders is emotion processing. In this work, we aim to identify the molecular mechanisms underlying emotion processing during acute stress response. Previously, we reported that high-risk individuals (siblings of schizophrenia patients) did not show default mode network suppression when performing an emotion picture task following a stressful condition, in contrast to healthy individuals. We mapped these differentially regulated brain regions (region of interest) identified using fMRI to gene expression data from the Allen Human Brain Atlas (AHBA). We identified 63 genes with significantly different expression levels between the region of interest and the rest of the cerebrum (two-tailed t-test, FDR-corrected $p < 0.05$, $\log_2$(Fold-Change) > 1) in at least 5 out of the 6 donors in the AHBA. These genes are enriched for known schizophrenia risk-loci (Fisher's exact test, $p = 0.0059$), including *KCNV1*, *DOC2A*, *NGEF*, *NRGN* and *MEF2C*. Moreover, these genes included *CAMK2A*, *DLX1*, *CCK* and its cognate receptor *CCKRB*, *VIP* and *NEUROD6*, which are known to influence behavior and stress response. Previously, we found *NEUROD6* to have specificity for the mineralocorticoid receptor over the glucocorticoid receptor. Together, these results suggest that higher expression of schizophrenia-associated genes is associated with changes in the adaptive brain response to stress in siblings of schizophrenia patients.

Title: Impaired epinephrine responses to acute insulin-induced hypoglycemia in germ free mice

Authors: *B. B. NANKOVA[1], P. GIRI[2], F. HU[3], E. F. LA GAMMA[4]
[1]Pediatrics & Biochem & Mol Biol, New York Med. College, BCHP, Valhalla, NY; [2]Pediatrics, Div. of Newborn Med., New York Med. College/Maria Fareri Children's Hosp., Valhalla, NY; [3]Pediatrics, New York Med. College, Boston Children's Hlth. Physicians, Valhalla, NY; [4]Dir Regional Neonatal Ctr., Maria Fareri Children's Hosp., Valhalla, NY

Abstract: Prematurely born infants are at increased risk of developing neurodevelopmental impairments. The ability to survive postnatal stressors such as hypoglycemia, hypoxia, and hypothermia correlates with the ability to respond by releasing catecholamines. The maturation of the stress response system occurs in the early postnatal period, in parallel with initial gut colonization and microbiota-gut-brain axis development. Whether gut microbes and their metabolites influence the adrenal component of the sympathetic nervous system is not known. Here we tested the hypothesis that germ free (GF) mice (lacking microbiome) will have altered sympatho-adrenal responses to metabolic stress. We show that GF mice have significantly lower basal levels of urinary epinephrine compared to control (normally colonized) mice. Further, they displayed attenuated epinephrine response to acute insulin-induced hypoglycemia, while corticosterone (HPA axis) and glucagon (parasympathetic signaling) release was similar to the observed rise in counter-regulatory hormones of controls. 60' after insulin injection adrenal TH mRNA levels were increased only in the control group (qRT-PCR). Both control and GF groups displayed significant rise in TH mRNA levels with longer exposure to stress. The trans-synaptic regulation of NPY gene followed the pattern described for TH. In addition, a 2-fold increase in c-fos immunoreactivity (marker of neuronal activation) was observed in both, C and GF animals following insulin injection although baseline adrenal c-fos levels were significantly lower (immunofluorescense) in GF mice. Using a genome-wide transcriptome profiling approach we found that under both, basal and stress conditions GF mice display markedly altered adrenal gene expression profiles and process networks including neuropeptide, insulin and leptin signaling pathways. Thus, imbalances of the sympatho-adrenal system caused by the lack of a microbiome (or dysbiosis) during development could contribute to the adverse outcomes in preterm neonates.

Controlled manipulation of the intestinal microflora may provide a new therapeutic approach to improve their adaptation to common stressors, survival and overall health. In addition, our approach evaluating the gut-microbiota-brain-interface at a *single* synapse (the excitatory preganglionic-adrenal chromaffin cell synapse, the final step in the multi-neuronal signaling pathways that results in release of epinephrine) provides an easily accessible model of the more complex CNS dopaminergic pathways.

Title: Aberrant CRH expression in the nucleus accumbens of adolescent mice after early-life adversity: A mechanism of anhedonia?

Authors: *Y. CHEN[1], C. A. ITOGA[2], A. K. SHORT[2], J. L. BOLTON[2], X. XU[2], T. Z. BARAM[3]
[1]Pediatrics, [2]Anat. and Neurobio., [3]Pediatrics, Anat. and Neurobiology, Neurol., Univ. of California Irvine, Irvine, CA

Abstract: Premise: Anhedonia, the reduced ability to experience pleasure, is an important early sign of several mental illnesses including depression and schizophrenia. However, the processes provoking anhedonia are not fully understood. Early-life adversity is a known antecedent and risk factor for mental illness, and we have recently reported that early-life adversity, and specifically rearing in cages with fragmented unpredictable maternal care (FRAG) leads to anhedonia (Bolton et al., 2018). Here we probed the mechanisms by which FRAG leads to anhedonia, testing the hypothesis that they involve aberrant development of the pleasure-reward brain circuitry. We focused on corticotropin-releasing hormone (CRH)-expressing pathways to the nucleus accumbens (NAc), an established region in the reward circuitry underlying fundamental processes of pleasure, reward and happiness. CRH influences dopamine release in NAc, and is often upregulated by adversity (e.g., Lemos et al., 2012; Dubé et al. 2015). Thus, alteration of CRH-mediated neurotransmission within NAc by early-life adversity is a logical candidate mechanism for maladaptive plasticity of the reward circuitry resulting from this insult. **Methods**: CRH-expressing cells and fibers were assessed in the NAc using stereological principles, and their origin examined using both traditional and viral-tracing methods.

Results: CRH-expressing axon terminals were augmented in the middle and posterior regions of the NAc shell in mice exposed to early-life adversity compared with controls. Viral tracing methods identified a novel monosynaptic, CRH-expressing amygdala-NAc pathway originating in the basolateral amygdala (BLA). Studies are ongoing to test if this NAc-directed BLA-origin CRH expressing pathway is augmented after early-life adversity.
Conclusions: These data suggest that increased innervation and activation of NAc cells by CRH inputs may underlie early-life adversity-induced anhedonia, with major implications for the developmental origins of mental illness.

Res. & MC, CEHR, Frederick, MD

Abstract: Severe stress can have drastic and systemic effects with dire implications on the health and wellbeing of exposed individuals. Particularly, the effect of stress on the immune response to infection is of interest because of its implications for vaccine efficacy and treatment strategy during stressful scenarios. Battlefield-like stress has previously been shown to cause an anergic state in the immune system that persists following exposure to a potent mitogenic toxin. In this study, genome-wide alterations of gene expression were characterized using leukocytes collected from (15 consented, all male) U.S. Army Ranger cadets immediately before and after training followed by exposure to a representative group of pathogens (bacterial: *Yersinia pestis*; viral: dengue virus; toxin: *Staphylococcus* enterotoxin B). Here, we observed predicted inhibition of pathways significantly associated with lymphopoiesis, wound healing, inflammatory response, lymphocyte activation, anti-apoptosis, and predicted activation of cellular response to oxidative

stress. Using weighted correlation network analyses, we showed that these pathways were preserved across the different infection plus stress combinations. And yet, we have not found significant variation in the complete and differential counts of leukocyte-subpopulations between the pre- and post-stress cohorts. In addition, we identified regulatory (and modular) networks comprising a common set of upstream regulators (transcription factors: GATA2, YY1, FOXM1, CEBPB, EPAS1, HMGB1, NFATC1, RUNX3, MEN1, CIITA, NFKB1, RELA, IRF1, IRF7, STAT1; and micro RNAs: miR-124-3p, miR-183-5p, miR-153-3p, miR-135A-5p, miR-211-5p). Inhibition or activation of these upstream regulators may be leading to suppression of protective immunity (antigen presentation, T-cell activation and immune effector processes), accounting for the suboptimal responses of severely-stressed people to vaccines. Given that there were no significant difference in cell counts, inhibited lymphopoiesis may also be partly responsible for compromised immunity and for further cellular anergy towards mitogens requiring presence of naïve lymphocytes (T-cells).

Title: Sex differences in amyloid-beta monomer distribution and neuronal injury in the coeruleo-cortical circuit of mice conditionally overexpressing corticotropin releasing factor in the forebrain

Authors: *J. A. ROSS[1], B. A. S. REYES[1], V. B. RISBROUGH[2], E. J. VAN BOCKSTAELE[1]
[1]Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: Accumulating evidence from preclinical and clinical studies point to the Locus Coeruleus (LC)-Norepinephrine (NE) system as an understudied area of research in the context of Alzheimer's Disease (AD). Stress is a risk factor for developing AD. Amplification of the stress system disrupts cellular and molecular processes at the synapse, promoting the production

and accumulation of the amyloid beta (Aβ) peptide. Stress-induced activation of the LC is mediated by corticotropin releasing factor (CRF) and CRF receptors exhibit sex-biased stress signaling. In the present study, we examined the cellular substrates for interactions between Aβ and tyrosine hydroxylase (TH), a marker of noradrenergic somatodendritic processes in the LC, and dopamine-β-hydroxylase (DβH), a marker of noradrenergic axon terminals in the infralimbic medial prefrontal cortex (ILmPFC) of mice conditionally overexpressing CRF in the forebrain (CRF OE) under a Doxycycline (DOX) regulated tetO promoter. Using high resolution immunoelectron microscopy, semi-quantitative analysis revealed that 41.3% (214/518) of TH-immunoreactive (ir) somatodendritic processes also exhibited Aβ-immunogold silver particles in DOX treated males, compared to 27.62% (137/496) in male transgenic littermate untreated controls and 54.7% (267/488) TH-ir somatodendritic processes also exhibited Aβ-immunogold silver particles in DOX treated females compared to 36.67% (95/259) in female transgenic littermate vehicle-treated controls. Results showed significant increases ($p<0.05$) in Aβ in TH-ir somatodendritic processes of the LC in females, and a trend towards an increase in males. Interestingly, early signs of neuronal injury, including the presence of lipofuscin and abnormal morphology of Aβ-ir lysosomal compartments were observed in female DOX treated mice. While preliminary western blot analysis revealed no significant differences in the expression of APP-α, BACE-1, or TH expression in the LC, there is a trend towards significance in APP-β ($p=0.053$), indicating differences between male and female treated DOX groups. Additionally, female DOX treated mice exhibited enlarged microvessels that were Aβ-ir, and with lipid laden vacuoles. In DOX treated females, 14.19% (88/599) of the DβH-ir axon terminals exhibited Aβ-ir compared to 6.21% (39/628) in vehicle-treated female transgenic littermates, indicating a significant ($p<0.05$) increase in frequency of localization of Aβ to NE axon terminals. These data indicate potentially important sex differences in Aβ peptide accumulation and neuronal injury in the coeruleo-cortical circuit in a model of chronic stress signaling.

Title: Examining genetic differences in binge drinking at baseline and in response to stress

Authors: *E. DIMITRATOS[1,2], B. SACHS[2]
[2]Psychological and Brain Sci., [1]Villanova Univ., Villanova, PA

Abstract: Binge drinking exerts a tremendous toll on American society through its numerous direct and indirect effects, including the promotion of increased risk-taking behaviors, aggression, sexual violence, poor academic performance, liver damage, and the development of psychological disorders, such as major depression. Two of the many factors that influence binge drinking are gender and stress. Although stress is typically considered to increase alcohol consumption, there is evidence to suggest that the relationship between stress and alcohol intake is complex and may be moderated by sex. For example, previous research has found that stress is positively associated with binge drinking in male college students but negatively associated with binge drinking in female college students. However, whether this clinically observed sex difference results from sexually dimorphic neurobiological responses to stress (or alcohol) in males vs. females or from societal or other factors has not been established. The current work sought to evaluate whether c57BL6/J mice exhibit sex differences in stress-induced alterations in binge drinking behavior. In addition to examining behavior, we also sought to provide new insight into the mechanisms through which stress might impact binge drinking in males and females. To do this, we used real-time PCR to examine stress and alcohol-induced alterations in gene expression in several brain regions that have been implicated in binge drinking. Given that the endorphin and glucocorticoid systems are both highly stress responsive and have been highly implicated in stress responses to alcohol, we compared the expression of several genes involved in endorphin and glucocorticoid signaling in male and female mice after chronic restraint stress and under control conditions. Although no significant sex differences in binge drinking were observed, stress was shown to significantly increase binge alcohol consumption and to lead to a significant upregulation of several genes in the amygdala, including corticotropin-releasing hormone and proopiomelanocortin. Overall, this study provides new insight into the effects of chronic stress on binge drinking and may help identify novel molecular targets to protect against or reverse stress-induced increases in alcohol consumption.

Title: Dendritic spine densities in hippocampus and amygdala reflect individual differences in aggressive and violent behavior in wild derived male rats

Authors: *S. ANILKUMAR[1,2,3], D. PATEL[4,1,3], B. BUWALDA[4], S. CHATTARJI[1,3,5]
[1]Neurosci., Natl. Ctr. for Biol. Sci., Bangalore, India; [2]Neurosci., Manipal Univ., Manipal, India; [3]Ctr. for Brain Develop. and Repair, Inst. for Stem Cell Biol. and Regenerative Med., Bangalore, India; [4]Neurobio., Groningen Inst. for Evolutionary Life Sci., Groningen, Netherlands; [5]Ctr. for Integrative Physiol. Deanery of Biomed. Sci., Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Aggressive behaviors in many social organisms play a pivotal role in the defense of territory against intruders, as well as in acquiring social status and resources like food and mates. Further, individual differences in aggressive behaviors have been considered as important indicators of different coping strategies. Hence, the goal of the present study was to identify morphological correlates of aggressive and violent behaviors in the amygdala and hippocampus in Wildtype Groningen rats that exhibit a much richer repertoire of aggressive behaviors.
Four month old Wildtype Groningen rats were first characterized for their coping style measuring frequency and duration of offensive aggressive behavior in the resident-intruder paradigm wherein in one group, they were confronted on 4 subsequent days with male intruder rats and more than 20 times in another sub group, which exhibit extremely violent behavior and are unable to control their aggression and attacked even the anesthetized intruders. Next we carried out morphological analyses of dendritic spine-density on principal neurons of the basolateral amygdala (BLA) and hippocampal area CA1. This revealed no difference between aggressive and non-aggressive rats. However, stellate neurons in the medial nucleus of the amygdala (MeA) exhibited a significant decrease in spine-density in highly aggressive rats compared to non-aggressive rats. Notably, morphological analysis in the sub-group of pathologically violent rats revealed enhanced spine-density in the BLA, but the opposite effect in the CA1 area of hippocampus.
Together our results point to several distinct patterns of changes in spine-density that vary with brain regions, as well as the levels of aggressive behavior displayed by Wildtype Groningen rats. In rats that exhibited a normal range of aggression, we found no difference in spine-density between the BLA and area CA1, two brain areas that are known to undergo contrasting patterns of morphological plasticity in response to physical stressors. Strikingly, the same brain areas exhibited contrasting changes in spine-density only in those animals that displayed violently aggressive behaviors indicating the possibility that amygdalar and hippocampal neurons undergo structural plasticity which depends on the intensity of aggression of individual animals. Furthermore, ethologically natural behaviors in wild-derived rats, such as aggression towards intruders, elicit morphological plasticity in the amygdala and hippocampus that are distinct compared to those triggered by more traditional models of physical stress.

Title: Hippocampal and amygdalar cell-specific translation is similar soon after stress but diverge over time

Authors: *J. S. MADAN[1], K. GUPTA[1], S. CHATTARJI[1,2,3], A. BHATTACHARYA[2]
[1]Natl. Ctr. for Biol. Sci., Bangalore North, India; [2]Ctr. for Brain Develop. and Repair, Inst. for Stem Cell Biol. and Regenerative Med., Bangalore, India; [3]Ctr. for Integrative Physiol., Deanery of Biomed. Sciences, Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Stress is known to cause contrasting patterns of morphological and physiological plasticity in the hippocampus and amygdala. An obligatory cellular process underlying such neural changes is de novo translation and alterations in proteomic expression. Yet the nature of the translational response to stress in neurons remains largely unexplored. Even less is known about how glia are affected. Using a click-chemistry-based method to label the de novo proteome in live brain slices, we monitored translation in neurons and astrocytes of the basolateral amygdala (BLA) and dorsal hippocampal areas CA1(dCA1) and CA3 (dCA3) of male rats 1hour(1h), 24hours(1d) and 10 days(10d) after a single 2-hour exposure to immobilization stress. We observed large enhancements in neuronal translation in all the three brain regions BLA, dCA1 and dCA3 1h after stress. However, the neuronal translation profiles of the three brain regions follow different trajectories from this initial enhancement. The initial increase in neuronal translation persisted in the BLA 1d and even up to 10d afterwards. Surprisingly, the dCA1 neuronal translation was observed to be not different from control level 1d later but was again significantly higher 10d later. Further, even though the dCA3 neuronal translation stayed higher 1d later, it gradually decreased to below control levels 10d later. Similar to neuronal translation, astrocytic translation in the BLA and dCA3 only, but not in the dCA1, was also enhanced 1h after stress. However, the astrocytic translation in the dCA1 was enhanced 1d and 10d after stress. Further, the BLA astrocytic translation peaked 1d later and continued to remain higher even 10d later. Interestingly, translation profiles of dCA3 astrocytes followed timelines similar to that of the dCA3 neurons; the astrocytic translation continued to stay higher 1d later and decreased to below control levels 10d after stress.

Together our results demonstrate that a single episode of immobilization stress causes a general and immediate upregulation of protein synthesis in both amygdalar and hippocampal neurons and astrocytes. However, these profiles diverge and we observe cell specific and brain region specific temporal profiles of protein expression well after the end of stress. These findings identify new metrics of stress-induced plasticity at the level of cell-type specific proteomic landscape that may provide important insights into the molecular basis of the divergent temporal effects of stress across brain regions and biological scales.

Title: Regulation of brain-specific splicing of Eef1d and activity control of its nuclear variant, eEF1BδL by stress-induced dephosphorylation

Authors: *T. KAITSUKA[1], M. MATSUSHITA[2]
[1]Dept. of Mol. Physiol., Kumamoto University, Fac. of Life Sci., Kumamoto, Japan; [2]Dept. of Mol. and Cell. Physiol., Univ. of the Ryukyus, Grad. Sch. of Med., Okinawa, Japan

Abstract: Alternative splicing machinery enables a gene to generate more than one protein, which often have different molecular function. One of those, *Eef1d* gene produce canonical eukaryotic elongation factor 1Bδ (eEF1Bδ) and non-canonical long variant, named as eEF1BδL. Previously, we reported that the expression of this variant is restricted in brain and testis via alternative splicing and its protein functions as a transcription factor of heat-shock responsive genes. Tissue-specific splicing is regulated by some RNA-binding proteins, named as splicing factor, which bind to pre-mRNA and activate or repress the splicing of specific exon. In this study, to clarify the machinery of brain-specific expression of eEF1BδL, we investigated splicing factor to regulate splicing of *Eef1d* pre-mRNA. Furthermore, it was shown that the function of translated eEF1Bδ protein is regulated by phosphorylation. Therefore, we also examined whether its activity is affected by phosphorylation and dephosphorylation.
Neuro-2a and HEK293 cells were transfected with siRNA of several splicing factors, and then total RNA was extracted. The expression levels of short and long variants were measured by RT-PCR using primers, which were designed across specific exon to long variant. To measure the phosphorylation state of eEF1BδL, primary cortical neurons were treated with heat stress, and

then subjected to western blot analysis.
We found the consensus sequences around specific exon to long variant, which splicing factor Nova1/2 and Mbnl1/2 are expected to bind to. When each protein is inhibited by siRNA in Neuro-2a cells, the expression of eEF1BδL mRNA significantly decreased by Nova2 inhibition, while Mbnl1/2 inhibition did not affect on that expression. Consistently, overexpression of Nova2 significantly increased eEF1BδL mRNA in HEK293 cells. On the posttranslational regulation, we found that its protein was dephosphorylated under heat stress. Next, we constructed plasmids expressing eEF1BδL with mutation of putative phosphorylation site and examined their transcriptional activity. As a result, the expression of mutant that mimic dephosphorylated state significantly increased transcription of heat-shock responsive reporter compared to wild-type.
In conclusion, it is suggested that the splicing to produce eEF1BδL is regulated by Nova2. After translated, transcriptional activity of its protein is regulated by dephosphorylation under heat stress. It was reported that *EEF1D* gene is related to neurodevelopmental disorders, therefore, our study provides useful insight for understanding the role of eEF1BδL in neural development.

Title: Sympathetic regulation of visceral adiposity and metabolism in a rat model of stress induced by sleep restriction

Authors: *L. E. AZUARA ALVAREZ, A. BÁEZ-RUIZ, O. RAMÍREZ-PLASCENCIA, S. CÁRDENAS-ROMERO, N. SADERI, R. SALGADO-DELGADO
Univ. Autónoma De San Luis Potosí, San Luis Potosi, Mexico

Abstract: The reduction of the hours dedicated to sleep is one of the most frequent causes of a stress response. Physiologically, stress is mediated by the Hypothalamus-Pituitary-Adrenal axis and the sympathetic nervous system. Prolonged stress, as it occurs of sleep insufficiency, increases plasma levels of corticosterone and catecholamine tone in the periphery. Metabolic homeostasis is particularly affected by stress and number of molecular and functional changes has been described in the adipose tissue (AT). In adipocytes, a mark of metabolic impairment

induced by stress is the increased activity of the 11β-Hydroxysteroid dehydrogenase type (11 β HSD1) enzyme, which catalyzes the local synthesis of glucocorticoids. In order to investigate the effect of sleep restriction-induced stress on both metabolic parameters and AT 11 β HSD1 levels/activity, we divided animal in 3 experimental groups: a group which was allowed to sleep for 6 hours (SR); a group that go through to sympathetic denervation of the AT (DX); a group that underwent to both sleep restriction and sympathetic denervation (SRDX), all of which were compared to control intact animals that slept *ad libitum* (CTL). The experimental protocol was carried out for 8 weeks, at the end of which animals were sacrificed. Body weight and food intake were monitored weekly. The glucose tolerance test (GTT) was performed on the eight week, before the sacrifice. Body temperature was registered by mean of a device placed intraperitoneally. During sacrifice, blood and AT samples were collected for the PCR analysis. Results showed that there were no changes in food intake among groups, but SR, DX and SRDX gained less weight; in particular, SRDX showed a significant decrease in AT mass. Denervation, but not sleep restriction, decreased the amplitude of body temperature daily fluctuations. Plasma adiponectin was augmented in SR, whereas leptin concentration was lower in SR and SRDX.These groups also showed glucose intolerance, although recovery was faster in denervated animals. Corticosterone levels were significantly higher in the SR group, whereas SRDX displayed intermediate levels between SR and CTL. In the AT, 11β HSD1 mRNA levels were upregulated in both DX and SRDX groups, while the enzymatic activity showed a significant increment only in DX animals. All these data demonstrate that indeed, sleep restriction induce a stress response and that affects metabolism. In addition we found that the sympathetic innervation has a protective role in the AT local glucocorticoids production

Abstract: Major depressive disorder (MDD) is a multifaceted, heterogeneous disorder and a leading cause of disability worldwide. The molecular changes that occur in the brain and body of depressed individuals and the extent to which common antidepressants influence these mechanisms to improve symptomatology remain poorly understood. To explore this, we utilized an ethologically validated mouse model of MDD where mice underwent chronic social defeat stress (CSDS) to induce MDD-like symptoms. A portion of the stressed mice display MDD-like behaviors, termed 'susceptible', whereas the remainder do not display MDD-like behaviors, termed 'resilient'. To capture the spectrum of molecular changes that occur within the brain and periphery, we performed metabolomic, lipidomic, and proteomic profiling on serum and on prefrontal cortex (PFC), nucleus accumbens (NAc), and ventral hippocampus (vHipp) of susceptible, resilient, and undefeated control mice. In serum, proteomic analysis identified 17 proteins affected in stress-exposed mice and three proteins uniquely affected in susceptible animals; lipidomic analysis identified >1170 lipid species and detected changes in resilient versus susceptible animals; and metabolomic analysis identified >50 significantly affected metabolites, and implicated dysfunctions in purine metabolism, fatty acid beta oxidation, and antioxidant function in stressed animals. In brain metabolomic analysis, we observed these same molecular pathways being differentially affected in susceptible versus resilient animals by brain region. Interestingly, we observed the same metabolites regulated in both the vHipp and NAc. However, changes observed in vHipp occurred within susceptible animals whereas changes observed in NAc occurred in resilient animals, suggesting that metabolic function of these regions may differentially contribute to stress susceptibility. Considering these findings, we investigated how an antidepressant affects these mechanisms to alleviate MDD-related symptoms. We performed injections of saline or 10 mg/kg imipramine and observed that imipramine treatment reversed MDD-like behavioral deficits, and specifically altered the levels of metabolites in the purine metabolism and fatty acid beta oxidation pathway to undefeated control levels. This work elucidates how brain region- and tissue-specific alterations in proteins, lipids, and metabolites are altered in a mouse depression model and how the behavioral effects of antidepressants are associated with regulation of key metabolic pathways. This approach reveals promising molecules and pathways as targets for potential therapies for MDD.

Title: The dimorphic role of apontic in olfaction and ethanol sedation in *Drosophila*

Authors: *F. J. VONHOFF, N. REGER
Dept. of Biol. Sci., Univ. of Maryland Baltimore County, Baltimore, MD

Abstract: Alcohol is a widely used drug that greatly affects the nervous system and animal behavior. In small quantities alcohol can cause hyperactivity while large quantities can have sedating effects. Numerous genes have been identified in *Drosophila melanogaster* that function in the sedating effect of ethanol including *apontic* (*apt*), a Myb/SANT-containing transcription factor. There is evidence suggesting that an animal's alcohol tolerance can alter its olfactory preference, although how this is accomplished molecularly is poorly understood. In order to better understand how *apt* functions within the nervous system to modulate an animal's response to ethanol a combination of olfactory and ethanol response assays were performed. Assays were performed on both males and females in order to identify potential sexual dimorphism in*apt* function. Both male and female *apt* mutants showed an increased resistance to ethanol vapor. Interestingly, even though *apt* mutants are more resistant to the sedating effects of ethanol it takes longer to recover from the sedated state, suggesting that these animals have a "hangover" like phenotype. In order to determine whether ethanol resistance because of *apt* can impart a change in olfactory preference, animals were presented with traps containing apple juice and apple juice supplemented with ethanol. At low concentrations ethanol enhances the attractiveness of the apple juice for wildtype flies, but at high concentrations ethanol becomes aversive, and flies will preferentially choose non-supplemented apple juice. *apt* mutants demonstrated a continued preference for apple juice supplemented with ethanol. Surprisingly, *apt* animals showed a decrease in response rate in olfactory assays with *apt* females (WT=86.0±0.0%, n=2, *apt*=4.9±2.2%, n=2) responding significantly less frequently than *apt* males (WT=88.7±4.7%, n=3; *apt*=42.0±9.0%, n=2). This suggests a novel role for *apt* in the development or function of the olfactory system. These results suggest that *apt*may function broadly within the nervous system during development as well as adulthood in order to generate wild-type ethanol behavior.

Title: Sex-specific behavioral endocrinology of BDNF Val66Met mice maintained on chronic oral corticosterone

Authors: *J. MARROCCO[1], N. R. EINHORN[1], G. H. PETTY[1], C. LE FLOCH[1], I. N. KARATSOREOS[2], F. S. LEE[3], B. S. MCEWEN[1]

Abstract: Sex and gender influence a variety of behaviors beyond reproduction, including the response to stress. Overexposure to stress induces chronically elevated cortisol/corticosterone (CORT) levels, leading to allostatic overload and sex-specific susceptibility to psychiatric disorders and metabolic dysfunctions. Little is known about the factors that may aggravate the effects of CORT overexposure, such as genetic variants and biological sex. Exogenous, chronic low-doses of CORT have been shown to blunt the endocrine response to stress, without disrupting the rhythmic levels of plasma CORT. Using a model of non-invasive chronic CORT treatment in mice, we investigated the metabolic and behavioral effects of oral CORT in heterozygous BDNF Val66Met (Het-Met) male and female mice, a model of genetic sensitivity to stress. Het-Met and wild type (WT) mice were treated with CORT (25mg/L) or vehicle in drinking water for 8 weeks. During treatment, a battery of behavioral tests was performed, body weights were recorded weekly, and blood was collected to measure glycaemia. We found that oral CORT did not affect body weight in either sex, but Het-Met females exhibited higher body weight than WT females independently of treatment. Fasting glycaemia was lower in CORT-treated males regardless of genotype, whereas Het-Met females showed reduced fasting glycaemia levels compared to WT females regardless of treatment. CORT-treated mice of either sex, but not Het-Met females, displayed lower adrenal gland mass than vehicle-treated mice. Consonant with that, CORT-treated mice of either sex, except Het-Met females, exhibited lower levels of glucocorticoid receptor (*Nr3c1*) in the ventral hippocampus. This suggested a lack of plasticity in females carrying the BDNF Met allele. Anxiety- and depressive-like behaviors, referred to as emotional behavior, were tested with the light-dark box and the splash test, respectively. When a z-normalization was applied across complementary measures of emotional behavior, we demonstrated that CORT significantly decreased z-score in Het-Met females but had an opposite effect in WT and Het-Met males. These findings indicate that the chronic oral

CORT model highlights sex-specific sensitivity to CORT overexposure that intersects the Met genotype.

Title: Cross-species epigenetic signature of stress-related psychiatric disorders

Authors: *N. R. EINHORN[1], H. LI[2], K. F. BERMAN[3], D. GOLDMAN[4], F. S. LEE[5], P. J. SCHMIDT[6], B. S. MCEWEN[1], J. MARROCCO[1]

Col., New York, NY; [6]Behavioral Endocrinol. Br., Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Behavioral neuroscience has used animal models of environmental and genetic sensitivity to stress to investigate targets for the treatment of mental health disorders. This research identifies genes conserved across species that may also serve a greater biological purpose, such as adaptation to environmental challenges. Here, we emphasized genes that regulate gene expression independently of cell type using comparative whole-genome RNA-seq analysis, encompassing mouse models and human studies. To this end, we used mice subjected to acute stress and ovariectomized mice treated with estradiol that were wild type (WT) or heterozygous for the BDNF Val66Met single-nucleotide polymorphism (Het-Met), which alters the sensitivity to stress. Human data consisted of subjects diagnosed with a spectrum of psychiatric disorders. RNA-seq data of a homogenous population of CA3 pyramidal neurons or ventral hippocampus (vHPC) isolated from mice were compared to data of central or peripheral tissues obtained from humans. When comparing mouse brains and lymphoblastoid cell lines isolated from women with premenstrual dysphoric disorder or healthy controls, we found genotype (mouse)- and diagnosis (human)-specific overlaps of several epigenetic modifiers. These genes included the Extra Sex Comb/Enhancer of Zeste (ESC/E(Z)) complex, an effector of

response to ovarian steroids. In the CA3 pyramidal neurons of another subset of mice, acute stress affected the expression levels of signaling- and transcription-related genes that were also shared across major psychiatric disorders (i.e. bipolar disorder, major depressive disorder, alcoholism, autism spectrum disorder, and schizophrenia). Interestingly, a number of regulatory genes that overlapped across species and cell types showed a pre-stressed and a pre-estrogen effect in Het-Met mice, i.e. the same genes that were activated without stress or estradiol were also induced in WT mice by stress or estradiol treatment. These findings suggest that the BDNF Met allele induces an epigenetic signature that recapitulates that of subjects who are vulnerable for major psychiatric disorders. Animal models of stress-related disorders can help shed light on epigenetic markers conserved across species relevant for novel diagnostic and therapeutic interventions.

Title: Control over stress engages a corticostriatal projection for the production of long-term stress resilience

Authors: *M. V. BARATTA, S. D. DOLZANI, I. P. FALLON, N. R. LESLIE, J. AMAT, G. D. TRAHAN, R. A. LAYNES, L. R. WATKINS, S. F. MAIER
Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Behavioral control over stress not only blunts the impact of the adverse event being controlled, but also blunts the impact of future adverse events, even those that are uncontrollable (termed “behavioral immunization”). The stress-buffering effects of behavioral control are enduring, trans-situational, and require the prelimbic region (PL) of the medial prefrontal cortex. It has been argued that the PL is critical to this process, in part, because it participates in a corticostriatal system that is sensitive to action-outcome contingencies that lead to what can be called an “expectation”. Here we investigated the role of the corticostriatal system in producing behavioral immunization. In EXP1, infusion of the NMDA antagonist, D-AP5 (30 mM), into

bilateral dorsal medial striatum (DMS) during the initial experience with control blocked the typical long-term protective effects of controllable stress. EXP2 and EXP3 addressed if the critical glutamatergic input to the DMS originates from the PL. DMS-projecting PL neurons were retrogradely labeled following deposit of fluorescent retrobeads in the DMS. Relative to yoked uncontrollable stress and home cage controls, controllable stress selectively increased Fos expression in retrobead-positive PL-to-DMS layer V neurons. Next we used a Cre-dependent, intersectional viral vector approach to express $G_{i/o}$-DREADDs selectively in PL afferents to DMS. Chemogenetic inhibition of this pathway also prevented the production of behavioral immunization. Lastly, EXP4 sought to determine if PL-to-DMS neurons, hypothesized to "DETECT" behavioral control, represents the same or separate population of PL cells hypothesized to "USE" control information to inhibit stress-responsive brainstem structures (PL-to-Dorsal Raphe Nucleus). Retrobeads tagged with different fluorescent markers labeled completely different but intermingled populations of PL layer V neurons following injection into DMS and DRN. In sum, the action-outcome corticostriatal circuit is critical for the production of behavioral immunization, but how control-related information transfers from the DETECT to USE systems remains unknown.

Title: Role of Akt in JAK2-mediated regulation of Arc expression in the orbitofrontal cortex-effects on reversal learning

Authors: *M. GIROTTI, J. D. SILVA, D. A. MORIALK
Pharmacol., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Cognitive flexibility is the ability to modify established behaviors or previous learning in response to a change in the environment. Reversal learning is a specific form of cognitive flexibility predominantly mediated by the orbitofrontal cortex (OFC). Our laboratory has shown that rats exposed to chronic intermittent cold stress (CIC, 6h per day at 4°C for 2 weeks), exhibit a selective and replicable cognitive deficit in reversal learning that resembles cognitive

components of stress-related psychiatric illnesses.
Using this model, we have found that basal activity of JAK2/STAT3 signaling in the OFC is required for optimal performance in reversal learning and that CIC stress reduces JAK2 activation in the OFC. Importantly, an acute injection of ciliary neurotrophic factor (CNTF), an endogenous activator of JAK/STAT, into the OFC increases JAK2 phosphorylation and corrects reversal-learning deficits produced by CIC stress. This phenomenon is observed also when CNTF is administered 24 h before testing, implying that activation of JAK2 results in long-term plastic changes in the OFC. Supporting this hypothesis, we have observed that silencing JAK2 reduces the expression of the synaptic plasticity protein Arc in primary neurons. In the present study, we set out to test the mechanism by which JAK2 regulates Arc, and its impact on reversal learning.
Interestingly, silencing STAT3, a major effector of JAK2 activation, in primary neurons did not impact Arc expression, suggesting the involvement of an alternate pathway. Indeed, within the OFC, we observed that low doses of CNTF did not increase activated STAT3 (pSTAT3) but did increase levels of pJAK2, pT-Akt and Arc, pointing to Akt as a potential intermediary. In support of this, we find that injecting a PI3 kinase inhibitor (LY294002, 4.3ng/0.5ul/side) into the OFC, 5 min before CNTF blocks Akt activation and prevents the increase in Arc levels produced by the neurotrophin.
In ongoing experiments we are testing the impact of LY294002 on reversal learning, predicting that inhibition of Akt will prevent the beneficial effects of CNTF on reversal learning in stress-compromised rats. In future experiments we will continue to test potential downstream effectors of Akt signaling involved in regulation of Arc expression. These studies will test the potential utility of targeting endogenous JAK2 signaling as a novel approach to treating cognitive impairment in stress-related psychiatric disorders.

Title: The role of the insula in anxiety

Authors: *J. STEHBERG[1], S. LINSAMBARTH[2], F. PEÑA[2], P. MUÑOZ[3], T. BAHAMONDE[2], D. QUINTANA[2]

[1]Univ. Andres Bello, Santiago, Chile; [2]Ctr. de investigaciones Biomédicas, Univ. Andrés Bello, Santiago, Chile; [3]Univ. de Valparaiso, valparaiso, Chile

Abstract: Abstract
The Insula has been associated to anxiety and anxiety-related disorders in humans, but a systemic study of its role on anxiety in rodents has not been performed to date. Here we present a series of studies using *in vivo* pharmacology and the elevated plus maze (EPM) in rats to determine the role of the insula in anxiety, to identify the regions within the insula that are relevant for anxiety and the cellular pathways by which stress hormones act on the insula to modulate stress responses and anxiety. We have found using AMPA antagonist CNQX intra-insular microinjections that different regions within the insula show differential involvement in anxiety. Pharmacological manipulation of the insula before EPM showed that anxiety is modulated by actions of noradrenaline and glucocorticoids at the insula, mediated by adrenergic, mineralocorticoid and membrane glucocorticoid receptors, and that noradrenaline inhibits slow spiking interneurons at the insula.

Title: Chronic stress causes circuit specific loss of inputs to the posterior parietal cortex

Authors: *G. LUR[1], Y. LIBOVNER[1], D. TABBA[1], M. HOLLEARN[2]
[1]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA; [2]California State Long Beach, Long Beach, CA

Abstract: Severe loss of excitatory synapses in key brain regions is thought to be one of the major mechanisms behind stress induced cognitive impairment. To date however, the identity of the affected circuits is elusive. Here we examined the effect of chronic, multi-modal stress on the connectivity of the posterior parietal cortex (PPC). We found that stress lead to layer specific elimination of excitatory synapses with the most pronounced loss observed in layer 1 and 5. Fluorescent labeling of input pathways highlighted that these layers are targeted by sensory feed-forward and frontal top-down axons. Quantitative analysis of these projections revealed a significant loss of sensory and frontal inputs to the PPC while contralateral projections were unaffected. The PPC is considered to be a cortical hub for multisensory integration, working memory and perceptual decision making. Our data suggests that sensory and top-down

information streams targeting the PPC are severely impacted by chronic stress, likely contributing to stress induced cognitive impairment.

Title: Exercise-induced neuronal activation differs following acute and chronic exposure to wheel running

Authors: *T. Y. YANG, J. C. GARDNER, N.-C. LIANG
Psychology, Univ. of Illinois-Urbana Champaign, Champaign, IL

Abstract: Acute exercise is a stressor that has immediate effects on energy metabolism whereas chronic exercise can become rewarding and produce multiple beneficial effects, including the maintenance of a healthy body weight and improvement of emotional and cognitive function. Human studies have found increased functional connectivity in the cortical network, which includes the insular (IC) and medial prefrontal cortex (mPFC), following chronic exercise. However, changes in neuronal activation following acute versus chronic exercise in this network have not been explored. We hypothesized that adaptation to exercise will alter patterns of neural activation in the IC and mPFC. To test this hypothesis, male Sprague-Dawley rats were exposed to acute (1 day) or chronic (18 days) wheel running (WR) after habituating to the running wheel cages with the wheel locked. The control rats remained sedentary (Sed) in standard cages throughout these periods. On the day of sacrifice, running activity was closely monitored starting 2 h before dark onset. WR rats were perfused ~1.5 h after a running burst (189 ± 41 revolutions). Brain sections of WR and Sed rats were processed for c-Fos immunohistochemical staining. c-Fos positive cells, which are indicative of neural activation, were quantified and analyzed in the mPFC and IC. Results showed that acute WR rats had significantly higher c-Fos immunoreactivity in both the mPFC and IC than their Sed controls whereas this was only true for the IC in chronic WR rats. Although the amount of running during the running burst did not differ, running induced greater neural activation in both the mPFC and IC in acute compared with chronic WR rats. Additionally, the amount of WR during the running burst was positively correlated with the number of c-Fos positive cells in the mPFC, but not IC, in chronic running rats. The result that neural activation in the mPFC and IC was lower after chronic relative to acute exercise implies that the chronic WR rats may have adapted to the stress of exercise.

Furthermore, the positive correlation between running activity and mPFC neuronal activation suggests that the mPFC, but not IC, may be responsible for mediating effects that are associated with the amount of exercise.

Title: Dynamic change of resting-state functional connectivity associated with acute stress

Authors: *M. KITAWAKI[1], M. R. DELGADO[2], M. HARUNO[3]
[1]Grad. Sch. of Frintier Biosci. Osaka Univ., Ibaraki-Shi, Japan; [2]Dept Psychol, Rutgers Univ. Newark, Newark, NJ; [3]Natl. Inst. of Information and Communication Technol., Osaka, Japan

Abstract: The experience of acute stress can have significant consequences on human behavior and well-being. While the effects of stress are often discussed in the context of particular processes, such as decision making (e.g., Porcelli & Delgado, 2017), less is known about the influence of stress on neural circuits when an individual is at rest and not performing a task. A previous study proposed that the abnormal activity of resting state brain networks (RSNs) under stress may work as a neurobiological marker for stress-induced increases in emotionality (Soares et al., 2013). However, systematic understanding of the whole-brain RSN dynamics in association with acute stress experience is still lacking. Here, we investigated whole-brain RSNs dynamics before and after the Cold pressor test (Silverthorn et al., 2013) using high temporal and spatial resolution 3T fMRI (TR=1s, 2x2x2 mm voxel, 10 minutes). Region of interest (ROI)-to-ROI resting-state functional connectivity analysis was conducted using the Functional Connectivity toolbox on MATLAB (CONN). Participants (n=25) were required to undergo a baseline resting-state fMRI scan. They were then exposed to the Cold pressor test, involving immersion of one hand in ice water (3~4 degrees Celsius) for 2 minutes. Next, they were scanned for a second resting-state fMRI session. Salivatory cortisol was acquired from participants to assess stress levels at different times: before and after the baseline scan; after the Cold pressor test, after the second scan and 20 minutes post experimental session. We found that general functional connectivity during baseline (first) scan was diminished post stress as observed in second scan. We hypothesized that functional connectivity changed dynamically during the second scan. Therefore, we analyzed the first and second half of the second scan separately. Most importantly, the caudate nucleus was found to constitute a network hub in the first 5 minutes of the post-stress scan ($p < 0.05$, FDR correction). In contrast, functional connectivity in the second half was highlighted by enhanced connections between regions such

as the premotor cortex, primary somatosensory cortex and temporopolar area ($p < 0.05$, FDR correction). These results highlight the dynamic change of RSNs and caudate centered network structures under acute stress.

Title: Effects of adverse maternal care on prefrontal cortex, hippocampal, and amygdalar development in rhesus monkeys: Relationship with brain serotonin function

Authors: *A. RATLIFF[1,2], K. KUITCHOUA[2], B. KOCHOIAN[2], E. L. MORIN[1,2], B. R. HOWELL[1,2,3], Z. KOVACS-BALINT[2], M. STYNER[4], M. SANCHEZ[1,2]

Abstract: Early life stress (ELS) is a major risk factor for numerous psychopathologies and social deficits. Adverse maternal care, including childhood maltreatment (abuse and neglect), is a devastating form of ELS and co-occurs with rapid brain development, leading to long-term effects on brain and behavioral development. How maternal maltreatment (MALT) affects neurobehavioral development is still not well understood. Additionally, it is difficult to isolate the effects of maltreatment from heritable factors in human studies. To circumvent these difficulties, we utilized a well-established cross-fostering design in a highly translational rhesus monkey model. Maternal care in rhesus macaques is similar to humans, and spontaneous maternal MALT occurs at rates comparable to human populations. Here we studied potential neurodevelopmental alterations underlying increased stress and emotional reactivity reported in MALT animals, focusing on the development of brain serotonin (5HT) and structural development of the amygdala, hippocampus and prefrontal cortex, all during the infant and

juvenile periods. We collected (1) structural MRI in 42 infant rhesus monkeys (20 Control (11 F, 9 M), 22 maltreated (MALT; 8 F, 14 M)) during infancy (2 wks, 3, 6 mo) and the juvenile period (12, 18 mo), and (2) cerebral spinal fluid (CSF) samples to measure central levels of 5HIAA, the main 5HT metabolite. Replicating previous reports in this model, MALT animals had lower CSF levels of 5HIAA than controls at 12 months of age ($t(29) = 1.71$, $p = 0.048$). In a subset of animals, (8 Control (5 F, 3 M), 7 MALT (3 F, 4 M)), we found group by age interactions in total brain volume ($F_{2,13} = 3.76$, $p = 0.04$, $\eta^2 = 0.22$), grey matter volume in the prefrontal cortex ($F_{2,13} = 5.45$, $p = 0.01$, $\eta^2 = 0.30$), and hippocampal volume ($F_{2,13} = 4.07$, $p = 0.03$, $\eta^2 = 0.24$), so that MALT animals showed blunted volumetric growth of total brain size, as well as region-specific volumes, emerging at the later ages. There was a negative correlation between maternal rejection rates during infancy and rate of growth in right hippocampus such that animals that experienced higher rates of rejection were at greatest risk for reduced hippocampal growth ($r=-0.638$, $p=0.035$). Studies in rodents suggest that early tactile stimulation is important for the development of 5HT in hippocampus, supporting that reduced levels could in turn play a role in its growth. We are currently exploring the possibility that reduced serotonin in the CSF is related to reduction in hippocampal volume. We plan to extend these studies to include the remaining subjects, additional regions of interest, and analysis of all time points collected.

Title: DTI-identified cerebral microstructural changes in mice overexpressing CRF in the forebrain

Authors: *J. DESLAURIERS[1,4], M. TOTH[1,4], M. SCADENG[2], R. RISSMAN[3], V. RISBROUGH[1,4], G. BROWN[1]
[1]Psychiatry, [2]Radiology, [3]Neurosciences, Univ. of California San Diego, LA Jolla, CA; [4]Veterans Affairs Ctr. of Excellence for Stress and Mental Hlth., La Jolla, CA

Abstract: Background/hypothesis: Corticotropin releasing factor (CRF) regulates endocrine and behavioral responses to stress. Excess CRF signaling has been linked to alterations in cortical and hippocampal functions, spine formation and related cognitive functions. In humans, CRF levels are increased in the cerebrospinal fluid of individuals with childhood trauma history and

some mood and anxiety disorders. By using diffusion tensor imaging (DTI), a methodology translatable across species, we tested the hypothesis that forebrain-specific CRF overexpression induces changes in brain microstructure, specifically in the medial prefrontal cortex (mPFC) and dorsal hippocampus (dHP).
Methods: Male and female mice with inducible forebrain-specific CRF overexpression were generated by crossing two genetically modified mouse lines carrying a CaMKIIα promoter-driven rtTA2 transgene and a doxycycline-regulated tetO promoter fused to the CRF gene to produce double mutant mice. CRF overexpression was induced with doxycycline (DOX) administration in mouse chow at a dose of 3.5 mg/g body weight/day from postnatal day ~90 - 120, after which DOX was removed. DTI was performed at three time points in each animal: baseline (before DOX treatment), ~3 weeks of DOX treatment, and again ~3 months after DOX treatment was ended. Histology showed significant increases in CRF protein levels in the cortex and hippocampus 3 weeks after start of treatment, which returned to normal 3 months after treatment had ended. DTI parameters fractional anisotropy (FA) and mean diffusivity (MD) were assessed in the mPFC and dHP.
Results: In the mPFC, CRF-overexpression induced a decrease in FA in male and female mice only 3 weeks after start of DOX treatment. No effect of time, CRF-overexpression or sex was found on MD. In the dHP, no significant effect of CRF-overexpression or time was found on FA in both males and females. In male mice, MD increased with time in the dHP of control mice, with significant higher MD 3 months after the first scan, whereas no change in MD was found across time in mice overexpressing CRF. These effects were not observed in females.
Discussion: CRF-overexpression was associated with cortical microstructural changes in the mPFC and appeared, surprisingly, to block aging-related elevations in MD, suggesting some potential modulatory effects of CRF on hippocampal microstructure. Previous studies implicate CRF both as a potential protective factor and a driver of tau-pathology in aging-related neurodegeneration. Future studies are required to delineate the mechanisms underlying the region-specific effects of CRF-overexpression, as well as the aging-induced effects on MD.

Title: Inhibition of prefrontal monoacylglycerol lipase promotes stress resilience

Authors: *N. B. WORLEY[1], J. A. VARELA[1], G. P. GAILLARDETZ[1], M. N. HILL[2], J. P. CHRISTIANSON[1]

Abstract: Neural activity within the ventromedial prefrontal cortex (vmPFC) is a critical determinant of stressor-induced anxiety. Pharmacological activation of the vmPFC during stress protects against stress-induced social anxiety suggesting that altering the excitatory/inhibitory (E/I) tone in the vmPFC may promote stress resilience. E/I balance is maintained, in part, by endogenous cannabinoid (eCB) signaling with the calcium dependent retrograde release of 2-arachidonoylglycerol (2AG) suppressing presynaptic GABA release. We hypothesized that raising 2AG levels, via inhibition of its degradation enzyme monoacylglycerol lipase (MAGL) with KML29, would shift vmPFC E/I balance and promote resilience. In acute slice experiments, bath application of KML29 (100nM) augmented evoked excitatory neurotransmission as evinced by a left-shift in fEPSP I/O curve, reduced paired-pulse facilitation, and decreased sEPSC amplitude and frequency. In vmPFC whole-cell recordings, KML29 increased resting membrane potential but reduced the after depolarization, bursting rate, membrane time constant and slow after hyperpolarization. Systemic administration of KML29 (40mg/kg, i.p.) 2h prior to inescapable stress (IS) exposure (25, 5s tail shocks) exacerbated the reduction in juvenile social exploration observed after IS in male rats that received vehicle injections. Conversely, intra-vmPFC (200ng/0.5μL/hemisphere) administration blocked the reduction in juvenile social exploration typically observed after IS. Raising 2AG in the vmPFC may promote resilience by augmenting the output of neurons that project to the proximal neural mediators of the stress response. The results support the continued investigation of the eCB system in stress resilience and susceptibility.

Title: A prefrontal-bed nucleus circuit limits both HPA output and passive coping behaviors

Authors: *S. B. JOHNSON[1], R. T. LINGG[1], E. B. EMMONS[2], R. M. ANDERSON[3], S. A. R. ROMIG-MARTIN, 52242[3], R. T. LALUMIERE[3], N. S. NARAYANAN[4], J. J. RADLEY[3]
[2]Interdisciplinary Neurosci. Program, [3]Dept. of Psychological and Brain Sci., [4]Dept. of Neurology, Carver Col. of Med., [1]Univ. of Iowa, Iowa City, IA

Abstract: The prelimbic subfield (PL) of the medial prefrontal cortex has received considerable attention for its role in directing behavioral, endocrine, and autonomic stress responses, yet the efferent pathways underlying these vital systems have yet to be elucidated. Our previous work has implicated the anteroventral subdivision of the bed nuclei of the stria terminalis (avBST) as a neural hub for the coordination of hypothalamo-pituitary-adrenal (HPA) and behavioral responses via divergent pathways to the paraventricular nucleus of the hypothalamus and ventrolateral periaqueductal gray area (vlPAG), respectively. These observations and those of tract tracing studies raise the prospect that avBST acts as a substrate for the prefrontal cortex to coordinate neuroendocrine and behavioral output and thus bias the organism toward certain response strategies. To assess this putative role, we employed an optogenetic approach to bidirectionally manipulate PL-avBST pathway activity while measuring HPA and behavioral responses during acute challenges. Photoinhibition of halorhodopsin(Halo)-expressing PL neuron axons in avBST during 10 min tail suspension augmented both immobility ($p<0.05$) and HPA output (adrenocorticotropin hormone 10 min, and corticosterone 30 min after stress onset; $p<0.05$), as compared with YFP controls. Photoexcitation of the pathway diminished passive immobility behavior ($p<0.05$) while HPA output was unaffected ($p>0.05$). Next, we examined the role of this circuit in the shock-probe defensive burying (SPDB) test which allows animals to engage in a broader range of behaviors, including both active (burying) and passive (immobility) coping responses. Animals receiving photoinhibition of the PL-avBST pathway spent more time immobile ($p<0.05$) and buried less than YFP controls ($p<0.05$). Photoexcitation of the pathway diminished freezing ($p<0.05$) but was insufficient to enhance burying behavior relative to YFP counterparts ($p>0.05$). Given recent evidence from our group implicating the avBST-vlPAG pathway in passive behavioral output, we next examined whether this pathway might act downstream of the PL-avBST pathway to modulate coping behavior. Here, animals receiving photoinhibition of the avBST-vlPAG pathway spent more time immobile ($p<0.05$) and buried less than YFP controls ($p<0.05$), recapitulating the effects of PL-avBST photoinhibition. Together, these studies point to a novel multisynaptic pathway mediating stress coping responses. Moreover, this work may point to a circuit mechanism linking withdrawal of top-down control with aberrant behavioral and endocrine responses in stress-related disorders.

Title: Enhanced activity of a vmPFC-DRN neural circuit in resistance to acute social defeat stress

Authors: *A. GRIZZELL[1], T. CLARITY[2], B. N. DULKA[2], M. A. COOPER[1]
[1]Dept. of Psychology, [2]Univ. of Tennessee, Knoxville, TN

Abstract: The ventromedial prefrontal cortex (vmPFC) plays a critical role in stress resilience through top-down inhibition of key limbic and hindbrain structures, including the dorsal raphe nucleus (DRN). Our laboratory developed a model of experience-dependent stress resistance in Syrian hamsters wherein following 14 days of dyadic encounters, dominant animals display less submissive/defensive behavior following an acute social defeat compared to their subordinate counterparts or social status controls. Subregions of the vmPFC are more active in dominant hamsters and pharmacological inhibition of the vmPFC prevents resistance to the effects of social defeat in dominants. While the DRN is a critical neural substrate regulating the effects of social defeat stress, it is unknown whether status-dependent differences in defeat-induced anxiety are associated with activity in a vmPFC-DRN circuit. In this project, we stereotaxically injected the retrograde tracer, Cholera Toxin B (CTB), into the DRN of dominant and subordinate hamsters as well as social status and non-stressed controls. After the formation of dominance relationships, animals were then exposed to an acute social defeat stress and euthanized 60 minutes afterward for a determination of defeat-induced neuronal activity via cFos protein expression. Preliminary immunohistochemical data demonstrate that dominant hamsters display more cFos and cFos + CTB labeled cells in both the infralimbic (IL) and prelimbic (PL) subregions of the vmPFC compared to subordinates and controls. These findings suggest that the reduced behavioral consequences of acute social defeat are associated with increased activity in a vmPFC-DRN pathway. Overall, social dominance may activate vmPFC neurons that are capable of inhibiting stress-induced DRN activity and thereby promote stress resistance.

Title: Neuroendocrine correlates of dominance relationships in female Syrian hamsters

Authors: A. L. LOEWEN, B. N. DULKA, J. A. GRIZZELL, A. V. CAMPBELL, *M. A. COOPER
Dept. of Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: Understanding the neuroendocrine mechanisms that support stress resilience is an early step toward developing more effective treatment options for patients who suffer from stress-related psychopathologies. Although social defeat models in male rodents are frequently used to investigate the cellular mechanisms of stress susceptibility and resilience, much less research has included female subjects. We have previously shown that male Syrian hamsters exhibit elevated social avoidance following acute social defeat stress. Interestingly, male hamsters with dominant social status exhibit elevated plasma testosterone, increased androgen receptor expression in the medial amygdala (MeA) and less defeat-induced social avoidance compared to subordinates and controls. The objective of this study was to investigate whether female hamsters show status-dependent differences in defeat-induced social avoidance and androgen and estrogen receptor expression in the MeA. Adult female hamsters were matched according to their estrous cycle and paired in 12 daily social encounters to establish dominance relationships. To avoid dyadic encounters when females were in estrous, we skipped encounters every four days. Immediately before the first dyadic encounter, 15 min after the first dyadic encounters, and 15 min after the 12^{th} dyadic encounter, blood was collected via retro-orbital eye bleed. After the final dominance encounter, animals experienced acute social defeat stress and 24 hours later received a social interaction test with a same-sex, unfamiliar, confined hamster. While acute social defeat stress produced social avoidance in the female hamsters, dominance status did not alter social avoidance, plasma testosterone, or androgen receptor expression in the MeA. We are currently testing whether dominance status alters the expression of estrogen-alpha and estrogen-beta receptors in the MeA. These findings suggest a sex-difference in the neuroendocrine mechanisms controlling the effects of social status on defeat-induced changes in behavior. This line of research improves our understanding of the neuroendocrine mechanisms regulating sex-differences in vulnerability to stress-related mental illness.

Title: The link between dominance status and passive and active coping strategies

Authors: *M. CANNON, E. L. GRAHAM, M. D. BURZINSKI, M. A. COOPER
Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: There are a great deal of individual differences in how humans and other animals cope with stress. Differences in coping abilities are linked to several environmental factors, including social dominance. The present study investigated whether coping strategies predict dominance status in male and female Syrian hamsters and whether the maintenance of dominance relationships alters subsequent coping strategies. We hypothesized that hamsters showing an active coping strategy would be more likely to achieve dominant social status compared to hamsters with a passive coping strategy. Also, we hypothesized that the maintenance of dominance relationships would increase active coping strategies in dominants and passive coping strategies in subordinates. Finally, we investigated whether changing dominance status would similarly change coping strategies. Male and female hamsters were weight-matched and paired with a same-sex partner in daily aggressive encounters for two weeks. Dyads quickly formed a dominance relationship that remained stable throughout the study. To assay coping strategies before and after the formation of dominance relationships, we tested animals in a series of behavioral tests, including open field, novel object exploration, elevated zero maze, light/dark transition, Porsolt forced swim, and social defeat tests. We found that dominance status has a greater effect on stress-induced anxiety-like and depression-like behavior in male hamsters compared to female hamsters. Because most preclinical neuroscience research is conducted exclusively in male animals, these data will extend our understanding of sex-differences in the expression of passive and active coping strategies. In addition, these data indicate that dominance status plays a role in the development of coping strategies and stress vulnerability.

Title: Chemogenetic activation of an infralimbic cortex to basolateral amygdala neural projection and resistance to conditioned defeat

Authors: *B. N. DULKA, E. D. BAGETALAS, K. S. BRESS, M. A. COOPER
Univ. of Tennessee, Knoxville, TN

Abstract: Stress is a contributing factor in the development of several mood and anxiety disorders, although there are significant individual differences in vulnerability. Animal models of social defeat are used to investigate the biological basis of stress susceptibility and resilience. Male Syrian hamsters are highly aggressive and territorial, but after an acute defeat experience they exhibit a conditioned defeat (CD) response which is characterized by increased submissive behavior and a failure to defend their home territory in a social interaction test with a smaller, non-aggressive intruder. Hamsters that achieve dominant social status show increased c-Fos expression in the infralimbic (IL) cortex following social defeat and display a reduced CD response at testing compared to subordinates and controls. Moreover, dominant hamsters show increased defeat-induced neural activity in IL neurons that send efferent projections to the basolateral amygdala (BLA) compared to subordinates and controls. In the current study, we aimed to determine if selective activation of these IL-to-BLA projections using Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) is sufficient to induce CD resistance in subordinates. To answer this question, we used a dual virus approach and injected a Cre-dependent Gq DREADD virus into the IL and a retrograde Cre virus into the BLA. This dual virus approach was first validated through c-Fos analysis. Next, we performed a control experiment to ensure that clozapine-N-oxide (CNO), the drug that activates the DREADD vector, in itself has no effect on CD behavior. Finally, we tested whether CNO-treated subordinate hamsters show a reduced CD response compared to vehicle-treated subordinates. This project extends our understanding of the neural circuits underlying resistance to social stress, which is an important step towards delineating a circuit-based approach for the prevention and treatment of stress-related psychopathology.

Title: Exploring the effects of locus coeruleus corticotropin-releasing factor on cortical network activity

Authors: *S. BATES[1], J. ARNER[2], A. L. CURTIS[3], S. BHATNAGAR[4]
[1]CHOP, Philadelphia, PA; [2]Res., Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Dept Anesthesiol., Children's Hosp. Philadelphia, Philadelphia, PA; [4]Dept Anesthesiol., Univ. Pennsylvania, Children's Hosp Philadelphia, Philadelphia, PA

Abstract: The LC is part of a stress responsive system that is involved in arousal and cognitive function. This is accomplished through extensive projections to many regions, including the prefrontal cortex (PFC). The reciprocal connection between the LC and the PFC has been shown to underlie the role of arousal on cognition. Additionally, this circuit is disrupted following chronic stress, which is thought to underlie impairment in executive function that arises during stress. Evidence suggests that stress-induced alterations of LC activity are mediated through the release of corticotropin-releasing factor (CRF) in the LC. A previous study from our lab in male animals showed that intracoerulear infusion of 20ng of CRF impacted performance in the attentional set shifting task, which engages the orbitofrontal cortex (OFC) and medial prefrontal cortex (mPFC). However, it is unknown how CRF release in the LC affects network activity of neurons in the OFC and in the mPFC to influence behavior. This study examined the effects of CRF administered into the LC of male and female rats on mPFC and OFC network activity, measured as local field potentials (LFPs). In awake, behaving animals, network activity was recorded in the mPFC and OFC for 30 minutes before and after intracoerulear infusion of aCSF or 20ng of CRF in male and female adult rats through a cannula. Following this, power spectral density (PSD) was calculated. Preliminary data (n=3/group) suggest that, following CRF infusion, there is increased activity in the beta frequency band in the OFC in both sexes, increased theta activity in the mPFC in females, and increased beta activity in mPFC in males as compared to their respective aCSF (control) groups. This is the first analysis of the effect of LC activation with CRF on network activity in these cortical areas and the preliminary results suggest a greater impact on cortical network activity following CRF actions in the LC of females compared to males. These data are consistent with sex differences in CRF receptor internalization. In ongoing studies, we are examining additional doses of CRF in both sexes and

determining if activating LC with CRF affects performance in the attentional set-shifting task in female rats, a paradigm that is dependent on cortical activity.

Title: Examining coherence between locus coeruleus and cortical network activity

Authors: *J. ARNER[1], S. BATES[2], A. L. CURTIS[3], S. BHATNAGAR[4]
[1]Res., Children's Hosp. of Philadelphia, Philadelphia, PA; [2]CHOP, Philadelphia, PA; [3]Dept Anesthesiol., Children's Hosp. Philadelphia, Philadelphia, PA; [4]Dept Anesthesiol., Univ. Pennsylvania, Children's Hosp Philadelphia, Philadelphia, PA

Abstract: The locus coeruleus (LC) is a major stress response system that is involved in arousal, vigilance and cognitive function. This is accomplished through extensive projections to several regions, including the prefrontal cortex (PFC). The reciprocal connection between the LC and the PFC underlies the role of arousal on cognition. Additionally, this circuit is disrupted following chronic stress, and this disruption is thought to underlie impairments in executive function that arise during stress. Interestingly, different activation levels of LC are associated with various cognitive states. More specifically, “phasic” LC activation underlies focused attention and task-oriented processes, while “tonic” LC activation underlies scanning attention and cognitive flexibility. While it is known that the LC-PFC circuit underlies these cognitive states, little is known about whether different levels of LC activity might drive distinct cortical regions to produce these cognitive states. We designed a study to examine functional connectivity between LC and PFC using network activity by assessing coherence in local field potentials (LFPs). Initial results with adult males (n=8) are reported here. Specifically, we recorded LFPs from medial prefrontal cortex (mPFC) and orbitofrontal cortex (OFC) because of our previous data revealing their roles in facilitating extradimensional shifting and reversal learning, respectively. Coherence is the result of complementary oscillations in different regions and represents functional connectivity between those regions. Network activity in adult, male rats was recorded before and after exposure to a novel cage for five consecutive days in LC, mPFC, and OFC. Coherence and power spectral density (PSD) were calculated. Coherence

between the two cortical regions was higher than coherence between LC and OFC or between LC and mPFC in all frequency bands. This coherence was unchanged by repeated novel cage exposure. This finding confirms that repeated exposure to a novel cage, typically a control for social defeat occurring in the cage of a resident rat, does not have significant effects on its own. This is the first analysis of the relationship between LC and OFC network activity. In ongoing studies, we are assessing the impact of repeated social defeat on coherence between LC, mPFC, and OFC and determining if differences in LC activity might lead to changes in LC drive to distinct PFC regions that might underlie different cognitive states. Additionally, we are assessing whether sex differences exist in LC activation following repeated stress and how these differences might alter PFC network activity and cognitive function.

Title: Acute restraint stress alters reward-related VTA and NAc activity

Authors: *D. C. LOWES[1], E. S. HOLT[3], J. A. GORDON[4], A. HARRIS[2]
[1]Pharmacol., [2]Columbia Univ., New York, NY; [3]Barnard Col., New York, NY; [4]Office of the Director, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Acute stress can impair the sensitivity to rewards in humans, and preclinical studies suggest that while mice are restrained, passively received rewards induce blunted activity of ventral tegmental area (VTA) dopamine neurons. However, it is unclear how acute stress contribute to lasting changes in VTA and nucleus accumbens (NAc) activity as individuals actively engage in rewarding behavior. We hypothesized that after acute restraint stress, reward would elicit reduced VTA and NAc neural activity. To test this hypothesis, we simultaneously recorded single unit and local field potential (LFP) activity in the VTA and LFP activity in the NAc of mice during a cued-reward task before and after they experienced acute restraint. We found that acute restraint stress decreases the rate at which mice lick in anticipation of a reward and increases the latency to reward retrieval (both $p<0.05$). In addition, we observed that restraint stress alters cue-evoked firing in the VTA, as well as a cue-evoked potential in the NAc (all $p<0.05$). Together, these data suggest that acute stress produces lasting changes in reward-seeking behavior and VTA and NAc neural activity.

Title: Effect of WAY 100,635 on the behavioral indicators of anxiety and anhedonia after exposure to chronic stress

Authors: *I. GONZALEZ RIVERA[1], O. GALICIA-CASTILLO[2], H. SANCHEZ-CASTILLO[3]
[1]Univ. Nacional Autonoma de Mexico, Mexico City, Mexico; [2]Univ. Iberoamericana, Mexico City, Mexico; [3]Univ. Nacional Autonoma de Mexico. Fac Psicologia, Mexico City, Mexico

Abstract: Actually, the serotonergic system it seems to play a major role in the regulation of the stress response, in fact, one of the main treatments for stress-related disorders is the use of serotonergic antidepressants. However, the specific mechanism by which they exert their therapeutic effects in such disorders remains unknown. 5-HT1A receptors could play an important role in the mechanism of regulation of the stress response. The aim of the present study was to evaluate the effect of a 5-HT1A receptor-specific antagonist (WAY 100,635) on behavioral indicators of stress. We used 40 male Wistar rats of 250-350 grams housed in standard laboratory conditions and treated in accordance with the ethical standards of use and care of laboratory animals. Rats were subjected to an unpredictable chronic stress protocol for ten days; then they were divided into four groups to be administered with WAY 100,635 at doses 0.0, 0.05, 0.1 and 0.2 mg/kg respectively. The administration was intraperitoneal with saline as a vehicle for seven days. Finally, they were measured in tests of anxiety, anhedonia, and cognition. Statistically significant differences were found in all tests between groups, showing an anxiolytic effect of WAY 100,635 on the stress model, this results are related to the effect of the drug on the 5-HT1A autoreceptors and it suggests that these particular receptors are importantly involved in the mechanisms of regulation of stress response.

Title: Social defeat stress induces similar transcriptional profile changes in California mice as compared to patients with depression in reward-related brain regions

Authors: *A. V. WILLIAMS[1], C. J. PENA[2], B. LABONTÉ[3], S. RAMOS-MACIEL[1], E. J. NESTLER[4], B. C. TRAINOR[5]
[1]Psychology, Univ. of California Davis, Davis, CA; [2]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Neurosci. and Psychiatry, Laval Univ., Quebec, QC, Canada; [4]Icahn Sch. Med. at Mount Sinai, New York, NY; [5]Univ. of California -Davis, Davis, CA

Abstract: Social defeat stress (SDS) is a widely used model of chronic psychosocial stress for inducing anxiety-like and depression-like behavioral abnormalities in rodents. It has been difficult to use SDS in female rodents due to a lack of aggressive behavior. However, female California mice show similar levels of territorial aggression as males, allowing us to study the effects of SDS in both sexes. Using this model, we exposed both male and female California mice to SDS. In order to assess the long-term effects of SDS, brains were extracted two weeks following the end of SDS and immediately flash frozen. Using RNAseq, we assessed SDS-induced transcriptional profile changes in the nucleus accumbens (NAc) of both stressed and unstressed male (unstressed = 7, stressed = 6) and female (unstressed = 8, stressed = 7) California mice. Additional analyses were also performed in the prefrontal cortex (PFC) in stressed and unstressed female (unstressed = 8, stressed = 7) California mice. These data sets were compared to transcriptional profiles observed in either the NAc or PFC from human tissue of both men (MDD = 13, control = 13) and women (MDD = 13, control = 9) patients with or without major depressive disorder (MDD). Using rank-rank hypergeometric overlap (RRHO) analyses, we found more overlap in genes that were decreased by stress in female California mice and decreased in women diagnosed with depression. Based on patterns observed using RRHO, we used gene ontology (GO) and KEGG analyses to look for highly enriched GO terms and pathways that were altered by stress and depression. In the NAc, one of the more highly enriched terms affected is G-protein coupled receptor (GPCR) signaling and regulation of GPCR, where both GPCR signaling and regulation of GPCR signaling are down-regulated by stress or in human depression. In the PFC, major terms arising using KEGG analyses are associated with ribosomal translation. In addition, many immediate early genes are

downregulated by stress and in patients with depression, suggesting less activity in the PFC in general. Follow-up qPCR analyses are in progress to confirm these findings in separate biological replicates. Together these results suggest that the California mouse model of social defeat may be particularly effective at modeling aspects of depression that involve transcriptional repression as opposed to transcriptional activation.

Title: Propranolol-mediated inhibition of the priming effect of acute social defeat stress to increased susceptibility to subsequent social defeat stress

Authors: *J. Y. ZHANG, C. FILLINGER, Y. S. GROSSMAN, D. DUMITRIU
Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Social defeat stress is an accepted animal model of human depressive-like symptoms with demonstrated predictive power and ethological validity. Chronic social defeat stress (CSDS, 10-day) induces pervasive depressive-like symptoms in mouse. When tested in a social interaction (SI) test following CSDS, defeated mice show lower SI ratio, indicative of social avoidance. The majority of animals that undergo CSDS develop this avoidant phenotype and are classified as “susceptible”. However, approximately one third of mice do not become socially avoidant and are classified as “resilient”. Because our lab is primarily interested in the pre-existing neural connectivity that mediates this divergent stress response, we developed an acute social defeat stress model (ASDS) that differentiates resilience and susceptibility one hour post-defeat, the time-point of maximal immediate early gene expression.This allows us to interrogate differences in the initial stress-activated neural ensemble. ASDS does not lead to pervasive depressive-like symptoms, but interestingly does prime animals to increased susceptibility to subsequent social stress, including subthreshold social defeat stress (StSDS). Here, we seek to determine whether the beta-adrenergic antagonist propranolol is capable of inhibiting ASDS-induced priming to future social stress. Propranolol has been shown to impair fear memory consolidation in the rat and reduce recall for negatively-valenced emotional content in both healthy and PTSD-afflicted adult humans. Our preliminary data suggests that propranolol has a

mediating effect on ASDS-induced stress priming. Further investigation of this mediating effect could offer insight into the mechanisms underlying selective resilience and susceptibility.

Title: Understanding the role of CRF receptor in the development of anxiety-like behaviors and obesity using diet manipulations in selectively-bred rat populations

Authors: *J. HAAN[1], P. J. VOLLBRECHT[2]
[2]Biol., [1]Hope Col., Holland, MI

Abstract: Epidemiological data shows that obesity continues to develop as a serious public health concern in the United States. Interestingly, anxiety disorders have been shown to be associated with obesity. However, cause and effect is not well established due to poor mechanistic understanding of the relationship between these conditions. Several brain regions have been shown to be affected by obesity and related to anxiety disorders such as the nucleus accumbens (NAc), prefrontal cortex (PFC), and hypothalamus. Here we tested the effects of diet and obesity development in both outbred and selectively bred obesity prone and obesity resistant rat populations.
Outbred and selectively bred animals were subject to three diets, standard chow, junk food diet (19.6% fat) used to mimic a western diet, or high fat diet (60% kcal from fat). Selectively bred obesity prone rats did not show increases in anxiety-like behavior when tested before obesity development. Both groups were tested for anxiety-like behaviors using open field and elevated plus maze behavioral paradigms following a 4-week diet manipulation. Outbred animals fed a high fat diet did not show significant differences in anxiety-like behaviors compared to chow-fed animals despite enhanced weight gain. However, post obesity development testing in obesity prone rats showed drastic increase in anxiety-like behavior compared to their obesity resistant counterparts, regardless of diet manipulation. These data suggest that a combination of both predisposition and obesity development are necessary to cause anxiety-like behaviors, while diet and obesity are not independently sufficient to cause changes in anxiety-like behaviors in our studies.
Following behavioral testing, NAc, PFC, and hypothalamus were dissected out and blood

samples were collected. Plasma corticosterone levels were quantified in outbred rats using ELISA analysis. No significant differences in corticosterone concentration were found between the diet groups showing a lack of direct effect of diet on HPA-axis activation. Furthermore, corticotropin-releasing factor receptor 1 (CRFR1) was analyzed in a variety of brain regions by western blot due to its role as a primary initiator of the HPA-axis. Increased CRFR1 has been observed independently in studies of both anxiety and obesity making it a possible link between the two conditions.
These studies indicate that anxiety development is dependent on both susceptibility and obesity development. Biochemical analysis of corticosterone levels and CRFR expression may help to better understand the relationship between obesity development and the development of anxiety-like behaviors.

Title: A potential screening paradigm for antidepressants using the nest building evaluation after acute social defeat stress (ASDS)

Authors: *H. OTABI[1,2], T. OKAYAMA[1,2], D. KOHARI[1,2], A. TOYODA[1,2]
[1]Tokyo Univ. of Agr. and Technol., Tokyo, Japan; [2]Ibaraki Univ., Ibaraki, Japan

Abstract: [Introduction] Appropriate models of depression and their behavioral evaluation are essential to identify potential antidepressant candidates. In our previous researches, we clarified that nest building behavior was significantly delayed in the subchronic mild social defeated mice (Otabi et al., Bahave Processes., 2016). Nest building is an instinctive and goal-directed behavior involved in hippocampus and prefrontal cortex. Furthermore, we confirmed that nest building behavior was also delayed in the acute social defeated stress (ASDS) mice. In this study, we tried to establish the paradigm for drug screening combining ASDS with nest building behavior. [Materials and methods] The animal experiments were described by the previous report (Otabi et al., Behav Processes., 2017). After injecting (i.p) of drugs such as SR-46349B, fluoxetine, methylphenidate, and duloxetine, C57BL/6J male mice were exposed to ASDS with ICR male mice. We assessed the nest score using the method as previously described (Deacon, Nat Protoc., 2006). [Results and discussion] The nest building delay in ASDS mice was partially rescued by

administering a specific 5-HT2a receptor antagonist (SR-46349B). However, a popular SSRI (fluoxetine), methylphenidate, and duloxetine could not rescue this nest building deficit. Possibly, nest building deficit in ASDS mice is based on the unknown mechanism in CNS, so the drug screening using the proposed paradigm will produce fruitful outcome in the drug discovery for depressive disorders. [Conclusion] Nest building evaluation after ASDS may be a potential method to discover novel antidepressants.

Title: Stress effects on neuronal connectivity in the orbitofrontal cortex

Authors: *S. M. ADLER, S. E. BULIN, M. GIROTTI, D. A. MORILAK
Pharmacol., Univ. of Texas Hlth. At San Antonio, San Antonio, TX

Abstract: Depressed patients often experience impairments in cognitive flexibility, a symptom dimension that may underlie illness maintenance and is poorly treated by classic antidepressants. One major risk factor for depression is chronic stress, which has frequently been utilized in rodent models to cause a depression-like phenotype. Using chronic intermittent cold stress (CIC), we can induce a deficit in the reversal learning phase of the attention set-shifting test (AST) in Sprague-Dawley rats ($p<.01$), and this deficit can be corrected by antidepressants like citalopram, vortioxetine, and ketamine ($p<.05$). We hypothesize that an increase in dendritic complexity and synaptic spine density induced in the orbitofrontal cortex (OFC) by cold stress causes an aberrant potentiation of afferent-driven response in the OFC, leading to dysregulated reversal learning.
Field potentials evoked acutely in the OFC by mediodorsothalamus (MDT) afferent stimulation in rats were potentiated after 2 weeks of CIC stress compared to baseline ($p<.01$). Additionally, CIC rats had an increase in distal apical spine density ($p<.05$) and distal apical dendritic complexity ($p<.05$) after stress, and this effect is specific to the medial region of the OFC. Finally, since functional changes in excitatory transmission correlate with altered AMPA receptor surface expression, we performed a surface labeling experiment and discovered that CIC rats have significantly more surface GluR1 in the medial OFC relative to non-stressed controls ($p<.05$).

To determine if increased activity in the OFC is sufficient to cause deficits in reversal learning, we plan to use optogenetics with the ChETA variant of channelrhodopsin, delivered by an AAV viral vector, to induce long-term potentiation (LTP) in the MDT to OFC pathway in non-stressed rats. In preliminary studies to first validate this approach, we successfully induced opto-LTP in this pathway. Further, to determine if the increase in spine density is necessary for the deficit in reversal learning after CIC, we will use a construct, AS-PA-Rac1, that expresses photoactivatable Rac1 to shrink recently potentiated spines upon laser stimulation. In preliminary studies to first validate this approach, we have demonstrated that the construct works as expected in neurons in culture.

Title: Effects of repeated and acute stress on expression of Arc/Arg3.1 in the rat hippocampus and prefrontal cortex

Authors: *A. MOGUL[1], E. TAYLOR-YEREMEEVA[1], A. KHAN[2], H.-Y. WANG[2], S. ROBINSON[1]
[1]Psychology Dept. and Neurosci. Program, Hamilton Col., Clinton, NY; [2]Dept Physiol , Pharmacol & Neurosci, CUNY Sch. of Med., New York, NY

Abstract: Stress has been shown to alter the structure and function of the hippocampal formation (HF) and prefrontal cortex (PFC), however the mechanisms by which these changes occur is not well defined. Of note, differential effects on mRNA and protein expression in these regions have been observed depending on the type of stress experienced. The activity-regulated cytoskeletal-associated protein (Arc/Arg3.1) is associated with dendritic spine morphology, long-term potentiation, and more broadly, learning and memory, which are all impacted by stress. Collectively, these data suggest that Arc protein expression may provide an entry point into understanding the connections between stress, cognition and learning-related protein expression. The purpose of the present study was to determine the effects of different types of stress on the expression of Arc in brain regions associated with cognition. We exposed male rats to either acute or repeated stress with the hypothesis that Arc expression in the acute group, but not the repeated stress group, would increase. To evaluate the stress paradigms, we measured body weight, behavior and hormone production. The data reveal that rats in the repeated stress group

gained less weight compared to acute and control groups and, as expected, both acute and repeated groups displayed anxious behavior on the open field test. Furthermore, rats in the repeated stress group showed reduced corticosterone levels, a common symptom of post-traumatic stress disorder. Together these data suggest that the stress paradigms successfully induced behavioral and physiological changes in stressed rats. Moreover, following these stress paradigms, in the HF, Arc expression was increased after acute stress and reduced after repeated stress, consistent with the view that high corticosterone levels elevate Arc expression, perhaps through glutamate-mediated mechanisms. Conversely, in the PFC, acute stress decreased Arc expression but repeated stress did not, highlighting a differential effect of both acute and repeated stress on the HF and PFC. Overall these data provide insight into Arc protein regulation that may underlie stress-induced structural and functional changes in neurons.

Title: Chronic social defeat stress increases ventral hippocampal - prefrontal synchrony

Authors: *A. HARRIS[1,2], L. A. CHAMBERLIN[1], L. KRETSGE[1], D. C. LOWES[1], M. A. TOPIWALA[1,2], A. I. ABBAS[1], A. J. PARK[1], P. ATSAK[1,2], E. D. LEONARDO[1], R. HEN[1], J. A. GORDON[3]
[1]Columbia Univ., New York, NY; [2]Res. Fndn. Mental Hygiene, Inc, New York, NY; [3]Office of the Director, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Anatomical evidence implicates the hippocampus and prefrontal cortex in patients with depression, and preclinical studies have revealed that chronic stress impacts the anatomy and functioning of these structures. Although we have previously demonstrated that ventral hippocampal (vHPC) medial prefrontal cortex (mPFC) communication plays a crucial role in mediating anxiety-related behavior, it remains unknown how chronic stress impacts this communication. Since vHPC-mPFC theta range (4-12 Hz) synchrony is enhanced in negative valence (anxiogenic) environments, we hypothesized that chronic social defeat stress (CSDS) - which leads to social avoidance in susceptible mice - would increase vHPC-mPFC synchrony.

To test this hypothesis, we recorded simultaneous vHPC and mPFC neural activity in mice and compared their synchrony before and after they underwent CSDS. We found that CSDS increases multiple measures of vHPC-mPFC theta range synchrony relative to baseline values (coherence $p<0.05$; power-power correlations $p<0.05$, paired sign rank test; n=13). Moreover, a sub-analysis revealed that these results held true for susceptible (n=9), but not resilient mice (n=4). These synchrony changes were pathway specific as they did not occur in the vHPC to nucleus accumbens pathway (n=7). Finally, we found that the degree of increase in vHPC-mPFC synchrony significantly correlates with social interaction scores of individual mice. Collectively, these data suggest that vHPC-mPFC communication plays a role in the manifestation of susceptible behavior seen after chronic social defeat stress.

Title: Chronic variable stress and nursing demand interact to alter depression-like behavior and hippocampal neurogenesis in postpartum rats

Authors: *J. MEDINA[1], R. M. DEGUZMAN[1], A. I. SAULSBERY[2], K. W. UNGER[1], E. CEBALLOS[1], J. L. WORKMAN[1,3]
[1]Psychology, Univ. at Albany, State Univ. of New York, Albany, NY; [2]Psychology, The Ohio State Univ., Columbus, OH; [3]Ctr. for Neurosci. Res., Albany, NY

Abstract: The postpartum period is characterized by dramatic peptide and steroid hormone fluctuations and represents a time of increased risk for developing depression. However, the underlying mechanisms of postpartum depression (PPD) are incompletely understood. Stress is a major risk factor for depression and lactational experience suppresses hypothalamic-pituitary-adrenal axis stress responsivity. Women who do not breastfeed or discontinue breastfeeding early have a higher risk of developing PPD compared with women who breastfeed exclusively. Further, prospective studies indicate that cessation of breastfeeding precedes PPD in some women. Thus, we sought to determine whether different lactational experience would alter susceptibility to stress-induced changes in depression-like behavior and hippocampal

neurogenesis during the postpartum period. Adult female Sprague-Dawley rats underwent thelectomy (thel; surgical removal of teats), sham surgery, or no surgery (control). Litters were rotated between yoked thel and sham dams every 12 h from postpartum days (PD) 0 – 26. Thus, thel dams had offspring contact throughout the postpartum period and sham rats bore a higher nursing demand. Control litters were rotated between paired control rats. From PD 2 – 25, dams and their litters were either left undisturbed or exposed to chronic variable stress. Stressors were presented once per day in a semi-random order and included wet bedding, empty water bottle, overnight illumination, tail pinch, dirty bedding, stroboscopic lighting, white noise, low bedding, and cage tilt. Maternal behavior observations revealed stressed rats spent more time with offspring compared with non-stressed rats, regardless of nursing condition. Sham and thel rats spent more time with offspring compared with control rats regardless of stress. Nursing and stress interacted to alter immobility in the forced swim test: among non-stressed rats, thel rats spent more time immobile compared with sham rats. Stress increased immobility in control and sham rats, but unexpectedly, reduced immobility in thel rats. Preliminary data also suggest that lactational experience interacts with stress to alter hippocampal neurogenesis. These data suggest that nursing does not necessarily yield resistance to stress-induced changes in depression-like behavior or neurogenesis. Thus, the relationship between absence of breastfeeding and PPD could be unrelated to stress susceptibility in non-breastfeeding women. These data will also be discussed in the context of allostatic load.

Title: Physical exercise-elicited adiponectin increase affects hippocampal neuronal plasticity and attenuates behavioral despairs in stressed mice

Authors: *A. LI, P. WANG, K.-F. SO, P. YU
GHM Inst. of CNS Regeneration, Jinan Univ., Guangzhou City, China

Abstract: Major depressive disorder causes profound personal suffering and economic burden. We have previously demonstrated that adiponectin, a neuroprotective cytokine secreted by mature adipocytes, may mediate physical exercise-elicited adult hippocampal neurogenesis, subsequently mitigating behavioral despairs. However, whether such antidepressive effect involves adiponectin's regulation of hippocampal plasticity in neurons other than neural precursor cells remains unexplored. By means of repeated corticosterone (COR) injections to mimic stress insult, we here showed that voluntary wheel running was sufficient to ameliorate depression-like behaviors in stressed wild-type (WT), but not adiponectin-knockout (KO) mice. Likewise, impaired neuronal morphology in hippocampal dentate gyrus following COR treatment could only be significantly restored by running in WT rather than KO mice, suggesting that adiponectin also directly affects hippocampal neuronal plasticity. Meanwhile, running increased serum and hippocampal levels of adiponectin in WT rather than KO mice receiving either COR or vehicle injections, whereas other well-known cytokines including brain-derived neurotrophic factor, insulin-like growth factor, vascular epithelial growth factor and nerve growth factor remain comparable between these two mouse strains, regardless of running or not. Overexpression of glucocorticoid receptors and the adaptor protein APPL2 have been reported to incur depressive phenotypes in mice. Interestingly, in WT but not KO mice, running downregulated the expression of these two targets, and yet left that of mineralocorticoid receptors, the adaptor protein APPL1 and adiponectin receptors unchanged. Taken together, our data suggest that adiponectin potentially mediates physical exercise-exerted antidepressive effect by restoring stress-triggered impairment on dendritic plasticity of hippocampal neurons through selectively reducing the expression of glucocorticoid receptors and APPL2.

Abstract: Corticosterone (CORT) is a stress hormone that can act centrally to mediate stress- and reward responses. The ventral hippocampus (vHipp) mediates stress responses and has a high expression of glucocorticoid (GR) and mineralocorticoid (MR) receptors, making it sensitive to CORT and stress. We previously found that a stress-relevant concentration of CORT infused into the vHipp of adult male Sprague-Dawley rats enhances dopamine (DA) output in the nucleus accumbens shell (NAcS) (n = 11). This effect is rapid, peaking 40 - 60 min post-infusion, and may provide a mechanism by which stress can enhance incentive salience to promote goal-oriented behavior. Interestingly, the same stress-relevant vHipp CORT infusion *reduces* NAcS DA output in amphetamine withdrawal (n = 11), when vHipp GR protein expression is reduced. This effect is rapid and bi-phasic, peaking at 30- and 75 min post-infusion, and suggests that reduced vHipp GR expression may contribute to reduced NAcS DA output and dysphoric states in amphetamine withdrawal. GRs and MRs can be cytosolic or membrane-bound, genomic or non-genomic, and differ in their affinity for CORT, and in their downstream signaling mechanisms and effects. For example, findings suggest GRs may be excitatory or inhibitory, and MRs may be excitatory or disinhibitory, depending on their location. To explore the receptor mechanisms that mediate the ability of vHipp CORT to alter NAcS DA release, we selectively blocked either GRs or MRs in the vHipp by infusing mifepristone or spironolactone (respectively) into the vHipp prior to a stress-relevant infusion of vHipp CORT in control- and amphetamine-withdrawn rats (n = 7 - 8 / group). *In vivo* chronoamperometry was used to assess accumbal DA output. Interestingly, all conditions resulted in vHipp CORT reducing NAcS DA levels, suggesting that vHipp MRs and vHipp GRs both reduce NAcS DA release in control- and withdrawal states. We then infused a stress-relevant concentration of membrane-impermeable CORT (CORT-BSA) into the vHipp of drug-naïve adult male rats (n = 8). This infusion rapidly increased NAcS DA output, peaking 20 min post-infusion, then returning to baseline 60 min post-infusion. This suggests that concomitantly activating MRs and GRs in the vHipp membrane has an excitatory effect on NAcS DA output, and may contribute to the rapid ability of stress to enhance NAcS DA levels and incentive salience in control conditions. These findings provide important information on vHipp CORT receptors, and implicate vHipp CORT in mediating stress-induced reward responses in healthy conditions and in diseased- and dysphoric states.

Title: Role of reproductive status on tau phosphorylation induced by chronic stress in the hippocampus of the female rat

Authors: *D. MUNOZ-MAYORGA[1], R. A. RISSMAN[2], T. MORALES[1]
[1]Inst. For Neurobio. UNAM, Queretaro, Mexico; [2]Neurosci, UCSD Sch. Med., La Jolla, CA

Abstract: Sex and the exposure to chronic stress have been identified as risk factors to develop Alzheimer's disease as documented by epidemiological studies. Although the majority of patients with this disease are women, the sex of the individual has been overlooked in most studies. Previous work in rodents showed that the exposure to physical and psychological stressors induces hyperphosphorylation of tau (tau-P), which has been shown to be tempered by reproductive status in female subjects. To test the hypothesis that the reproductive status can modulate stress-induced tau-P in the hippocampus of females, cohorts of virgin, lactating (4-5 days pp), and 1-month postweaned rats were subjected to a daily episode of 30 minutes of restraint stress or handling (control) for 14 days, and were sacrificed either 20 min or 24 h after their last stress/handling episode. Two well characterized AD-relevant tau-P epitopes (AT8 and PHF-1) and possible phosphorylation mechanisms such as GSK3 and ERK1/2 were analyzed by Western blot. This analysis showed no differences at 20 min in hippocampal tau-P among the reproductive conditions, although a trend to increase in tau-P levels was observed in stressed virgin rats sacrificed at 24 h after their last stress episode. No changes were detected in GSK3 or ERK1/2 levels in rats sacrificed 20 min after the last stress episode. Immunodetection of s422 epitope revealed increased tau-P in CA3 and CA4 subfields of the hippocampus of virgin rats exposed to chronic stress. Whereas stress did not modify labeling of s422 in the lactating and 1-month postweaned stressed groups. These results suggest a slightly higher sensitivity of the virgin rats to increase tau-P in the hippocampus after chronic stress compared to that in lactating and postweaned rats. Since no differences were detected between lactating and postweaned rats, current results support the idea of reproductive experience having an impact on tau processing in the brain of the female.

Title: Hippocampal RNA editing mediates the long-term effects of prenatal stress

Authors: G. BRISTOW[1], A. SEGISMUNDO[2], *M. S. SODHI[3]
[1]Biomed. and Life Sci., Lancaster Univ., Lancaster, United Kingdom; [3]Mol. Pharmacol. and Therapeut., [2]Loyola Univ. Chicago, Maywood, IL

Abstract: A post-transcriptional process known as RNA editing, which is catalyzed by ADAR enzymes, regulates brain development. Although ADAR enzymes alter the sequences of thousands of mRNA and miRNA targets, one of the most important targets is the mRNA encoding the GluA2 subunit of the AMPA glutamate receptor (AMPAR). RNA editing reduces the trafficking of GluA2-AMPARs to the synaptic surface, a process that is critical for synaptic maturation, synaptic plasticity, learning and memory. These processes are impaired in psychiatric disorders that are exacerbated by stress, including schizophrenia. In this study, we investigated a developmental model of schizophrenia, where we exposed mice to environmental stress during gestation i.e. prenatal stress (PRS). PRS mice have abnormal brain development and abnormal behavior in adulthood. We treated adult PRS mice and controls with haloperidol (1mg/kg), clozapine (5mg/kg) or saline twice daily for 5 days. 16hrs after the final injection, we assessed mice for social interaction behavior and locomotor activity. We analyzed the frontal cortex and hippocampus of each mouse for the expression of the RNA editing enzymes (ADARs 1-3) in addition to performing tagged next-generation sequencing analysis of the RNA editing levels of 24 genes, including the AMPAR subunits. PRS mice exhibited reduced social interaction behavior, which was inversely correlated with hippocampal RNA editing of the AMPAR subunits GluA2-4, the potassium channel Kv1.1, and the serotonin2C receptor (5-HT2CR), in addition to other mRNA targets of the ADAR enzymes. Treatment with clozapine, but not haloperidol, eliminated deficits of social interaction in the PRS mice, and reduced abnormal GluA2 RNA editing in the hippocampus. We also observed increased ADAR3 expression in the clozapine-treated PRS mice, indicating that PRS and clozapine both alter transcriptional pathways associated with RNA editing in the hippocampus. Our data indicate that PRS produces long-term changes in behavior that may be due to abnormal development of the hippocampus, which are mediated by RNA editing. These data indicate that RNA editing may contribute to the pathophysiology of schizophrenia, and may contribute to the antipsychotic efficacy of clozapine.

Title: PKA phosphorylation of the L-type, voltage-gated calcium channel $Ca_V1.2$ positively regulates learning and anxiety behaviors

Authors: *K. E. IRETON, A. GROVER, J. HELL
Neurosci., UC Davis, Davis, CA

Abstract: The L-type, voltage-gated calcium channel (VGCC) $Ca_V1.2$ is a primary mediator of neuronal post-synaptic Ca^{2+} influx in the brain, and consequently influences cellular excitability, gene expression, and synaptic plasticity. Its activity is known to be modulated by stress, mediated by norepinephrine (NE), which effectively increases Ca^{2+} influx through $Ca_V1.2$ by increasing probability of channel opening. $Ca_V1.2$ modulates learning, stress, and reward related behaviors in rodents, and mutations in its gene CACNA1C are implicated in human autism spectrum disorder, bipolar disease, schizophrenia, and major depressive disorder pathologies. However, it has not been known how NE regulation of $Ca_V1.2$ specifically impacts behavior, if at all. NE regulates CaV1.2 activity by downstream activation of PKA via the β_2-Adrenergic receptor, which then causes phosphorylation of the channel C-terminal tail at Ser^{1928}, its most prominent site of PKA phosphorylation. Our lab has demonstrated previously that phosphorylation of $Ca_V1.2$ at Ser^{1928} is necessary for the induction of prolong-theta-tetanus long term potentiation (PTT-LTP) in rodent hippocampal brain slices, and thus hypothesized that spatial learning behaviors would be impaired in mice carrying a knock-in mutation at Ser^{1928} to prevent PKA phosphorylation (S1928A). We now present evidence that S1928A spatial learning is impaired relative to wildtype in the Morris Water Maze during acquisition of the platform location during training, although not after further training. Impairments in short-term memory and anxiety related behaviors also appeared in S1928A mice. These behavioral data show that PKA phosphorylation of $Ca_V1.2$ is not only relevant to learning and stress-related behaviors, but that it positively regulates them, indicating the potential importance of NE regulation of this VGCC in the brain to animals *in vivo*.

Title: Understanding neural mechanisms of resilience to stress: Role of hippocampal brain-derived neurotrophic factor

Authors: *K. ALVINA, M. JODEIRI-FARSHBAF, H. BLAKLEY, J. BLAKLEY, D. CHERKOWSKY, E. X. LEE, D. J. SMITH
Biol. Sci., Texas Tech. Univ., Lubbock, TX

Abstract: Stress is a powerful stimulus that can modify neural processes and ultimately precipitate the onset and/or exacerbation of neuropsychiatric disorders. Extensive research has shown that glutamatergic synaptic transmission is an important target of stress. In the CA3 area of the hippocampus for instance, one of the most stress-sensitive brain regions, chronic stress causes severe dendritic retraction in CA3 pyramidal cells. These changes depend on NMDA-type glutamate receptors (NMDARs), however the actual mechanisms of action are not entirely clear. Therefore, we focused on NMDAR-mediated synaptic transmission in the CA3 area of the hippocampus and intracellular pathways altered by stress. One such molecule is the brain-derived neurotrophic factor (BDNF), which is highly expressed in the hippocampus and contributes to cell growth and proliferation, synaptic transmission and plasticity. Thus, using a mouse model of chronic stress we studied changes occurring in the hippocampus of stressed female and male mice, combining virally-mediated gene manipulation, behavioral analysis and in vitro electrophysiology. Behavioral analysis showed that mice subjected to a chronic stress paradigm spent significant more time in the periphery of an open field test and in the closed arms of the elevated plus maze, indicating a heightened level of anxiety. Similarly, both female and male chronically stressed mice showed increased immobility in the forced swimming test, indicating depression-like behavior. Furthermore, excitatory post-synaptic potentials in hippocampal slices showed decreased responses in the CA3 region of stressed mice compared to controls. However, when pharmacologically isolated, NMDAR-mediated responses showed increased amplitude in stressed mice, suggesting that stress differentially modulates the function of glutamate receptors. Lastly, using a virus-mediated strategy we probed the role of hippocampal BDNF in mediating stress-induced changes in behavior. Our results show that reducing BDNF via shRNA expression in the CA3 region reduces circulating levels of corticosterone and recapitulates the anxiety-like behaviors observed in stressed mice. In summary, our results link stress-induced alterations in excitatory synaptic transmission in the CA3 area of the hippocampus with specific behavioral deficits and reduced BDNF levels. Understanding the physiological mechanisms affected by stress could provide important clues to understand resilience and to explore possible therapeutic avenues.

Title: Experience of wheel-running and food restriction in adolescent female rats results in increased GABA response and mIPSC frequency in hippocampal pyramidal neurons despite fewer GABAergic axo-somatic synapses

Authors: T. G. CHOWDHURY[1], Y.-W. CHEN[1], G. S. WABLE[1], K. TATEYAMA[1], I. YU[1], J.-Y. WANG[1], A. D. REYES[1], *C. J. AOKI[2]

Abstract: Adolescence is marked by increased vulnerability to mental disorders, due, in part, to increased stressors that evoke maladaptive behaviors even in healthy individuals. Food-restriction (FR) stress evokes an innate behavior of foraging, which translates to increased wheel running exercise (EX) for caged rodents with wheel access. EX within a cage is maladaptive, since it does not improve food access and exacerbates weight loss. While almost all adolescents increase EX following FR, many also exhibit resilience by the 3rd or 4th day by suppressing EX: this helps survival by minimizing weight loss. We asked whether plasticity of the GABAergic system in dorsal hippocampus (dHPC) may underlie this resilience to FR. In vitro slice physiology by whole-cell recording revealed that response of pyramidal neurons in the dHPC of food-restricted animals with wheel access (FR+EX) to bath-applied GABA is more than doubled, compared to CON without FR or EX ($p=0.01$), even though mIPSC amplitudes trended towards a decrease (-15%, $p=0.09$). This suggests the emergence of extrasynaptic $GABA_AR$s, which would not contribute to mIPSC amplitude measurements but would contribute to bath-applied GABA response. mIPSC frequency of FR+EX neurons is greater by 46%, compared to CON ($p=0.02$), but electron microscopic immunocytochemical labeling of GAD-terminals revealed a trend towards decrease in the number of axo-somatic GABAergic axon terminals on pyramidal cells (-25%, $p=0.07$) and only a modest difference (+26%, $p=0.02$) of GABAergic synapse lengths. This suggests un-silencing of GABAergic synapses through addition of $GABA_AR$s at previously receptor-less axo-somatic synapses or increased probability of vesicular release. Moreover, an individual's mean length of GABAergic synapses correlated strongly with the extent of wheel running suppression ($R=0.9$, $p=0.01$). GABAergic changes evoked by FR+EX were distinct from the changes following EX or FR, alone, indicating that EX can have dual roles - exacerbate weight loss during FR but also promote resilience by dampening excitability of the dHPC. Anorexia nervosa (AN) is a mental illness with high mortality rate, surpassing that of depression and is still without accepted pharmacological treatments. The rodent paradigm of FR+EX captures maladaptive behavioral hallmarks of AN - excessive EX plus voluntary FR. Using adolescent female rats in this model, we uncovered plasticity in the

GABAergic system of the dHPC only of rats exhibiting behavioral signatures of resilience - suppressed wheel running and suppressed weight loss, providing clues regarding individual differences in vulnerability to AN and therapeutic interventions.

Title: Epigenetic regulation of retrotransposons by corticosterone mediates NLRP3 inflammasome complex activation in the rat hippocampus

Authors: *M. J. CLARK[1], A. A. BARTLETT[2], R. G. HUNTER[2]
[2]Psychology, [1]Univ. of Massachusetts Boston, Boston, MA

Abstract: Stress and immune signaling converge in the hippocampus to alter synaptic function. Glucocorticoids are capable of regulating expression of pro-inflammatory cytokines but the precise mechanisms remain unknown. The acute stress induced repressive histone modification histone H3 lysine 9 trimethyl (H3K9me3) regulates retrotransposon (RT) expression. RT expression in neurodegenerative diseases such as macular degeneration has been associated with the immune response (i.e NLRP3 complex assembly) however, these mechanisms have yet to be understood within the brain (Tarallo et al., 2012). The NLRP3 inflammasome, a multiprotein complex made up of NLRP3, caspase-1 and ASC proteins, facilitates the production of mature pro-inflammatory cytokines. Glucocorticoids (e.g. corticosterone in the rat) are released from the adrenal glands, and circulate throughout the body and brain binding to glucocorticoid receptors (GRs). In the rat, acute restraint stress increases H3K9me3 within the hippocampus, accumulating at RTs thereby decreasing RT expression. RT abundance has been linked to the NLRP3 inflammasome activation. Data from acute corticosterone (CORT) treated-adrenalectomized animals supports the idea that CORT is sufficient for increased hippocampal H3K9me3 within the CA1 and DG (n=6, CA1: $p<.05$, DG: $p<.01$). CORT-induced hippocampal H3K9me3 is effectively blocked through pretreatment of chaetocin, a H3K9me3-specific methyltransferase inhibitor (n=6, CA1: $p<.05$, DG: $p<.01$). *In vitro*, CORT dynamically regulates RT expression -increasing expression acutely and repressing expression via H3K9me3 upon depletion (Bartlett and Hunter, 2017). Our data shows that in the acute CORT treated rat, blocking CORT-induced H3K9me3 via chaetocin co-treatment is permissive for NLRP3-

inflammasome assembly in the CA1 and DG regions of the hippocampus observed via immunofluorescent co-localization of NLRP3 and caspase-1 (n=6 per group, CA1: $p<.05$, DG: $p<.001$). We further investigated the relationship between H3K9me3 and NLRP3 complex activation with a new cohort of animals (n=6 per group, control, CORT alone and CORT/chaetocin co-treatment). We examined cleaved caspase-1, a required subunit of the NLRP3 inflammasome, within the CORT alone and chaetocin co-treatment group. We also examined RT expression within these groups to determine if chaetocin co-treatment correlated with increased RT expression. These results may suggest a novel molecular epigenetic link between stress and immune axes with significant implications for hippocampal function.

Abstract: In an effort to find early markers of Gulf War Illness (GWI) to efficiently screen therapies in preclinical trials, we have used a validated mouse model of GWI that is based on exposure to relevant doses of pyridostigmine bromide (PB; a cholinesterase inhibitor), permethrin (PER), and DEET combined with behavioral stress. We found latent post-exposure markers of the illness: anxiety, brain neuroinflammation, cholinergic, GABAergic, and neurotrophic factor abnormalities. In the current study, we have used this mouse model of GWI to test the effects of 7,8-dihydroxyflavone (7,8-DHF), a TrkB agonist that mimics BDNF signaling. Adult male and female mice (70 days old) were exposed daily to PB, PER, DEET, and 5 min of restraint stress for 28 days or exposed to vehicle only (unexposed control). Two months later, mice were orally treated with 7,8-DHF for 1 month. At the end of treatment, anxiety-like behavior was assessed using the elevated plus maze, after which mice were euthanized and brains collected for analysis by Western blot and *in vitro* magnetic resonance spectroscopy

(MRS). Western blot analysis of hippocampal extracts showed that treatment with 7,8-DHF resulted in a significant increase in phosphorylated TrkB (p-TrkB) levels with no effect on the levels of full length TrkB or the truncated form of the receptor, indicating successful activation of the BDNF-TrkB signaling pathway. In addition, we found that treatment with 7,8-DHF neutralized the increased levels of anxiety that were detected in mice following exposure to GW-associated chemicals and stress. We also detected decreased levels of GAD67 protein, the rate limiting enzyme in the synthesis of GABA, in the hippocampus in response to chemical exposure and stress, which were restored by treatment with 7,8-DHF. However, by *in vitro* MRS we detected a decrease (−19.7±2%; $p < 0.01$) in NAA (a marker of neuronal health), and GABA (−17.3±4%; $p < 0.05$) neither of which were affected by 7,8-DHF. Our results show that 7,8-DHF treatment can alleviate some of the anxiety-related changes observed in this mouse model of GWI and suggest that additional research is needed to determine if 7,8-DHF treatment alone or in combination with other treatments can be an effective strategy for treating GWI.

Title: MircoRNA regulation by stress and estradiol in the hippocampus of the mouse

Authors: *K. C. NICHOLSON[1], C. E. CREIGHTON[1], E. R. MARTIN[2], J. LAMARRE[1], N. J. MACLUSKY[1]
[1]Biomed. Sci., [2]Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Stress and gonadal hormones exert sexually-differentiated effects on the structure and function of the hippocampus. While several different receptors and cell signaling pathways have been implicated in these interactions, the underlying mechanisms have yet to be clearly delineated. MicroRNAs (miRNAs), small 19-23 nucleotide non-coding RNAs that are involved in post-transcriptionally regulating gene expression, are known to regulate synaptic plasticity and other important neuronal functions. Furthermore, miRNAs have been proposed to exert effects on estrogen receptor expression, while estradiol has been shown to alter the expression of specific miRNAs in non-neural tissues. Acute and chronic stress exposure has been shown to exert effects on miRNA regulation within stress-sensitive regions of the brain, such as the hippocampus. However, the relationship between the effects of estradiol and stress on miRNA

expression in the brain has yet to be determined.
To explore the potential role of miRNAs as mediators of estradiol and stress hormone interactions, two month old male and female CD1 mice were gonadectomized and randomly allocated to four treatment groups 7-10 days later: (1) control untreated, (2) handed but non-injected, (3) subcutaneously injected with 3 μg/kg estradiol, or (4) subcutaneously injected with the sesame oil injection vehicle (n=9-11 mice per group). Six hours following treatment, mice were sacrificed for brain extraction, removal of the hippocampus, and subsequent isolation and quantification of RNA. Using next-generation sequencing for small RNAs followed by RT-qPCR, differences in miRNA expression levels were analyzed and compared relative to untreated ovariectomized controls. Estradiol treatment significantly reduced expression of miR-204-5p when compared to control and vehicle treated females. In addition, significant sex differences were noted in expression of miR-34c-5p and miR-148a-3p, with both targets being higher in males than females. Sex differences were also noted between miR-216b and miR-217-5p in vehicle-treated and handled groups, respectively (n=5-12 mice per group), with females showing significantly higher expression than males. These differences were eliminated in groups that had received estradiol injection. These results suggest that interactions between estradiol and stress hormones in the regulation of specific miRNA expression may contribute to sex differences in hippocampal function.

Title: Role for mGlu2 receptors in a circuit signaling mechanism underlying rapid behavioral responses to LAC

Authors: *B. BIGIO[1], J. DOBBIN[1], P. DE ANGELIS[1], H. M. CATES[2], O. ISSLER[3], E. J. NESTLER[4], B. S. MCEWEN[1], C. NASCA[1]
[1]Lab. of Neuroendocrinology, Rockefeller Univ., New York, NY; [2]Mount Sinai Sch. of Med., New York, NY; [3]Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Icahn Sch. Med. at Mount Sinai, New York, NY

Abstract: Regulation of the glutamatergic signaling is increasingly recognized as a promising mechanism for fast-acting medications to treat major depressive disorder (MDD). Our group and others have shown that supplementation of acetyl-L-carnitine (LAC) leads to rapid behavioral responses that have been observed after few hours to days of administration. The mechanism of action of LAC has been suggested to involve increased transcription and translation of the metabotropic glutamate receptors-2 (mGlu2Rs), a regulator of spontaneous glutamate release, in the ventral Hip (vHip). Supplementation with LAC also increases expression of the neurotrophin BDNF in the medial prefrontal cortex (mPFC). Here we studied whether targeting mGlu2Rs in the vHip with the use of LAC regulates gene expression in the mPFC. Our findings confirmed previous work from our group and others by showing that short-term treatment with LAC reduced immobility at the forced swim test (FST) as well as increased time in the social zone at the three-chamber sociability test (ST) in wild-type (WT) male mice. As previously showed, the behavioral responses to treatment with LAC are associated with up-regulation of mGlu2Rs transcripts and proteins in the vHip. Preliminary RNAseq data and bioinformatics analyses show transcriptome-wide alterations in the mPFC of WT male mice in response to short-term treatment with LAC (adjusted-$p < 0.15$, fold change >1.3) or vehicle. Among these genes, WT mice receiving treatment with LAC showed increased transcripts of synaptic plasticity markers, including the neurotrophin BDNF in the mPFC as compared to age- and sex-matched WT mice that received vehicle. Using gene ontology (GO) analyses, we found that both WT mice receiving treatment with LAC showed altered transcription of several signaling pathways with meaningful gene categories that include for example synaptic transmission, metabolic processes and immune responses. Expressional and functional validation of the most significant genes is underway in the circuit between the vHip and mPFC. This data shows that the action of LAC involves key synaptic plasticity markers that are known targets for the rapid antidepressant action of ketamine. Therefore, this data suggests that regulation a yet-to-be-determined common pathway in a circuit between the vHip and mPFC may be required for rapid antidepressant action.

Sch. of Med., Palo Alto, CA

Abstract: The lack of biomarkers to identify target populations greatly limits the promise of precision medicine for major depressive disorder (MDD), a primary cause of ill health and disability. The endogenously produced molecule acetyl-L-carnitine (LAC) is critical for hippocampal function and several behavioral domains. Converging evidence has demonstrated that supplementation with LAC has rapid antidepressant responses via epigenetic regulation of hippocampal glutamatergic function in rodents with a deficiency in the levels of the endogenously-produced LAC in plasma and mood regulatory brain regions. Responses to standard antidepressant medications required repeated weeks of administration in the experimental models. This mechanistic model led us to evaluate LAC levels in humans with major depressive disorder (MDD). Our data show that LAC levels, and not the levels of free-carnitine, were decreased in patients with MDD as compared to age- and sex-matched healthy controls in two independent study centers. Furthermore, the degree of LAC deficiency reflected both the severity and age of onset of MDD. In a subgroup of patients defined for history of treatment resistant depression (TRD), we find that decrease in LAC was larger and was associated with history of childhood trauma, and specifically emotional neglect. Supported by an initial validation in two independent cohorts, these findings suggest that the LAC deficiency may aid with the diagnosis of a clinical phenotype of depression. Further studies of LAC as a therapeutic target may help to define individualized treatments in biologically-based depression subtype consistent with the spirit of precision medicine.

Title: Rapid behavioral responses to treatment with ketamine or acetyl-L-carnitine in males and females

Authors: *J. DOBBIN, B. BIGIO, P. DE ANGELIS, D. ZELLI, T. LAU, B. S. MCEWEN, C. NASCA

Abstract: Currently available antidepressants that mainly act through the monoamine system have several limitations, including a long therapeutic lag. Pioneering research has demonstrated that ketamine, a noncompetitive NMDA antagonist, has fast-acting antidepressant efficacy. However, ketamine faces known roadblocks that limit its use, highlighting that there remains a need for safe, fast-acting treatments for major depressive disorder (MDD). Recently, our group and others have shown that administration with acetylcarnitine (LAC) has rapid and enduring antidepressant efficacy in rodent with a deficiency in the endogenously-produced levels of LAC. LAC is an essential molecule for mitochondrial functioning and a biomarker of insulin resistance. The mechanism of action of LAC has been suggested to involve increased transcription and translation of the mGlu2 receptors, a glutamate inhibitor in the ventral hippocampus (vHip). Here, we compared the antidepressant efficacy of LAC to that of ketamine in ameliorating the prolonged effects of chronic stress in male and female mice. We quantified the effects of LAC and ketamine on two core behavioral domains of MDD, that is sociability and psychomotor behavior, in either the chronic restraint stress (CRS) paradigm in both males and females or the chronic social defeat stress (SDS) in males. Mice that underwent CRS paradigms showed decreased time spent in the social interaction zone of sociability tests and increased immobility in the forced swim test (FST) as compared to unstressed age and sex matched controls. These behavioral phenotypes were brought closer to those of control animals either by treatment with ketamine (10 mg/kg, IP injection) or with LAC (3% in water, oral intake; 100 mg/kg, IP injection), suggesting rescue from the depressive-like phenotype. Similarly, in male mice subjected to SDS, sociability was improved by either ketamine or LAC administration when compared to that of stressed vehicle-treated controls, with animals treated with LAC showing a more dramatic improvement. Our work suggests that LAC is superior to ketamine in ameliorating depressive-like symptoms in experimental rodent models. Further research should focus on elucidating the mechanisms of LAC action, including the suggested role of mGlu2 receptors in the vHip. Future research should also continue to investigate the molecular targets of ketamine, including any effect it may have on mGlu2. Improved understanding of fast-acting antidepressants will allow for the development of more effective rapid and target-directed treatments.

Title: The fast antidepressant actions of MRK-016 on anhedonia and synaptic function are mediated by binding at the benzodiazepine site of the $GABA_AR$

Authors: *T. TROPPOLI[1], P. ZANOS[2], T. GOULD[3], S. THOMPSON[1]
[1]Physiol., [2]Pharmacol., [3]Pharmacology, Anat. and Neurobiology, Psychiatry, Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Major depression is a common debilitating psychological disorder. Current clinical treatment options are primarily reuptake inhibition of monoamine neurotransmitters, but these drugs are only effective in half of patients and have a delayed onset of therapeutic action. Negative allosteric modulators of $GABA_A$ receptors containing α5 subunits (GABA-NAMs), such as MRK-016, exhibit rapid antidepressant properties in preclinical models of stress-induced anhedonia and restore stress-weakened glutamatergic excitation at hippocampal temporoammonic-CA1 synapses (TA-CA1). Here we test the prediction that the anti-anhedonic and synaptic responses to these compounds require binding to the benzodiazepine binding site of $GABA_ARs$. Six-week old, male C57BL/6 mice were subjected to a 10 day chronic stress paradigm, sufficient to induce anhedonia, as assayed with sucrose preference and female urine sniff tests. IP injections of MRK-016 (3mg/kg) significantly reversed deficits in these reward behaviors, whereas vehicle (DMSO) or the benzodiazepine antagonist flumazenil (20mg/kg) alone did not. The strength of TA-CA1 synaptic transmission was increased in stressed animals treated with MRK-016 compared to those given vehicle or flumazenil alone, as quantified via fEPSP AMPA:NMDA ratios. In contrast, MRK-016 failed to restore reward-seeking behavior or TA-CA1 synaptic strength in stressed animals pretreated with flumazenil. Unstressed animals showed no change in reward-seeking behavior or AMPA:NMDA ratios following treatment with MRK-16. We have suggested previously that transient GABA-NAM - induced increases in EEG gamma-power in mood-relevant brain structures is responsible for its persistent antidepressant activity. Preliminary results indicate that that the MRK-016-induced increase gamma-power was also inhibited by pretreatment with flumazenil. We conclude that GABA-NAMs act via the benzodiazepine binding site of the $GABA_AR$ to produce a transient increase in correlated neuronal discharge at gamma frequencies and that this correlated discharge induces intrinsic activity-dependent synaptic strengthening in critical reward circuits that account for its anti-anhedonic actions. Together, these data provide additional support that alpha5 selective GABA-

NAMs have promise as novel, fast-acting antidepressants and provide new clarification for their mechanism and site of action.

Abstract: Negative allosteric modulators of GABA-A receptors (GABA-NAMs) with an alpha5 subunit (such as L-655,708) have been reported to produce rapid antidepressant effects in rodent models of anhedonia. We examined multiple aspects of L-655, 708 including sex specific behavioral differences, long-lasting effects of L-655, 708 and important neuroanatomical areas. As expected, in male rodents chronic exposure to stress significantly reduced sucrose intake compared to control animals. However, sucrose intake in female rodents significantly increased with stress exposure. One injection of L-655, 708 (0.7mg/kg) reversed sucrose intake patterns in both male and female chronically stressed animals within 24 hours normalizing the intake to that of control animals. In the forced swim test one injection of L-655, 708 significantly reduced immobility time in CUS exposed females compared to vehicle injected animals 24-hours following injection, an effect previously reported in male rodents. Additionally, we found the antidepressant behavioral effects of L-655, 708 to persist in measures of social interaction and sucrose intake for up to one week despite continued exposure to chronic stress.

Title: Inhibiting ventral dentate gyrus activity reduces anxiety-like behavior

Authors: *C. ANACKER[1], V. M. LUNA, 10032[1], G. STEVENS[1], A. MILETTE, 10032[1], R. SHORES, 10032[1], B. CHEN, 10032[1], R. HEN[2]

Abstract: The hippocampus is crucially involved in stress responses and emotional behavior. Within the dentate gyrus of the hippocampus new neurons are being generated during adulthood, but how these new cells contribute to dentate gyrus function remains elusive. Here, we exposed transgenic iBax mice with increased adult neurogenesis (1.8±0.2 fold) to chronic social defeat stress (10 days) and tested anxiety-like behavior in a social interaction test. We then virally-expressed the Ca^{2+} indicator, GCamp6f, in mature granule cells of the ventral dentate gyrus and we used *in vivo* Ca^{2+}-imaging with head-mounted miniature microscopes (Inscopix, CA) to investigate dentate gyrus activity in response to stress. Wild-type mice spent less time interacting with a novel mouse following chronic stress than undefeated control mice (***p=0.001, n=12-14 mice), while iBax mice with increased neurogenesis spent as much time interacting with a novel mouse as controls. Social defeat increased the number of dentate gyrus granule cells that selectively respond to stressful attacks in both wild type mice (by 34%) and in iBax mice (by 29%). However, the Ca^{2+} activity of these "attack"-selective cells was decreased in iBax mice with increased neurogenesis (U=12725, ***p<0.0001; n=169-211 cells). The number of cells that were selectively active during periods at which no attacks occurred were unaffected by stress and their Ca^{2+} activity was not different in iBax mice with increased neurogenesis. Direct inhibition of the ventral dentate gyrus by activating a virally-expressed inhibitory DREADD receptor (hM4Di) during stress reduced anxiety-like behavior in the social interaction test, mimicking the effect of neurogenesis (*p=0.01, n=9-10). We then activated the 5-HT1A receptor with the agonist 8-OH-DPAT in transgenic mice expressing 5-HT1A only in the dentate gyrus.

Activation of 5-HT1AR during chronic stress also silenced dentate gyrus activity and reduced social avoidance in the social interaction test (**p=0.009, n=18). Our findings suggest that adult-born neurons in the hippocampus inhibit a specific subpopulation of "stress-responsive" cells in the ventral dentate gyrus to reduce anxiety-like behavior, and that direct inhibition of the dentate gyrus, potentially by pharmacologically activating 5-HT1A receptors, could represent a new strategy to treat stress-induced psychopathology.

Abstract: Early life experiences have pronounced effects on brain function and behavior. Maternal separation in rodents is a widely used animal model used to induce early-life stress. This model has reliably demonstrated an increased risk of depressive-like behavior later in life. Clinically, adversity in early life increases the risk for the development of psychiatric disorders, such as Major Depressive Disorder (MDD), in adulthood. Mood disorders produce changes in neurochemistry and brain structure. Patients with MDD have exhibited learning and memory deficits. In addition to changes in hippocampal volume, patients with MDD have been found to have elevated levels of peripheral and central inflammatory factors including IL-6 and TNFa. Microglial activity has been associated with atrophy and inflammatory signaling in brain regions affected by MDD. Given that patients with MDD display alterations in hippocampal circuits, we hypothesized that early life adversity would be characterized by increased protein expression of inflammatory markers, morphological changes in microglia and dynamic changes in cellular matrix activity in the hippocampus. In the present study, Sprague Dawley male and female pups were separated from PND 2 to PND 14 for three hours a day with and without indirect (in utero

and lactational) minocycline. A control condition of non- separated pups was maintained. First, we examined behavioral tasks during adolescence and found separated offspring spent more time in closed arms of an elevated plus maze. Second, we found preferential activation of RelA expression and other inflammatory markers in distinct compartments of the hippocampus via Western Blot. Next, to understand the functional connectivity of our findings, we used immunofluorecence to examine the morphology of Iba1 positive cells. Finally, cytoskeletal dynamics of microglia play an active role in the response to stress as we found alterations in cofilin-related proteins. Overall, our results may provide insight to the molecular mechanisms responsible for inflammation and cellular reorganization in cortico-limbic circuits related to MDD and early life adversity.

Ctr., Baltimore, MD; [5]Pharmacol., Univ. of Maryland, Baltimore, MD; [6]Dept. of Anat. and Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD; [7]Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Rewards reinforce behaviors that promote survival. This creates strong evolutionary pressure to retain salient contextual information associated with these rewards. Changes in the drive to obtain rewards are observed in diseases such as addiction and depression. The neuronal circuits underlying the perception and processing of rewarding stimuli have been extensively examined, however, the requisite synapses and underlying neurophysiology involved in the encoding of contextual information within these circuits remains unknown. The hippocampus is a key brain region for processing and storing spatial information. It innervates the shell of the

nucleus accumbens (NAc), a structure that integrates information from multiple brain regions to process rewarding stimuli and convey signals to guide goal-oriented behaviors. The excitatory input from the hippocampus to the NAc is important for driving NAc activity, and modulation of the strength of this input may serve to regulate goal-oriented behaviors. Using *in vivo* electrophysiology and optogenetics, we demonstrate *in vivo* induction of long-term potentiation (LTP) at this synapse. Furthermore, this *in vivo* LTP is sufficient to drive conditioned place preference demonstrating an important role for plasticity at this synapse in the regulation of reward related behavior. We then used a chronic stress paradigm to induce depression-like behavior as measured by anhedonia. Using whole-cell electrophysiology, we observed a decrease in AMPA:NMDA ratio and LTP deficits specifically in D1-expressing medium spiny neurons in response to chronic stress. Additionally, exposure to chronic stress impaired hippocampus-NAc LTP-induced conditioned place preference. Taken together, this suggests that chronic stress weakens these synapses. The behavioral and electrophysiological changes induced by chronic stress exposure were rescued with antidepressant treatment. This work defines a specified neuronal circuit responsible for regulating contextual reward behavior and furthers our understanding of excitatory synaptic strength as a critical mediator of this process. Understanding the neuronal changes that underlie depression and antidepressant response will provide key insight into developing new, more effective treatments for this disorder.

Title: Contribution of the nucleus basalis of Meynert to cerebral blood flow responses in the ipsilateral but not controlateral primary somatosensory cortex during nociceptive processing

Authors: *T. PAQUETTE[1,3], R. TOKUNAGA[2,3], H. LEBLOND[1,3], M. PICHÉ[2,3]
[1]Dept. d'anatomie, [2]Dept. of Chiropractic, Univ. du Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada; [3]CogNAC research Group (Cognition, Neurosciences, Affect et Comportement), Trois-Rivières, QC, Canada

Abstract: Neurovascular coupling is a physiological process that involves a local hemodynamic response associated with surrounding neuronal activity. This coupling in mainly driven by glucose metabolism and the release of vasoactive agents, such as nitrite oxide. However, cerebral blood flow (CBF) is also regulated by the nucleus basalis of Meynert (NBM), which sends cholinergic projections to the cortex. Accordingly, the NBM regulates CBF independently of local neuronal activity in the cortex during somatosensory stimulation. However, the role of the NBM in CBF regulation during nociceptive stimulation associated with changes in mean arterial pressure has never been investigated. This is critical for neuroimaging of nociceptive and pain-related brain activity. Thus, the objective of this study was to investigate the contribution of the NBM to the CBF responses in the primary somatosensory cortex during nociceptive processing.
All experimental procedures were approved by the Université du Québec à Trois-Rivières animal care committee, and were in accordance with the guidelines of the Canadian Council on Animal Care. Experiments were conducted in 8 male Wistar rats under isoflurane anaesthesia (1.2%). After thinning the skull, cerebral blood flow of the entire cortex was examined using laser speckle contrast imaging. CBF responses to graded electrical stimulation of the right sciatic nerve was compared between intact conditions and after electrolytic lesion of the left NBM. For both conditions the stimulation protocol included 10 intensities ranging between 0.05 and 9.6 mA.
Electrical stimulation produced intensity-dependent increases in mean arterial pressure ($p<0.001$) and these changes were almost identical between the intact condition and after NBM lesion ($p=0.96$). In both conditions, electrical stimulation also produced intensity-dependent CBF responses ($p<0.001$) that were greater in the primary somatosensory cortex contralateral to the stimulation compared with the ipsilateral one ($p=0.004$). After NBM lesion, CBF responses were decreased in the primary somatosensory cortex ipsilateral to NBM lesion compared with the intact condition ($p=0.02$). However, CBF responses contralateral to NBM lesion were not significantly different between conditions ($p=0.46$).
These results indicate that NBM contributes to CBF responses to nociceptive stimulation in the ipsilateral but not controlateral primary somatosensory cortex and these effects are not confounded by changes in mean arterial pressure. This highlights the importance of NBM integrity for nociceptive and pain-related hemodynamic responses in the primary somatosensory cortex.

Inst., Oregon Hlth. & Sci. Univ., Potland, OR

Abstract: Cerebral hypoperfusion, by large vessel occlusion and stenosis is a key mechanism contributing to vascular cognitive impairment (VCI). Our previous work showed bilateral common carotid stenosis (BCAS), in a mouse model, leads to gliovascular disruption and increased vascular amyloid accumulation (Holland et al., 2015 and Salvadores et al., 2017). The paravascular pathway (glymphatic system) is a brain-wide pathway for waste clearance via the gliovascular network. It has been reported to be important in the removal of metabolic waste products and solutes such as amyloid-β and tau. We hypothesised that glymphatic function would be impaired in a model of carotid stenosis and further exacerbated in the presence of amyloid. Male wild-type and Tg-SwDI (a model of microvascular amyloid) mice were subjected to BCAS or sham surgery (n=7-10 per group), and at 3 months after hypoperfusion glymphatic function and resting cerebral blood flow (rCBF) were evaluated. We demonstrate that BCAS causes a regional reduction of paravascular cerebrospinal fluid (CSF) tracer influx in the dorsal lateral cortex (DLCTX) and CA1-DG molecular layer (CA1-DG) in parallel with reduced cerebral blood perfusion. To further investigate the mechanisms that may lead to these changes we measured, in a multiphoton study, the pulsation of cortical vessels and found a significant decrease in pulsation in pial arteries. This data suggest that carotid stenosis may influence VCI by an effect on vessel pulsation and impaired paravascular pathway.

Title: Noradrenergic modulation of neurovascular coupling in awake behaving mice

Authors: *Q. ZHANG[1], K. W. GHERES[2], P. J. DREW[1,3,4]
[1]Ctr. for Neural Engineering, Dept. of Engin. Sci. and Mechanics, [2]Grad. Program in Mol. Cell. and Integrative Biosci., [3]Dept. of Biomed. Engin., [4]Dept. of Neurosurg., The Pennsylvania State Univ., University Park, PA

Abstract: Hemodynamic signals are widely used to infer neural activity in functional brain imaging techniques (e.g., fMRI). Previous work (Huo et al., J. Neurosci., 2014) has shown that neural activity in the frontal cortex increases without corresponding changes in hemodynamic signals during locomotion, and we sought to mechanistically understand this decoupling. We hypothesized that neuromodulatory input, specifically a noradrenergic (NA) vasoconstrictory signal, interact with neural activity-driven vasodilation to shape the hemodynamic response. Here, we investigated the NA modulation of neurovascular coupling by measuring hemodynamic responses (intrinsic optical signal imaging) and neural activity (multi-laminar linear electrode arrays) to voluntary locomotion in awake, head-fixed mice. Noradrenergic tone was decreased or increased by systemic administration of antagonists of α1- (prazosin) and α2-adrenoceptors (atipamezole), respectively. Compared to vehicle controls, cerebral blood volume changes during locomotion were increased by prazosin in both the frontal and somatosensory cortices, while atipamezole decreases the amplitude the locomotion-related response in the somatosensory cortex. These results suggest that in addition to local vasodilatory signals released from neurons and astrocytes, changes in neuromodulatory tone (especially noradrenergic tone) play an important vasoconstrictory role in shaping hemodynamic signals during behavior. We are exploring the role of peripheral and central noradrenergic innervation on controlling the hemodynamic response using intracortical infusion of noradrenergic antagonists and performing an acute chemical sympathectomy. These results will elucidate the role of NA effects on hemodynamic signals.

Title: Quantifying the neural and non-neuronal components of inter-hemispheric hemodynamic correlations

Authors: *K. L. TURNER[1,2], A. T. WINDER[2], P. J. DREW[1,2,3]
[1]Dept. of Biomed. Engin., [2]Ctr. for Neural Engineering, Dept. of Engin. Sci. and Mechanics, [3]Dept. of Neurosurg., Pennsylvania State Univ., University Park, PA

Abstract: Hemodynamic signals in the brain are used to infer neural activity, and strong correlations in hemodynamic signals between bilateral cortical areas have been observed in the absence of a task (‘functional connectivity during the resting-state’). Understanding the relationship between these bilateral hemodynamic signals and the underlying neural activity is important for the interpretation of these hemodynamic signals. Previous work has proposed that hemodynamic signals are a sum of a neurally-evoked component and a putatively non-neuronal component. Importantly, the relative contributions of the neural and non-neuronal components depends on the behavioral state of the animal. Here we investigate the role of behavior and neural activity in sculpting bilateral hemodynamic signals. We used intrinsic optical signal imaging through chronically implanted thinned-skull windows to measure bilateral changes in cerebral blood volume in parallel with electrophysiological recordings in the somatosensory cortices of awake mice. We continuously monitored both animal motion and whisking behavior to classify behavioral state. We also stimulated the whiskers to compare the strength of neurovascular coupling in the evoked condition with neurovascular coupling in the resting state. To test the influence of the neural activity in driving bilateral hemodynamic correlations, we suppressed local neural activity in the somatosensory cortex of one hemisphere, allowing us to directly measure the strength of non-neuronal correlations between hemispheres. These experiments will elucidate the neural contribution to bilateral functional connectivity across behavioral states.

Title: Pericyte structural plasticity in the adult mouse brain

Authors: *A. Y. SHIH[1,3], D. HARTMANN[4], A.-A. BERTHIAUME[2,4]
[1]Ctr. for Developmental Biol. and Regenerative Med., [2]Seattle Children's Res. Inst., Seattle, WA; [3]Neurosci., [4]Med. Univ. of South Carolina, Charleston, SC

Abstract: Direct contact and communication between pericytes and endothelial cells is critical for maintenance of cerebrovascular stability and blood-brain barrier function. Capillary pericytes have thin processes that reach hundreds of micrometers along the capillary bed. The processes of adjacent pericytes come in close proximity but do not overlap, yielding a cellular chain with discrete territories occupied by individual pericytes. Little is known about whether this pericyte chain is structurally dynamic in the adult brain. Using *in vivo* two-photon imaging in adult mouse cortex, we show that while pericyte somata are immobile, the tips of their processes undergo extensions and/or retractions over days. The selective ablation of single pericytes provoked exuberant extension of processes from neighboring pericytes to contact uncovered regions of the endothelium. Uncovered capillary regions had normal barrier function, but were persistently dilated until pericyte contact was regained. Pericyte structural plasticity may be critical for cerebrovascular health and warrants detailed investigation.

Abstract: Many studies on blood-flow of the cortical vascular that relates to that of the brain activity have been reported. However, it is difficult to continuously measure brain activity and blood-flow in a small animal. Wehave developed a chronic blood-flow imagingdevice for continuously observing brain activity and blood-flow in a small animal brain.We already succeeded to observe blood-flow on the brain surface using the green LEDs with an emission wavelength of 535 nm, at which one of the absorption peaks of hemoglobin in blood appears [1]. The developed device included a CMOS image sensor mounted on a small electronic substrate, a light source with green LEDs. This simple structure enabled us to measure brain blood-flow in a small animal. In this study, we have modified our previous device to perform a long-term measurement. We have improved devise's structure and developed an implantation method of a special chronic window in a small animal. The modified device measured the blood-flow changing with the LED light sources at a primary somatosensory cortex with stimulation. The new method allowed observation for more than one month in an animal. Next work, we will use this device to observe cerebrovascular disease in a behavioral experiment and evaluate of drug efficacy to the disease. All animal procedures conformed to the animal care and experimentation guidelines of the Nara Institute of Science and Technology. [1]M. Haruta, C. Kitsumoto, Y. Sunaga, H. Takehara, T. Noda, K. Title: A new model for molecule delivery and clearance in brain microvascular system: Consequences of capillary occlusions in Alzheimer's disease

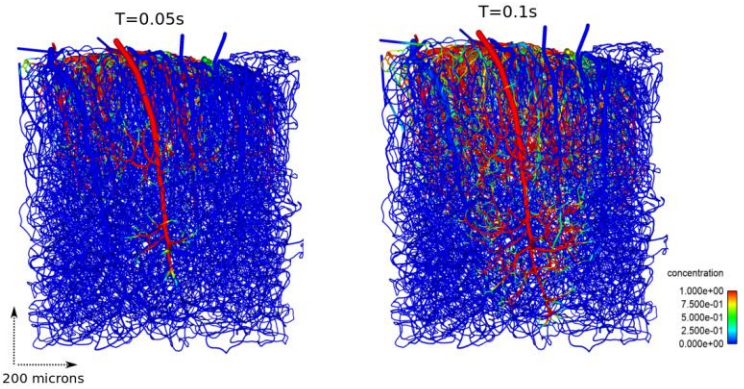
Authors: *M. BERG[1], O. BRACKO[2], Y. DAVIT[1], M. QUINTARD[1], N. NISHIMURA[2], C. B. SCHAFFER[2], S. LORTHOIS[1]
[1]CNRS, Toulouse, France; [2]Biomed. Engin., Cornell Univ., Ithaca, NY

Abstract: The brain microvascular system is a key actor in Alzheimer's disease (AD) development. Indeed, a significant decrease of cerebral blood flow is the earliest biomarker of AD (Iturria-Medina Nat Com 2016).
In vivo TPLSM of cortical vasculature in APP/PS1 mice suggests the mechanism underlying the blood flow reduction is capillary occlusions. Leucocytes adhere to inflamed vessel walls and limit the flow (Cruz-Hernandez BioRxiv 2017).
The impact of capillary occlusions on blood flow has been quantified numerically in large (>10000 vessels) anatomical networks in humans and mice (Berg SFN 2017). The regional blood flow has been found to depend linearly with no threshold effect on the fraction of capillary occlusions, so that a small fraction of stalls (2-4%) yields a significant decrease in blood flow (5-12%).
Such flow decrease has a strong impact on nutrient delivery and waste clearance. That is why we devised a new model to study the effect of capillary stalling on molecule transport. The geometry of anatomical networks is too complex to use classic numerical approaches like finite elements. Instead, our model, inspired by pore-network approaches, reduces computational costs while capturing most of the underlying physics.
To derive this model, we apply upscaling methods (Davit Adv Wat Res 2013) to the 3D transport equations within each vessel to obtain 1D average equations along the axis. Contrary to previous models, this new formulation describes accurately radial concentration gradients, capturing effects like longitudinal dispersion.
We further use a Green's function formulation inpired by Secomb (ABE 2004) to calculate the concentration fields inside the tissue where diffusion and reaction occur. The coupling between vessels and tissues is modelled using a membrane condition (Fraser Micr 2015) representing the blood brain barrier.
This new molecule transport model is coupled with our previously validated blood flow model to examine the effects of capillary stalling on molecules delivery and clearance in transient and stationary regimes in anatomical networks.



Simulation of Intravascular transport of a passive tracer in a large mouse brain anatomical network (TPLSM post mortem acquisition, P.Tsai J. Neuroscience 2009).

Title: Head-down tilt as a model for intracranial pressure changes during spaceflight

Authors: *C. A. FULLER, E. L. ROBINSON, A. L. MCELROY, H. GOMPF, T. M. HOBAN-HIGGINS
Dept of Neurobiology, Physiol. & Behavior, Univ. of California, Davis, CA

Abstract: Introduction: In addition to the unweighting of the muscle and skeletal systems which normally counteract Earth's gravity, the microgravity environment of an orbiting spaceflight removes the hydrostatic pressure gradient, which produces a pronounced cephalic fluid shift. This study used the well-established rat hind-limb (HLS) suspension model to investigate the hypothesis that this fluid shift results in an increased intracranial pressure (ICP). Increased ICP could, in turn, underlie some of the ocular changes seen in astronauts during and following long-duration spaceflight. Methods: The HLS model, functionally equivalent to human head-down bedrest, was used to examine the relationship between cephalic fluid shifts, the regulation of intracranial pressure (ICP) and ophthalmic responses. In this model, a tail-suspension apparatus maintains the animal in a ~30° head down orientation. The forelimbs remain in contact with the floor and a pulley system allows the rat free access to all areas of the cage. Long Evans rats served as subjects for this project. Four groups of rats were studied to examine the effects of gender, age and hypercapnic exposure on the responses. In this presentation, we report on the results from rats 9 months of age at the start of the experiment. This group mimicked the age of the older astronauts studied in whom the prevalence of ocular changes was more prevalent. Subjects were studied for 180 days consisting of 90 days of HLS and then a 90-day post-HLS recovery period. An additional population of age-matched animals were similarly studied as cage controls. All animals had *ad lib* access to food and water. A 12:12 LD cycle was present. Biotelemetry (DSI) was used to record ICP, EEG, body temperature and activity. MRI imaging of the brain and eyes was performed at baseline and every 45 days thereafter. Intraocular pressure (IOP) was also measured. Ophthalmological measures included: OCT, fundoscopy, refraction and measurement of the length of the eyeball axis. Results and Conclusions: The 90-

day duration of the HLS was chosen to mimic an exploration class mission. A sustained small increase in ICP was seen during HLS. These observations agree with recent data collected from human subjects showing a small increase in ICP during spaceflight. Similarly, a small elevation of IOP was seen in the HLS subjects. MRI revealed reversible shifts in structures, including possible dilation of the optic nerve sheath and a dorsal shift in the location of the eyes. Differences in refraction, similar to those seen in astronauts, were also evident.

Title: Regulating pericytes with optogenetics

Authors: *A. R. NELSON, Y. WANG, Z. ZHAO, B. ZLOKOVIC
Zilkha Neurogenetic Inst., USC, Los Angeles, CA

Abstract: Pericytes are essential for blood-brain barrier formation and maintenance, and perform multiple functions at the neurovascular unit including regulation of **1)** BBB permeability and bulk flow fluid transcytosis, **2)** capillary diameter, **3)** cerebral blood flow (CBF) velocity, **4)** angiogenesis (the formation of blood vessels from existing vessels) and subsequent microvascular stability and network architecture, **5)** phagocytotic clearance of toxic metabolites from the CNS, **6)** pro-inflammatory responses, e.g., leukocyte trafficking, and **7)** multipotent stem cell activity. However, whether or not pericytes are contractile cells has been a continuous debate dating back to 1873 when they were first described by Rouget as regularly arranged longitudinal amoeboid cells that have a muscular coat on capillaries. Here, we test the hypothesis that capillary level pericytes are contractile cells. To test this hypothesis, we developed a novel pericyte-specific Cre mouse using a double-promoter approach with both the *Pdgfrβ* and *Cspg4* promoters, crossed to either a Cre-dependent channelrhodopsin (ChR2) mouse with a YFP reporter gene, termed *Pericyte-ChR2*, or crossed to a Cre-dependent halorhodopsin (eNpHR3.0) mouse with a YPF reporter gene, termed *Pericyte-eNpHR3.0*. First, we confirmed that ChR2 and eNpHR3.0 are only expressed in pericytes by performing immunofluorescent staining with anti-CD13 antibody and which colocalized with the YFP reporter gene. Using the *Pericyte-ChR2* mice, we performed optogenetics experiments *in vivo* and found that stimulation of ChR2 caused

pericytes to contract and the underlying capillary to constrict. Using *Pericyte-eNpHR3.0* mice, we performed optogenetics experiments *in vivo* and measured changes to pericyte contractility and underlying capillary diameter.

Title: Development and validation of an open source software for brain perfusion imaging in rodents

Authors: *J. PRINCE[1], K. SHAH[1], M. D. SWEENEY[1], S. BARNES[2], M. T. HUUSKONEN[1], R. E. JACOBS[1], A. MONTAGNE[1], B. V. ZLOKOVIC[1]

Abstract: Magnetic resonance imaging (MRI) can be used to image vascular dynamics, for instance, cerebral blood flow (CBF), to study normal brain physiology and pathophysiology with high temporal resolution. A technique to measure CBF established on MRI is dynamic susceptibility-contrast (DSC) perfusion, which comprises of intravenous injection of an exogenous contrast agent (CA), *i.e.*, gadolinium- or iron oxide-based compound. Various software packages do exist in the market, however, most of them only give relative/semi-quantitative CBF and CBV values. We insinuate a MATLAB program which is transfigured to a user-friendly interface, to convert the ΔR2* signal intensity recorded during a DSC scan into quantitative cerebral blood flow (CBF), cerebral blood volume (CBV), but also time-to-peak (TTP) and mean transit time (MTT) brain maps. We tested our DSC sequence and MATLAB program in chronic hypoperfusion (unilateral common carotid ligation) and Alzheimer's (*5xFAD*) mouse models. We found a severe CBF reduction (~-40-50%) in the ipsilateral hemisphere when compared to the contralateral side 24 hours post-carotid ligation. We also observed subtle regional CBF changes (~-10-30%) in 6-month-old Alzheimer's *5xFAD* mice compared to age-matched littermate controls in the primary somatosensory cortex, striatum, hippocampus and corpus callosum. Notably, we validated our DSC results in both models using

golden standard quantitative ^{14}C-iodoantipyrine (IAP) autoradiography using same exact animals for direct comparison. In conclusion, this is a unique perfusion user-interface which allows detection of subtle microcirculatory dysfunctions in the rodent brain. Moreover, our DSC method was corroborated using IAP method - a technique that takes about 3-4 weeks long for an *ex vivo* procedure contrary to a 2-min MR sequence for rapid DSC post-processing *in vivo*, which is also worthwhile for longitudinal studies. Finally, this software will be valuable not only in Alzheimer's Disease but also in Cerebral Small Vessel Disease and ischemic strokes involving vascular injuries and blood flow dysregulations.

Title: Development of neural activity and neurovascular coupling in the somatosensory cortex of the awake mouse

Authors: *K. W. GHERES[1], P. J. DREW[2]
[1]Huck Inst. of the Life Sci., Pennsylvania State Univ. Univ. Park, University Park, PA; [2]Dept. Engin. Sci. and Mechanics, Pennsylvania State Univ., University Park, PA

Abstract: In the adult somatosensory cortex, behavior-driven increases in neural activity evoke large, spatially restricted changes in blood volume through arterial and venous dilations. However, as both human and rodent studies have shown neurovascular coupling can be weak, absent, or inverted in the juvenile brain we sought to understand how the stimulus evoked hemodynamic response matures during the postnatal period in mice. We investigated the underlying cellular mechanisms of neurovascular coupling in whisker barrel cortex using two-photon microscopy, intrinsic optical signal (IOS) imaging, and in-vivo extracellular electrophysiology. We found administration of the dilator isoflurane to P10 mouse pups was sufficient to induce arterial dilations, demonstrating arteries in the second postnatal week have resting muscle tone and are capable of dilating. In awake behaving animals, whisker stimulus increases neural activity in barrel cortex beginning in the second postnatal week, however, appreciable stimulus-evoked arterial dilations and blood volume increases do not appear until the third postnatal week, demonstrating an initial decoupling of the neurovascular relationship. After initiation of neurovascular coupling in the third postnatal week, increases in stimulus evoked

spike rates and local field potentials during the later juvenile period are matched by increases in stimulus evoked blood volume changes. This work suggests that prior to the third postnatal week, local neurons lack a fast acting mechanism to relay local neural activity to neighboring arteries, making it difficult to interpret hemodynamic signals in the developing brain.

Title: Extreme vasodynamics in cortex accompany REM sleep

Authors: *C. MATEO[1], D. KLEINFELD[2]
[1]Physics Dept, UCSD, La Jolla, CA; [2]Univ. of California at San Diego, La Jolla, CA

Abstract: Brain arterioles exhibit continuous dynamics, including changes in diameter linked to neuronal activity. We previously showed that slow (0.1 Hz) changes in the power of fast (gamma band) neuronal activity in the cortex of awake mice entrains the vasomotor activity of local arterioles and, consequently, modulates the oxygen supply to the parenchyma (Mateo et al. 2017). Here, we observed that the diameter of arterioles in the cortex undergo large phasic dilations that saturate at the maximum diameter of the vessels and last up to hundreds of seconds. The results from concurrently obtained electromyograms, local field potential measurements in cortex, behavioral monitoring, and assays of neuromodulators leads to the conclusion that this extreme dilation occurs when mice enter a rapid eye movement (REM) sleep phase. They persist as long as the REM sleep epoch and add to the wealth of phenomena that connect the sleep cycle with neuronal and metabolic changes (Petit and Magistretti, Neurosci 2016). We are currently exploring the source of this dilation. Vasoactive acetylcholine (ACh) and norepinephrine (NE) in subcortical neurons have been shown to have dramatic discharge pattern changes during sleep cycle (Boucetta et al. J Neurosci 2014). We monitored the volume transmission of ACh and NE with the use of implanted cell-based neurotransmitter fluorescent engineered reporters (CNiFERs) (Nguyen, Schroeder et al. Nat Neurosci 2010; Muller, Joseph et al. Nat Meth 2014). We find that ACh dramatically increases during REM sleep with a time lag of tens of s relative to the start of the large arteriole dilation. Local cortical ACh is therefore unlikely to be responsible for the onset of the arteriole dilation. The vasoconstrictor NE increases upon arteriole constriction and waking. We are currently measuring the activity of specific neuron populations

across vigilance states in superficial layers. Moving forward, we will use CNiFERs to probe dopamine and the neuropeptides NPY, orexin, and VIP, and other means to probe NO, during REM sleep. Changes in neuronal and vascular dynamics across brain states that may contribute to the restorative effects of sleep on cognition. Two hypotheses follow from our findings. One is the potential involvement of the dilation as a means to augment the clearance of metabolites in the brain during sleep (Xie et al. Science 2013). Toward this aim, we concurrently image the same vessel at different depths. A second hypothesis is that expansion of arteries increases oxygenation in the brain and compensates for metabolic load during REM sleep (Dash et al. Sleep 2012).

Title: Effects of acute aerobic exercise on behavioral and prefrontal hemodynamic responses to a fatiguing cognitive task

Authors: *C. AUSENHUS[1], G. GOEBEL[1], K. HALLDIN[1], D. C. MONROE[3], B. HUNT[1], N. THOM[2]
[1]Applied Hlth. Sci., [2]Biol., Wheaton Col., Wheaton, IL; [3]Dept. of Neurol., UC Irvine, Irvine, CA

Abstract: Objectives: Despite having expended a significant amount of energy, people report lower levels of fatigue after exercise. We sought to explore the mechanisms that underlie this apparent paradox by measuring the effects of aerobic exercise on feelings of fatigue and prefrontal cortex (PFC) hemodynamic response during a fatiguing cognitive task. We hypothesized that exercise would reduce feelings of fatigue and improve task performance, changes that would be pronounced among those with elevated baseline fatigue, and partially explained by PFC hemodynamic response to the fatiguing task.
Methods: Healthy college students (16 males; 15 females) completed three lab visits: familiarization with graded exercise test, rest, and exercise sessions. A modified Paced Auditory Serial Addition Task (mPASAT) was administered before and after each Condition, with fNIRS recorded simultaneously. Self-reported fatigue, block-averaged reaction time weighted for accuracy (WRT) on the mPASAT, and block-averaged hemodynamic response (HbO, HbT, and HHb) were analyzed using an RM-ANOVA across Condition (Rest, Exercise), Time (Pre-, Post-

Condition), and Block (1, 2, 3), with Bonferroni corrections for multiple comparisons. Huyhn-Feldt was used to adjust F-values for differences in variance across Block levels. Pairwise comparisons were computed to decompose Block effects.
Results: Completing the mPASAT was fatiguing across Blocks independent of Condition and Time [$F(3,90)=55.77$, $p< 0.01$, $\eta^2=0.68$]. Fatigue increased across all blocks relative to pre-task baseline (all ps < 0.01). Weighted reaction time on the mPASAT decreased across Blocks independent of Condition and Time [$F(2,58)=16.42$, $p< 0.01$, $\eta^2=0.36$]. Pairwise comparisons revealed differences between blocks 1 and 2 ($p<.01$), blocks 1 and 3 ($p<0.01$), but not between blocks 2 and 3 ($p=0.11$). PFC hemodynamic responses to the mPASAT changed across Blocks independent of Condition and Time. There were significant effects of Block for HbO, HHb, and HbT [$F(2,44)=9.18$, $p<.01$, $\eta^2=0.29$; $F(2,44)=15.00$, $p<.01$, $\eta^2=0.41$; $F(2,44)=3.50$, $p=0.04$, $\eta^2=0.14$]. Pairwise comparisons revealed differences between blocks 1 and 2, 1 and 3, but not 2 and 3 for HbO (ps=.01, .02, 1.00) and HHb (ps=.01, .01, .78) and for blocks 1 and 2 for HbT (ps=.04, .18, 1.00)
Conclusion: These findings suggest that the mPASAT can be used to manipulate fatigue in a healthy sample of young adults in a laboratory setting. Contrary to expectations, exercise did not protect against the fatiguing effects of the task. The uncoupling of feelings of fatigue, performance, and PFC activity on a fatiguing task after exercise in this sample necessitate further exploration.

Title: Label-free measurement of flow speed in cortical blood vessels in mice using third harmonic generation microscopy

Authors: *N. RUIZ[1], S. AHN[2], C. B. SCHAFFER[2]
[2]Meinig Sch. of Biomed. Engin., [1]Cornell Univ., Ithaca, NY

Abstract: The measurement of blood flow speed in individual brain blood vessels of rodents is essential for understanding healthy and diseased state physiological processes. Two-photon excited fluorescence (2PEF) microscopy, which enables 3D, micrometer resolution *in vivo*

imaging of fluorescently-labeled structures deep into tissue, has emerged as a technique of choice for such measurements. To study vessel topology and function, the blood plasma is labeled by intravenously injecting high molecular weight dextran with conjugated fluorescent dyes. The red blood cells (RBCs) remain unlabeled, so they form dark patches whose motion can be tracked to quantify blood flow speed in individual vessels. While this approach has enabled detailed studies of blood flow in rodents, the penetration depth of 2PEF imaging restricts measurement to vessels in the top 0.5 mm of the cortex. Recently, the emergence of three-photon excited fluorescence (3PEF) microscopy has enabled imaging of blood vessels as deep as the hippocampus through the intact cortex in mice. Another nonlinear optical process called third harmonic generation (THG) occurs primarily at optical interfaces and can be resonantly enhanced by optical absorption peaks. For example, RBCs produce bright THG when excited with 1,300 nm light, due to the optical absorption peak of hemoglobin at 425 nm. In this study, we used 3PEF of FITC-dextran and THG from RBCs to quantify blood flow speed in arterioles, capillaries, and venules at depths of up to ~1 mm beneath the cortex. Because the THG signal is produced primarily from RBCs, while the 3EPF of FITC-dextran shows blood plasma, we were also able to quantify the width of the cell free layer adjacent to the vessel wall. Finally, we took advantage of the label-free nature of THG imaging to quantify the impact of injecting high molecular weight dextran on blood flow speed. We measured blood flow speed and tube hematocrit in the same vessels with and without FITC-dextran, and found a ~20% decrease in flow speed in arterioles and venules associated with the injection of ~100 µL of 5% w/v 2 MDa FITC-dextran (45 vessels across 4 mice). Interestingly, we did not observe slower flow speeds in capillaries and instead noted a ~35% decrease in tube hematocrit in capillaries associated with the injection of FITC-dextran (56 capillaries across 4 mice). With this study, we have shown the potential of THG as a label-free imaging approach for studying blood flow deep in the brain of rodents. In addition, the large changes in flow speed and hematocrit we observed with dextran injection suggest that careful consideration must be given when using this labeling strategy.

Title: Tonic and bidirectional regulation of arteriole tone by astrocyte steady-state Ca^{2+}

Authors: *J. HAIDEY, G. R. GORDON
Univ. of Calgary, Calgary, AB, Canada

Abstract: Astrocyte-mediated neurovascular coupling has conventionally been examined in the context of transient neuronally-evoked calcium (Ca^{2+}) events triggering phasic changes in arteriole diameter. Our research group has recently demonstrated that driving astrocyte free endfoot Ca^{2+} to zero elicits prominent vasoconstriction in adjacent arterioles, suggesting that the basal, 'steady-state' astrocyte Ca^{2+} level maintains resting arteriole tone; thereby controlling brain blood flow tonically. However, it is unclear how subtle fluctuations in steady-state astrocyte Ca^{2+} may regulate vascular tone. Previous work has revealed that the resting astrocyte Ca^{2+} concentration ranges from ~70-130 nM, which may be altered by experience or disease. The objective of our investigation was to clamp astrocyte Ca^{2+} concentration both above and below resting levels, measuring any resulting changes in arteriole diameter and if so, determine if arteriole tone maintained a new, stable level. This was accomplished using two-photon fluorescence imaging and patch-clamp in acute cortical brain slices acquired from male Sprague Dawley rats (P21-30). We used various ratios of BAPTA and free Ca^{2+} to clamp astrocyte free Ca^{2+} at low (25 nM; n=7), near-resting (100 nM; n=5), moderate (250 nM; n=8), and high (750 nM; n=8) levels. Our preliminary data show that clamping astrocyte Ca^{2+} at either 25 nM or 750 nM increases arteriole tone (vasoconstriction), whereas clamping at 250 nM Ca^{2+} decreases arteriole tone (vasodilation), and each condition was met with a stable tone change that lasted a 10min recording. In contrast, both the 100 nM Ca^{2+} clamp solution and the EGTA control solution produced no substantial changes in arteriole diameter. Each Ca^{2+} clamp manipulation was met with a corresponding change in astrocyte Ca^{2+} fluorescence measured using Rhod-2. These results suggest that moderate deviations in astrocyte cytosolic free Ca^{2+} from resting levels stably set basal vascular tone in a bidirectional manner.

Title: GIRK channel direct activation with ML297 depresses a capsaicin-induced increase in microcirculatory blood perfusion in the rat cheek

Authors: *X. S. XIE[1], K. XIAO[1], C. PASCUAL[1], B. ZOU[1], W. CAO[1], C. LINDSLEY[2], C. WEAVER[2]
[1]Afasci Res. Laboratories, Afasci, Inc., Redwood City, CA; [2]Dept. of Pharmacol., Vanderbilt Univ., Nashville, TN

Abstract: A clinical experimental pain model and sensory response test utilizes capsaicin-induced neuroinflammatory pain in healthy volunteers. Functional imaging studies demonstrate that capsaicin induces central sensitization and suggests that these methods can potentially be used to guide the selection of effective analgesics for neuropathic pain in early drug development (Wanigasekera, et al., 2016). We attempted to "reverse" translate this clinical test into a preclinical assay and test the hypothesis that direct activation of G protein-gated inwardly-rectifying potassium (GIRK) channels can depress capsaicin-induced changes in microcirculatory blood perfusion in the rat cheek.
The total local tissue perfusion measured using Laser Doppler Imaging (Perimed Doppler) was stable for at least 30 min in individual rats. Due to large variation among individual rats, all perfusion levels (in an arbitrary value per a 1 min block) were normalized to the 10 min time point just prior to the topical cheek application of capsaicin (10 µL, 30µM in 70% ethanol). Tissue perfusion was gradually increased and reached a plateau level by 10 min and was maintained for another 10 min after capsaicin (but not ethanol alone) application under control conditions. Injection of ML297 (5 mg/kg, 0.4 mL I.V.), a direct GIRK channel activator, significantly inhibited capsaicin-induced enhancement of tissue perfusion. The peak effect was observed at approximately 7-min after drug application and tissue perfusion was 115.5%±9.3 compared to 183.2%±19.1 of vehicle control (n=9 for each group, $p<0.05$); whereas ML297 had no significant effects on the normal tissue perfusion with topical ethanol application (n=8, $p>0.05$). These results demonstrated that GIRK channel activation with ML297 preferentially depressed the capsaicin-induced perfusion increment. The objective measurement of capsaicin-induced tissue perfusion change and its response to drug treatment can be a powerful tool for analgesic evaluation in preclinical and early clinical proof of concept studies.

Title: Precapillary sphincters on penetrating arterioles regulate brain capillary flow

Authors: *S. GRUBB, C. CAI, L. KHENNOUF, B. O. HALD, S. ZAMBACH, M. J. LAURITZEN
Univ. of Copenhagen, Copenhagen N, Denmark

Abstract: Research objective
In the brain, mural cells at the branch points of penetrating arterioles (PA) regulate blood flow to the capillary bed. Precapillary sphincters (PS) are mural cells encircling the initial segment of the PA branch and are well-known in mesenteric microcirculation and from numerous text-book examples of microcirculation, but their existence in other organs, including the brain, has been questioned. We provide evidence that they do exist in the mouse brain, and that they play a significant role in blood flow regulation.
Methods
We performed *in vivo* experiments in anaesthetized adult NG2-DsRed mice (male or female), which express DsRed in smooth muscle and pericytes under the NG2 promotor. The mouse was administered FITC-dextran i.v. to visualize branch points of PAs in layer 1-3 of the right barrel cortex by two-photon microscopy. We investigated the PS function by timelapses of dilatory responses during whisker pad stimulation and resonance line scanning to measure red blood cell (RBC) velocity through the PS. We also observed PS responses to cortical spreading depolarization.
Results
We found that PS exist in the mouse brain as mural cells encircling the initial segment of PA branches in layer 1-3. The PS was often followed by an expanded vessel lumen only sparsely covered by DsRed-positive cells which we named 'the bulb'. Under baseline conditions, the diameter of the PA lumen was 14±2 µm at the branchpoints (n=25). The diameter of the PS lumen (4±1 µm) was narrower than the bulb (8±1 µm), but comparable to the rest of the 1. order capillary (6±1 µm) (n=20-25, ±SD, one-way ANOVA). Upon whisker pad stimulation, the PS lumen dilated (26±3%) comparable to the rest of the 1. order capillary (28±3%) but more than the bulb (17±3%) or the PA (13±2%). In the minutes after stimulation, the PS lumen diameter narrowed (12±2%), sometimes only allowing plasma skimming. Line scanning revealed that RBCs pass quickly through the PS but when they enter the larger volume of the bulb they slow down, change to parachute form and line up, suggesting that the bulb might have a role in readying the RBCs for the capillary bed. During the early and late constriction phases of cortical spreading depolarization, the PS lumen also narrowed to a diameter where the RBCs in the capillary were either slowed or stopped, suggesting a bottleneck function of PS during hemodynamic changes evoked by cortical spreading depolarizations.
Conclusions
Precapillary sphincters exist in the mouse brain, and they actively regulate the blood flow by forming a bottleneck of vascular resistance at the very beginning of the capillary bed that can be released or tightened to match the nerve activity with blood flow.

Title: *In vivo* micro-puffing of ATP-sensitive potassium channel opener leads to brain capillary vasodilation

Authors: *S. A. ZAMBACH, C. CAI, M. LAURITZEN
Dept. of Neuroscience, Univ. of Copenhagen, Kobenhavn N, Denmark

Abstract: Neurovascular coupling adjusts cerebral blood flow according to the metabolic needs of brain tissue. Cerebral blood flow is regulated by arteriolar smooth muscle cells, but new discoveries show that cerebral pericytes, contractile cells on capillary walls, actively regulate blood flow in capillaries, even prior to the upstream smooth muscle cells. However, it is still unclear what signaling pathway and channels of pericytes are involved in regulation of capillary diameter. Previous studies have shown that ATP-dependent potassium channels (Katp) are highly expressed in cerebral pericytes; while until now the regulation of blood flow by Katp channels have only been studied in vascular smooth muscle cells of big surface arteries of the brain. The aim of this study is to examine if pericyte Katp channels have the potential to modulate brain capillary blood flow in physiological state. Guided by two-photon microscopy, a glass micro-pipette containing Katp opener (pinacidil) was inserted and approached to the proximity of 1st, 2nd and 3rd order of capillary and penetrating arteriole in NG2DsRed mouse brain. Air pressure puffing of pinacidil in this local region was imaged by two-photon microscopy to study the vascular diameters. Vessel borders in two-photon time-series were calculated after ROI placement by an active contour algorithm. Vessels diameter increased (penetrating arteries mean = 4.83%, STD = 1.57%, 1st order capillary mean = 20.07%, STD = 2.07%, 2nd order capillary mean = 16.69%, STD = 2.1%, 3rd order capillary mean = 12.72%, STD = 6.98%) and stayed at a long-lasting plateau following puffing of pinacidil (n=9) compared to pre-puff baseline. Vasodilation of both 1st and 2nd order of capillaries were significantly larger than that of the penetrating arteriole. Control puffing of aCSF (n=3) showed small fluctuations of vessel diameter around the baseline. Preliminary data from 4D (continuous fast z-stack) scanning experiments showed similar results. This indicates that Katp channels are abundant in near arteriole pericytes and have ability to regulate pericyte contractile state and capillary blood flow.

Title: Investigating neurovascular coupling in the visual cortex and hippocampus of behaving mice using two-photon imaging

Authors: *K. SHAW[1], D. M. GRIJSEELS[2], O. BONNAR[2], K. BOYD[2], C. N. HALL[2]

Abstract: In the healthy cortex, increases in neuronal signalling typically result in a local influx of oxygenated blood, via a process termed neurovascular coupling. The accurate interpretation of the relationship between neuronal activation and the cerebral vasculature, underpin blood oxygen level dependent (BOLD) functional MRI (fMRI), but are not yet fully understood. Some recent research has indicated that neurovascular coupling may be altered in subcortical regions. For instance, decreased fMRI signals were observed in caudate-putamen, despite increased neuronal activity (Mishra et al., 2011); and hippocampal BOLD signal has been demonstrated to show no correlation with local field potential (Ekstrom et al., 2009). Results such as these will have important implications for understanding fMRI data taken from subcortical brain areas, emphasising the need for further work which characterises neurovascular coupling throughout the entire brain. We used two photon imaging to chronically record from the visual cortex (V1) or hippocampus (HC) of awake, head-fixed mice. First, a craniotomy was performed on the skull covering the area of interest, for V1 a glass coverslip was inserted, and for HC the overlying cortex was aspirated and a cannula with glass coverslip implanted. Excitatory neuronal activity was measured using fluorescence changes of the genetically coded calcium indicator GCaMP6f under control of the Thy1 promoter. The red blood cell velocity and diameter changes of nearby blood vessels were simultaneously collected by labelling the lumen with intravenous Texas Red dextran. Laser Doppler flowmetry and optical spectroscopy were also used to gain additional haemodynamic information, such as blood flow, blood volume and oxygen metabolism measurements. Using these techniques, both the effects of sensory stimulation and of locomotion on neurovascular responses across brain regions are being elucidated. We have observed that local blood flow changes are small in hippocampus, relative to the amount of excitatory neuronal activity (and therefore energy use), and when compared to the neurovascular relationship in visual cortex. Thus, the BOLD signal may be a less sensitive proxy for underlying neural activity in the hippocampus than in visual cortex.

Title: Visual cortex neurons driving neurovascular coupling during visual stimulation and locomotion

Authors: *K. BOYD, K. SHAW, D. M. GRIJSEELS, C. N. HALL
Univ. of Sussex, Brighton, United Kingdom

Abstract: Blood oxygen level-dependent (BOLD) functional magnetic resonance imaging is used to measure changes in blood flow and extrapolate this to neuronal activity. However little is known about how activity of neuronal subtypes and BOLD signal are related, limiting the extent to which BOLD signal can be understood. Production of vasoactive molecules in pyramidal cells and several interneuron types has been linked to blood vessel dilation, and different cell populations are involved in neurovascular coupling (NVC) after whisker or basal forebrain stimulation[1]. However, we do not yet understand what cell types are involved in NVC during physiological behaviours, and how NVC might vary as neuronal activity changes. Studying visual cortex allows alteration of neuronal activity in different populations, while additionally allowing us to measure modulation by locomotion. We are investigating how changes to the presentation of a drifting grating affects pyramidal, SST and VIP cells in V1, while simultaneously recording diameter changes in proximal blood vessels throughout the vascular tree.
We use 2 photon imaging of V1 in awake transgenic mice expressing the genetically encoded calcium indicator GCaMP6f in specific subpopulations of neurons to measure changes in neuronal activity, and inject Texas Red dextran (70 MW) IV to visualise the vascular lumen. We present drifting gratings of varying contrast and size, aiming to modulate the balance of activity across different neuronal populations and relate changes of activity to vascular responses. Mice are free to run on a cylinder, allowing us to determine any effects of locomotion on the relationship between neuronal activity and vascular responses.
We compare the size of vascular dilations in response to stimulation to local calcium activity

next to that vessel and to population calcium, across different neuronal subtypes and vessel types (capillaries and penetrating arterioles). Our data suggest capillaries and arterioles both dilate to the same extent in V1. Excitatory neuronal activity is greater local to a vessel when that vessel dilates compared to when it does not respond, however SST activity local to a vessel does not seem related to whether that vessel dilates. The net population activity of SST cells does, however, correlate with the degree of vascular dilation. We are currently investigating how these responses vary with stimulus type and locomotion across the different cell types.

Title: Characterization of neurotransmitter receptors that mediate retinal neurovascular coupling

Authors: *A. L. GARCIA, M. N. TAPIA, D. MULLER, D. PELAEZ, S. K. BHATTACHARYA, L. E. VAZQUEZ

Abstract: Neurovascular coupling and regulation of blood floow in the retina remains poorly understood. Our objective is to characterize VSMC cell surface receptors and downstream signaling pathways that regulate vascular tone to further understand neurovascular coupling in the retina. To achieve this aim, retinas from SMA-GFP transgenic (a.k.a. “OTO2-10”) mice, which express GFP under the acta2 promoter, were dissected and dissociated with papain into single cell suspensions. Confocal microscopy of SMA-GFP retinal flat mounts found GFP expression to be exclusive to the vascular tree. VSMCs were then purified by collecting GFP positive cells via fluorescence activated cell sorting (FACS) and submitted to liquid chromatography-mass spectrometry (LC-MS) to establish protein profiles of these cells. The purification of FACS cells was confirmed by western blot where we stained for alpha-smooth muscle actin (α-SMA). In addition, immunohistochemistry staining of retinal flat mounts with various targets identified by our exploratory LC-MS profile were used. A total of 6,175 proteins

were found in 3 biological replicates of SMA-GFP transgenic mice with 100 high confidence proteins (FDR < 0.01), 18 medium confidence proteins (FDR 0.01 - 0.05), and 6057 low confidence proteins (FDR > 0.05). The presence of identified VSMC cell surface receptors was examined by immunostaining retinal flat mounts. Neuronal and astrocytic coupling to VSMCs was examined by colocalization of NFH and GFAP to these receptors. We speculate that these interactions play a key role in the regulation of vascular resistance in the retina. These findings may shed light on the control of hyperemic responses in health and disease.

Title: Dissecting the neural control of baseline and evoked vascular tone in the brain

Authors: *C. ECHAGARRUGA, P. DREW
Biomed. Engin., The Pennsylvania State Univ., State College, PA

Abstract: Changes in local neural activity drive vasodilation and vasoconstriction of the cerebral vasculature, and these changes in the cerebral blood flow are essential for brain tissue health. While previous work has suggested that activity of interneurons is the primary drivers of arteriole diameter changes, the signaling mechanisms that control blood flow and arterial diameter are not completely understood. To test the role of neural activity in manipulating vascular tone, we used chemogenetics and pharmacology in the somatosensory cortex of awake mice, allowing us to bi-directionally manipulate neural activity in specific cellular subpopulations. We assayed changes in neural activity and vascular responses to voluntary locomotion using electrophysiology and two-photon microscopy. We found that modulating the activity of all neurons produced corresponding changes in resting and evoked arteriole diameters. However, while modulation of excitatory neurons produced changes in the electrophysiologically-recorded population activity, there were no corresponding changes in resting or evoked arterial tone. Decreasing the activity of nNOS-expressing neurons or inhibition of NO production both blocked the hemodynamic response to locomotion and impacted resting tone similarly. Due to the changes in vessel tone, ratiometric imaging of hemodynamic signals can give misleading results when measured across conditions where background neural activity

may change. Our results show that both baseline and evoked hemodynamics signals reflect the activity of a small set of neurons, not the average activity of entire neural population.

Title: Neurovascular coupling can provide a driving force for glymphatic flow

Authors: *R. KEDARASETTI[1,2], C. ECHAGARRUGA[1,3], B. GLUCKMAN[2,1,3], F. COSTANZO[2,1,4], P. J. DREW[2,1,3]
[1]Ctr. for Neural Engin., [2]Engin. Sci. and Mechanics, [3]Biomed. Engin., [4]Dept. of Mathematics, The Pennsylvania State Univ., University Park, PA

Abstract: The brain lacks a traditional lymphatic system for clearance of metabolites. Recent work has suggested the existence of a "glymphatic system" where metabolites are removed from the brain's extracellular space by convective exchange between interstitial fluid (ISF) and cerebrospinal fluid(CSF) along the paravascular spaces around cerebral blood vessels. While there is some evidence that arterial pulsations can cause fluid movement, the driving mechanism for fluid circulation in the brain parenchyma is not fully understood. Also, there is no agreement on whether there is convective transport in the brain tissue. Due to experimental limitations, a better understanding of the movement of CSF and ISF in the brain requires computational modeling of the movement of these fluids and their interactions with the brain. Using a combination of computational modeling and in vivo two-photon microscopy, we investigate the nature of the movement of fluid in the perivascular space driven by vascular dilations and pulsations

Previous modeling work investigating the role of vascular pulsations in the glymphatic system has (unrealistically) treated the brain as a rigid structure that does not deform, when in fact brain tissue is very soft. We created a more realistic model of a blood vessel surrounded by a perivascular space and embedded in brain tissue, where the brain tissue can deform when pressure is applied. We use in-vivo two photon imaging in Thy1/YFP mice to measure the tissue deformation in the somatosensory cortex induced by vessel dilations and pulsation to verify the assumptions in our model.

When we extend previous computational models of flow in the perivascular space to account for deformation in the cerebral tissue in response to vascular motion, we find that there is no

significant fluid flow due to cardiac driven pulsations of arteries. Our results suggest that under biologically plausible conditions, movement of fluid in the brain is primarily driven by vasodilation. As vasodilation of arteries in the brain is coupled to increases in local neural activity, this mechanism would facilitate the exchange of CSF/ISF after the production of neural metabolic waste, providing another role for neurovascular coupling in maintaining brain health. Because functional hyperemia is very sensitive to anesthesia, our model can explain the sensitivity of CSF circulation to anesthesia. We are currently extending these models to simulate the brain as a porous, elastic solid that is saturated with fluid.

Title: Cerebral blood flow dynamics of the hemodynamic response function in human visual cortex

Authors: *J. KIM, A. TAYLOR, D. RESS
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Neural activity evoked by brief stimulation creates changes in cerebral blood flow (CBF) and oxygen uptake that together create the hemodynamic response functional response (HRF). We used arterial spin labeling (ASL) magnetic resonance imaging (MRI) to measure CBF responses in human cortex with high spatiotemporal sampling to understand the underlying CBF dynamics. **Methods**: Stimulus was a 2-s presentation of three round regions of 4-Hz flickering colored dots accompanied by bandpass filtered white noise, followed by a 32.5-s inter-stimulus interval. Dot regions appeared for 0.67 s at a random sequence of locations, each of which corresponded to a particular color and sound tone. Subjects were requested to push a button corresponding the presentation position. fMRI data was obtained on a 3T Siemens Trio scanner with a 32-channel head coil. Acquisition used an ASL sequence (PICORE/QUIPPS2 tagging scheme) on 25 quasi-axial slices with 2-mm voxels. TR was 2.5, so that alternating tag and control measurements were obtained every 5 s. We used a dithering method that varied the timing of the stimulus in four steps to improve temporal sampling to 1.25 s. We obtained a total of 4 runs of ASL measurements, each with16 events. In each session, we also measured the

fMRI HRF with simultaneous multi-slice echo-planar imaging (2 mm voxels, TR = 1.25 s) for 2 runs that obtained 12 events on the same prescription. **Results**: The audiovisual stimulus with its fast-paced task was effective in evoking strong CBF responses in visual cortex (Fig. A) that included an initial peak followed by an undershoot. Parameter analysis across subjects and ROIs quantified to magnitude and reliability of the undershoot (Fig. B). The timing of the peak and undershoot were also quantified and found to be stereotypical. Interestingly, we also found reliable variations of baseline flows across ROIs in visual cortex (Fig. C). **Conclusions**: We successfully obtained dynamics of CBF with ASL MR imaging. The result confirmed significant undershoot and stereotypical temporal response of the CBF evoked by brief neural activation.

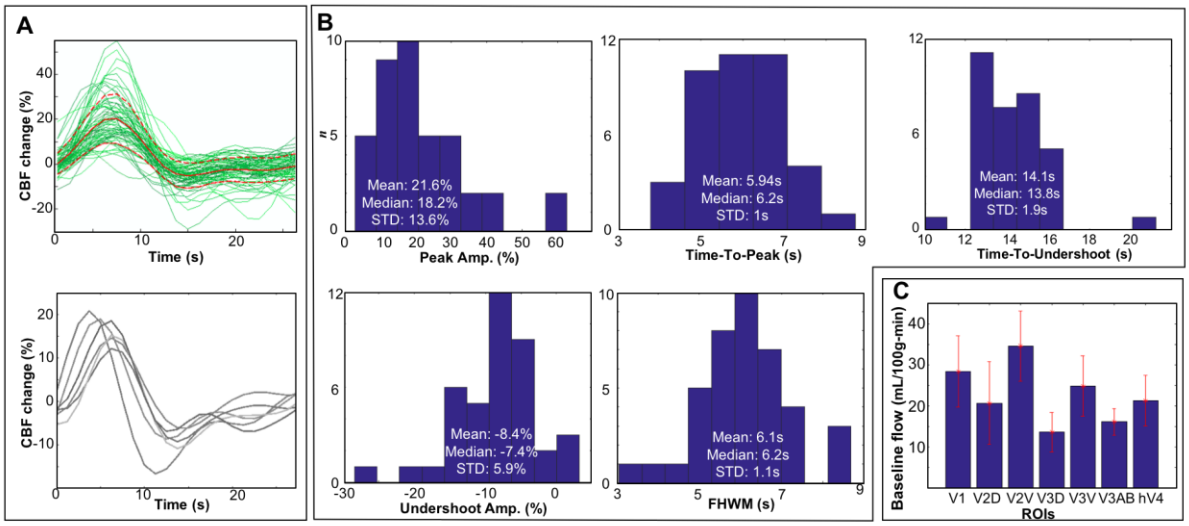

Fig. A) (upper) mean and standard deviation (red) of CBF responses across subjects and ROIs (green: individual data); (lower) examples of CBF within a subject for different ROIs. B) Histograms of CBF across subjects and ROIs. Distributions were obtained from bootstrapping data across subjects and ROIs. C) Flow baseline value for individual ROIs across subjects

Title: Endothelial NMDA receptors are critical mediators of neurovascular coupling in awake behaving mice

Authors: *A. D. HOGAN-CANN[1,2], P. LU[1,2], C. ANDERSON[1,2]
[1]Pharmacol. & Therapeut., Univ. of Manitoba, Winnipeg, MB, Canada; [2]Neurosci. Res. Program, Kleysen Inst. for Advanced Med., Winnipeg, MB, Canada

Abstract: Functional hyperemia (FH) ensures that active brain regions receive proportional delivery of blood flow. FH requires both local effects and coordinated upstream conduction of vasodilatory signals in an endothelium-dependent manner. There is strong literature consensus that this local response is mediated by neuronal N-methyl-D-aspartate (NMDA) receptors and nitric oxide produced by neuronal NO synthase (nNOS), or by inducing release of vasodilatory gliotransmitters from perisynaptic astrocytes with perivascular endfeet processes. However, neither of these mechanisms is endothelium-dependent, leaving neuro-endothelial coupling as a key conceptual deficit in understanding FH. We have observed that isolated middle cerebral artery segments free of neurons dilate in response to NMDA receptor agonists in a manner that requires functional endothelium and endothelial NOS. We also found that two-photon photolysis of caged astrocyte Ca^{2+} in mouse cortical slices led to NMDA receptor and eNOS-dependent vasodilation. The current study was designed to test the possibility that endothelial NMDA receptors participate in neurovascular coupling by measuring the hemodynamic responses in awake, head-fixed mice following sensory stimulation. To distinguish between neuronal and endothelial NMDA receptors we created conditional endothelial NMDA receptor loss of function mice that were characterized by greater than 50% loss of endothelial GluN1 (eGluN1) expression. Laser-Doppler flowmetry revealed that targeted whisker stimulation increased regional cerebral blood flow (CBF) in the somatosensory cortex of wild-type mice. This hyperemic response was dramatically impaired in eGluN1 deficient mice. Using two-photon microscopy, we measured vascular lumen diameter and red blood cell (RBC) velocity to better understand the dynamics of neurovascular coupling at the single vessel level in awake mice. In eGluN1 knockdown mice, the increase in lumen diameter and RBC velocity following whisker simulation was dramatically impaired relative to littermate controls. Spatial and temporal mapping of the vascular responses revealed signals that originated at cortical microvessels and were propagated throughout the vascular network to reach upstream pial arteries. Interestingly, pial vascular responses were unaffected by eGluN1 knockdown. These results suggest that eGluN1 loss of function reduces local vasodilatory effects while the upstream propagation of these signals is spared. Our results identify a novel mechanism of neuro-endothelial coupling by showing that endothelial NMDA receptors mediate activity-dependent, neurovascular signaling.

Title: Spatiotemporal dynamics of mural cell Ca^{2+} and tissue oxygenation in awake, behaving mice

Authors: *G. PERINGOD[1], L. YU[3], K. MURARI[3], G. R. GORDON[2]
[1]Dept. of Neurosci., [2]Dept. of Physiol. and Pharmacol., Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada; [3]Electrical and Computer Engin., Schulich Sch. of Engineering, Univ. of Calgary, Calgary, AB, Canada

Abstract: Arteriole smooth-muscle cells and contractile pericytes on pre-capillaries ("mural cells", collectively) respond to neural signals and are the ultimate end effectors in cerebral blood flow control. Basic excitation-contraction coupling rules for these cells stipulate that elevations in Ca^{2+} decrease blood flow, and that decrements in Ca^{2+} increase blood flow. Since the contractile activity of mural cells determine local oxygen delivery, they are directly linked to functional imaging modalities such as BOLD fMRI. However, the cerebral microvascular network exhibits complex intrinsic and extrinsic regulation, and experiences modulation both locally and at the network-level, to meet the energy demands of the brain. Little is known about the spatial dynamics of mural cell Ca^{2+} across the neocortex, or how faithfully tissue oxygenation tracks vascular Ca^{2+}, in vivo in conscious animals. Here, we developed a widefield imaging system that permits simultaneous measurement through intact bone of mural cell Ca^{2+}, blood volume and tissue oxygenation across the entire top of the cerebral cortex in awake, behaving mice exposed to whisker stimulation, volitional locomotor activity, or startle stimuli. We used Cre-Lox knock-in mice (PDGFRb-Cre x LSL-GCaMP6s), wherein a genetically-encoded calcium indicator is expressed in mural cells, to examine 'mesoscale' Ca^{2+} fluorescence signals from the vasculature. We observed these signals spread specifically from region-to-region across the neocortex in wave-like patterns, similar to previously-reported neuronal Ca^{2+} signals in the resting awake state. Unlike startle stimulation, which elicited a large bilateral reduction in Ca^{2+}, minimal whisker-stimulation elicited relatively localized signals of much

lower magnitude. In summary, our preliminary efforts highlight the use of PDGFRb-GCaMP6s animals to study vascular network functions through the skull in awake and active mice. Ongoing efforts seek to examine these signals in relation to intrinsic optical measures of hemodynamic activity during different behavioural states, and follow-up experiments will test whether any existing relationships are perturbed in mouse models of cerebrovascular dysfunction.

Title: Cerebrovascular morphology and mechanics in rodent models of hypertension and heart failure

Authors: *C. ACOSTA, C. M. ANDERSON, H. ANDERSON
Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: There is growing evidence that heart failure (HF) is a risk factor for dementia and Alzheimer's disease (AD). In fact, HF patients often exhibit cognitive deficits, although the prevalence of AD in HF is unknown. Hypertension often precedes HF and in itself, is an independent risk factor for dementia. This may be related to the arterial wall remodeling, stiffening, and dysfunction that, by reducing lumen diameter, may compromise blood flow. Indeed, cerebrovascular remodeling leads to inadequate brain perfusion, and arterial stiffening is associated with dementia. We investigated cerebrovascular remodeling and stiffening as putative underlying mechanisms. Morphological and mechanical changes were characterized in middle cerebral arteries (MCAs) and penetrating arterioles (PAs) using genetic animal models of hypertension alone (spontaneously hypertensive rat, SHR) and hypertension associated with risk for HF (spontaneously hypertensive heart failure rat, SHHF). Vascular properties of isolated MCAs and PAs from Wistar Kyoto (WKY) and SHR, as well as, Sprague-Dawley (SD) and SHHF rats were measured by pressure myography. SHHF MCAs exhibited eutrophic remodeling, as evidenced by increased media-lumen ratio (15.9±2 vs. SD 8.9±0.5, $p<0.05$) and unchanged media cross-sectional area (mCSA). An increasing trend in the latter, however, resulted in a growth index of 44%, suggesting hypertrophic growth was in process. SHHF MCAs also exhibited mechanical changes in terms of stiffening and reduced compliance *(*vs. SD, *$p<0.01$).* In contrast, smaller, downstream PAs in SHHF exhibited solely eutrophic remodeling (increased media-lumen ratio (*$p<0.01$*) in the absence of any change (significant or trend) in mCSA. SHHF PAs experienced less arteriolar wall stress (0.003±0.0001 vs. SD 0.004±0.0001,

p<0.01) and were less compliant (13.1±0.8 vs. SD 9.3±0.5, *p<0.01*). SHHF PAs were significantly stiffer (0.07±0.01 vs. SD 0.04±0.002, *p<0.01*) due to greater wall component stiffness (23.9±4 vs. SD 10±0.6, *p<0.01*). Similar to SHHF, SHR PAs exhibited eutrophic remodeling (*p<0.01*) and were exposed to reduced stress on their arteriolar walls (0.0028±0.0001 vs. WKY 0.004±0.0001, *p<0.01*). However, in contrast to SHHF, SHR PAs were significantly more compliant (8.2±0.1 vs. WKY 11.2±0.09, *p<0.01*), less stiff (0.03±0.002 vs. WKY 0.04±0.002, *p<0.01*), and had unchanged wall component stiffness. This study identified eutrophic remodeling in both SHHF and SHR PAs, as well as, changes in mechanical properties that may be protective against HF and HF-induced dementia in SHR but are absent in SHHF.

Title: Effects of food maternal restriction on palatable food consumption of the offspring in preadolescence and adulthood in rats

Authors: *E. BARRIOS DE TOMASI, A. E. MARTÍNEZ-MARTÍNEZ, J. JUAREZ
Inst. De Neurociencias, Jalisco, Mexico

Abstract: Food maternal restriction has morphological and functional implications in the central nervous system of the offspring, like a decrease in the hormone leptin, changes in the conformation of the hypothalamus and in the disposition of dopaminergic receptors. Preadolescence is another vulnerable period, in which the early exposure to rewarding substances, such as the ingestion of drugs or alcohol, as well as palatable food consumption, can facilitate the dependence in adulthood. On this basis, it is important to know how food restriction during the fetal period affects the consumption of appetizing food in preadolescence, considering that both are sensitive periods for the development of obesity in adulthood. We used 16 pregnant Wistar female rats, which were divided into a control group and a restriction group. The control group was given food and water *Ad libitum* throughout the gestation period and the restriction group had access to 50% of the standard food that consumed by the control group (gestation day 10-22). During the lactation period, both groups had free access to standard food. At postnatal day (PD) 25 offspring were assigned to four groups: Control males (MCN), control females (HCN), restriction males (MRS) and restriction females (HRS). From PD 28 to 39, they were exposed to high-caloric food and standard food ad libitum for 24hrs/12 days. From PD 70 to 98, the four groups were again exposed to the consumption of high-caloric and standard meals for 28 days following the criteria above mentioned. We observed that the rats exposed to the maternal

food restriction had a higher percentage of weight gain at the end of the high-caloric food access in preadolescence and adulthood, despite there were no differences in food consumption between control and restriction group. Males had a greater percentage of weight gain and a higher consumption of standard food in both ages, however, the females had the highest consumption of high-caloric food in adulthood. Results suggest that the maternal food restriction generates changes in the metabolism of offspring rats but no in the preference for high-caloric foods, generating a greater long-term weight gain that could be affected by leptin and sex hormones, particularly estrogens, which would serve as a protective factor for females that result in a lower body weight gain than males.

Title: Selenoprotein M promotes hypothalamic leptin signaling and thioredoxin antioxidant activity

Authors: *T. GONG[1], A. C. HASHIMOTO[1], V. S. KHADKA[2], M. J. BERRY[1], M. W. PITTS[1]

Abstract: Abstract
Selenoproteins are an essential class of proteins involved in redox signaling and energy metabolism. However, the means by which selenoproteins influences energy homeostasis is enigmatic, as the functions of many selenoproteins are not clearly established. Selenoprotein M (SELENOM), an ER-resident oxidoreductase bearing structural similarity to thioredoxin (TXN), is among those yet to be fully characterized. This protein is highly expressed in hypothalamic regions involved in leptin signaling and has been previously linked to energy metabolism, as *Selenom*$^{-/-}$ global knockout mice develop adult-onset obesity. Moreover, it was recently shown that ablation of hypothalamic selenoprotein synthesis impedes leptin signaling. Herein, we performed a series of studies using i*n vivo* and *in vitro* models to investigate the specific influence of SELENOM on hypothalamic leptin signaling. Microarray analysis was also conducted in parallel to the identify genes and pathways most affected by SELENOM

deficiency. Collectively, our findings conclusively demonstrate that SELENOM is a positive regulator of both leptin signaling and thioredoxin antioxidant activity in the hypothalamus.

Title: Pigment epithelium-derived factor regulates energy balance via adipose triglyceride lipase in the brain of mice

Authors: M.-G. SONG[1], H.-J. KIM[1], B.-Y. JIN[1], N.-H. HA[1], H.-J. LEE[1], S.-H. CHOI[1], *D.-H. KIM[2]

Abstract: Pigment epithelium-derived factor (PEDF) known as an antiangiogenic and neurotrophic factor, plays a role in the regulation of lipid metabolism and insulin sensitivity in humans and rodents. However, its role in energy balance remains unclear. In this study, we investigated central role of PEDF in the regulation of energy balance and its underlying mechanism in mice. We monitored food intake, energy expenditure and weight gain after administering PEDF into the third ventricle (ICV) of C57BL/6 mice and compared activities of energy sensors including AMP-activated protein kinase, acetyl-CoA carboxylase (ACC), and signal transducer and activator of transcription 3 (STAT3) in the mediobasal hypothalamus by western blot. We performed a conditioned taste aversion test in mice to identify whether ICV administration of PEDF was associated with non-specific illness. In addition, we investigated a role of adipose triglyceride lipase (ATGL), a receptor of PEDF, in central PEDF-induced anorexia by using ATGListatin, an ATGL inhibitor, and ATGL knockout mice. ICV administration of PEDF significantly decreased food intake and weight gain with no change in energy expenditure compared to control and it was not associated with non-specific illness. ICV administration of PEDF increased hypothalamic ACC and STAT3 activities compared to control, implying an involvement of lipid sensing and leptin signaling in central PEDF-induced anorexia. Consistently, PEDF had a synergic effect with leptin on the regulation of energy balance in the

brain of mice. In addition, central PEDF-induced anorexia was reinstated by pretreatment with ATGListatin and it was attenuated in ATGL knockout mice compared to wild-type mice. Taken together, these results suggest a central role of PEDF via ATGL in the regulation of energy balance in mice.

Title: Why do mice overeat high-fat diets? how high-fat diet alters the regulation of daily caloric intake in mice

Authors: *J. A. LICHOLAI[1], K. P. NGUYEN[2], W. C. FOBBS[3], C. J. SCHUSTER[4], M. A. ALI[5], A. V. KRAVITZ[1]

Abstract: The obesity epidemic is a multifaceted problem with a range of health problems and associated costs. Over-eating is thought to contribute to weight gain and obesity, however the factors involved in over-eating are not well understood. *Ad libitum* high-fat diets (HFDs) spontaneously increase caloric intake in rodents, which correlates positively with weight gain. However, it remains unclear why rodents overeat HFDs. Here, we investigated how changing the proportion of diet that came from HFDs altered total daily caloric intake in mice. Mice were given *ad libitum* chow supplemented with 25%, 50%, or 90% of their daily caloric need from HFD. We hypothesized that HFD may interfere with satiety mechanisms, such that additional calories would be required for mice to become sated on HFD. If true, we predicted that the total calorie intake would increase as we increased the proportion of daily calories from HFD. Contrary to our hypothesis, however, HFD supplements did not increase total daily caloric intake, even when 90% of their daily calories were obtained from HFD. Importantly, these same mice increased their daily caloric intake when given *ad libitum* HFD. We concluded that HFD appropriately engages satiety signaling, yet mice over-eat HFD in spite of satiety. A follow up experiment confirmed that sated mice consumed 50% of their daily calories from HFD in 30

minutes. These results suggest that over-eating of HFD may be driven by hedonic mechanisms, and not by impairing mechanisms that regulate daily caloric intake.

Title: Central effects of peripherally administered oleoylethanolamide in rats subjected to surgicalsubdiaphragmatic vagal deafferentation

Authors: *J. B. KOCZWARA[1], A. ROMANO[1], C. A. GALLELLI[1], E. K. AZARI[2], A. MANSOURI[3], M. ARNOLD[3], S. GAETANI[1]
[1]Sapienza Univ. of Rome, Roma, Italy; [2]Sanford Burnham Prebys Med. Discovery Inst., Orlando, FL; [3]ETH Zurich, Schwerzenbach, Switzerland

Abstract: Oleoylethanolamide (OEA), a PPAR-alpha agonist, is a mediator of satiety. After peripheral administration, OEA induces c-Fos (a marker for neuronal activation) in areas of the central nervous system (CNS) involved in the control of eating behavior, such as the nucleus of the solitary tract (NST) and the area postrema (AP) in the brainstem, as well as the paraventricular (PVN), supraoptic (SON) and ventral tuberomammillary (vTMN) nuclei in the hypothalamus. Moreover, the OEA-induced behavioral and neurochemical effects were abolished after lesion of the noradrenergic projections that originate in the brainstem and project to the hypothalamus. Although previous reports suggested an involvement of visceral vagal fibers in mediating OEA effects, recent findings demonstrate that abdominal vagal afferents are not necessary for the anorectic effect of OEA. In fact, OEA is able to decrease food intake both in rats that underwent a subdiaphragmatic vagal deafferentation (SDA), a surgical procedure that eliminates all abdominal vagal afferents but spares about 50% of the vagal efferents, and in SHAM-operated controls. Thus, the aim of the present work was to further elucidate the role of abdominal vagal afferents in mediating OEA's effects on the CNS. In particular, we aimed to investigate the effects of OEA administration (10 mg/kg, i.p.) on the expression of c-Fos and dopamine-β-hydroxylase (DBH, a marker of noradrenergic neurons) within the NST and AP, and on the expression of c-Fos in areas of the hypothalamus involved in the control of eating. To this end, we subjected male rats to SDA or SHAM (control) surgery. Two hours after OEA or vehicle administration, the rats were sacrificed and brains were collected. By using

immunohistochemistry, we assessed c-Fos and DBH expression patterns in the NST, the AP, and in the hypothalamus. Consistent with the behavioral results, OEA increased c-Fos expression in the NST and in the AP in both SHAM and SDA rats. Moreover, SDA did not alter DBH expression in these areas. In the hypothalamus, in line with the behavioral results, OEA increased c-Fos expression in the PVN and the vTMN, even though in the latter nucleus the increase did not reach statistical significance. Interestingly, in the SON, the OEA-induced increase in c-Fos expression was blunted by the SDA surgery, suggesting a direct involvement of vagal afferents in the activation of this nucleus. Overall, our findings indicate that vagal afferents, which are not necessary for the satiety effect of OEA, are also not necessary for most of the neurochemical changes induced by i.p. OEA, although appear to mediate the OEA-induced activation of the SON.

Title: Leptin receptor-expressing neurons in the nucleus of the solitary tract receive input from capsaicin-sensitive C-type vagal afferents

Authors: *D. NEYENS[1], S. M. APPLEYARD[2]
[1]Integrated Physiol. and Neurosci. (IPN), [2]Neurosci. Program, Washington State Univ., Pullman, WA

Abstract: Leptin is a hormone that regulates energy homeostasis and reduces food intake. The nucleus of the solitary tract (NTS) in the hindbrain is an important hub of integration for signals controlling food intake, including incoming vagal afferents carrying satiety information from the gastrointestinal tract that enter via the solitary tract (ST). Leptin receptors (LepRs) are expressed on both vagal afferents and NTS neurons, and direct injections of leptin into the NTS reduce food intake. Previous work from our lab showed that LepR expressing neurons receive glutamate inputs from ST afferents, including cholecystokinin (CCK) sensitive afferents. In addition, leptin increases ST activation of action potentials in LepR neurons; however, the phenotype of these ST inputs has not been fully characterized. ST afferents can be myelinated (A-type) or unmyelinated (C-type) fibers, with C-type fibers shown to contribute to satiety reflexes. Here we use capsaicin (a TRPV1 agonist and activator of C-type fibers) to determine whether C-type

afferents activate LepR neurons. We also determined whether LepR neurons have ST-evoked asynchronous inputs characteristic of C-type afferents. We used patch-clamp electrophysiology in horizontal brain slices to measure ST-evoked synchronous excitatory postsynaptic currents (eEPSCs) and asynchronous events as well as spontaneous glutamate inputs (sEPSCs). We targeted LepR neurons in the NTS using a transgenic mouse line that expresses Cre-dependent td-Tomato driven by the leptin receptor promoter (LepRCre-tdTom). The majority of LepR neurons examined received both monosynaptic and polysynaptic inputs from ST afferents as well as spontaneous glutamatergic inputs. All LepR neurons tested also displayed asynchronous activity, characterized by a large but transient increase in sEPSC count during the 100 ms following ten 50 Hz stimulations of the ST (average 15 fold-increase ± 3, n = 11). In addition, bath application of 1 μM capsaicin dramatically increased sEPSC frequency in all cells (n = 11). Furthermore, capsaicin reduced the amplitude of ST-evoked EPSCs by 76% (n = 6, $p < .005$), likely due to depletion of glutamate as has been shown previously for other NTS neurons. Taken together with our previous finding that CCK activates these neurons, these data suggest that NTS LepR neurons receive direct inputs from C-type sensory afferents involved in satiety reflexes.

Abstract: Background: Thousands of nodose ganglion (NG) neurons act as gatekeepers of abdominal organ sensory information and play critical roles in metabolic and feeding disorders, gastrointestinal (GI) diseases, and inflammatory conditions. Here, we report our first experiments to assess the simultaneous signaling from this neuronal population, using 32-channel electrode

arrays. There were three study objectives: (1) determine the stability of multiple single-unit responses from the ferret nodose ganglion during several hour duration *in vivo* electrophysiology studies; (2) measure the activation patterns to abdominal vagus nerve electrical stimulation; and (3) assess the phenotypes of these neurons to prototypical stimulation, such as gastric distension. **Methods**: All animal experiments were approved by the University of Pittsburgh IACUC. Acute experiments were performed in 6 anesthetized ferrets, using inhalational isoflurane or urethane (ip) anesthesia. A 32-chan 4x8 Utah Electrode Array (Blackrock Microsystems, UT) was inserted in the nodose ganglion using a pneumatic inserter. A balloon-catheter was advanced into the stomach through a small incision on the lateral edge of the gastric fundus; 5, 10 and 20 ml volumes of saline were infused into the balloon to provide distension. Nerve cuff electrodes (Micro-Leads Inc.) were placed on the ventral abdominal vagus trunk. Initial single-unit activity was classified online using Ripple LLC's Trellis software. **Results**: Ganglionic single-unit activity was successfully recorded from the NG for up to 9.5 hours after insertion of the microelectrode array. Approximately 72 single, discriminable units were recorded, yielding 12-13 units per ferret. In two ferrets, we found that approximately 40% of units were sensitive to gastric distention. Of the gastric sensitive units, some units only responded at higher volumes of saline infusion. **Conclusions**: These results show the feasibility to record multiple single-unit responses from the ferret nodose ganglia. A subset of neurons were responsive to gastric distension. Other cells, some activated by abdominal vagus electrical stimulation, could provide additional modalities, such as GI chemical detection and metabolic signals from the liver and pancreas. Future effort could focus on the design of vagus electrical stimulation therapy to modulate specific components of vagal sensory transmission to treat obesity and GI disease.

Title: Human hypothalamic microglia and POMC neurons are differently affected by anti-diabetic treatment in type 2 diabetic patients

Authors: *M. KALSBEEK, S. E. C. WOLFF, I. V. MILANOVA, N. L. KORPEL, C.-X. YI
Academic Med. Center, Amsterdam, Amsterdam, Netherlands

Abstract: Hypothalamic dysfunction plays a key role in the development of obesity, type 2 diabetes mellitus (T2DM) and other metabolic disorders, which casts a huge burden on modern day society. Our previous studies showed that mice on a long-term obesogenic diet not only become morbidly obese, but also a robust decrease of the appetite-curbing pro-opiomelanocortin (POMC) expressing neurons and an increase of microglial activity in the hypothalamic arcuate nucleus. In humans, a similar decrease of hypothalamic expression of POMC was found in T2DM patients. Whether microglia activity is also affected in the hypothalamus of T2DM patients, and whether anti-diabetic treatments can reverse these changes remains unknown.
In this project, we set out to investigate in human hypothalamus the findings from the rodent studies. We've collected human post-mortem hypothalamic brain tissue from 20 control subjects and 40 subjects diagnosed with type 2 diabetes. Investigation of the medical records confirmed these diagnoses, as T2DM subjects had significantly higher HbA1c (glycated hemoglobin) levels compared to control. Immunohistochemistry was used to visualize microglia and POMC neurons in the hypothalamic infundibular nucleus (equivalent to the arcuate nucleus in rodents). Interestingly, male T2DM subjects who had not received insulin treatment showed significantly lower hypothalamic POMC expression compared to control males, while in T2DM males who had received insulin treatment, the POMC expression was similar to the level of control subjects. Intriguingly, none of these changes were found in female subjects. Furthermore, we did not find differences in microglia expression when subjects were compared based on their received insulin treatment. However, microglia expression was significantly lower in T2DM subjects who had received metformin treatment compared to those who had not received metformin treatment and control, these decreases were found in both males and females. Our data suggest that insulin has a clear gender specific effect on POMC neurons, while the impact of metformin on microglia is not gender-dependent. The mechanism behind these observations will be further studied.

Abstract: Several studies have reported that menopause causes a greater perception to painful stimuli and an increase in adipose tissue, which promotes a greater body weight gain compared to men. Additionally, it is known that weight gain is related to changes in the perception of pain; however, its mechanism is not clear. Objective. The aims of this study were to analyze the behavioral responses of hypoestrogenic overweight Wistar rats to thermal stimuli and to analyze the glucose and insulin levels in this population. Methods. Animals with hypoestrogenism induced by bilateral ovariectomy were used. Animals received either a hypercaloric diet (30% sucrose) or regular water with standard laboratory food *ad libitum* for 4 weeks; the thermal nociception and body weight were measured during this period. Four weeks after treatment, the glucose and insulin levels and the abdominal fat weight were measured in both groups. Nociception was assessed using the "Plantar test". Results. Overweight ovariectomized Wistar rats displayed significantly higher body weight and abdominal fat weight than did the control group. A hyperalgesic response was observed in animals fed sucrose. Thermal latency was also significantly decreased during the 4th week in these animals compared to that of controls. There were no differences in glucose levels, but the insulin levels were altered between groups. Conclusions. Our data indicate that increased body weight, abdominal fat and increases in insulin levels are associated with the hyperalgesic responses observed in ovariectomized overweight female rats.

Title: Characterization of the relationship between phenotype, diet, and mitochondrial function in a *Drosophila* model of epilepsy

Authors: S. GENEUS, A. CAREY, *E. R. REYNOLDS
Program in Neurosci., Lafayette Col., Easton, PA

Abstract: Drosophila mutants known as “bang-sensitive” have been utilized as models for neurological conditions including epilepsy, sensorineural deafness, and age-dependent neurodegeneration. These mutants also have a shortened lifespan. While the mechanisms producing these phenotypes are unique to each strain, some of the gene products suggest mitochondrial dysfunction as a possible underlying cause. Diet is an important factor in determining energetics. For example, a ketogenic diet has been shown to be an effective treatment for refractory epilepsy in humans, and diet can manipulate lifespan. We wanted to more clearly define the connection between diet, mitochondrial function and phenotype in this fly model system. Bang-sensitive mutant strains were reared on a standard molasses, yeast and cornmeal (MYC), which is a low protein/high carbohydrate diet, or a protein-rich yeast sugar (YS) diet. The mutants display a lower percentage of seizures on the YS food, but also reduced viability and lifespan. Several biochemical methods were utilized to define the effects of diet. Cytochrome oxidase (CO) in mutants is reduced as compared to wildtype, with increased CO levels in all flies raised on the YS food. In this case, alterations in mitochondrial function correlate with improvement in epilepsy phenotype. In addition, citrate synthase activity and other metabolic indicators suggest that both the mutant phenotype and diet interact in complex ways to produce the defects in excitability and aging.

Title: Precision medicine: Genetic predisposition to fructose consumption in diverse mouse strains

Authors: *Z. YING[1], G. ZHANG[1], H. BYUN[1], Y. ZHAO[1], X. YANG[1], F. GOMEZ-PINILLA[1,2]

Abstract: The escalating prevalence of metabolic syndrome (MetS) poses a significant public health threat worldwide. Fructose consumption is a major risk for MetS and influences a cascade

of genes that can regulate long-term response to metabolic and neurological disorders (Meng et al., BioMedicine, 2016). MetS predisposes individuals to neurological and psychiatric disorders; however, there is a large range of individual variability. To explore mechanisms involved in the genomic variability in the metabolic predisposition to fructose, genetically diverse mice C57/B6 (B6), DBA and FVB, were fed with 8% fructose for 12 weeks. Fructose-fed DBA mice gained significantly higher amount of body weight and glucose intolerance from the 4th to the 12th week compared to control group, while B6 and FVB showed no differences. Increases in fat mass were only observed in DBA mice, elevated insulin levels were found in DBA and FVB mice, while cholesterol levels were uniquely elevated in B6 mice. RNA sequencing was used to investigate the effect of fructose on the transcriptional profiles of liver, adipose and hypothalamus tissues. Consistent with the differences in phenotype changes, different strains showed distinct patterns of transcriptional and pathway perturbations in a tissue specific manner. Among pathways altered in the liver by fructose, fatty acid and cholesterol metabolic pathways were prominent in B6 mice, while DBA mice showed unique over-representation of pathways related to PPAR signaling pathway. In adipose tissue, pathways are more related to fatty acid metabolism and oxidation in B6 mice, whereas no metabolic pathways were found to be enriched for differential genes in DBA and FVB mice. In hypothalamus tissue, only B6 showed significant enrichment for pathways involved in protein folding, pancreatic secretion and fatty acid beta-oxidation. Using network modeling, we predicted potential key regulators of fructose response such as Fgf21 and Sqle in liver, Cav1and Dpp4 in adipose tissue, and Fmod in hypothalamus. Our findings provide molecular evidence into the mechanisms by which individuals respond differently to the effects of fructose or other environmental factors. Results provide important insight for the design of individualized preventative and therapeutic strategies against MetS or other disorders.

Title: Expression of functional leptin receptors in the anterior insular cortex: Sexually dimorphic behavioral and metabolic correlates

Authors: *S. R. SPIERLING[1], S. N. PUCCI[2], D. KIRSON[2], A. L. SCOTT[2], S. T. M. REHAN[2], C. A. WILLIAMS[2], S. Y. FANG[2], M. ROBERTO[3], E. P. ZORRILLA[3]
[1]The Scripps Res. Inst., La Jolla, CA; [3]Dept. of Neurosci., [2]The Scripps Res. Inst., LA Jolla, CA

Abstract: Receptors for leptin, an adipocyte hormone originally identified for its role in regulating hypothalamic energy balance circuits, also are synthesized in many extra-hypothalamic brain regions where their functions remain largely uncharacterized. Via TaqMan qPCR, we found that LepR mRNA expression is expressed in the anterior insular cortex of young adult male and female Wistar rats (n=49) at levels about half those expressed in the arcuate nucleus of the hypothalamus. Male rats had significantly greater LepR mRNA expression (~1.5-2-fold) in the anterior insula vs. female rats. Twelve weeks of continuous access to a palatable, high-sucrose diet that increased adiposity tended to increase LepR mRNA levels, but not significantly (p=0.08), with intermittent, long access (24 hr/day, 3 days/week) rats intermediate. However, we identified sexually dimorphic correlations of LepR expression levels with behavioral and metabolic endpoints: in female rats (n=30), independent of diet schedule, greater insular LepR expression in the insula correlated with greater operant fixed-ratio food self-administration (r=0.45, p<0.02) and less nocturnal energy expenditure (r=-0.42p<0.03), measured by indirect calorimetry. In contrast, in males (n=19), greater insular LepR expression correlated with greater diurnal energy expenditure (r=0.49, p<0.05) and was not directly related to food self-administration (r=-0.37). In males, but not females, insular LepR expression also directly and strongly correlated with initial adiposity (% body fat) before diet schedules (r=0.73, p<0.001). A functional role for insula LepR receptors was supported by whole-cell voltage- and current- clamp slice electrophysiological studies, in which bath leptin application (~60 nM) elicited rapid excitatory effects on glutamatergic neurons in the anterior insular cortex. Collectively, the results suggest a functional role and sexual dimorphism of LepR in anterior insula circuits, with levels of expression relating to appetitive behavior, adiposity, and whole-body metabolism. Mechanistic understanding of this novel extra-hypothalamic, leptin-responsive circuit may further understanding of leptin's physiologic and pathophysiologic roles in interoception and higher-order cognitive and motivational processes relevant to obesity and disordered eating.

Title: Taste preferences in male and female rats after soda consumption

Authors: *K. S. CURTIS, D. SISCO, M. JACOBS
Dept. Pharmacol & Physiol, Oklahoma State Univ. Ctr. for Hlth. Sci., Tulsa, OK

Abstract: Our previous work showed no effect of chronic soda intake on body weight in male rats. The goal of the present study was to further evaluate the effect of soda consumption on body weight in male and female rats, and to determine whether soda consumption altered preferences for salt and sucrose taste solutions. Adult ovariectomized (OVX) female rats given estradiol benzoate (EB; n = 5) or oil vehicle (OIL; n = 5), and adult male rats (n = 8) had 2-hr access to store-brand soda for 4 days/week on alternate weeks for 4 weeks, with water only on the other weeks. At the end of each week, rats were given 2-bottle tests (0.5 M NaCl and water or 0.05 M sucrose and water) to assess preferences for the taste solutions. Intake of each solution was measured after 2 hours, and a preference score was calculated (intake of taste solution/total intake). EB- and OIL-treated OVX rats drank similar amounts of soda during the experiment; male rats, which weighed more, drank more soda. Soda intake did not affect body weight in EB-treated rats, but reduced the typical weight gain in both OIL-treated rats and male rats. Although EB-treated rats drank less sucrose in 2-bottle tests after soda access, all rats consumed very little water. Thus, the preference for sucrose taste was not affected by soda access in either OIL- or EB-treated OVX rats, or in male rats. In contrast, salt taste preferences were reduced after soda access in both OIL- and EB-treated OVX rats, as well as in male rats; however, only EB-treated rats preferred salt taste without soda access. Interestingly, all groups increased water intake during the salt and water 2-bottle tests after soda access. Thus, while intermittent access to soda does not increase body weight, it selectively alters taste preferences, particularly in females with estrogen. This effect may be associated with soda-induced changes in central reward circuitry. Levels of dopamine in the Nucleus Accumbens were slightly increased after access to soda and levels of the dopamine metabolite, HVA, were significantly increased. Together, these data suggest that access to soda alters the preference for tastes associated with high calorie/high sodium food by altering dopaminergic activity in the Nucleus Accumbens, which ultimately may facilitate the consumption of these unhealthy foods.

Title: Role of selenium utilization in hypothalamic control of energy metabolism

Authors: *D. TORRES, M. W. PITTS, A. C. HASHIMOTO, M. J. BERRY
Cell and Mol. Biol., Univ. of Hawai'i at Manoa Dept. of Cell and Mol. Biol., Honolulu, HI

Abstract: Selenium (Se) an essential trace element known mainly for its antioxidant properties is critical for proper brain function and may also play an important role in whole-body energy metabolism. Dietary Se is incorporated into selenoproteins in the form of the unique amino acid selenocysteine (Sec), which requires its cognate selenocysteine-tRNA (Trsp) to be synthesized. Whole-body knockout (KO) of Sec lyase (Scly), a critical participant in selenium recycling, increases susceptibility to developing metabolic syndrome (MetS) in mice. Scly KO mice also have decreased expression of several selenoproteins in the hypothalamus, a key regulator of energy homeostasis. The purpose of this project is to elucidate the mechanisms underlying the link between disrupted hypothalamic selenium utilization and the associated metabolic disturbances. Agouti-related peptide (Agrp)-positive neurons are a nutrient-sensing hypothalamic sub-population that promote positive energy balance. Reduced sensitivity to the anorexigenic hormone leptin in Agrp neurons has been linked to energy dyshomeostasis. We generated a mouse line with Cre-driven Agrp neuron-specific Scly KO (Scly-Agrp KO mice) to determine the contribution of these neurons to the MetS phenotype observed in whole-body Scly KO mice. Preliminary characterization suggests Scly-Agrp KO mice have increased body weight and feeding behavior, as well as reduced glucose tolerance. We also generated Agrp-neuron specific Trsp KO mice (Trsp-Agrp KO mice) to evaluate ablation of selenoprotein synthesis within these neurons. Trsp-Agrp KO mice had reduced body weight and improved glucose sensitivity. These results may be due to impaired leptin signaling within Agrp neurons.

Title: Characterization of leptin-receptor expressing cells of the arcuate nucleus of hypothalamus during sexual maturation

Authors: *T. T. ZAMPIERI, T. M. BOHLEN, L. C. LANA, R. FRAZÃO
Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Previous studies have demonstrated that GnRH and kisspeptin neurons are under higher presynaptic inhibitory tonus in prepubertal animals, suggesting that the release of this neural restrain may represent an essential step for puberty onset. Considering the importance of the hormone leptin as a permissive factor for puberty onset and maintenance of the reproductive functions, we investigated whether leptin receptor expressing (LepR) neurons in the ARH exhibit morphological or electrophysiological changes during development. LepR-Cre/tdTomato-reporter or wild-type female mice were used to study LepR cell morphology or activity. Sexual maturation was assessed daily by determining the age at the vaginal opening and at the first occurrence of vaginal cornification (first estrus). Animals were selected for experiments at different ages: 8-12 days (prepubertal), 38-42 days (pubertal) and 60-90 days (adult). Brain sections were processed to perform histological quantification of ARH LepR neurons and measurement of neuronal area (μm). ARH micropunches were obtained and processed for LepR gene expression. Additionally, whole-cell patch-clamp recordings of brain slices were performed to evaluate spontaneous inhibitory and excitatory postsynaptic currents (sIPSC and sEPSC), resting membrane potential (RMP) and leptin responsiveness of ARH LepR neurons throughout the development. Our results demonstrated that the number of LepR neurons increased in the rostral ARH during development, whereas the number of LepR neurons in the caudal ARH remained unchanged. The mean neuronal area of LepR expressing cells in the ARH was similar in all ages evaluated. In addition, LepR gene expression was similar during development. Interestingly, the frequency of sEPSC and sIPSC was significantly decreased in ARH LepR neurons of prepubertal female, compared to prepubertal and adult mice, despite no differences in the mean sEPSC or sIPSC amplitude. Unexpectedly, leptin induced no changes in RMP, input resistance or the frequency of action potential in ARH LepR neurons of female mice. In conclusion, our findings indicate that LepR expressing neurons in the ARH have a lower excitatory and inhibitory presynaptic tonus, which is increased during puberty and adulthood. Suggesting that puberty may be follow by a significant change in the presynaptic tonus of different neural populations involved in the sexual maturation.

Title: Inhibition of mitochondrial fission in the dorsal vagal complex of the brain prevents hyperphagia in high fat diet fed rats

Authors: *B. PATEL, L. NEW, J. DEUCHARS, B. FILIPPI
Univ. of Leeds, Leeds, United Kingdom

Abstract: Worldwide obesity has more than doubled since 1980, with over 600 million cases in 2014. Obesity can lead to many adverse metabolic effects of the cardiovascular and endocrine systems and in the brain. In rodents, the dorsal vagal complex (DVC) of the brain regulates glucose homeostasis and controls food intake through insulin signalling. A 3-day high fat diet (HFD) has shown to induce insulin resistance thus affecting the DVC's ability to regulate glucose metabolism and food intake, though exact mechanistic effects of this are still unknown. HFD feeding is associated with an increase in mitochondrial fission in the DVC. Mitochondrial fission is regulated by dynamin related protein 1 (Drp1), and an increase in Drp1 activity in the DVC has shown to inhibit the insulin signalling pathway. Adenoviruses expressing a constitutively active form of Drp1 (S637A), a dominant negative form of Drp1 (K38A) and a GFP expressing control were injected into the nucleus of the solitary tract (NTS) of the DVC. Our data has shown, rats expressing Drp1-S637A in the DVC, do not decrease food intake in response to an acute insulin treatment, compared to the GFP controls. Confirming that increases in mitochondrial fission results in impaired insulin sensitivity. Furthermore, we found that after 14 days, Drp1-S637A expressing rats were hyperphagic and had an overall increase in body weight and fat accumulation. Following this, we determined if inhibition of Drp1 can restore insulin sensitivity in HFD fed (insulin resistant) rats. Acute insulin treatment, decreased food intake in the HFD fed Drp1-K38A expressing rats, but not in the HFD fed GFP expressing rats, confirming that inhibition of Drp1 can restore insulin sensitivity. In addition, chronic inhibition of Drp1, resulted in a decrease in food intake, body weight and fat accumulation.

Title: Hypothalamic neuronal circuits regulating hunger-induced taste modification

Authors: O. FU[1,2], Y. IWAI[1], *T. MISAKA[1], Y. MINOKOSHI[2], K. NAKAJIMA[2]
[1]The Univ. of Tokyo, Bunkyo-Ku, Japan; [2]Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Gustatory system plays a critical role in sensing appetitive and aversive taste stimuli for evaluation of food quality. Although taste sensitivity and taste preference are known to change depending on internal state such as hunger, the mechanistic insight remains unclear. Here we show that neuronal mechanism regulating hunger-induced taste modification in the mouse brain.

Starved mice exhibit increased sensitivity for sweet taste and tolerance for aversive taste, respectively (C57/BL6J mice, male, 10 weeks, n=6). As Agouti-related peptide (AgRP)-expressing neurons located in the arcuate nucleus of the hypothalamus (ARC) play a key role in driving hunger by sending inhibitory inputs towards multiple brain regions. we thus investigated whether optogenetic stimulation of AgRP neurons (AgRP-ires-Cre mice expressing ChR2 in AgRP neurons, male, 10 weeks, n=6) lead to the taste modification. Selective activation of AgRP neurons projecting to the lateral hypothalamus (LH) but not other brain regions recapitulated the hunger-induced change in taste sensitivities.

Immunohistochemical analysis indicates AgRP neurons connect to parts of the glutamatergic Vglut2-expressing neurons in the LH. We thus evaluated the role of these neurons in taste sensitivities. Chemogenetic inhibition of $Vglut2^{LH}$ neurons (Vglut2-ires-Cre mice expressing inhibitory DREADD, hM4Di in $Vglut2^{LH}$ neurons, male, 8~16 weeks, n=7) changed taste sensitivities as observed under physiological hunger. By contrast, activation of $Vglut2^{LH}$ neurons (Vglut2-ires-Cre mice expressing excitatory DREADD, hM3Dq in $Vglut2^{LH}$ neurons, male, 8~16 weeks, n=6) completely cancelled the hunger-induced phenotype.

$Vglut2^{LH}$ neurons send dense projections to the lateral septum (LSI), the anteriordorsal nucleus of thalamus (AD), and the lateral habenula (LHb), we conducted pathway-selective chemogenetic inhibition experiments to identify the key area on the taste modification. Interestingly, $Vglut2^{LH}$ projection in the LSI only increased sensitivity for sweet taste. By contrast, $Vglut2^{LH}$ projection in the LHb decreased tolerance for aversive taste.

In summary, we found that 1) hunger-induced taste modification is caused by activation of the LH-projecting AgRP neurons and the following inhibition of $Vglut2^{LH}$ neurons and that 2) the two differential inhibitory circuits ($AgRP^{ARC}$-$Vglut2^{LH}$-LSI and $AgRP^{ARC}$-$Vglut2^{LH}$-LHb) regulate sensitivity for sweet taste and tolerance for aversive taste, respectively. These hypothalamic circuits for taste modification would be important for optimizing feeding behavior under an energy deficit.

Title: Roux-en-Y and vagotomy increase DNA fragmentation in vagal afferent neurons of rats within 24h

Authors: *D. M. MINAYA CABA[1], A. TURLEJ[1], S. C. FARUQUE[1], V. LACMANOVIC[1], A. JOSHI[1], A. HAJNAL[2], P. M. DI LORENZO[3], K. CZAJA[1]
[1]Vet. Biosci. and Diagnos. Imaging, Univ. of Georgia, Athens, GA; [2]Dept Neural & Behav Sci., Penn State Univ., Hershey, PA; [3]Psychology, Binghamton Univ., Binghamton, NY

Abstract: Roux-en-Y gastric bypass (RYGB) is one of the most effective long-term weight loss treatments for obesity. Although the effects of RYGB on the gut-brain vagal connection are largely unknown, prior studies have shown that RYGB triggers a degenerative response in vagal afferents similar to the response observed after subdiaphragmatic vagotomy (VAX). However, these observations have only been recorded several weeks after the procedure. The aim of this study was to investigate the short-term effects of RYGB and VAX on plasticity of vagal afferents in the nodose ganglia (NG) and Nucleus Tractus Solitarius (NTS) in male and female rats. Sprague-Dawley rats underwent RYGB, VAX, or sham surgery. Twenty-four hours later, animals were sacrificed and NG and NTS were collected. Neuronal cell damage was determined by TUNEL assay. Inflammation was determined by quantifying the fluorescent staining against the ionizing calcium adapter binding molecule 1 (IBA 1). Reorganization of vagal afferents was evaluated by fluorescent staining against Isolectin 4 (IB4). Results of the study revealed that RYGB and VAX significantly increased DNA fragmentation in vagal neurons in the NG of male and female rats. In males, RYGB and VAX decreased the density of vagal afferents projecting to the NTS. RYGB did not trigger microglia activation in the intermediate NTS, but VAX increased microglia activation. RYGB and VAX decreased microglia activation in the rostral NTS. In females, RYGB decreased the density of vagal afferents projecting to the intermediate NTS. However, we observed an increase in fibers projecting the rostral NTS. In contrast, VAX did not affect the density of vagal fibers projecting to NTS. RYGB decreased microglia activation in the NTS, but we did not observe an inflammatory response after VAX. The changes observed in vagal presynaptic projections to the NTS indicate that RYGB and VAX surgery induce rapid neuronal damage in the NG. Furthermore, the current data suggests that reorganization of vagal afferents and the inflammatory response previously reported in the NG and NTS ten days after RYGB and VAX surgery develop progressively over that time course.

Title: The physiological effects of PYY is dependent upon time of day

Authors: M. J. MARONI, K. M. CAPRI, A. V. CUSHMAN, I. K. MONTEIRO DE PINA, M. H. CHASSE, *J. A. SEGGIO
Biol. Sci., Bridgewater State Univ., Bridgewater, MA

Abstract: Food consumption during the inactive periods, which is common for individuals experiencing circadian disruption, have been liked to metabolic diseases, including Type-2 diabetes mellitus and obesity. Recent studies show that restricting food intake during the active period only can attenuate or reverse these metabolic problems in animal models. One hormone which plays a large role in food consumption patterns is PYY, a hormone released by the hindgut after food consumption which interacts with NPY2 receptors in the hypothalamus to modulate hunger. This study aimed to uncover the circadian variation of food consumption and the secretion of hormones related through metabolism through supplementation of PYY 3-36 in male CD-1 mice under a standard 12:12 LD cycle. In the first part of the study, blood was collected from 12 hour fasted mice at ZT 0, ZT 6, ZT 12, and ZT 18, and the amount of PYY 3-36 were measured. In the second part, mice were fasted for 12-hours; afterwards, they were given an injection of PYY 3-36 or saline at the aforementioned zeitgeber times and were given food to determine the levels of food consumption and hormones observed under each injection type and time point. Endogenous fasting levels of PYY 3-36 exhibit time of day differences, peaking at ZT 6. PYY 3-36 is most effective at suppressing food intake and body weight, compared to saline injected controls, when injected during the subjective night than the subjective day. Interestingly, PYY3-36 led to overall increases in glucose levels and disrupted the circadian glucose response to a meal after a fast. Injections of PYY 3-36 also led to an overall reduction of insulin regardless of time of day. These results illustrate that the effectiveness of PYY 3-36 in modulating food consumption and hormone secretion is dependent upon the time of day given.

Title: Sex differences and similarities in stress-induced eating behavior

Authors: *N. CLAUSS
Oklahoma State Univ., Stillwater, OK

Abstract: Stress-induced consumption of highly palatable (HP) food could be one potential pathway from stress to obesity. However, it is unclear whether males engage in stress-induced eating to a similar extent as females (e.g. Grunberg & Straub, 1992; Zellner et al., 2007). The current study hypothesized that exposing male and female participants to sex-specific stressors would lead to similar levels of stress-induced consumption of HP food between sexes.A preliminary power analysis indicated a sufficient sample size would be 165 participants. Participants were 167 undergraduate students recruited from a southern United States university, a majority of whom were female (52.6%), Caucasian (73.10%), and between the ages of 18-21 (92.6%) Participants were randomly assigned to one of three conditions: achievement stress, social rejection, and control. Participant heart rate and post-condition food intake were measured. A two-way between-groups ANOVA was conducted to explore the impact of sex and experimental condition (achievement, social rejection, control) on stress (as measured by respiratory Sinus Arrhythmia). There was a significant interaction effect for sex and experimental condition (F [2, 159] = 6.73, $p < .01$). Males demonstrated higher stress after an achievement stressor (MD = -.88, SE, .34, p = .01, $C;_{.95}$[-1.56, -.20]), and females demonstrated higher stress after a social rejection stressor (MD= -1.05, SE = .40, p = .01, $C;_{.95}$[-1.85, -.25]). A two-way between-groups ANOVA was conducted to explore the impact of sex and sex-specific laboratory stressor on HP food consumption (HPFC). The interaction between sex and amount of HPFC was not statistically significant. However, there was a main effect for condition (F [2, 157] = 4.23, $p < .01$). Post-hoc comparisons demonstrated that males and females both consumed a significant amount of HP food after either the social rejection or the achievement condition than they did after the control condition. For female participants, HPFC was also associated with current menstrual cycle such that overall consumption of HP food was significantly increased among females in the luteal phase, and consumption of specifically HP salty food was significantly greater among females in the ovulation phase. Given the finding that RSA provided an accurate measure of stress that resulted in stress-induced eating, it is possible that biofeedback could be used to reduce instances of stress-induced consumption of non-nutritious, hyper-energetic foods. The preliminary result that females HPFC may be influenced by menstrual cycle could have implications for the role of hormones in stress-induced eating behavior.

Title: single cell resolution hindbrain neuronal dynamics reveal convergent appetitive and consummatory processes in both hunger and thirst

Authors: *R. GONG[1], S. M. STERNSON[2]
[1]Ashburn, VA; [2]Janelia Res. Campus, HHMI, Ashburn, VA

Abstract: Feeding and drinking behavior are comprised of sequential appetitive and consummatory phases. Interoceptive neurons that monitor energy or hydration state can be used to artificially induce hunger or thirst states in order to examine circuits responsible for need-based behaviors. Activation of AGRP neurons or SFO^{Nos1} neurons can induce seeking and consumption of food or water, respectively. To identify brain areas sensitive to both AGRP neuron and SFO^{Nos1} neuron activation, we used optogenetic activation of these neurons and determined brain areas that contain Fos-immunoreactivity after acute activation. Stimulation of AGRP neurons or SFO^{Nos1} neurons induced strong Fos expression in both lateraldorsal tegmental area (LDTg) neurons and neurons in the pre locus coeruleus (preLC). Cre-dependent trans-synaptic anterograde herpes simplex virus starting from AGRP neurons also labeled neurons in these areas, raising the possibility that these regions play an important role in feeding and drinking behavior. To investigate these regions, we developed a stable cellular-resolution endoscopy calcium imaging method in the hindbrain that stabilizes unwanted hindbrain movement so that we could readily obtain neuronal dynamics in freely moving mice. We found that GABGAergic neurons are highly correlated with locomotoer activity, indicating a role in food- and water-seeking behaviors; whereas glutamergic neurons are strongly modulated during the consummatory phase. Thus two independent populations of neurons in these adjacent brain regions actively take part in the sequential appetitive and consummatory phases of hunger and thirst behaviors. Collectively, these data show the convergence of circuits regulating hunger and thirst in hindbrain areas that respond to locomotion and consummatory behaviors.

Chem. and Pharmacology, Sch. of Medicine, Univ. of California, Irvine, CA

Abstract: The fatty acid ethanolamide, oleoylethanolamide (OEA), is a lipid mediator that regulates feeding and stimulates lipolysis and fatty acid oxidation in adipocytes and hepatocytes through activation of nuclear peroxisome proliferator-activated receptor type-alpha (PPAR-α). Fasting is accompanied by a substantial elevation in liver OEA levels, but the biochemical mechanism and physiological implications of this effect are unknown. The neurotransmitter histamine plays an important role in the control of feeding behavior and contributes to the anorexic effects of systemically administered OEA. In the present study, we describe an unprecedented paracrine mechanism that regulates fasting-induced ketogenesis through stimulation of OEA signaling in the liver. Histidine decarboxylase-null ($HDC^{-/-}$) mice, mast cell-deficient ($C57BL/6J\text{-}Kit^{W\text{-}v}/J$) mice, $NAPE\text{-}PLD^{-/-}$ mice and their wild-type littermates (all males) were subjected to three different conditions: a) free feeding (FF); b) 12 h food deprivation (FD) and c) 1 h refeeding after food deprivation (RF). Histamine (0.45 μmol or 0.9 μmol in sterile saline) was slowly injected into the liver using an insulin syringe (injection volume 0.1 mL). 30 min later, the mice were killed and their livers were collected. H_1 antagonist fexofenadine (10 mg/kg), H_2 antagonist famotidine (10 mg/kg), H_3 antagonist ciproxifan (3 mg/kg) and H_4 antagonist JNJ7777120 (20 mg/kg) were administered by intraperitoneal injection 1 h before tissue harvest. Alpha-fluoromethylhistidine (α-FMH), a suicide inhibitor of HDC, was administered by intracerebroventricular infusion (1 μg/μl in physiological saline). Endogenous OEA, N-oleoyl-PE, oleic acid and histamine levels were quantified by liquid chromatography/mass spectrometry (LC/MS) analyses and ketone body production was measured in plasma and liver samples using a colorimetric assay kit. We found that: 1) a 12-h fast stimulates mast cells to release histamine into the hepatic portal circulation; 2) the biogenic amine travels to the liver, where it activates G protein-coupled H_1 histamine receptors, which

activate in turn OEA biosynthesis; 3) this signaling cascade enhances fasting-induced ketogenesis, without affecting lipolysis or other responses to food deprivation. Note that disabling histamine-dependent OEA signaling, either genetically or pharmacologically, cuts down overall ketone body production in fasting mice by approximately 50%. The results reveal an unexpected role for histamine in the control of bioenergetics homeostasis, and suggest that dysfunctions in histamine-dependent OEA signaling might contribute to metabolic disease.

Title: Ventral hippocampus ghrelin elevates meal size via interactions with gut-derived satiation signals

Authors: *A. N. SUAREZ[1], C. LIU[2], E. NOBLE[3], A. CORTELLA[1], S. E. KANOSKI[1]

Abstract: In addition to classic gastrointestinal-hindbrain pathways that control meal size, emerging findings reveal that higher-order brain substrates influence satiation processing as well. Our recent findings show that the gut-derived "hunger" hormone ghrelin acts in the ventral subregion of the hippocampus (vHPC) to not only stimulate conditioned aspects of feeding but also increase spontaneous meal size. Here we investigate whether vHPC ghrelin signaling elevates meal size through interactions with vagally-mediated within-meal satiation signals, including the intestinal hormone cholesystokinin (CCK) and mechanical distension of the stomach. Results show that a dose of vHPC ghrelin that is subthreshold for feeding effects alone attenuates the satiating efficacy of both peripheral CCK administration and gastric distension following methylcellulose gavage. To determine the descending neural pathways potentially mediating these effects, we utilized a multisynaptic virus-based tracing method to identify multi-order neural pathways from the vHPC (CA1) to the dorsal vagal complex (DVC) in the hindbrain. Results identify the lateral hypothalamic area as a relay connecting the vHPC to the DVC. We conclude that vHPC ghrelin signaling increases meal size through interactions with gut-derived vagally-mediated satiation signals and that these effects may occur through a newly identified descending pathway connecting the vHPC to the caudal brainstem via the lateral hypothalamic area.

Abstract: Hypothalamic circuits that regulate feeding, dynamically respond to the perception of food, and function to govern consummatory behaviors. How sensory information is processed and relayed to the hypothalamus, and how such circuits function towards regulating feeding related behavior remains largely unknown. Here, we investigated a subset of excitatory neurons that reside in the mouse basal forebrain, a structure that has previously been implicated in appetite suppression and have uncovered a potent role for this circuit node in regulating feeding behavior through food avoidance mechanisms. Utilizing in-vivo microendsocopy and cell-type specific expression of GCaMP6m, we identified a group of basal forebrain excitatory neurons selectively activated by food odor presentation. Chronic activation of basal forebrain excitatory neurons resulted in severe hypophagia that ultimately led to starvation and death. Moreover, we found that basal forebrain excitatory neurons receive monosynaptic cholinergic inputs, and project to the lateral hypothalamus. Optogenetic activation of both basal forebrain excitatory neuron cell-bodies and targeted lateral hypothalamic projections confirmed that this extrahypothalamic circuit node functions in the observed reduced food intake. We also discovered that this acute hypophagic phenotype was in part due to avoidance behavior towards food and food-related stimuli. Together, our data highlight a role for the basal forebrain as a potent integrator of sensory information, capable of governing consummatory behaviors in response to the perception of food.

Title: Essential and sex-specific effects of mGluR5 in the ventromedial hypothalamus facilitating glucose and lipid homeostasis

Authors: *M. RIOS[1,2], M. PANESSITI[4], D. AMEROSO[5], A. N. ROCK[6], J. L. MAGUIRE[3]
[1]Cell Mol. & Dev Biol., [2]Dept. of Neurosci., [3]Neurosci., Tufts Univ. Sch. of Med., Boston, MA; [4]Tufts Univ., Boston, MA; [5]Neurosci., Tufts Univ. Sackler Sch. of Grad. Biomed, Boston, MA; [6]Brain + Cognitive Sci., MIT, Cambridge, MA

Abstract: Brain-derived neurotrophic factor (BDNF) and its receptor TrkB promote neuronal survival, differentiation and synaptic plasticity and play required roles in the central regulation of energy and glucose balance. Indeed, mice with global central BDNF depletion ($BDNF^{2L/2LCk\text{-}cre}$) exhibit excessive feeding, obesity, insulin resistance and hyperglycemia. Furthermore, *Bdnf* was identified as one of the top loci linked to obesity susceptibility in humans. The ventromedial hypothalamus (VMH), an energy and glucose balance-regulating center containing anorexigenic and glucose sensing neurons, is an important site of BDNF action. Accordingly, VMH neurons in $BDNF^{2L/2LCk\text{-}cre}$ mutant mice exhibit diminished excitatory drive and selective deletion of *Bdnf* in this region triggers obesity and the associated metabolic syndrome. To gain insight into the underlying mechanisms, we conducted an analysis of the transcriptome of VMH cells of control and $BDNF^{2L/2LCk\text{-}cre}$ mice and found that metabotropic glutamate receptor 5 (mGluR5) was significantly downregulated in male and female mutants. Because mGluR5s play paramount roles in excitatory synaptic plasticity in other brain regions, we hypothesized that they might facilitate energy and glucose balance control acting downstream of BDNF in the VMH. To test this, we examined the effect of deleting mGluR5 in $SF1^{+}$ neurons, which in the brain are exclusive to the VMH. We found that this deficit produced alterations in glycemic control, insulin sensitivity and lipid metabolism without affecting body weight in mutant ($mGluR5^{f/f:SF1\text{-}cre}$) females but not in male mice. Alterations in synaptic physiology and in the intrinsic excitability of $SF1^{+}$ neurons and diminished sympathetic tone were observed exclusively in $mGluR5^{f/f:SF1\text{-}cre}$ females and underlie these metabolic abnormalities. Notably, the beneficial effects of estrogen on glucose balance control are blunted in $mGluR5^{f/f:SF1\text{-}cre}$ females. To ensure

scientific rigor, all experiments involved appropriate use of controls, power analysis to determine cohort size and statistical analysis to determine significant differences. Collectively, these findings indicate a novel an essential role of mGluR5 in female VMH facilitating estrogen signaling, neuronal activity, glucose homeostasis and lipid metabolism. They also inform mechanisms underlying the reported higher risk of insulin resistance and metabolic disorders in post menopausal women.

Abstract: Recent researches showed that intracerebroventricular (ICV) administration of leptin could normalize blood glucose levels (BG) in rodent models of insulin-dependent diabetes mellitus (IDDM). As a mechanism by which leptin improves glucose homeostasis in IDDM, central leptin is supposed to enhance glucose uptake in both brown adipose tissue and soleus muscle via the activation of sympathetic nervous system. Protein tyrosine phosphatase 1B (PTP1B) negatively regulates leptin signaling via the direct dephosphorylation of Jak2 and have been implicated as an important regulator of energy homeostasis. On the other hand, it is still unclear whether PTP1B affect the leptin action in IDDM. In the present study, we investigated the role of PTP1B in leptin action for treating IDDM by using PTP1B deficient (KO) mice. At first, wild-type (WT) and KO mice were intraperitoneally injected with 150 mg/kg streptozotocin (STZ) to generate IDDM model for each study group. After 1 week of the procedure, the BG at the end of dark cycle were monitored in IDDM mice every third day. We also measured BG in mice received two kinds of treatment. One is to implant mice subcutaneously with an osmotic mini-pump providing leptin (20 μg/day) or saline systemically, and the other is to implant with the pump in the same way, which was connected to ICV cannula to enable continuous infusion

of leptin (0.25 μg/day) or saline only centrally. STZ treatment significantly increased BG in both WT and KO mice compared to control mice, but the BG was significantly lower in KO mice compared to WT mice. Systemic or central leptin treatment decreased BG in WT mice, although the BG was still significantly higher than those in control mice. In contrast, in KO mice both kinds of leptin treatment decreased BG to almost same levels as control mice. No differences were detected in body weight and food intake between genotypes. These results suggest that PTP1B deficiency enhanced leptin action in the brain to improve blood glucose levels in IDDM and may provide a potential approach for treating IDDM.

Title: A fully implantable, closed-loop wireless recording and stimulation system for the treatment of obesity

Authors: W. KIM[1], C. CAMPOS[2], R. D. PALMITER[2], *S. PARK[1]
[1]Texas A&M Univ., College Station, TX; [2]Univ. of Washington, Seattle, WA

Abstract: Over the past several decades, obesity has grown into a major global epidemic. In the United States, more than two-thirds of adults are now overweight and one-third is obese [1]. Unfortunately, the current available treatments for obesity are often ineffective, and do not treat the underlying pathology. Moreover, therapies for these conditions are limited by our inability to understand and control the network of neuronal circuitry, in particular **vagus afferent fibers**, that regulate energy homeostasis [1]. Meal cessation is to a large extent mediated by feedback from the gut to the brain. Distension of the stomach, the absorption of nutrients and the release of satiety hormones (GLP-1, peptide YY, and cholecystokinin) cells can activate the vagus nerve that then signals the nucleus tractus solitarius (NTS) in the hindbrain [2]. Neurons in NTS then relay signals to the parabrachial nucleus (PBN) and other nuclei to suppress feeding [3]. Because the **vagus** is a major origin of satiation signals, it is a logical place to intervene to treat obesity. Furthermore, several studies indicate that the vagus becomes insensitive to satiation signals in obese animals. Consequently, the ability to bypass this obesity-induced insensitivity and experimentally activate the vagus has significant potential [4]. However, a human nodose ganglion contains 100,000 neurons which can innervate many different internal organs [5]. Therefore, cellular level control of nerves is crucial to this pursuit. In addition, there is no way to

directly record the activity of vagal neurons in awake mice, which can provide real insights into how satiety information is processed. Thus, all the experiments that suggest that the vagus becomes insensitive to nutrients and hormones in response to obesity are indirect [4]. Here, we propose soft, miniaturized implantable battery-free wireless device that can offer exceptional spatial/temporal resolution, optogenetic stimulation, and capabilities in wireless recording. These innovative and disruptive technologies allow experiments that examine subtypes suppressing feeding, thereby identifying a signaling pathway that could regulate food intake to treat obesity. Here, we use adult male mice (C57/BI6 background) for experiments and inject AAV9-Syn-DIO-ChrimsonR-TdTomato virus into nodose ganglion to infect vagus nerve.

Title: Regulation of pancreatic islet oxytocin by autonomic nervous system agonists

Authors: J. S. WESTWRIGHT[1], A. SZETO[2], *A. HELLER[2], P. M. MCCABE[2], A. J. MENDEZ[3]
[1]Psychology, [2]Univ. of Miami, Coral Gables, FL; [3]Diabetes Res. Inst., Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Objective: The neuropeptide oxytocin (OT) is a well-established regulator of reproductive processes that has gained recent attention as a modulator of social behavior. Peripheral effects of OT are classically thought to result from central release, yet OT and its receptor have also been detected in peripheral tissues, including the endocrine pancreas. OT has been implicated in glycemic control and metabolism, but regulation of its release from pancreatic islet cells is not well understood. OT release in the central nervous system is modulated by classical neurotransmitters such as norepinephrine (NE). Similarly, autonomic nervous system (ANS) derived NE and acetylcholine (ACH) are known to play a role in pancreatic metabolic processes (e.g. insulin and glucagon secretion). Thus, the present study examined whether ANS

agonists modulate OT secretion in pancreatic islet cells in vitro, and whether OT influences insulin secretion.
Methods: Isolated human or rat pancreatic islets or mouse MIN6 cells (a cancerous, pancreatic beta-islet cell line) were primed in low glucose media for one hour, then subsequently incubated in media containing low (3 mM) or high (20 mM) glucose with or without NE or ACH (10 µM). Secretion of OT and insulin were quantified by enzyme-linked immunosorbent assay (ELISA). To evaluate the effect of OT on glucose-stimulated insulin secretion, rat pancreatic islets were incubated with low or high glucose in the absence or presence of 1nM OT.
Results: In the presence of high or low glucose, NE significantly increased secretion of OT from islet cells. Ten µM NE decreased and 10 µM ACH increased insulin secretion from the mouse beta-cell line MIN6 and human islets, consistent with previous research. In the presence of high glucose, incubation with OT significantly increased insulin secretion from rat islets.
Conclusions: Treatment with NE, regardless of glucose concentration, stimulated release of OT from pancreatic islets. These results suggest that OT secretion from the endocrine pancreas may be regulated by the ANS. Furthermore, OT enhances insulin secretion in the presence of high glucose. Future experiments will evaluate the relationship between pancreatic OT and insulin to determine whether OT, directed by the ANS, may act as a secondary system to optimize glycemic control in times of challenge.

Title: The comparative study on anatomical and functional innervation between parasympathetic nervous system and liver in mouse and human

Authors: *D. CHEON, C. NAMKOONG, H. J. CHOI
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: The liver is innervated by both the sympathetic and the parasympathetic nerve system. Human liver parasympathetic nerves are well characterized in neuroanatomical pattern in the human liver is unknown. In the present study, we investigated the parasympathetic innervation of human and mouse liver by passive tissue clearing method for 3D-images. We were optimize passive clearing method and immunofluorescent labelling of parasympathetic neurons in human

liver and mouse tissue. In addition to visulaising of parasympathetic nerve in liver. We performed liver passive clearing and immunohistochemistry analysis to confirm 3D-anatomical interaction of parasympathetic neurons and hepatocytes. The images show complex and dense neuronal circuit in the liver. We next investigated the role of parasympathetic in regulation of liver glucose metabolism by chemogenetic methods using DREADDs (designer receptors exclusively activated by designer drugs). We confirm that our chemogenetic virus and mouse model is working by electrophysiology of DMV neurons showing that CNO activates the neurons. Acute activation of neurons in DMV region results in increasing hepatic lipogenesis and gluconeogenesis. These results suggest that specific activation/inhibition of parasympathetic neurons to might be involved in the regulation of lipid and glucose metabolism.

Title: Metabolomic and structural brain connectomic evidence validating traditional Chinese medicine diagnostic classification of major depressive disorder

Authors: *Z.-J. ZHANG[1], L.-Y. LIU[3], H.-J. ZHANG[4], X.-P. XU[2]
[1]Sch. of Chinese Med., The Univ. of Hong Kong, Pokfulam, Hong Kong; [2]The Univ. of Hong Kong, Hong Kong, Hong Kong; [3]Dept. of Psychiatry, Tongde Hosp. of Zhejiang Province, Hangzhou, China; [4]Zhejiang Acad. of Traditional Chinese Med., Hangzhou, China

Abstract: Major depressive disorder (MDD) is a highly heterogeneous mental illness. Further classification may help characterize its heterogeneity. The purpose of this study was to examine metabolomic and brain connectomic associations with traditional Chinese medicine (TCM) diagnostic classification of MDD. Fifty unmedicated depressed patients were classified into Liver Qi Stagnation (LQS, n = 30) and Heart and Spleen Deficiency (HSD, n = 20) subtypes according to TCM diagnosis. Healthy volunteers (n = 28) were included as controls. Gas chromatography-mass spectrometry (GC-MS) and diffusion tensor imaging were used to detect serum and urinary metabolomic profiles and whole-brain white matter connectivity, respectively. In metabolomic analysis, 28 metabolites were identified for good separations between TCM subtypes and healthy controls in serum and urine samples. While both TCM subtypes had similar

profiles in proteinogenic branched-chain amino acids and energy metabolism-related metabolites that were differentiated from healthy controls, the LQS subtype additionally differed from healthy controls in multiple amino acid metabolites that are involved in the biosynthesis of monoamine and amino acid neurotransmitters. Several metabolites are differentially associated with the two subtypes. In connectomic analysis, The LQS subtype showed significant differences in multiple network metrics of the angular gyrus, middle occipital gyrus, calcarine sulcus, and Heschl's gyrus when compared to the other two groups. The HSD subtype had markedly greater regional connectivity of the insula, parahippocampal gyrus, and posterior cingulate gyrus than the other two groups, and microstructural abnormalities of the frontal medial orbital gyrus and middle temporal pole. The insular betweenness centrality was strongly inversely correlated with the severity of depression and dichotomized the two subtypes at the optimal cutoff value with acceptable sensitivity and specificity. These results suggests that the LQS subtype may represent an MDD subpopulation mainly characterized by abnormalities in the biosynthesis of monoamine and amino acid neurotransmitters, closer associations with stress-related pathophysiology, and aberrant connectivity of the audiovisual perception-related temporal-occipital network, whereas the HSD subtype is more closely associated with hyperconnectivity and microstructural abnormalities of the limbic-paralimbic network. Certain metabolomic and connectomic variables are potential biomarkers for TCM diagnostic subtypes which is perhaps an alternative classification for depressive disorders.

Title: A genetic insight into the pathogenesis of depression from gene set enrichment analysis

Authors: *D. DAI[1,2], N. MA[2], Q. ZHOU[1], Z. LIU[2], J. FENG[2,3]
[1]Shanghai Ctr. for Mathematical Sci., Fudan Univ., Shanghai City, China; [2]Inst. of Sci. and Technol. for Brain-Inspired Intelligence, Shanghai, China; [3]Dept. of Computer Sci., University of Warwick, United Kingdom

Abstract: Background: Depression as a heterogeneous disorder, results from a complex interaction between vulnerability genes and environmental factors. Genome-wide association study (GWAS) has greatly facilitated the understanding of genetic basis of depression.

Distribution of depression-related genes in the human brain is not clear yet, which can be very informative to identify key brain regions and genetic mechanism underlying the altered brain functions in depression.
Methods: Based on GWAS results of major depressive disorder (MDD) from the Psychiatric Genomics Consortium, we obtained MDD-related genes within a 50Kb distance of SNPs with significant effects on the developing of MDD (p value <0.001). ABAEnrichment R package was applied to MDD-related gene get enrichment analysis. GO (Gene Ontology) enrichment analysis was performed by R package clusterProfiler to identify biological processes, molecular functions and cellular components regulated by those MDD-related genes. At last, a region of interest (ROI) to voxel analysis was conducted to identify any voxels that differently connected to paracentral lobule (posterior part) between 282 depressed patients and 254 healthy subjects (two-sample t-tests, AlphaSim correction threshold of p value < 0.05).
Results: Those MDD-related genes were found to be significantly enriched in three human brain regions (p value <0.05). Anterior orbital gyrus and habenula, which have been both implicated in reward processing and depression, were identified to be enriched with MDD-related genes. To our surprise, posterior part of paracentral lobule representing body sensory information was indicated as the brain region with most significant enrichment expression of MDD-related genes. Those three regions were all found in the right part of the human brain. ROI analysis indicated altered functional connectivity between paracentral lobule with some brain regions including putamen and thalamus in depressed patients.
Conclusion: Paracentral lobule, anterior orbital gyrus and habenula might get involved in the pathogenesis of depression via disrupted reward processing, especially for the somatosensory information. The altered functional connectivity may underlie the structural and functional abnormality of putamen and thalamus in depressed patients, indicating paracentral lobule might involve in reward processing related subcortical dysfunction in depression. Together with the gene set enrichment analysis, we pointed out key brain regions in the pathogenesis of depression.

Abstract: *Objective:* Depression and other mood disorders frequently emerge in adolescence, pointing to this life stage as a critical period for such disorders. The identification of biomarkers in adolescence that can reliably assess and predict depression is a vital step towards enhanced treatment of these conditions. The current study aimed to identify frontoinsular biomarkers for assessing and predicting mood health in an adolescent sample, using task-based neuroimaging. *Method:* The sample consisted of adolescents (n=42, ages 14-19) exhibiting high variance in severity of depressive symptoms. All participants completed a baseline neuroimaging session, which utilized an emotional executive functioning task. A subset of participants (n=28) completed a two-week follow-up, comprised of a daily diary report of negative affect and a final report of depressive symptom severity. Regression analyses tested associations between task-based functional connectivity in frontoinsular networks and measures of current or future mood health. Additional analyses examined associations between task performance and measures of anxiety and rumination, as well as associations between those measures and functional connectivity. *Results:* Frontoinsular task response was correlated with multiple dimensions of poor mood health, including current and future depressive symptom severity, as well as future intensity and variability of negative affect. Specifically, these indications of increased mood difficulties were associated with hyperconnectivity between insula and midline or temporal regions of the default network, and hypoconnectivity between insula and lateral prefrontal regions of the frontoparietal network. Associations between future mood health and frontoinsular activity were significant controlling for baseline symptoms, demonstrating the complementary utility of these biomarkers alongside other measures of risk. *Conclusion:* Frontoinsular connectivity appears to be a promising target of investigation for its potential therapeutic relevance for mood disorders.

Title: Impaired reinforcement learning signal representation in depression

Authors: *S. HEO[1], Y. KIM[3], Y. SUNG[2], E. KANG[2], S. LEE[2]

Abstract: Decision making is guided by two distinct systems: Model-Based (MB) and Model-Free (MF) system. Previous studies revealed that depressed individuals show impaired performance in reinforcement learning task. However, the neural mechanism underlying these abnormal decision making is not well understood. To address this, we analyzed neural response underlying decision making in depressive people using machine learning method. We especially focus on frontopolar prefrontal cortex (FPC) and interior lateral prefrontal cortex (ilPFC), areas known to integrate MB and MF systems. Twenty eight participants performed a two-stage Markov decision task, which is designed to drive one strategy over the other during the task and fMRI images were acquired. Based on the computational model (Lee 2014), we calculated the underlying signals such as MB/MF reliability (how much subjects rely on each system during the task) and Pmb (how much probability is finally assigned to each system). To understand the depression effect on information processing in FPC and ilPFC, we conduct two analysis: General Linear Model (GLM) and Multi Voxel Pattern Analysis (MVPA). GLM results show that information about integration of two systems (maximum value of the MB, MF reliability) is significantly less represented in FPC and left ilPFC as depression scale increases. On the other hand, MVPA results indicate that MF reliability and Pmb information is more clearly represented in these areas as people get more depressed. In summary, our findings indicate that proper integration of two reinforcement learning systems is impaired in depression, and this might be due to the elevated sensitivity of MF system in depression.

Col., New York, NY

Abstract: Neuropeptides are one of a number of substrates that have been implicated in the pathophysiology of major depressive disorder (MDD). Unlike the biosynthesis of classical neurotransmitters, neuropeptides undergo a series of processing steps to release active neuropeptide(s) from their larger, inactive precursors. The first enzymatic step in this process is carried out by proprotein/prohormone convertases (PCs), which typically cleave inactive peptide precursors C-terminal to paired basic amino acid residues (e.g., Lys/Arg). Two members of this family, PC1/3 and PC2, are stored in secretory granules and act on peptide precursors processed within the regulatory secretory pathway. We have previously shown that PC1/3 and PC2 expression levels are decreased at the level of the anterior hippocampus of MDD subjects when compared to non-psychiatric control subjects. At the level of the posterior hippocampus, MDDs had decreased 7B2 (a modulator of PC2) expression compared to controls, and together with findings in the anterior hippocampus suggest a dysregulation in the initial peptide processing steps in MDD. Here, we extend these studies to examine expression of two additional peptide processing molecules that function subsequent to the PCs in the generation of active neuropeptides: carboxypeptidase E (CPE) and peptidyl-glycine alpha-amidating monooxygenase (PAM). CPE is the primary carboxypeptidase involved in the biosynthesis of regulated secretory pathway neuropeptides, is broadly distributed in the brain and functions in mature secretory granules to remove C-terminal basic residues on intermediate cleavage products previously generated by PCs. PAM is a bifunctional molecule and sole known enzyme responsible for peptide amidation which is required for full functionality of around half of known neuropeptides. In this study, frozen 10µm sections through the hippocampus of MDD and non-psychiatric control subjects were processed for *in situ* hybridization using radiolabeled cRNA probes for CPE or PAM. Quantitative measurements of CPE or PAM mRNA expression using ImageJ are currently ongoing in the anterior and posterior hippocampal formation (HF). Initial evaluation of the distribution of CPE and PAM mRNA indicates that both are expressed in all regions of the HF, with CPE more abundantly expressed than PAM, consistent with previous studies carried out in the rat. Together with our previous findings, we anticipate that differences in the expression of CPE and/or PAM will contribute to a more thorough understanding of the molecular and anatomical specificity underlying the dysregulation of neuropeptides in the postmortem HF of depressed individuals.

Title: Depression and brain network profiles of the hippocampus and the prefrontal cortex in patients with borderline personality disorder: A focus on episodic memory

Authors: *T. J. ATTISHA[1], T. D. MERAM[1], A. Z. CHOWDURY[1], E. KALLABAT[1], P. SOLOFF[2], V. A. DIWADKAR[1]
[1]Dept. of Psychiatry, Wayne State Univ. Sch. of Med., Detroit, MI; [2]Dept. of Psychiatry, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Background: Borderline Personality Disorder (BPD) is characterized by impulsivity, mood instability and suicidality (Paris, 2005). Major depressive disorder (MDD) is frequently comorbid (Yoshimatsu et al., 2014), yet, how MDD affects the brain's connectivity profiles in BPD patients is unknown. We investigated this in the context of a hippocampal episodic memory paradigm, known to reliably distinguish BPD from controls (Soloff et al., 2015). We were interested in understanding how network profiles during Encoding of, and Recognition for affective valenced images (Lang et al., 2008) are modulated by valence.
Methods: 36 BPD patients (BPD_{MDD+}=15) underwent fMRI (3.0 T Siemens Trio) during which subjects performed the episodic memory task using images from the International Affective Pictures System (IAPS). Subjects were required to remember pictures (Encoding), after which memory for those pictures was tested (Recognition). fMRI data were processed using standard methods (SPM8). Network profiles of the Hippocampus (Encoding) and the dorsolateral prefrontal cortex (dlpfc, Recognition) were estimated using Psychophysiological Interaction (PPI) (Friston et al., 1997, p<.05, cluster level). Separate second level analyses were created (one for each seed). In each, Group (BPD_{MDD+} vs. BPD_{MDD-}) and Valence (-ve, +ve, neutral) were factors.
Results: a) Negatively valenced pictures: BPD_{MDD+} showed *decreased* hippocampal modulation of the supramarginal gyrus, and *decreased* dlpfc modulation of the rolandic operculum, fusiform and superior temporal pole. b) Positively valenced pictures: BPD_{MDD+} showed *decreased* hippocampal modulation of the superior temporal gyrus and middle temporal gyrus, and

decreased dlpfc modulation of the caudate nucleus and anterior cingulate gyrus. In contrast, BPD_{MDD+} showed *increased* hippocampal modulation of the insula and temporal lobe, and *increased* dlpfc modulation of the mid occipital gyrus. c) Neutral valence: The effects were singularly different. BPD_{MDD+} showed increased hippocampal modulation of the frontal middle gyrus and superior frontal lobe, and increased dlpfc modulation of the supramarginal gyrus and frontal medial orbital gyrus.
Discussion: During both encoding and recognition, negative *and* positive valences interfere with brain network profiles in BPD_{MDD+}. Depression appears to interfere with affective context dependent processing, leading to patterns of hypo-connectivity during memorial processing. Our results are generally consistent with the idea (from metaanalyses of rsFC) that MDD is characterized by hypo-connectivity (Kaiser et al., 2015).

Title: Association between depression and perseveration during reversal learning across samples of healthy individuals and psychiatric patients

Authors: *S. C. BROLSMA[1,2], J. N. VRIJSEN[2], E. VASSENA[1], A. H. SCHENE[2], R. COOLS[1,2]
[1]Donders Inst., Nijmegen, Netherlands; [2]Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: Adaptive decision making depends on a balance between goal-directed and habitual behaviors. Excessive focus on the habitual system leads to compulsive behavior, a symptom of several psychiatric disorders. A typical failure of the habitual system is perseveration, i.e. the inability to modify behavior based on feedback. In depression, rumination is thought to be a general manifestation of perseveration. In the healthy population there is large variability in the severity of depressive symptoms. However, the relationship between such variability and habitual behavior has never been investigated. In this study we hypothesized that perseveration, as an index of habitual behavior, correlates with severity of depressive symptoms.
To this end, we administered a probabilistic reversal learning task to a group of young

participants selected randomly from the normal population (study 1, n=78, ages 18-35) and to a heterogeneous group of psychiatric patients with depression, anxiety, autism, ADHD, or multiple disorders (study 2, n=208, ages 18-78). The task consisted of a series of choices between two stimuli. In 70% of the trials (80% for study 2), choice of one stimulus led to positive feedback, and choice of the other stimulus to negative feedback. Participants learnt these contingencies, and chose the stimulus that was most often correct. At some point in the task, and unbeknownst to participants, these contingencies reversed. After reversal, participants were required to switch, and select the previously incorrect stimulus. Failing to switch resulted in a perseveration error. Perseverative errors were counted when participants committed at least two consecutive errors in the reversal phase.
The results of study 1 showed a positive correlation: Participants with higher depressive symptom scores committed more perseverative errors. This was not the case for errors committed in the acquisition phase. Study 2 replicated this effect: Patients with more severe depressive symptoms also committed more perseverative errors (with no difference for acquisition errors). Critically, this effect was selective for depressive symptoms; anxiety, autism and ADHD symptom scores did not correlate with perseveration.
These findings demonstrate that severity of depressive symptoms is associated with compulsive, perseverative responding across samples of healthy individuals and psychiatric patients.

Title: Luxotonic signals in human frontal-polar cortex: A possible substrate for effects of light on mood

Authors: *J. N. SANES[1,2,3], S. SABBAH[1,2], R. WAUGH[1], M. S. WORDEN[1,2], D. M. BERSON[1,2]
[1]Neurosci., [2]Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [3]Ctr. for Neurorestoration and Neurotechnology, Providence VA Med. Ctr., Providence, RI

Abstract: A distinctive component of retinal output encodes absolute light intensity (irradiance) in the visual environment. This derives largely from melanopsin-expressing *intrinsically photosensitive retinal ganglion cells (ipRGCs)*. These cells innervate multiple subcortical targets and drive diverse physiological effects of light including circadian entrainment, pupillary reflexes, neuroendocrine and sleep modulation, along with retinal and visual brain development. In mice, unnaturally rapid light cycles (7 hr period) trigger depression-like symptoms, but this effect is abolished if ipRGCs are selectively killed (LeGates et al. 2012, Nature 491:594). New evidence suggests that the light cycle effects on mood may be mediated by a circuit linking ipRGCs through a thalamic region abutting the lateral habenula (the perihabenular nucleus), which then projects to the medial prefrontal cortex (Fernandez et al. 2017, ARVO meeting). To determine whether a similar light-intensity-dependent functional pathway affects human frontal cortex, we used BOLD functional MRI (3T Siemens Prisma, 2 mm isotropic voxels) to explore whole-brain activation patterns in response to full-field diffused light stimuli of four light intensities (10.2, 12.1, 13.1, and 13.8 log photons cm^{-2} s^{-1}; 30 sec epochs). Sustained monotonic increases in the fMRI signal were detected throughout visual cortex, including striate cortex and extrastriate regions as far anterior as the occipital border of the occipital-parietal sulcus. We also found strong luminance-dependent modulation in the frontal-polar cortex (frontopolar gyrus). The most anterior regions of the frontal-polar cortex exhibited persistent monotonic increases in activation with increasingly bright diffuse light. A second region, posteriorly adjacent to the first and including the subgenual medial prefrontal cortex, exhibited monotonic *reductions* in fMRI signal as a function of light intensity. These cortical regions have been implicated in mechanisms of major depression. We conclude that environmental light intensity modulates activity of certain regions of limbic neocortex. This circuit may contribute to diverse emotional and hedonic responses to environmental light, including seasonal affective disorder, mood elevation by phototherapy, a preference for well-lit spaces, and aversion to excessive light. Animal studies suggest that ipRGCs and the dorsomedial limbic thalamus are critical elements of this neural circuit. Preliminary results show evidence for photic activation of thalamic regions near the habenula, but a targeted regional analysis is needed and the possible role of ipRGCs remains to be tested.

Title: Connectivity differences with subgenual anterior cingulate cortex during self-referential processing in depressed and healthy participants

Authors: *L. HIMES[1], N. HUBBARD[4], M. P. TURNER[2], B. P. RYPMA[3,5]
[1]Behavioral and Brain Sci., [2]Sch. of Behavioral and Brain Sci., [3]Behavioral & Brain Sci., Univ. of Texas at Dallas, Richardson, TX; [4]McGovern Inst. for Brain Res., MIT, Cambridge, MA; [5]Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Cognitive theories of depression posit a key role for negative, or depressive, self-referential thought. A network of brain regions at rest have been associated with depressive and neutral self-referential processing in persons diagnosed with depression. One such region, subgenual anterior cingulate cortex (sACC) is a hub in this network and is implicated in sad emotion in both depressed and healthy controls (HCs). What is currently unknown is whether patterns of sACC functional connectivity are altered in depressed persons during actual depressive and neutral self-referential processing. We assessed which regions are most strongly connected with sACC during depressive and neutral self-referential processing using functional magnetic resonance imaging to assess the functional connectivity (FC) between this region and the rest of the brain in individuals diagnosed with a current Major Depressive Episode (MDE) and HCs during a depressive and neutral self-referential processing task (DST and NST, respectively). 15 participants with MDE and 21 HCs completed DSTs and NSTs during scanning. Participants viewed either a neutral (e.g., “I like to eat meat”) or a depressive (e.g., “I have no friends”) self-referential statement and indicated whether that statement was representative of him or her by button press. Left Brodmann area (BA) 25 (encompassing sACC) was used as the seed region, and whole-brain, voxel-wise correlations (p=.005, k=30) were calculated. MDE individuals had higher FC compared to HCs between sACC and insula and middle temporal gyrus during DST. During DST, HCs had higher FC between sACC and the cuneus, superior frontal gyrus (BA 6), parahippocampal gyrus, and medial prefrontal cortex (mPFC; BA 10) than MDE individuals. During NST, MDE individuals had higher FC between sACC and dorsolateral PFC (DLPFC; BA 46) and mPFC than HCs. HCs during NST had higher FC between sACC and posterior and anterior cingulate, parahippocampal gyrus, superior temporal gyrus, and mPFC. These results suggest that HCs utilize neutral self-referential processing (mPFC) regions when engaging in
both depressive and neutral self-referential processing, while different regions are utilized by individuals within an MDE. Further, individuals with MDE require use of cognitive control regions (e.g., DLPFC) during NST, reflecting a possible increased need to control for depressive self-referential thought during neutral self-referential processing. Differing connectivity patterns between MDE individuals and HCs in self-referential processing could underlie the abnormal self-referential thought that occurs in MDE.

Title: Towards a more useful heritability scale for genetic studies in depressive disorders: Comparison of trait and state depression scales in depressed and healthy men and women in a human population isolate

Authors: *M. KVARTA[1], E. HONG[2]
[1]Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Maryland Psychiatric Res. Ctr., Baltimore, MD

Abstract: Our understanding of the genetic basis of mood disorders, including depression, is incomplete. In genetic studies, defining the phenotype by diagnosis may miss risk-allele carriers without depressive disorders, forcing a continuum of symptom profiles and severities into a dichotomy. Future patients could be erroneously included as healthy controls, as first mood episodes can occur later in life. Furthermore, although quantitative assessments of mood have gained more attention, many depression studies in humans rely on assessments that are heavily weighted towards recent or current state of mood, generally using scales designed to identify recent or active mood episodes. Whether this approach can fully capture the genetic vulnerability for depression remains to be seen. We hypothesized that quantitatively detected symptoms of depression would identify a trait that may track with vulnerability for depressive disorders and is also significantly heritable. The Maryland Trait and State Depression Scale (MTSD) measures existence of depression "state" (i.e., symptoms within the last 7 days) and depression "trait" (i.e., symptoms experienced in lifetime excluding the last week). We administered the MTSD to a sample of Old Order Amish and Mennonites (OOA/M) with large family pedigrees. The OOA/M is a population isolate with high environmental homogeneity and a prevalence of mood disorders similar to that of the general population. Heritability was estimated using the variance components method implemented with SOLAR-Eclipse software. This is an ongoing study. Preliminary analysis was performed on currently available data from 309 individuals, including patients with mood disorders and their healthy family members. We found that the heritability estimates of the both lifetime depression trait score ($h2 = 0.47$, s.e. = 0.13, $p = 0.00004$) and current depression state score ($h2 = 0.48$, s.e. = 0.13, $p = 0.000026$) showed similar and highly significant heritability estimates. Unlike current depression reporting, lifetime depression assessments are prone to memory errors and other related confounds. The finding of a strong

heritability in the trait score is encouraging, suggesting additional effort is warranted to determine whether trait depression may serve as an additional quantitative depression endophenotype that could be a valuable tool to supplement the diagnosis phenotype in human depression studies.

Title: Habenula connectivity in adolescent mental illness

Authors: *B. A. ELY[1], J. G. XU[2], V. GABBAY[3,4]
[2]Radiology, Neurosci., [3]Psychiatry, Neurosci., [1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Nathan S. Kline Inst. for Psychiatric Res., Orangeburg, NY

Abstract: Introduction: Adolescence is a critical period in development when many psychiatric illnesses, including major depressive disorder (MDD), first emerge. Converging evidence suggests that the habenula (Hb), a small nucleus bordering the dorsomedial thalamus, plays an important role in MDD, particularly the symptom of anhedonia. In animal models, the Hb inhibits dopaminergic reward signaling by the ventral tegmental area (VTA) and downstream nucleus accumbens (NAc). Task fMRI studies indicate a similar Hb response profile in healthy humans (Lawson 2014), which is disrupted in MDD (Lawson 2017). Building on our recent findings of highly significant resting-state functional connectivity between the Hb and VTA in healthy young adults (Ely 2016), independently corroborated at 3T (Hesu 2016) and 7T (Torrisi 2016), we examined Hb connectivity with the VTA, NAC, and whole brain during the critical, emergent stages of psychiatric illness. **Methods:** We recruited 49 adolescents with psychiatric diagnoses (primarily MDD and anxiety disorders) and 15 healthy controls. Subjects completed a semi-structured diagnostic interview with a clinician and questionnaires to assess depression severity (BDI), anhedonia levels (TEPS), and anxiety symptoms (MASC). Human Connectome Project (HCP)-style MRI was performed on a 3T Siemens Skyra, including 0.9mm isotropic T1w and T2w anatomical scans and a resting-state fMRI scan (2.3mm isotropic, TR=1s, 600 volumes). Data were preprocessed using the HCP minimal preprocessing pipelines (Glasser

2013) and denoised using ICA-FIX, CompCor (5 WM + 5 CSF PCA components), 5mm FWHM spatial smoothing, and bandpass (0.1-0.01Hz) filtering. Functional connectivity was modeled using the CONN toolbox (ROI-to-ROI) and Connectome Workbench + FSL PALM (ROI-to-whole-brain). **Results:** Consistent with our previous findings, we observed highly significant Hb connectivity with the VTA ($p<10^{-8}$) and NAc ($p<10^{-6}$) in the full sample, as well as the dorsal anterior cingulate cortex (ACC), bilateral insula, and early sensory cortices in the whole-brain analysis ($p_{FWE}<0.05$). In the full sample, anhedonia severity was positively correlated with Hb-VTA connectivity ($r=0.29$, $p_{uncorrected}=0.042$), while anxiety scores were negatively correlated with Hb-NAc connectivity ($r=-0.29$, $p_{uncorrected}=0.044$) only in the clinical sample. **Conclusions:** Our findings indicate that Hb connectivity with key reward regions (i.e. VTA, NAc, ACC) develops early in life, and moreover that connectivity within these pathways may be associated with anhedonia and anxiety severity during adolescence, supporting the potential role of the Hb in the onset of mental illness.

Title: An EEG-fMRI-TMS system for investigating BOLD response to alpha phase-locked TMS

Authors: *Y. LIN[1], J. FALLER[1], J. DOOSE[2], G. T. SABER[2], J. R. MCINTOSH[1], R. I. GOLDMAN[4], M. S. GEORGE[3,5], P. SAJDA[1], T. R. BROWN[2]
[1]Dept. of Biomed. Engin., Columbia Univ., New York, NY; [2]Dept. of Radiology and Radiological Sci., [3]Dept. of Psychiatry and Behavioral Sci., Med. Univ. of South Carolina, Charleston, SC; [4]Ctr. for Healthy Minds, Univ. of Wisconsin–Madison, Madison, WI; [5]Ralph H. Johnson VA Med. Ctr., Charleston, SC

Abstract: Pulsing transcranial magnetic stimulation (TMS) in synchrony with endogenous brain rhythms may have greater effects on both local and distributed neural activity than non-synchronized stimulation with this change being of possible clinical significance. To better understand the mechanisms that underlie treatment efficacy, we developed an instrument that can trigger synchronized stimulation at a target phase via real-time processing of the electroencephalogram (EEG) while concurrently recording hemodynamic response at high spatial resolution via functional magnetic resonance imaging (fMRI). EEG was recorded and

processed at a sampling rate of 488Hz. For phase tracking and prediction, the prefrontal alpha oscillation was recovered using a finite impulse response filter (order 50) on the spatial average of four left frontal EEG electrodes (FP1, AF3, F3 and F7). Subsequently, a sine model was fit onto a time window that was extracted from 307 to 102ms before the most recently acquired EEG sample. Fitting was accomplished by minimizing root mean squared error (RMSE) via nonlinear optimization for the free amplitude, frequency and phase parameters. RMSE was then computed for phase and amplitude between the model prediction and the signal in a test window from 102 to 0ms prior to the same reference point as before. If the RMSE values for the test window were below fixed conservative thresholds, the time point for the next target-phase in the alpha rhythm was predicted up to 123ms in the future and a pulse event was registered once the predicted time had passed. Triggering was always followed by a refractory period of 5s, in which new EEG data was preprocessed but sine fitting and triggering remained disabled. To establish a performance baseline, the system was first tested outside the scanner with eleven healthy subjects, where the system was able to mark a phase target of 90 degrees at a mean phase error of 0.8 degrees (standard deviation: 45.4). During subsequent tests on three healthy subjects where fMRI data was recorded concurrently, all EEG data processing was preceded by real-time gradient artifact removal. Phase prediction accuracy was found to be comparable to recordings outside the scanner. The performance achieved by this instrument will allow us to probe causal hypotheses relating the phase of ongoing endogenous oscillations to behavior and the TMS induced BOLD response.

Title: Resting state oscillatory power and amotivation in depressed patients

Authors: *C. S. GALIANO, J. R. GILBERT, A. C. NUGENT, E. D. BALLARD, C. A. ZARATE
Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Lack of motivation is known to be a common symptom of depression. For example, a recent exploratory factor analysis of common depression rating scale scores from a group of depressed patients identified amotivation as a potential depression biotype, suggesting that the use of this unidimensional construct might lead to more precise treatment and greater response efficacy (Ballard et al., 2018). However, little is known about the brain circuitry supporting amotivation in depression. Given this limited knowledge, we sought to investigate the relationship between amotivation scores and magnetoencephalographic (MEG) oscillatory power changes in the delta, theta, alpha, beta, gamma, and high gamma bands during rest. Resting-state MEG data were acquired using a 275-channel CTF system (VSM MedTech Ltd.) in 1 to 2 sessions from 29 depressed subjects after an intravenous infusion of both ketamine hydrochloride (0.5 mg/kg) and a placebo saline infusion. A factor score from an exploratory factor analysis reflecting amotivation was calculated for each participant and was composed of items from the Beck Depression Inventory (BDI) (Ballard et al., 2018). A linear mixed effects model in AFNI was used to calculate the relationship between oscillatory power and amotivation scores. There was a significant association between gamma and high gamma power and amotivation scores in left middle occipital cortex (MOC), such that a loss of power in both gamma and high gamma in MOC during rest were associated with increased amotivation scores (gamma: $F=15.4$, $p<0.05$ fwe-corrected; high gamma: $F=23.0$, $p<0.01$ fwe-corrected). No other significant power differences were associated with amotivation in the other frequency bands explored. These findings provide MEG evidence of the distinct role of the MOC in amotivation. More generally, baseline activity in MOC has been shown to predict treatment response in depressed patients for both an emotion working memory task (Furey et al., 2013) and a selective attention task with emotion modulation (Furey et al., 2015). Our findings add to this by demonstrating that reduced resting-state gamma power within this region is associated with increased amotivation scores. Importantly, several MEG studies have demonstrated that ketamine induces spontaneous gamma power within cortical networks (Cornwell et al., 2012; Shaw et al., 2015), suggesting that increased cortical excitability within the MOC might lead to improvements in motivation following ketamine administration.

Title: Neural signatures of genetic and socioeconomic risk for psychiatric illness

Authors: *M. A. COLLINS, K. M. ANDERSON, R. CHIN, A. J. HOLMES
Dept. of Psychology, Yale Univ., New Haven, CT

Abstract: Genetic and environmental factors, including socioeconomic status and social support, influence risk for psychiatric illness. Affective illness is marked by subtle neuroanatomical shifts across multiple aspects of association cortex. However, there remains a pressing need to understand the interplay between genetic and environmental factors and their effects on brain anatomy that accompany risk for illness onset. The current study utilized structural magnetic resonance imaging (MRI) data to assess the associations linking the thickness of cortical gray matter with social and economic factors in a population-based sample (n=7,785) of individuals ages 44-73 from the UK Biobank study, including a subset who presented with a lifetime history of psychiatric illness (n=2,585). Variables of interest included a derived composite measure of the quality and frequency of social interactions, as well as the Townsend Index, which assesses economic deprivation based on community factors. Multiple linear regression models were used to predict cortical thickness from 1) economic deprivation, 2) social impairment, 3) polygenic risk for major depressive disorder (MDD), and 4) the interaction of economic deprivation and genetic risk for depression. Across the sample, variables of interest were associated with a shared pattern of reduced cortical thickness in regions including cingulate and prefrontal cortices and the insula. Cortical thinning in these regions was linked to the interaction of polygenic risk for MDD and economic deprivation, even after accounting for the main effects of both variables. This interaction demonstrated that genetic risk for depression had a stronger relationship with cortical thinning in more economically disadvantaged individuals, that the combination of genetic risk and high levels of economic deprivation may amplify differences in brain anatomy associated with psychiatric illness. A similar, yet more robust, anatomical profile was evident in individuals with a history of psychiatric illness. These data suggest a continuous relationship between genetic, psychosocial, and structural correlates of psychiatric illness that is evident across the general population and enhanced in individuals with a current or past diagnosis.

Engin., Univ. of Oklahoma, Norman, OK; [6]Stanley Div. of Developmental Neurovirology, Johns Hopkins Univ., Baltimore, MD

Abstract: Major Depressive Disorder (MDD) is associated with impaired adaptive immunity, increasing vulnerability to infectious diseases, including those caused by cytomegalovirus (CMV), a member of the human herpesvirus family. After initial infection, CMV can persist in myeloid cells as well as in the central nervous system (CNS), and is reactivated by stress and other immunosuppressive conditions. There is growing awareness that repeated reactivation of CMV has negative sequelae including premature immunoscenesence that accentuates the inflammation associated with aging. This investigation aimed to determine whether MDD individuals who are CMV positive (CMV+) show evidence of CNS changes that have been associated with inflammation.
A free-water algorithm was used to correct the raw diffusion tensor imaging (DTI) data to quantify extracellular free water (FW), a putative marker of neuroinflammation and FW-corrected fractional anisotropy (cFA), an index of white matter (WM) integrity, in 242 individuals with MDD (64% F, age = 34±11, 56% CMV+) and 49 healthy controls (HC, 55% F, age = 33±11, 41% CMV+). Anti-CMV IgG antibodies were quantified using a commercially-available solid-state array.
After controlling for age and sex, there was a higher prevalence of CMV in the MDD group versus the HC group that trended significant (p=0.064, adjusted OR=1.82, 95% CI: 0.97-3.47). After controlling for age, there was a significant main effect of CMV serostatus on FW with

higher values in CMV+ subjects (regardless of diagnosis) in several WM locations (p<0.05 Threshold-Free Cluster Enhancement corrected), including the anterior thalamic radiation (bilateral), the corticospinal tracts (bilateral), the cingulate gyri (bilateral), longitudinal inferior fasciculus (L), uncinate fasciculus (L), middle cerebral peduncle, splenium of corpus callosum, and posterior corona radiata (L). Similarly, lower cFA was found in CMV+ subjects (regardless of diagnosis) in all of the above regions with the exception of the corticospinal tracts. There was no main effect of diagnosis or interaction between diagnosis and CMV serostatus for either the FW or the cFA analyses.
The results provide support to the hypothesis that CMV infection may have neuroinflammatory effects that impact WM integrity. However, contrary to our hypothesis, this effect may not be limited to the MDD group. The results should be considered preliminary given the cross-sectional design and the relatively smaller number of HCs which may have limited the power to detect a diagnosis-by-serostatus interaction.

Title: Both medicated and unmedicated subjects with Mood and Anxiety Disorders show dysregulated interoceptive processing

Authors: *R. KUPLICKI[1], K. BURROWS[1], W. K. SIMMONS[2], M. P. PAULUS[1]
[1]Laureate Inst. for Brain Res., Tulsa, OK; [2]Janssen Res. & Development, LLC., LaJolla, CA

Abstract: Major depressive disorder (MDD) is among the most disabling conditions worldwide, yet only about 1 out of 3 patients remit after treatment with a first-line antidepressant. Recent study from our institute has revealed that individuals who are unmedicated with MDD show abnormal activity in the insula when processing interoceptive information (Avery et al., 2014). However, it is unclear whether medication status contributes to altered interoceptive processing. To address these questions, 261 adults underwent fMRI while performing a task requiring interoceptive attention to visceral sensations or exteroceptive attention in a visual target detection condition. Participants were recruited as part of the Tulsa 1000 (Victor et al., 2018), a naturalistic longitudinal study of treatment seeking individuals with mental health conditions including

mood/anxiety, substance use, and eating disorders as well as healthy controls. Exclusion criteria for the T1000 included bipolar disorder, schizophrenia, history of significant brain trauma, and neurological disorders. Additionally, this study includes only participants from the first 500 recruited who met criteria for mood/anxiety disorders (MA, PHQ-9 ≥ 10 or OASIS ≥ 9, n=217) and healthy controls (HC, n=44), but not substance use or eating disorders. MA participants were divided into medicated (MA-med, n=146) and unmedicated (MA-unmed, n=71) groups based on whether or not they were currently taking psychotropic medications. fMRI data were acquired on two identical GE Discovery MR750 3T scanners. A whole-brain voxel-wise analysis was conducted to examine group differences in the interoceptive (heart and stomach) versus exteroceptive (target) conditions using AFNI. Results show both MA-unmed and MA-med had decreased contrast in the dorsal-mid insula compared to healthy controls (voxel-wise $p<0.005$), but the two MA groups did not differ from each other. Using the dorsal-mid insula ROI defined by the above whole brain voxel-wise analysis, the average contrast values were extracted for each subject. Then, only within the MA group, we tested separately for linear effects of PROMIS Anxiety and PROMIS Depression. This revealed significant negative effects for both Anxiety ($p=0.0024$, $R^2=0.043$) and depression ($p=0.016$, $R^2=0.027$). Taken together, these findings indicate that individuals with MDD show altered interoceptive processing, which is independent of medication status. Future studies will need to investigate whether the dorsal mid-insula could be an anatomical treatment target for depression. This work was supported by the William K Warren Foundation.

Title: Attentional Bias Modification alters fMRI response towards negative stimuli in depression

Authors: *E. G. HILLAND[1,2], N. LANDRØ[2], C. HARMER[3], M. BROWNING[3], L. MAGLANOC[2], R. JONASSEN[2]

Abstract: Background Modification of attentional biases (ABM) in residual depression may lead to more adaptive emotion perception and emotion regulation reflected in changes in brain activity. There are growing efforts to characterize the neural underpinnings of ABM in depression, but task related emotion processing has so far not been investigated in a larger sample.
Methods A total of 134 previously depressed individuals with residual symptoms were allocated to 14 days of ABM or placebo in a pre-registered RCT followed by an fMRI modified emotion perception task.
Results ABM was associated with reduced amygdala and anterior cingulate cortex (ACC) activation compared to placebo during negative images. Response within the insular cortex was associated with the induction of positive affective biases following ABM and with improvement in symptoms.
Conclusions ABM training has an early effect on brain function within circuitry associated with emotional appraisal and the generation of affective states.

Title: Computational phenotyping of brain-behavioral relationships underlying approach-avoidance decision making in major depressive disorder

Authors: *M. L. PEDERSEN[1], M. IRONSIDE[2], C. L. MCGRATH[3], K.-I. AMEMORI[5], M. KANG[4], A. M. GRAYBIEL[6], M. J. FRANK[7], D. A. PIZZAGALLI[4]

Inst., Kyoto Univ., Inuyama, Japan; [6]MIT, Cambridge, MA; [7]Brown Univ., Brown Inst. for Brain Sci., Providence, RI

Abstract: Adaptive decision making requires balancing the reward and aversiveness associated with outcome of choices. Non-human primate studies have implicated a circuit linking pregenual anterior cingulate cortex and striatum in such processes, which are also altered in affective disorders such as Major Depressive Disorder (MDD), but the underlying mechanisms remain understudied. Computational psychiatry methods can be used to improve diagnostics and classification and to infer mechanisms underlying mental illness. Here we apply computational modeling of dynamic decision processes to extract latent parameters that relate brain activities to behavioral output, and to assess how they are altered in MDD. We use hierarchical Bayesian parameter estimation of the drift diffusion model (HDDM) to infer decision processes that explain choices and response time distributions during approach-avoidance conflict in healthy controls and patients with MDD. We further extracted BOLD-activation from regions of interest in ACC and striatum and analyzed the impact of their trial-to-trial variation on latent decision processes. Preliminary results indicate that variation in reward and aversiveness, and in neural activity tracking these quantities, are predictive of decision parameters, and that these are altered

in MDD. A machine learning classifier based on brain-behavior model parameters was shown to be diagnostic of patient status beyond that afforded by using raw behavioral data alone.

Title: Cortical reorganizations for the recovery from depressive state after spinal decompression surgery

Authors: *M. SAWADA, T. NAKAE, T. MUNEMITSU, M. HOJO
Neurosurg., Shiga Med. Ctr. for Adults, Moriyama / Shiga, Japan

Abstract: Background: Depressed mood following neuronal damage not only impedes functional recovery, but negatively affects quality of life for many patients. Depressed patients with cervical myelopathy often show improvement in both mood and motor function following spinal decompression surgery; however, the neural mechanism underlying this psychological benefit from the surgery remains unclear. The aim of this study is clarifying the brain sites that relates to the alleviation of depression following the spinal decompression surgery. **Methods:** We compared the brain activity of cervical myelopathy patients (n = 6) with those of healthy controls (n = 5) using functional magnetic resonance image (fMRI). In the second step, we analyzed the fMRI data to find the brain region(s) that correlated with depression severity (n = 12: six preoperative patients and six postoperative patients). Then we compared preoperative with postoperative imaging data from patients. **Results:** Spinal decompression surgery alleviated depression and diminished the activity of anterior cingulate cortex (ACC). Simultaneously, the activity of the supplementary motor area (SMA), which was enlarged in myelopathy patients compared with controls, was diminished following the surgery. **Conclusion:** Traditionally, surgical indications for myelopathy are determined by the severity of sensorimotor symptoms without considering psychological symptoms. We anticipate our results will lead to more informed surgical decisions for cervical spondylosis myelopathy.

Title: Resting state cortical frequencies in human EEG are differentially associated with negative cognition in adults with and without a history of major depressive disorder

Authors: *A. ALARIO[1], J. LABRADA[3], R. STEWART[3], N. R. GRIFFIN[2], J. J. ALLEN[4], C. BEEVERS[3], D. M. SCHNYER[5]
[1]Neurosci., [2]The Univ. of Texas at Austin, Austin, TX; [3]Univ. of Texas at Austin, Austin, TX; [4]Univ. Arizona, Tucson, AZ; [5]Univ. of Texas, Austin, Austin, TX

Abstract: Major depressive disorder (MDD) is characterized not only by mood disturbances, but also by persistent negative thoughts. In addition to these disturbances, extensive research has examined alterations in the frequencies of brain electrical activity associated with MDD, such as alpha band (8-12Hz) activity recorded at rest. Greater alpha activity in the frontal left hemisphere relative to the right (frontal alpha asymmetry; FAA) is associated with current MDD as well as prior history of MDD. Alternatively, the relationship between frontal alpha patterns and the negative cognition associated with MDD has not been explored in full detail. This study recruited 216 adults from the Austin community who participated in two identical laboratory sessions 1 week apart. Of the 216, 156 are included in the present report due to incomplete data sets. Participants were recruited so that depression severity would be normally distributed. Diagnosis of current and past psychopathology was determined through clinical interviews by research assistants. The current analysis examines data collected on Day 1, including a period of resting EEG where the participants alternated between eyes open and closed every 1 minute for a total of 8 minutes of recording. To measure negative attention bias, a standard dot-probe task with sad face stimuli was performed without EEG. Trial level bias scores estimated attention bias directed towards sad stimuli relative to neutral stimuli. 64-channel EEG data was preprocessed to remove artifacts and eye-movements and then re-referenced using a current source density (CSD) reference. A Fast Fourier Transform was utilized to determine frequency power in the alpha band. FAA scores were calculated by subtracting log transformed right less log transformed left total alpha power. The present study determined that frontal left alpha power positively correlates ($r = 0.17$, $p = 0.03$) with attention bias towards sad faces. Additionally, a history of MDD correlates with low FAA scores particularly for the F8-F7 electrode pair locations, indicating greater left hemisphere alpha activity than the right when with a history of

MDD. More severe depressive symptom severity measured with Beck Depression Inventory-II negatively correlated ($r = -0.22$, $p = 0.04$) with FAA scores but only for those with a history of MDD. The current results indicate that alpha band power is associated both with depressive symptoms, previous history of MDD, and negative attention bias. Future analyses will focus on test-retest reliability and the relationships with other frequencies.

Title: Investigation of the effect of electroconvulsive therapy on monoamine oxidase A expression in treatment resistant depression using positron emission tomography

Authors: *G. GRYGLEWSKI, P. BALDINGER-MELICH, C. PHILIPPE, G. M. JAMES, C. VRAKA, L. SILBERBAUER, L. NICS, T. VANICEK, A. HAHN, M. MITTERHAUSER, W. WADSAK, M. HACKER, S. KASPER, R. FREY, R. LANZENBERGER
Med. Univ. of Vienna, Vienna, Austria

Abstract: Background: Electroconvulsive therapy (ECT) constitutes one of the most effective antidepressant therapies and is being applied routinely in patients with limited response to approved psychopharmacological treatment options. Despite the consistent observation of increases in hippocampal volumes and neurotrophic factors, the mechanism warrants further investigation [1]. In our previous study, a decrease in serotonin 1A receptor binding potential in many brain areas could be observed following an ECT series in depression [2]. As monoamine oxidase A (MAO-A) was found to be increased in major depression [3] and is a molecular target for several antidepressants, we investigated if ECT affects its expression in patients with treatment resistant depression (TRD). **Methods**: 16 patients (12 female, aged 46±9 years) with unipolar depression according to DSM IV and a Hamilton Rating Scale for Depression ($HAM\text{-}D_{17}$) score ≥ 23 (mean 25±3) were included. All patients underwent adequate treatment trials with at least two antidepressant or augmentative drugs and had a stable medication for at least 10 days prior to measurements. Two PET measurements were carried out prior to ECT and one after a series of at least 8 right unilateral ECT treatments applied three times a week. The target

specific tracer [^{11}C]harmine was injected and quantification of MAO-A distribution volume (V_T) was carried out in PMOD using Logan plots and metabolite-corrected arterial input functions. **Results**: Depressive symptoms decreased significantly to 10.8±4.5 HAM-D following ECT treatment ($p<0.001$). Repeated measures ANOVA did not indicate significant changes in MAO-A V_T in any brain region studied at any time point, neither in voxel-wise nor regions of interest analysis. Whole-brain MAO-A V_T was 18.3±4.3, 18.1±4.2 and 17.8±3.7 at PET session 1, 2 and 3, respectively. **Conclusion**: In the current naturalistic sample of TRD patients undergoing ECT we could not observe any effects on MAO-A expression in the brain. A potential limitation may be that all patients included were medicated and treatments were applied only unilaterally. Our findings indicate that the mechanism underlying the efficacy of ECT is not associated with a downregulation of the MAO-A enzyme. Furthermore, these results may provide a rationale for the use of MAO-inhibitors as an independent treatment option after completion of ECT treatment.

Title: Prediction of rTMS treatment outcome in depression: A machine learning approach

Authors: *J. CORLIER, A. C. WILSON, I. A. COOK, A. F. LEUCHTER
Univ. of California Los Angeles, Los Angeles, CA

Abstract: Repetitive transcranial magnetic stimulation (rTMS) for the treatment of Major Depressive Disorder (MDD) is commonly administered to the left dorsolateral prefrontal cortex (LDLPFC) at 10 Hz with response rates of 30-50%. Although it is an effective treatment, many patients do not benefit and it is not fully understood what distinguishes responders from non-responders.
The goal of this study was a) to identify qEEG-biomarkers that would allow us to predict clinical outcome for rTMS treatment and b) to investigate the underlying physiological characteristics.

Specifically, we used a machine learning approach to classify responders and non-responders to 30-sessions of rTMS treatment, based on the electroencephalogram (EEG) from pre- and post-1st rTMS session. We successfully applied this approach to a large patient sample (N = 112) receiving either a unilateral left (UL) or bilateral (BL) rTMS treatment and also to more homogeneous cohorts split according to treatment type. We compared the performance of 3 predictors: coherence, envelope correlation, and a newly developed biomarker, alpha dynamic response (αDR). Features for these biomarkers represented connections between stimulation sites and all other channel locations (783 total features). First, we show that responders and non-responders have significantly different probability distributions of change in connectivity (Kolmogorov-Smirnoff test $p = 0.008$). While responders were more likely to decrease overall coherence and envelope correlation, they were also more likely to increase αDR from pre- to post- 1st session TMS than non-responders. The features with largest T-statistic value comparing the two groups were found to connect regions of the fronto-parietal control network. Secondly, the elastic net models were best for envelope correlation and αDR with an area under receiver operating curve (AUC) over 80% for internal and over 60% for external cross-validation. Model performance was further improved in the homogenous cohorts UL and BL, which is potentially more generalizable within the respective population.
Overall, we propose a way of predicting rTMS clinical outcome based on 1st session EEG, which can help optimize clinical routine and practice.

Title: The relationship among individual alpha frequency, stimulation frequency, and clinical outcome of repetitive transcranial magnetic stimulation (rTMS) treatment of major depressive disorder

Authors: *A. LEUCHTER[1], J. CORLIER[1], A. C. WILSON[1], I. COOK[1], L. L. CARPENTER[2]
[1]Univ. of California Los Angeles, Los Angeles, CA; [2]Brown Univ., Providence, RI

Abstract: rTMS for treatment of Major Depressive Disorder (MDD) is commonly administered to left dorsolateral prefrontal cortex (DLPFC) at a frequency of 10 Hz. 10 Hz stimulation leads to response rates of 30-50%, but many patients do not benefit. 10 Hz is the center frequency of the alpha (α) band, which plays a central role in linking the activity of brain regions within resting state networks (RSNs). The range and peak frequency of α oscillations, however, vary across individuals. This variability suggests that tuning stimulation within each patient's individual α frequency (IAF) may better engage RSNs and enhance treatment outcomes. We examined the relationship among IAF, stimulation frequency, and treatment outcome in 137 patients undergoing clinical rTMS treatment for MDD. All patients received 10 Hz rTMS stimulation administered to left dorsolateral prefrontal cortex (DLPFC) at the beginning of treatment: 70 subjects continued with only 10 Hz stimulation at left DLPFC, while 67 subjects received left DLPFC rTMS treatment at 10Hz or other types of rTMS treatment for the majority of their treatment sessions.
We examined the absolute value of the numerical difference between patients' IAF and the 10Hz stimulation frequency in relation to clinical outcome. This difference was significantly correlated with percentage change in depression severity from baseline to rTMS treatment session 30 in patients who received 10 Hz stimulation for all or most of their treatment course($P < 0.02$), but not those who received treatment at other frequencies for most of their treatment. In the 10-Hz stimulation group, the responders and non-responders had significantly different IAF probabilities (Kolmogorov-Smirnoff test $p = 0.008$). Notably, the responders were almost twice as likely to have an IAF close to 10 Hz (within 1 Hz distance) than the non-responders ($p = 0.73$ vs $p = 0.41$), with a median distance of 0.48 Hz between the two groups). These findings indicate that a patient's IAF is an important factor to consider in selecting a stimulation frequency for patients receiving rTMS treatment for MDD.

Title: Different patterns of functional connectivity between sensorimotor network, thalamus, and neurotransmitter-related nuclei in psychomotor excitation and inhibition: A resting state fMRI study in manic and depressive phases of bipolar disorder

Authors: *M. MARTINO[1], P. MAGIONCALDA[1], B. CONIO[1], M. AMORE[1], M. INGLESE[2], G. NORTHOFF[3]
[1]Dept. of Neurosci., Univ. of Genoa, Genoa, Italy; [2]Dept. of Neurology, Radiology and Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Mind, Brain Imaging and Neuroethics, Univ. of Ottawa Inst. of Mental Hlth. Res., Ottawa, ON, Canada

Abstract: *Background*: Manic and depressive phases of bipolar disorder (BD) show opposite core psychomotor symptoms. At a neural level, these may be related to functional disorganization of the sensorimotor system. Thus, the aim of the study was to investigate the functional relationships between sensorimotor network (SMN), subcortical loops, dopamine-related substantia nigra (SN) and serotonin-related raphe nuclei (RN), in healthy controls (HC), as well as in mania and inhibited depression, as characterized by psychomotor excitation and inhibition respectively. *Methods*: This is a resting state functional magnetic resonance imaging (fMRI) study, conducted with 67 HC and 100 BD patients - 34 in manic, 37 in depressive (subdivided in 21 inhibited depressed and 16 agitated depressed), and 29 in euthymic phases (age between 18 and 60). A functional connectivity (FC) analysis was performed using a region of interest (ROI)-to-ROI approach. Firstly, in HC, we calculated: the FC between thalamus and SMN and its modulus (i.e. the absolute value of this parameter without regard to sign); the FC of SN or RN with basal ganglia (BG) and thalamic regions. A partial correlation analysis was then performed between the thalamus-SMN FC and SN-BG/thalamus FC, as well as between the

thalamus-SMN FC and RN-BG/thalamus FC (with age, gender, and motion as covariates). Secondly, in BD, the same measures of thalamus-SMN FC (and its modulus), SN-BG/thalamus FC and RN-BG/thalamus FC were calculated and compared (with age, gender, and motion as covariates) between manic patients, inhibited depressed patients, and HC. Agitated depressed and euthymic patients were also included as control. Finally, a replication study was performed. *Results*: In HC, the thalamus-SMN FC showed a quadric correlation with SN-BG/thalamus FC (confirmed by its positive linear correlation with the modulus |thalamus-SMN FC|) and a linear negative correlation with RN-BG/thalamus FC. In BD, mania showed an increase in thalamus-SMN FC toward positive values with a concomitant reduction of RN-BG/thalamus FC. By contrast, inhibited depression showed a decrease in the modulus |thalamus-SMN FC| toward around-zero values with a concomitant reduction of SN-BG/thalamus FC and RN-BG/thalamus FC. The results were replicated in an independent HC dataset (n=108), and in an independent BD dataset (n=40). *Conclusions*: These findings suggest a functional link between networks, subcortical-cortical loops and neurotransmitter-related areas within the sensorimotor system, which may be disrupted in mania and inhibited depression, finally resulting in opposing psychomotor alterations.

Title: Bipolar disorder can be predicted by neural network and logistic regression analyses of facial principal components derived from images of self-declared bipolar and control individuals

Authors: *J. CANNON[1,2], T. M. BIELINSKI[2], C. ANZULEWICZ[2], A. LAU[1]
[1]Dept. of Psychology, [2]Neurosci. Program, Univ. of Scranton, Scranton, PA

Abstract: Embryological development of the face and anterior brain occur in synchrony, can be influenced by common genes, and have the potential to be dramatically and characteristically altered by genetic abnormalities and environmental insults. Bipolar disorder is thought to be caused by genetic and environmental factors that have the potential to affect the development of the brain and face. Previous studies have identified bipolar disorder-related abnormalities in striatum, amygdala, prefrontal cortex, and lateral ventricles (Strakowski, DelBello, & Adler, 2005). Decreased brain-derived neurotrophic factor has also been connected to manic and depressive episodes of bipolar disorder (Angelo et al., 2005). Both the face and bipolar disorder

have been shown to be highly heritable (McGuffin et al., 2003, Claes et al., 2018). The face has been found to potentially contain useful biomarkers differentiating bipolar and non-bipolar individuals (Hennessy et al., 2010).
Photographs were obtained from publicly available resources such as Google Image, IMDb, etc. Using ImageJ, x-y coordinates of 75 landmarks were measured blind. Using MorpoJ, coordinates were subjected to a full Procrustes transformation and reduced to seven principal components (PCs) accounting for 78% of the total variance in the dataset. There were significant Pearson correlations between bipolar disorder and PC2 ($p = 0.049$) as well as PC7 ($p = 0.003$). While PC4 did not reach statistical significance, it was the next most related ($p = 0.143$); the remaining PCs had probabilities greater than 0.32. All seven PCs were then analyzed using a logistic regression to assess their predictive value with regards to bipolar disorder. Null prediction rate was 51% correct. Percent correct using the PCs increased to 82.1. Receiver operating characteristic (ROC) curves gave area under the curve (AUC) values of 0.705 for PC2, 0.611 for PC4, and 0.776 for PC7; the remaining PCs had AUCs no greater than 0.566. To further assess predictive value, the PCs were used to train ($n = 22$) and test ($n = 17$) a neural network that, when tested, predicted bipolar disorder with 82.4% overall accuracy (bipolar = 100%, non-bipolar = 62.5%). An ROC curve for the neural network data gave an AUC of 0.968. These results are congruent with previous literature and further support that facial landmarks have potential as biomarkers for bipolar disorder.

Abstract: It is now well understood that astrocytes intimately interact with neurons to support and regulate their functions in many aspects. One of most discussed functions of astrocytes concerns their role in extracellular potassium spatial buffering. A wealth of investigations has focused on the astroglial-neural interactions at the tripartite synapses, where astrocyte processes tightly wrap around pre- and post-synaptic sites. In contrast, not as much attention has been placed on astroglial-neural interaction in proximity to neuronal soma. Particularly, how astrocytes regulate intrinsic firing patterns of neurons, and what structural basis may underlie this regulation, are much less explored.

The interest of lateral habenular (LHb) in negative emotion is surging, but only limited attention has been given to astrocytes and their potential roles in LHb hyperfunction in depression. In the accompanying poster, we demonstrate that bursting activity of LHb neurons are greatly enhanced in animal models of depression. LHb burst drives depressive-like behaviors and is a prominent target of the rapid antidepressant ketamine. However, the cause of this enhanced burst of LHb neurons remains unsolved.

Here using high-throughput quantitative proteomic screen, we identified an astroglial potassium channel, Kir4.1, to be upregulated in the LHb of animal models of depression. Kir4.1 shows exquisite expression pattern on the astrocytic membrane processes tightly wrapping around the neuronal soma. Electrophysiology and modeling data demonstrate that the level of Kir4.1 on astrocytes tightly regulates the degree of membrane hyperpolarization and the amount of burst activity of LHb neurons. Astrocyte-specific overexpression of Kir4.1 in LHb drives more neuronal bursting and causes depressive-like symptoms. Conversely, knocking down Kir4.1 or overexpression of its dominant negative form in LHb reduces neuronal bursting and ameliorates behavioral despair and anhedonia. Together, these results reveal a new form of glial-neural interaction in setting neuronal firing mode in a devastating psychiatric disease, and discover the therapeutic potential of targeting LHb Kir4.1 for treating major depression. We also expect that the perisomatic K+ buffering mechanism described here may have a more widespread function.

Abstract: Introduction The neurobiological basis underlying rapid antidepressant responses remains incomplete despite extensive research investments. In this study we have recorded EEG (electroencephalogram) signatures of acute drug treatments in adult mice with the aim of identifying shared EEG features that correlate with the activation of BDNF (brain-derived neurotrophic factor) receptor TrkB and inhibition of GSK3β (glycogen synthase kinase β) - proposed key molecular effectors of ketamine's action. **Methods** Medetomidine, an α_2 agonist used in animal anesthesia, and three putative rapid-acting antidepressants (ketamine, nitrous oxide, flurothyl) were administered for acute EEG recordings and the investigation of molecular markers implicated in antidepressant responses (pTrkB, pGSK3β, immediate early genes). All experiments were conducted with adult C57BL6 mice using standard experimental techniques (e.g. western blot, qPCR). Antidepressant-like behavioral phenotypes were assessed with the learned helplessness model. **Results** Rapid-acting antidepressants evoked rebound slow EEG oscillations after the peak of pharmacological effects had subsided, and TrkB and GSK3β signaling also became altered during these rebound periods. Medetomidine facilitated slow EEG oscillations and TrkB signaling directly without preceding cortical excitability, but these effects were not translated into antidepressant-like behavioral changes in the learned helplessness paradigm. **Conclusions** Our findings indicate that rapid-acting antidepressants produce a transient period of cortical excitability followed by homeostatic slow EEG oscillations which coincide with the activation of TrkB and GSK3β signaling. Taken together, these observations provide important conceptual advance in the field and promote new ways to approach the development of novel therapeutics against major depressive disorder.

Title: Ketamine and attentional bias to threat: MEG correlates of stimulus-evoked neural response

Authors: *J. R. GILBERT, C. GALIANO, A. NUGENT, C. ZARATE
Exptl. Therapeut. and Pathophysiology Br., Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The glutamatergic modulator ketamine elicits rapid antidepressant response in many patients with treatment-resistant major depressive disorder (MDD). Thus, modulation of glutamatergic transmission must be a critical feature of treatment efficacy, although the mechanisms of ketamine's antidepressant response are not fully understood. Recent work has suggested that AMPA-mediated glutamatergic neurotransmission following synaptic potentiation leads to increased stimulus-evoked gamma responses, providing an account for how ketamine might influence mood. Our study sought to extend these findings by probing magnetoencephalographic (MEG) stimulus-evoked neural responses in theta, alpha, beta, and gamma frequencies to an attentional bias to threat task. Nineteen drug-free patients with MDD participated in a double-blind, crossover, placebo-controlled experiment where an intravenous subanesthetic dose of ketamine hydrochloride was compared to a placebo infusion. The Montgomery-Asberg Depression Rating Scale (MADRS) was administered 230 minutes post-infusion to measure change in depression scores. MEG recordings were collected ~6.5 hours following both infusions using a 275-channel CTF system. During scanning, the neural correlates underlying facial processing and attentional bias were examined using a dot probe task with emotional faces. The multiple sparse priors routine in SPM12 was used to localize theta, alpha, beta, and gamma frequency activity from -100-1000 msec peristimulus time. A linear mixed effects model in AFNI was used to assess significant source-localized differences in each frequency of interest. Behaviorally, there were no significant differences in reaction time or

accuracy. Group-level source analyses identified a network of regions showing enhanced stimulus-evoked gamma-band responses during our task following ketamine. In addition, left inferior frontal gyrus showed significant source-level interactions in beta for infusion by emotion. Right lingual gyrus showed significant source-level interactions in gamma for infusion by congruency and in alpha for infusion by emotion by congruency. Finally, bilateral amygdala showed robust theta and gamma source-level interactions for infusion by MADRS. These findings add to a growing literature showing that processing of emotional faces with attentional bias recruits a network of brain regions. It also adds to a growing literature on stimulus-evoked neural responses following ketamine administration, particularly in gamma. Ongoing work will model ketamine-mediated connectivity between early visual cortex, higher order brain areas, and the amygdala.

Title: Ketamine normalizes lateral habenula excitability and reduces depressive-like behavior following maternal deprivation

Authors: *R. D. SHEPARD[1], L. D. LANGLOIS[3], C. A. BROWNE[2], M. E. AUTHEMENT[1], A. BERENJI[5], I. LUCKI[4], F. S. NUGENT[1]
[1]Pharmacol., [2]Pharmacol. & Mol. Therapeut., Uniformed Services Univ., Bethesda, MD; [3]Pharmacol., [4]Dept. of Pharmacol. and Mol. Therapeut., Uniformed Services Univ. of the Hlth. Scienc, Bethesda, MD; [5]Old Dominion Univ., Norfolk, VA

Abstract: Depression is a current concern in mental healthcare due to the lack of fast and long-lasting treatments available to patients. Ketamine has emerged as a novel fast- and long-acting anti-depressant; however, the mechanism by which ketamine exerts this effect is still unknown. Recent attention has been called to the importance of the lateral habenula (LHb), a critical hub for the regulation of dopamine (DA) and serotonin (SERT) within the context of aversion and motivated behaviors. Thus, LHb dysfuction could contribute to changes in DA or SERT

signaling that are a component in the development and pathophysiology of psychiatric disorders. Using whole cell patch clamp recordings from LHb neurons in rat brain slices, we previously showed that maternal deprivation (MD), a severe early life stressor that is known to predict psychiatric illnesses later in development, induces hyperexcitability of LHb neurons in juvenile rats (P21-P28). Now, we show that this neuroadaptation persists into young adulthood (P42-50). Furthermore, we show that when subjected to the Forced Swim Test, MD induces significant immobility in comparison to control rats. We found that in response to a single i.p. injection of ketamine (20 mg/kg), LHb neuronal excitability is normalized up to 72hrs post-injection and corresponding MD-induced immobility is decreased 24hrs post-injection. This suggests that one of the sites of action for ketamine's anti-depressant effects could be through modulation of LHb neuronal firing in this stress model, thus influencing other monoamergic signaling pathways. In addition, we also identified that mature BDNF (mBDNF), an important neurotrophic factor that impacts synaptic plasticity and mediates part of ketamine's anti-depressant effects, might be dysregulated following MD and thus supports LHb dysfunction. We hypothesize that one of the ways in which ketamine exerts an anti-depressive mechanism of action is through changes in the expression of mBDNF in the LHb that involves epigenetic mechanisms.

Title: Signaling pathways connected to rapid antidepressant responses of ketamine are activated by hypnotic-sedative drugs but not hydroxynorketamine

Authors: *M. ROSENHOLM[1], S. KOHTALA[1], W. THEILMANN[1], L. PENNA[1], P. KIURU[1], J. YLI-KAUHALUOMA[1], A. B. KLEIN[2], N. MATSUI[3], T. RANTAMAKI[1]
[1]Univ. of Helsinki, Helsinki, Finland; [2]Univ. of Copenhagen, Copenhagen, Denmark; [3]Tokushima Bunri Univ., Tokushima, Japan

Abstract: Aims Dissociative anesthetic ketamine has been shown to rapidly alleviate depressive symptoms at subanesthetic doses. A recent study has proposed ketamine's metabolite hydroxynorketamine (HNK), a non-sedative AMPA receptor potentiator, to be responsible for

these antidepressant effects. Our recent data however suggests that a volatile anesthetic isoflurane regulates similar signaling pathways as ketamine, namely activation of BDNF receptor TrkB and inhibition of GSK3β (glycogen synthase kinase 3β). Here, we have examined the ability of ketamine (at subanesthetic and anesthetic doses), HNK, and various hypnotic-sedative, anesthetic and stimulant drugs to regulate TrkB and GSK3β signaling. **Methods** Adult male C57BL/6JRccHsd mice were subjected to the following treatments: 1) ketamine HCl (10-100 mg/kg i.p.) 2) cis-6-hydroxynorketamine HCl (20 mg/kg i.p.) 3) 6,6-dideuteroketamine (100 mg/kg i.p.) 4) gamma-hydroxybutyrate HCl (GHB, 275 mg/kg i.p.) 5) hydroxyzine HCl (50 mg/kg i.p.) 6) gaboxadol HCl (10 mg/kg i.p.) 7) atipamezole HCl (1 mg/kg i.p.) 8) dextroamphetamine HCl (10 mg/kg i.p.) 9) isoflurane (4% induction, 2% maintenance in O_2). Prefrontal cortex and hippocampi were collected after treatments and analyzed for $TrkB^{Y816}$ and $GSK3\beta^{S9}$ phosphorylation with western blotting. **Results** Ketamine, unlike cis-6-HNK, dose-dependently increases $TrkB^{Y816}$ and $GSK3\beta^{S9}$ phosphorylation. These signaling effects were also activated by 6,6-dideuteroketamine, a modification of ketamine with strongly reduced metabolism to HNK. Remarkably, anesthetic doses of ketamine produced most significant effects on TrkB and GSK3β signaling. Indeed, pharmacologically diverse hypnotic-sedative drugs readily regulate TrkB and GSK3β signaling, whereas stimulant drugs have no such effects. Instead, amphetamine partially blocks TrkB and GSK3β signaling alterations induced by hypnotic drug medetomidine. Our further studies using isoflurane suggest that TrkB and GSK3β signaling remains regulated as long as animals remain anesthetized. **Conclusions** Our findings imply that the ability of ketamine to regulate TrkB and GSK3β signaling is by no means restricted to subanesthetic doses shown to bring antidepressant-like behavioral changes in rodents and that HNK is not responsible for these signaling effects. These results rather present an intriguing correlation between pharmacologically induced state of sedation and TrkB signaling effects and suggest that mere activation of these signaling pathways is not sufficient to elicit rapid antidepressant effects.

Abstract: The personal and societal impact of major depressive disorder (MDD) is compounded by low efficacy rates and the time lag for efficacy of currently available monoaminergic antidepressants. In contrast, recently identified drugs such as ketamine, an NMDA receptor antagonist, exert rapid antidepressant actions within hours in humans and in animal models. Rapastinel is a novel NMDA receptor modulator that also exerts rapid and sustained antidepressant effects, but without the side effects of ketamine. We are interested in mechanistic similarities and differences between ketamine and Rapastinel that could point to critical antidepressant mechanisms, as well as different side effect profiles. Chronic stress exposure in animal models can produce core behavioral features of depression, as well as morphologic changes that are consistent with those observed in post-mortem MDD brains. Ketamine and Rapastinel, and other rapid-acting agents have been shown to reverse stress-induced depressive behavior and synaptic deficits in rodent models (Li et al., 2011; Burgdorf et al., 2015).
The aim of the present study was to examine GABA inhibitory synaptic elements, as well as excitatory synapses that are regulated by stress and by rapid acting antidepressants.The expression of synaptic proteins following a single acute administration of ketamine or Rapastinel in mice was examined by Western blot and immunohistochemistry. Synaptic responses related to GABA and glutamatergic neurotransmission were assessed in whole-cell recordings in PFC pyramidal neurons. Ketamine and Rapastinel both increased GABA-related synaptic proteins (i.e., GAD65, GAD67, vGAT, gephyrin) in PFC 24 hr after single acute administration and both drugs also increased glutamate-related synaptic proteins (GluR1, PSD95, synapsin 1, vGLUT1), although the profiles were not identical. Whole-cell patch recordings in pyramidal cells indicate that ketamine and Rapastinel similarly increase the frequency of spontaneous and induced

excitatory postsynaptic currents (EPSCs) and that this effect may be balanced by a similar effect on inhibitory postsynaptic currents (IPSCs) for Rapastinel and to a lesser extent for ketamine. Ketamine and Rapastinel both showed efficacy in reversing the deficits in excitatory and inhibitory synaptic function resulting from chronic stress. We hypothesize that the different primary actions of these two drugs may lead to recruitment of overlapping as well as unique circuitry that is important for the antidepressant behavioral consequences and the side effect profiles of these agents. Additional ongoing studies are required to test this hypothesis.

Title: Role of GABAergic interneuron GluN2B subunits on the antidepressant actions of ketamine in male and female mice

Authors: *D. M. GERHARD[1], R. S. DUMAN[2]
[1]Psychiatry, Yale Univ., New Haven, CT; [2]Yale Univ. Sch. Med., New Haven, CT

Abstract: Recent studies highlight the rapid antidepressant actions of the NMDA receptor antagonist ketamine. Rodent studies show that ketamine rapidly increases glutamate release, activates mTORC1 signaling and increases translation of synaptic proteins in the medial prefrontal cortex (mPFC) shortly following acute treatment. Furthermore, additional studies show that selective GluN2B receptor antagonists produce similar behavioral and molecular signaling effects. However, the initial cellular trigger underlying the actions of ketamine has not been identified. Collectively, these studies suggest that blockade of GluN2B-containing NMDARs may be a critical mediator for the rapid antidepressant effects of ketamine. We used Camk2-, Gad1-, parvalbumin (Pvalb)-, and somatostatin (Sst)-Cre mice and AAV-GluN2B shRNA to produce Cre-dependent knockdown of GluN2B receptors in glutamate and GABA neurons, as well as subpopulations of GABA neurons. AVV-GluN2B shRNA was infused into the mPFC of the cre recombinase lines and after 3 weeks, the mice were tested before and after ketamine administration in the forced swim test (FST) and novelty suppressed feeding test (NSFT). Viral-mediated knockdown of GluN2B in the mPFC of Gad1-Cre mice produced a

significant antidepressant response in the FST and occluded the antidepressant effects of ketamine in this model; preliminary studies suggest similar effects in the NSFT. Knockdown of GluN2B on pyramidal neurons in Camk2a-Cre mice did not significantly block the antidepressant response to ketamine in the FST or NSFT. Preliminary results in Sst- and Pvalb-Cre mice suggest a role for both interneuron subtypes in the antidepressant effects of ketamine. Using mice with a global, conditional, cell specific deletion of GluN2B in Sst-Cre mice we find that adult male knockout mice, when compared to wild-type littermates, have baseline behavioral effects in the FST, comparable to findings from our region-specific viral knockdown experiments in male Sst-Cre adults. Furthermore, genetic knockdown of GluN2B subunits on Sst+ neurons decreases mPFC layer V pyramidal cell responses to monoamine evoked inhibition and increases baseline spontaneous excitatory post-synaptic currents (sEPSCs). Preliminary results in adult, female Sst-deletion mutant mice suggest no baseline behavioral or electrophysiology differences compared to wild-type littermates; however, further analysis is underway on the effects of estrous cycle on behavior and electrophysiology in females. Additional experiments are being conducted to explore the cellular and behavioral antidepressant efficacy of ketamine in both male and female mice.

Title: Sestrin2 Modulator NV-5138, shows ketamine-like rapid antidepressant effects via direct activation of mTORC1 and BDNF signaling

Authors: *R. S. DUMAN[1], S. POTHULA[1], T. KATO[1,2], R.-J. LIU[1], C. DUMAN[1], R. TERWILLIGER[1], G. P. VLASUK[3], E. SAIAH[3], S. HAHM[3]

Abstract: The NMDA receptor antagonist ketamine produces rapid antidepressant actions, even in patients considered treatment resistant, addressing a major limitation of currently available medications. In preclinical rodent models the antidepressant behavioral actions of ketamine are associated with increased number and function of synapses in the medial prefrontal cortex (mPFC) and these effects are dependent on mTORC1 and BDNF signaling. The mTORC1 pathway is a cellular regulator of protein synthesis and is modulated by neuronal activity,

endocrine and metabolic signals, including amino acids, notably leucine, which activates mTORC1 signaling via the binding to sestrin2. We have recently demonstrated that NV-5138, a novel, specific small molecule modulator of sestrin2 that penetrates the blood brain barrier, produces rapid antidepressant behavioral responses in the rat forced swim test (FST), female urine sniffing test (FUST), and novelty suppressed feeding test (NSFT), and reversed the anhedonia caused by chronic stress exposure. As expected, the antidepressant actions of NV-5138 were dependent on mTORC1 signaling. We also found that NV-5138 rapidly increased the number and function of spine synapses in mPFC layer V apical dendrites. Here we tested the requirement for BDNF signaling in the actions of NV-5138. The results demonstrate that the infusion of a function blocking BDNF neutralizing antibody into the mPFC blocks the antidepressant behavioral actions of NV-5138 in the FST and NSFT, but had no effect on locomotor activity or home cage feeding. In addition, in mice with a knockin of the BDNF Val/met polymorphism, which blocks the processing and activity dependent release of BDNF, the antidepressant actions of NV-5138 in the FST and NSFT were completely blocked. Taken together, the results demonstrate that NV-5138 produces rapid synaptic and antidepressant behavioral responses via the direct activation of the mTORC1, and these effects also require activity-dependent BDNF release and signaling in the mPFC, supporting the possibility that sestrin2 modulation is a novel target for development of rapid acting antidepressants.

Title: Projection-specific optogenetic stimulation of medial prefrontal cortex neurons expressing dopamine D1 receptors produces rapid antidepressant effects

Authors: *R. SHINOHARA, B. D. HARE, S. POTHULA, R. S. DUMAN
Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Depression is a leading cause of disability throughout the world with more than 300 million of people suffering with major depression. A single, subanesthetic dose of ketamine, a non-competitive NMDA receptor antagonist, produces rapid and sustained antidepressant effects in patients with depression. Ketamine infusions into the mPFC or optogenetic activation of principal neurons in the mPFC are sufficient to produce rapid and long-lasting behavioral changes in rodent models, demonstrating the importance of mPFC in the antidepressant response to ketamine. mPFC layer 5 principal neurons can be divided into at least two subtypes, referred to as Type A and B, based on morphological complexity, physiological properties, and projection targets. These subtypes can be targeted by expressing Cre recombinase (Cre) under the control of dopamine D1 (Type B), or D2 (Type A) receptor promotor. We recently found that optogenetic stimulation of Type B cells, but not Type A cells, in the mPFC is sufficient to produce rapid and sustained antidepressant behavioral responses concomitantly with immediate early gene expression in the basolateral amygdala (BLA) and bed nucleus of the stria terminalis (BNST). However, circuit mechanisms underlying the antidepressant responses of ketamine and optogenetic stimulation of Type B cells remain to be elucidated. To address this question, we expressed channelrhodopsin-2 (ChR2) selectively in Type B cells of the mPFC and examined the effects of photostimulation of ChR2-expressing axon terminals in the BNST or BLA. Photostimulation at a frequency of 10 Hz for 60 minutes in respective brain regions was performed 24 hours before the forced swim test (FST) and novelty suppressed feeding test (NSFT). Selective terminal stimulation of mPFC Type B cells in the BLA produced an antidepressant response in the FST and an anxiolytic response in the NSFT; these effects were evident 24 hours after stimulation. Although selective terminal stimulation of mPFC Type B cells in the BNST produced no obvious antidepressant response in the FST, the anxiolytic response in the NSFT was observed at least 24 hours after stimulation. These results indicate that projection-specific optogenetic stimulation of mPFC Type B cells is sufficient to produce antidepressant and anxiolytic responses, with the mPFC-BLA projection implicated in both, whereas the mPFC-BNST projection only in the anxiolytic response. Experiments are currently being conducted to test whether these circuits are necessary for the antidepressant and anxiolytic effects of ketamine.

Abstract: Preclinical studies indicate that (*2R,6R*)-hydroxynorketamine (HNK) is a fast-acting antidepressant devoid of ketamine's untoward side effects. Although NMDA glutamate receptor (NMDAR) inhibition has been proposed to underlie ketamine's antidepressant effects, its contribution to (*2R,6R*)-HNK's antidepressant effects remains to be elucidated. This study systematically assessed the effects of (*2R,6R*)-HNK, compared to ketamine, on NMDAR activity. The forced-swim and novelty suppressed feeding tests established antidepressant effectiveness of (*2R,6R*)-HNK at 10 mg/kg, i.p., in male CD-1 mice. (*2R,6R*)-HNK concentrations were measured in hippocampal microdialysates obtained from awake mice as well as in whole brain tissue and in plasma of mice at various times after the i.p. injection of 10 mg/kg (*2R,6R*)-HNK. The effectiveness of ketamine or (*2R,6R*)-HNK to prevent NMDA (250 mg/kg, i.p.)-induced lethality in mice was also examined. The effects of ketamine and (*2R,6R*)-HNK were evaluated *in vitro* on: (i) NMDAR-mediated field excitatory postsynaptic potentials in the mouse hippocampus, (ii) NMDAR-mediated miniature excitatory postsynaptic currents in rat CA1 pyramidal neurons, (iii) NMDA-evoked currents in CA1 pyramidal neurons, and (iv) recombinant GluN1/2A, GluN1/2B, GluN1/2C, and GluN1/2D NMDARs expressed in *Xenopus* oocytes. The effects of the *S*-isomer of (*2R,6R*)-HNK, i.e. (*2S,6S*)-HNK, on NMDAR-mediated fEPSPs in the mouse hippocampus and on NMDA receptors ectopically expressed in oocytes were also analyzed. Concentrations necessary for 50% reduction of NMDAR responses (IC_{50}) *in vitro* were calculated for each compound. During data collection and analyses, researchers were blind to the treatments. The antidepressant dose of (*2R,6R*)-HNK generated maximal plasma, brain tissue, and extracellular hippocampal concentrations of approximately 10 µM, which had no effect on NMDAR-mediated responses *in vitro*. (*2R,6R*)-HNK IC_{50} values were at least six times higher than its maximal plasma concentration following therapeutic dosing. *In vivo* and *in vitro*, ketamine inhibited NMDAR-mediated responses with 10-20-fold greater potency than (*2R,6R*)-HNK. In addition, (*2S,6S*)-HNK was more potent than (*2R,6R*)-HNK, but less potent than ketamine in inhibiting NMDA-mediated responses. These data suggest that NMDAR inhibition is unlikely to contribute to the (*2R,6R*)-HNK's antidepressant behavioral effects. NMDAR inhibition is a major determinant of ketamine's undesirable side-effects, and thus (*2R,6R*)-HNK, and next generation drugs sharing similar pharmacodynamics, may be better tolerated antidepressants than ketamine.

Title: Comparative phosphoproteomic analysis using frontal cortices from type 3 adenylyl cyclase knockout and wild-type mice

Authors: *Y. ZHOU, L. QIU, F. CHU, X. CHEN
Univ. of New Hampshire, Durham, NH

Abstract: The type 3 adenylyl cyclase (AC3) is predominantly expressed neuronal primary cilia throughout the brain. To date, how AC3 regulates neuronal signaling and function is unknown. We employed a mass spectrum(MS)-based phosphoproteomic approach to identify phosphoproteome differences between tamoxifen-inducible AC3 knockout (KO) and wild-type (WT) mice. Proteins of frontal cortex tissues from KO and WT mice (both genders) were extracted and digested with trypsin. Phosphopeptides were enriched using a TiO_2 enrichment method and then subjected to HPLC-MS/MS analysis. All target peptides spectra were reviewed and verified manually. Phosphopeptides were identified using their MS spectra to search against proteomic database. Here we report that 4188 phosphorylated modification sites were detected from 1767 proteins. Comparison of KO and WT female samples led to identification of 18

posttranslational phosphorylation modifications that had significant enrichment in female KO samples (e.g. Sh3gl1), whereas 4 modifications were found to be selectively present in female WT samples. Comparative analysis of KO and WT male samples revealed 10 modifications present only male KOs (e.g. Pde1b). We also identified 18 modifications having gender differences with 7 only identified in females and 11 in males (e.g. Ctnnd2, Ctnna2). We also examined the relative abundance of phospho-serine, phospho-threonine and phospho-tyrosine residues in each sample. On average, (p)Ser accounted for 85% of total phosphorylated residues, (p)Thr 13%, and (p)Tyr 1%, respectively. Interestingly, in phospho-serine residues, motifs matching proline-directed kinases had higher abundance ($P<0.05$, $n = 8$ pairs) in WT mice than KO mice, indicating that ablation of AC3 affects the overall activity of proline-directed kinases in the brain. This work provides useful clues to understand how AC3 modulates neuronal signal pathways and their function.

Title: CD1 and BALB/c mice did not differ in the additive influence of ZMA, & ketamine (1 mg/kg) on the anti-depressive index, "swimming time" produced during the forced swimming test

Authors: *V. J. MEDINA ARANDA[1], A. L. ROSADO PEREZ[2], S. A. VILLALOBOS CETINA, JR[1], M. A. VILLALOBOS CETINA, JR[1], J. PINEDA[4], J. HERRERA[3]
[1]Res. Dept., [2]Undergraduate Student, [3]Univ. Autonoma de Yucatan, Merida, Mexico; [4]Univ. Autonoma de Yucatán, Merida, Mexico

Abstract: Depression is a disorder with a high rate of resistance to treatment. Ketamine, an antagonist of N-methyl-D-aspartate (NMDA) receptors, produces a rapid and sustained antidepressant effect in patients with treatment-resistant depression. But in therapeutic doses it produces psychomimetic symptoms which limits its use. We found that ZMA (11 mg of pyridoxine, 450 mg of magnesium and 30 mg of zinc) potentiates the antidepressant influence of ketamine in undeffective doses to reduce depressive indices in BALc mice expressing a depressive phenotype. However, its influence has not been proven in other strains with different sensitivity to antidepresant drugs such as the mice strain CD1. So in this work we compared the

influence of co-administration of sub-threshold doses of Ketamine with ZMA on the behavior of CD1 mice in the forced swimming test and compare such influence whith that produced in BALc mice. Methods: 32 CD1 mice and 32 BALB/c were divided into 8 groups of 8 mice each, received a dose of: Ketamine (1 mg / kg); Ketamine (1 mg / kg) + ZMA (0.028125mg / kg); Or ZMA in the same dose; 24 hrs. Later the mice were subjected to the open field test, (6 minutes). One week after the open field test the same treatment was repeated and 24 hrs. Later the mice were subjected to the forced swimming test for 6 minutes. When vehicle was applied to the mice, the immobility time in the last 4 min of the test was 42 ± 2, 43 ± 4 bins. After Ketamine, was: 33 ± 3 and 34 ± 3 bins. After Ketamine + ZMA: 23 ± 3, 22 ± 3 bins and after ZMA: 22 ± 2 and 18 ± 3 bins. Bonferroni´s posttest showed that only the influence of ketamine on the ST was different between both mice strains. No changes were detected in the CT ($p > 0.05$). The distance traveled by CD1 mice, was larger than in BALc mice in all the conditions tested ($p < 0.01$). Even though, there were no differences with any treatment. Conclusion: CD1 strain traveled distance in the open field test was significant larger than BALB/c homologous group and 1 mg/kg of ketamine increases antidepressant-like index in BAL/c, but not in CD1 mice. ZMA expressed the same antidepressan-like activity in both strains.

Title: Ketamine blocks bursting in the lateral habenula to rapidly relieve depression

Authors: *Y. YANG[1], Y. CUI[2], K. SANG[2], Y. DONG[2], Z. NI[2], S. MA[2], H. HU[2]
[1]Ctr. of Neuroscience, Zhejiang Univ., Zhejiang, China; [2]Ctr. of Neurosci., Hangzhou, China

Abstract: The discovery of the rapid antidepressant effects of the N-methyl-D-asparate receptor (NMDAR) antagonist ketamine is arguably the most significant advance in the field of psychiatry. But the mechanism of how ketamine elevates mood so quickly has remained elusive. A single administration of ketamine elicits fast and sustained antidepressant effects both in human clinical trials and animal models of depression. It also has a fast metabolic turnover rate, with a half life of 3hrs in humans. This rapid “hit-and-go” temporal profile suggests that ketamine is likely to act on a system that has ongoing activity with open NMDAR channels. The lateral habenula (LHb) has recently emerged in the coding of negative emotionand

pathophysiology of major depression. LHb hosts primarily glutamatergic neurons, but it inhibits brain's reward centers (including the dopaminergic ventral tegmental area (VTA) and the serotonergic dorsal raphe nucleus (DRN), whose hypoactivity has been implicated in depression) either through relay at the GABAergic rostromedial tegmental nucleus (RMTg) or local interneurons within VTA and DRN. Although accumulating evidence suggest that aberrantly overactive LHb is crucial to depression, it remains unknown how the spike patterns of LHb neurons are altered during depressive state and what role it may play in depression etiology and the fast antidepressant effects of ketamine. We recently found that a significant portion of LHb neurons are spontaneously active and intrinsically prone to burst firing. LHb neurons have significant increase in burst activity and theta-band synchronization in depression, which is reversed by ketamine. Our pharmacology and modeling experiments reveal that LHb bursting strongly requires both NMDAR and low-voltage-sensitive T-type calcium channels (T-VSCCs). Behaviorally, burst-evoking photostimulation of LHb drives despair and anhedonia. Furthermore, local blockade of NMDAR or T-VSCCs in the LHb is sufficient to be rapidly antidepressant. Our results suggest a simple model whereby ketamine quickly elevates mood by blocking NMDAR-dependent bursting activity of LHb neurons to disinhibit downstream reward centers, and provide a framework for developing new rapid-acting antidepressants.

Title: Discriminative stimulus properties of the ketamine metabolite (2R, 6R)-hydroxynorketamine (HNK) and ketamine enantiomers in C57BL/6 mice

Authors: *R. RICE, F. ZHANG, H. NANGUNURI, A. N. BALDWIN, J. H. PORTER
Psychology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Major Depressive Disorder (MDD) afflicts an estimated 17% of US citizens during their lifetime (Kessler et al., 2005). For 50 years, the monoamine hypothesis of MDD has prevailed, but it doesn't fully explain the delay of therapeutic effects and the approximately 40% of treatment-resistant patients. Clearly, there is a critical need to develop better, alternative treatment targets for MDD. After the demonstration that a single, subanesthetic dose of ketamine (0.5 mg/kg i.v.) produced a rapid and relatively long lasting (3 days) improvement of symptoms in MDD patients (Berman et al 2000), there is increased focus on glutamatergic mechanisms for the treatment of MDD (Hillhouse and Porter 2015). Animal research also has reported

antidepressant-like effects with ketamine (Maeng et al., 2008; Zhou et al., 2014), but these promising findings are limited by ketamine's abuse liability and aversive psychomimetic side-effects.Ketamine is a noncompetitive antagonist at NMDA glutamate receptors, but the mechanisms responsible for its antidepressant effects are unclear. Zanos et al (2016) recently reported that the ketamine metabolite (2S,6S;2R,6R)-hydroxynorketamine (HNK) is important for its antidepressant effects. The antidepressant-like actions of HNK were independent of NMDAR inhibition and appeared to lack many of ketamine-related side effects (e.g. abuse liability). A preclinical assay that has proven to be very valuable for predicting the abuse liability of drugs is Drug Discrimination. The discriminative stimulus properties of drugs reflect their subjective (interoceptive) effects and are mediated by specific receptor actions. The present study trained adult male C57BL/6 mice to discriminate 5.0 mg/kg racemic ketamine from saline in a two-lever food reinforced operant task. After establishing ketamine discrimination, substitution testing was conducted with HNK (10 and 60 min injection times) with the (*R*) and (*S*) ketamine enantiomers. While both the (*R*) and (*S*) ketamine isomers shared discriminative stimulus properties with racemic ketamine, the HNK metabolite did not, producing only saline-lever appropriate responding. The lack of shared subjective effects with ketamine suggests that HNK lacks many of ketamine's side effects. In contrast, both the (*R*) and (*S*) isomers fully substituted for ketamine; (*S*)-ketamine isomer was more potent (ED_{50} = 1.067 mg/kg) than (*R*)-isomer (ED_{50} = 2.69 mg/kg) or racemic ketamine (ED_{50} = 2.032 mg/kg). While clinical trials are being conducted with racemic ketamine and (*S*)-ketamine for the treatment of MDD, current preclinical findings suggest that HNK and (*R*)-ketamine also should be tested in clinical trials.

Title: Rapid antidepressant response to ketamine is mediated by Drd1 expressing principal neurons in the medial prefrontal cortex

Authors: *B. D. HARE, R. J. LIU, R. SHINOHARA, S. POTHULA, R. J. DILEONE, R. S. DUMAN
Psychiatry, Yale Sch. of Med., New Haven, CT

Abstract: The rapid antidepressant actions produced by ketamine administration require medial prefrontal cortex (mPFC) activation. Consistent with this, optogenetic activation of mPFC pyramidal neurons results in rapid synaptic changes that are mechanistically linked to the

antidepressant behavioral responses to ketamine. mPFC pyramidal cell subtypes have been distinguished by morphological complexity, response to neurotransmitters, projection targets, and physiological properties. The role of pyramidal cell subtypes in the antidepressant response is unclear. The current study addresses this issue using transgenic mice that express Cre recombinase under the control of the promoters for dopamine *Drd1* or *Drd2*, which distinguish two major pyramidal neuron subtypes in the mPFC, for targeting optogenetic viral constructs. Studies utilized male and female mice (*Drd1*cre, *Drd2*cre, littermate controls). In initial studies placement of Cre-dependent optogenetic constructs in to the mPFC was followed by photostimulation/inhibition and behavioral testing. Testing included the forced swim test (FST), elevated plus maze (EPM), and novelty suppressed feeding test (NSF) and occurred 24 hours or more after optogenetic manipulations. We observed that photostimulation of the *Drd1* cell subtype resulted in a rapid (24hrs) and prolonged (7days) antidepressant response, as well as reduced anxiety like behavior. In contrast, photostimulation of the *Drd2* containing subtype failed to produce antidepressant or anxiolytic effects. Importantly, photoinhibition of mPFC *Drd1* containing cells immediately after ketamine administration blocked ketamine associated behavioral effects. In support of the optogenetic results, additional studies demonstrated that mPFC infusion of a D1 agonist (SKF81297) produced an antidepressant response 24 hours after administration, while mPFC infusion of a D1 antagonist (SCH39166) blocked the antidepressant response produced by ketamine. These results demonstrate a critical role for the mPFC *Drd1* containing cell population in the rapid antidepressant actions of ketamine. Experiments are underway to examine the necessity of the *Drd2* population to the rapid antidepressant response and to identify the key target projection regions for these effects.

Title: Cellular target and downstream signaling mechanisms underlying the rapid antidepressant actions of rapastinel

Authors: *S. POTHULA[1], T. KATO[1], D. GERHARD[1], P. BANERJEE[2], R. S. DUMAN[1]
[1]Dept. of Psychiatry, Yale Univ., New Haven, CT; [2]Allergan Inc., Hillsborough, NJ

Abstract: Rapastinel (Glyx-13) is a novel NMDA receptor (NMDAR) modulator that enhances NMDAR function. It exerts rapid antidepressant effects similar to ketamine but lacks the ketamine-like psychotomimetic effects. Recent studies revealed that the antidepressants actions of both rapastinel and ketamine are mediated by similar downstream mechanisms, including BDNF release, mTOR activation, synaptogenesis, and AMPAR and NMDAR-dependent synaptic plasticity. Dopamine D1 receptor (D1R), Src family kinases (SFKs) and STEP61 are all known to regulate the surface expression of NMDARs and NMDAR function but the initial cellular trigger and the role of these signaling molecules in rapastinel's rapid antidepressant actions and enhancement of NMDAR function remain unknown. Here, we use a combination of AAV2-viral mediated cell specific knockdown, behavioral, pharmacological and biochemical approaches to identify the cellular target and to examine the role of NMDAR subunits and downstream signaling in the actions of rapastinel. The results demonstrate that knockdown of GluN2B subunits on glutamatergic but not GABAergic neurons in the medial prefrontal cortex (mPFC) blocks the antidepressant effects of rapastinel. In contrast, the actions of ketamine were blocked by knockdown of GluN2B on GABAergic but not glutamatergic neurons. Also, rapastinel significantly increases the surface expression of GluN2B, phosphorylation of GluN2B and SFKs, and decreases the levels of STEP61 in the mPFC. Further, pharmacological inhibition of D1R and SFKs in the mPFC blocks the rapid antidepressant behavioral actions of rapastinel in the forced swim test and Novelty suppressed feeding test. Together, our findings suggest that the GluN2B subunit on glutamatergic neurons act as cellular target for rapastinel to trigger a downstream signaling cascade. The results also show that D1Rs and SFKs are required for the rapid antidepressant actions of rapastinel and these signaling molecules may underlie the enhanced surface expression and function of NMDARs. Ongoing experiments are evaluating the role of D1R, SFKs and STEP61 in the regulation of surface expression of NMDARs and antidepressant effects observed in response to rapastinel treatment.

Title: Role of cortical somatostatin and parvalbumin interneurons in the rapid antidepressant actions of scopolamine

Authors: *M. FOGACA, R. DUMAN
Psychiatry, Yale Sch. of Med., New Haven, CT

Abstract: Major depressive disorder (MDD) is a debilitating psychiatric illness that affects approximately 17% of the population, causing substantial health and socioeconomic burdens. This reflects in part the low efficacy, delayed response and low adherence of patients to present-day drug treatments. A single dose of scopolamine, a nonselective muscarinic acetylcholine receptor antagonist induces rapid antidepressant effects in patients. Previous evidence demonstrates that scopolamine acts through blockade of M1-type receptors on GABA interneurons, and here we are conducting additional studies to extend this work. Using Cre-dependent Design Receptors Exclusively Activated by Designer Drugs (DREADD), we tested the effects of stimulating GABA interneurons in the medial prefrontal cortex (mPFC) on the antidepressant actions of scopolamine. We also evaluated if scopolamine effects could be mediated by M1 receptors specifically located in somatostatin (SST) interneurons, as well as the cellular mechanisms underlying activity-dependent synaptic effects of scopolamine, such as vesicular transporters (VGLUT1, VGAT, VCHAT) and GABA synthetic enzyme (GAD1). Here we used mice that express Cre-recombinase in GABA interneurons (Gad1-Cre) or in specific subpopulations, including parvalbumin (Pv-Cre) and somatostatin (Sst-Cre). The viral vector (pAAV-hSyn-DIO-hM3D(Gq)-mCherry) was infused into mice mPFC to induce Cre-recombinase-dependent expression of Gq-coupled hM3Dq receptors, which are sensitive to clozapine-N-oxide (CNO). Two weeks later, mice received 3 injections (every 48 h) of CNO (1 mg/kg) followed, 20 min later, by saline or scopolamine (25 µg/kg). Moreover, we have generated mice with Sst-Cre conditional deletion of M1 that were also tested. Twenty-four hours after the last injection, the mice were subjected to the forced swim test (FST), and 48 hours later, to the novelty suppressed feeding test (NSFT). The efficiency of viral infusion was confirmed at the end by histology and electrophysiological recordings. Stimulation of Gad1-, Pv- and Sst-Cre interneurons by CNO injections prevented the antidepressant effects of scopolamine in the FST and NSFT. In addition, the actions of scopolamine in the FST and NSFT were blocked in the Sst-Cre M1 deletion mice. Scopolamine administration increased levels of the glutamatergic and GABAergic-related proteins in the mPFC. The results are consistent with the hypothesis that the initial trigger for the rapid antidepressant action of scopolamine is antagonism of M1 receptors on mPFC interneurons, which then promotes a more long-term balance between GABAergic and glutamatergic neurotransmission.

Title: Behavioral deficits caused by inescapable shock

Authors: *A. STEPHENS[1], D. A. MORILAK[1,2,3], D. J. LODGE[1,2], A. FRAZER[1,2,3], F. R. CARRENO[1,2]
[1]Dept. of Pharmacol., UT Hlth. San Antonio, San Antonio, TX; [2]Ctr. for Biomed. Neurosci., San Antonio, TX; [3]South Texas Veterans Hlth. Care Syst., San Antonio, TX

Abstract: Stress is a precipitating factor in the development of Major Depressive Disorders (MDD) as well as Post Traumatic Stress Disorder (PTSD). In order to develop a pre-clinical model sensitive to stress that is able to produce a variety of behavioral deficits that are relevant for depressive- and PTSD-like symptomatology, we used the inescapable shock (IS) paradigm. IS session of 60 x 15 sec shocks on two consecutive days produced significant escape deficits in about 70% of the rats that lasted up to 3 weeks when they are placed into the same box where they received shock when compared to control non-shocked rats (NS). The effect of IS on the performance of rats in the forced swim test (FST) and shock probe defensive burying (SPDB) test was measured as well. Rats received IS for 2 consecutive days and the FST was performed 24h later. They were tested in the SPDB test the next day. IS caused a significant increase in immobility in the FST and changed the coping behavior of rats in the SPDB test, i.e., it produced a significant increase in the time the animal spent immobile.
In subsequent experiments, NS controls were replaced with escapable shock (ES) controls, which received foot shocks in the same boxes as IS, but were allowed to escape to the other side to terminate the shock. In order to evaluate possible hedonic deficits of IS, the female urine sniffing test (FUST) was used. Baseline performance in the FUST was measured at least 24h before rats received IS or ES. Rats then received two consecutive days of IS or ES and 24h later were tested in the FUST. After IS, but not ES, rats showed a decrease in preference for female urine, which lasted for up to 3 days. In a small cohort of animals, we tested the effect of the α5-$GABA_A$ NAM, L-655,708 on the behavioral deficits in the FUST. I.P. injections of L-655,708, but not vehicle, partially restored the IS-induced reduction of time spent sniffing female urine.
Thus, we have developed a stress paradigm that produces robust behavioral deficits that are relevant to MDD- and PTSD-like symptomology and and we will continue to study the effects of novel compounds that have relevance for the treatment of MDD and/or PTSD, such as L-655,708.

Abstract: Major depressive disorder (MDD) involves diverse symptomatology of low mood, anhedonia, cognitive deficits, and highly comorbid anxiety. Past neuroimaging studies found altered neuronal activity associated with MDD severity, suggesting a mechanism bridging cellular- and symptom-level deficits. Parallel imaging and postmortem studies further identified GABAergic deficits linked to reduced measures of inhibition across mood-related brain regions. These findings suggest that regional excitation-inhibition imbalances play a causal role in MDD. However, it is unclear how regional changes contribute to the emergence of specific symptoms. To address this, we assessed depressive-, anxiety-, anhedonia-like, and cognitive behavioral dimensions, and quantified c-fos expression via immunohistochemistry (IHC) across stress-/mood-related brain regions in mice exposed to unpredictable chronic mild stress (UCMS) or chronic restraint stress (CRS). 3 groups of adult C57BL/6J mice (n=12/group; 50%♀) underwent 5-week UCMS (random mild stressors, 2-4x/day), CRS (1h 2x/day), or handling (controls). Week 0-5 deficits were characterized with repeatable weekly phenotyper, sucrose consumption, and fur coat tests. In weeks 6-8, endpoint tests assessed depressive/anxiety-like behaviors (tests aforementioned plus open field, elevated plus maze, novelty-suppressed feeding, novelty-induced hypophagia), and cognition (object recognition, y-maze). At week 8, mice were sacrificed 90min after an acute stressor. Extracted brains were cryosectioned for IHC analysis. Density of c-fos+ cells was quantified in 23 brain regions (processing/segmentation with ZEN Blue). One-way ANCOVA (sex covariate) was used for between-group comparisons, Pearson's r assessed relationships between regional cell densities and behavior, and z-scoring compiled behavioral dimensions i.e. anxiety-, anhedonia-like behavior, and cognition. We found that

UCMS and CRS induced elevated anxiety-like behavior starting in W1. Across endpoint tests, both groups had elevated z-anxiety, CRS elevated z-anhedonia, whereas UCMS more consistently reduced z-cognition. Across both stress groups, c-fos+ cell density was elevated in cortical area 24b and ventral hippocampus CA1 and CA3. These changes each correlated with z-scores for depressive-/anxiety-like behaviors across several tests. Ongoing analyses will assess glutamate/GABA markers to investigate cellular underpinnings of increased neuronal activity. Together, this work supports a link between altered neuronal activity in limbic regions associated with chronic stress exposure and specific MDD symptom dimensions.

Title: The impact of binding on crayfish aggression

Authors: *S. GARRETT-RUFFIN, B. SIZEMORE
Psychology, Bowling Green State Univ., Bowling Green, OH

Abstract: The aim of this study was to develop a new crayfish model of depression. Our model of depression involved binding the claws of crayfish and using aggressive behavior, as well as, exploratory behaviors as indexes of depression. Aggression was defined by the amount of time crayfish spent near a mirror reflection of themselves. Using a matched design based on weight, thirty crayfish of the species *procambarus clarkia* were randomly assigned to either a bound or unbound condition. Interestingly, the bound crayfish engaged in more exploratory behavior, as well as, spent more time in the area with the mirror reflection, which was interpreted as aggressive behavior. We found no differences in weight between bound and unbound crayfish which suggests similar feeding behaviors across groups. Our work also involved developing a model of crayfish depression based on the behavioral data from this study coupled with previous behavioral and neurochemical studies on crayfish aggression.

Title: Experimentally induced glioblastoma and its treatment with rapamycin alters neurobehavioral functioning in rats

Authors: *M. HADAMITZKY[1], A. HERRING[2], L. LÜCKEMANN[1], E. M. MARTINEZ-GOMEZ[1], I. BENDIX[3], U. SURE[4], M. SCHEDLOWSKI[1], M. UNTEROBERDÖRSTER[4]
[2]Inst. of Neuropathology, [3]Dept. of Pediatrics I/ Exptl. Perinatal Neurosci., [4]Dept. of Neurosurg., [1]Univ. of Essen, Sch. of Med., Essen, Germany

Abstract: Neurobehavioral symptoms are common and often multiple in patients with brain tumors such as glioblastoma (GBM). The causation can be multifactorial and greatly restrict patients` quality of life. Dysfunction of mTOR signaling is a key driver of GBM progression. Coincidently, mTOR signaling has been implicated in the modulation of neurobehavioral disorders. Against this background, effects of treatment with the mTOR inhibitor rapamycin on tumor growth, behavior, and brain protein expression were analyzed in a rat model of experimentally induced GBM. Male Fisher 344 rats were intracranially implanted with syngen RG2 cells and treated with rapamycin (3mg/kg) for 7 days following surgery. Subsequently, mood and anxiety-related behavior were assessed and brain and blood samples were taken for biochemical analyses. Systemic treatment with rapamycin inhibited GBM-cell proliferation in vitro and impacted tumor morphology in vivo. GBM-bearing rats displayed less stress-coping strategies assessed in the forced-swim test (FST) an effect that was prevented by treatment with rapamycin. Importantly, the rapamycin-treated GBM animals showed elevated levels of anxiety-related behavior in the elevated plus maze (EPM). Correspondingly, protein expression of glucocorticoid receptors (GR) protein expression in these animals was decreased in the hippocampus, but increased in the amygdala. These findings show for the first time that, as seen in humans, GBM disease progression in an experimental preclinical setting is associated with neurobehavioral alterations. Together, these findings provide novel insights in central effects of systemic rapamycin in subjects with a neurological disorder. The results of the present approach point towards a modulatory role of central mTOR-dependent mechanisms on RG2-induced GBM disease progression and behavior.

Title: Antidepressant effect of pramipexole in a dexamethasone induced depressive-like behavior model

Authors: *L. C. SOUZA, M. M. MUNOZ, J. M. TURNES, E. L. MOURA, R. ANDREATINI, M. A. B. F. VITAL
Pharmacol., Univ. Federal do Parana, Curitiba, Brazil

Abstract: Major depressive disorder is a common psychiatric disease characterized by diverse debilitating symptoms that include hopelessness and anhedonia. Systemic exposure to glucocorticoids like dexamethasone (DEX) has been shown to induce some of the behavioral features of depression in humans and thus has been used as an animal model of the disease. Pramipexole (PPX) is a non-ergot dopaminergic agonist with higher affinity for the D2/D3 dopamine receptors and several studies both in humans and animals have demonstrated that it has a antidepressive potential. The present study investigated the acute effects of pramipexole in the depressive-like behavior induced by prolonged exposure to dexamethasone. Wistar rats were first submitted to a dose-response curve (experiment I) to establish the PPX dose that would be used in experiment II. The modified forced swimming test (FST) were used for testing 3 different doses of PPX (1, 2 and 3mg/kg; i.p.). The rats were also submitted to the open field test (OFT) for evaluation of the locomotor activity. All three doses of PPX reduced the immobility time in the FST in comparison with the control group, however only the 1mg/kg dose did not reduce locomotor activity. Thus, the 1 mg/kg dose was chosen. After the dose definition, we started the prolonged dexamethasone treatment for the evaluation of the possible antidepressant-like effect of acute PPX (experiment II). The rats were treated for 21 days with dexamethasone (1mg/kg; i.p.) or its vehicle, weighted every two days, and the preference for sucrose and locomotor activity were evaluated weekly along the 21 days of treatment. The FST test was run on day 22, after the acute treatment with pramipexole (1mg/kg) 23, 5 and 1h before the test. The DEX group demonstrated a significant weight loss (anorexic effect) along the experiment. Also, the DEX treatment reduced the sucrose solution preference on day 21 and the locomotor frequency since day 7 until the end of the experiment. In the FST, the dexamethasone-treated group displayed a higher immobility time when compared to the control group, demonstrating a depressive-like behavior. The PPX acute treatment was capable of reducing the time of immobility in the DEX+PPX group in comparison with the control group, indicating an

antidepressant-like effect, without any effect in the locomotor activity. The present study demonstrated that the prolonged dexamethasone administration was able to induce a depressive-like behavior, and in agreement with our hypothesis, the acute treatment with pramipexole showed an antidepressant-like effect, reinforcing its potential as an antidepressant.

Title: Purinergic receptors gene expression in the brain of male adolescent mice submitted to chronic social defeat stress

Authors: *S. CHIAVEGATTO[1], H. ULRICH[2], J. C. CORRÊA-VELLOSO[2]
[1]Biomed. Sci. Inst. - Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Dept. of Biochem., Chem. Inst., Sao Paulo, Brazil

Abstract: Stressful early life experiences can induce several behavioral dysfunctions associated with mental illness, which may extend well into adulthood. Prolonged stress is one of the main factors involved in the etiology of depression. Accordingly, exposure to psychosocial stress during adolescence is implicated in the development of depression. The underlying mechanisms are poorly understood. Purinergic signaling and the activity of specific purinergic receptors have been shown to play a role in several psychiatric disorders, like depression. In this study, we used social defeat (SD) stress, a valuable animal model for depression to study expression patterns of P2X and P2Y purinergic receptors in the prefrontal cortex (PFC) and hippocampus (HC) of male adolescent mice. C57BL/6 (30 day-old) were subjected to daily bouts of SD with an aggressive adult male CD-1 mouse for 10 days. Twenty-four hours after the last defeat, mice were evaluated in the social approach-avoidance and sucrose preference (SP) tests. Approximately 50% of adolescents were susceptible, displaying social avoidance ($p<0.0001$) and reduced SP (anhedonia) ($p<0.001$). The remaining defeated mice were similar to controls ($p>0.05$) and were classified as resilient. Twenty-four hours after the last behavioral test, animals were sacrificed and brain areas of interest were collected. Reverse transcription followed by qPCR was conducted to evaluate the expression levels of purinergic receptors. In PFC, resilient and susceptible groups showed different patterns of purinergic receptors expression. Resilient mice

showed a decreasing trend of P2X7 receptor expression (p=0.06) whereas susceptible group displayed an increased P2Y1 receptor expression (p<0.01). On the other hand, in HC an overall increase of P2X4 receptor expression (p<0.05) and a decrease in P2X5 receptor expression (p<0.05) was observed for both defeated groups. This is the first description of purinergic receptor expression patterns in the social defeat model, as well as, during adolescence. Our results suggest a participation of specific purinergic receptors in depressive-like behavior of male adolescent mice submitted to social defeat. Additionally, purinergic signaling seems to be relevant on the molecular mechanisms involved in the resilience process.

Title: Behavioral and biochemical analyses of C57BL/6J mice with available voluntary exercise: Considerations for enrichment in laboratory rodents

Authors: *M. A. MARTINEZ, JR[1], J. M. FLINN[2], C. L. C. NEELY[2]
[1]Dept. of Biol., [2]Dept. of Psychology, George Mason Univ., Fairfax, VA

Abstract: Behavioral and biochemical analyses of C57BL/6J mice with available voluntary exercise: Considerations for enrichment in laboratory rodents
Strong evidence has demonstrated the beneficial effects of exercise on both physical and mental health; indeed, not only is physical activity linked to better physical outcomes (i.e., weight reduction, cardiovascular health) but also to improved quality of life and longevity (CDC, 2017; Penedo & Dahn, 2005). In rodent studies, most research focuses on the beneficial effects of exercise and the improvement in learning and memory as assessed by the Morris Water Maze. We sought to explore the effects of availability of voluntary exercise on rodent wellbeing and affective measures not as commonly studied in this domain of research. Forty-four 3-week old C57BL/6J male (24) and female (20) mice were group-housed in homecages containing a functional running wheel (BioServ) or a non-functional, “locked” running wheel for approximately 30 days. Mice were run through the open field test (OFT), elevated zero maze (EZM), nesting, burrowing, and the forced swim test (FST). Mice with running wheels constructed better nests compared to mice with locked running wheels ($F[1, 40] = 4.28$, $p <$ 0.05), with female mice with locked wheels building the lowest-quality nests compared to the

other groups. Mice with running wheels also burrowed more rocks over a 12 hour period compared to their locked-wheel counterparts, $F(1, 40) = 3.86$, $p = 0.06$. These data suggest that enrichment in the form of running wheels improved general wellbeing. We did not see differences in anxiety and depression as measured by the OFT, EZM, or FST. This led to a focus on biochemical signatures within the brain related to social behavior and other measures indicative of general wellbeing. Western blotting and immunohistochemistry will examine oxytocin and vasopressin receptor expression in brains obtained from these mice. Findings from this study will elucidate the importance, or perhaps the need for, enrichment and how it may promote animal health and prosocial behavior in laboratory rodents.

Abstract: Depression is a devastating mental disorder affected by change of brain metabolism. Although several studies have reported the correlation between depression and dysregulated glucose metabolism, the molecular mechanism in the pathophysiology of depression is still unclear. A small percent of glucose is converted to uridine diphosphate-N-acetylglucosamine (UDP-GlcNAc) via the hexosamine biosynthetic pathway, which serves as a donor molecule for the transfer of β-N-acetyl-D glucosamine (GlcNAc) to protein. O-GlcNAcylation is a dynamic, reversible post-translational modification by attaching of GlcNAc to serine and threonine residues. O-GlcNAcylation of protein is catalyzed by O-GlcNAcase (OGA) and O-GlcNAc transferase (OGT) that is implicated in brain function including cell signaling, synaptic plasticity. In this study, we tested how increased levels of O-GlcNAcylation by Oga heterozygosity affect animal behavior and synaptic function. Interestingly, *Oga heterozygous* (*Oga* $^{+/-}$) mice showed decreased immobility in the forced swim test, suggesting that *Oga* $^{+/-}$ mice exhibit an antidepressant-like phenotype. Synaptic function in the medial prefrontal cortex (mPFC) is

known to be associated with the pathogenesis of depression, but molecular mechanisms are poorly understood. We recorded spontaneous excitatory postsynaptic current and spontaneous inhibitory postsynaptic current (sEPSC and sIPSC) in the layer II/III prelimbic cortex (PrL) of *Oga* $^{+/-}$ mice and found that *Oga* heterozygosity led to a significant decrease in sIPSC frequency, without affecting in sEPSC in layer II/III PrL.Therefore, our studies indicate that alternation of O-GlcNAcylation could be associated with an antidepressant-like phenotype and that impaired synaptic function in layer II/III PrL may underlie the phenotype. Also, importantly, OGT and OGA may serve as a novel target for the antidepressant.

Title: Chlorogenic acid from hawthorn berry (crataegus pinnatifida fruit) prevents stress hormone-induced depressive behavior, through monoamine oxidase B-reactive oxygen species signaling in hippocampal astrocytes of mice

Authors: *M. UM[1], J. LEE[2]
[1]Korea Food Res. Inst., Wanju-Gun, Korea, Republic of; [2]Div. of Functional Food, Korea Food Res. Inst., Jeonju, Korea, Republic of

Abstract: Oxidative stress has been implicated in mental disorders, including depression. Chlorogenic acid (CGA), a phenolic compound abundant in herbs and fruits, has been reported to have antioxidant and free-radical scavenging properties. In this study, we investigated the antidepressant-like effects and active mechanisms of CGA from the extract of Crataegus pinnatifida (CP) fruit. Depression-like phenotypes were induced in mice by daily injection of stress hormone for 1-2 weeks. The brains of these animals exhibited reduced brain-derived neurotrophic factor expression and increased astrocytic hypertrophy, which are typical markers of depression in animal models. Stress hormone injection 1) upregulated monoamine oxidase B (MAOB) expression and 2) reduced spine numbers along neuronal dendrites, which indicates synaptic depression. The oral administration of CGA (30 mg/kg) or CP (300 mg/kg) prevented MAOB activation following reactive oxygen species (ROS) production and had an ameliorative effect on depressive behavioral tests (e.g., tail suspension and forced swim tests). In vitro assays performed on cultured C8-D1A cells revealed that CGA and CP inhibited MAOB activity and ROS production.

Title: Changes in affective behaviors associated with a lack of creatine

Authors: *Z. I. ABDULLA[1], J. L. PENNINGTON[1], A. GUTIERREZ[2], M. R. SKELTON[1]
[1]Neurol., Cincinnati Children's Res. Fndn., Cincinnati, OH; [2]Neurosci., The Scripps Res. Inst., San Diego, CA

Abstract: It is estimated that approximately 20% of adults in the U.S. will experience an affective disorder during their life. While it is well established that serotonin (5-HT) is a crucial factor in mood, it is important to note that impaired cellular bioenergetics are also implicated. The role of bioenergetics in affective disorders has gained substantial interest, with most of the work focused on energy production in neurons. Creatine (Cr), through the Creatine/Phospho-Cr shuttle, maintains high ATP concentrations in the neuron. This system may be implicated in the bioenergetic deficits seen in affective disorders, as reduced Cr and Phospho-Cr concentrations are found in the brains of those with major depressive and bipolar disorders. As an adjunct, clinical trials have shown that Cr supplementation can improve mood in treatment resistant depression and can improve mood in patients with neurological disorders. In rodents, Cr reduces forced swim and tail-suspension immobility times. We have shown that mice lacking Cr due to mutations in the Cr transporter (Crt) gene (*Slc6a8*; *Slc6a8*$^{-/y}$ mice) have increased levels of 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) in the striatum and hippocampus, suggesting that the lack of Cr disrupts 5-HT function. Given 5-HT's and Cr's role in mood, we have hypothesized that mice lacking Cr will develop an altered affective phenotype. To this end, we are testing *Slc6a8*$^{-/y}$ on behaviors assessing anxiety and depression. *Slc6a8*$^{-/y}$ mice display an anxiety-resistant phenotype, as suggested by results in the elevated zero maze, while the tail-suspension test indicated a potentially depressive phenotype. Interestingly, *Slc6a8*$^{-/y}$ produced faster escape latencies in learned helplessness results, potentially indicating an increased resilience to behavioral despair. Conversely, this data could be interpreted to indicate deficient fear learning in mice lacking Cr. Additionally, Crt deficient mice have an increased response to para-chloroamphetamine, a serotonergically mediated stimulant, suggesting a hypersensitivity of the 5-HT system. Given the increase in 5-HIAA it is interesting to note that western blots revealed no differences in tryptophan hydroxylase-2 or monoamine oxidase content in the hippocampus or striatum. Our results indicate that Cr plays a complex role in affective disorders, warranting

further investigation. Future studies will assess these behaviors in mice specifically lacking serotonergic Cr.

Title: Deletion of CRTC1 is associated with strong neuroenergetic dysfunctions in a mouse model of mood disorders

Authors: *A. CHERIX[1], G. DONATI[1], C. POITRY-YAMATE[1], J.-R. CARDINAUX[2], R. GRUETTER[1,3,4]
[1]Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; [2]Ctr. for Psychiatric Neurosciences, Univ. Hosp. of Lausanne CHUV, Lausanne, Switzerland; [3]Dept. of Radiology, Univ. of Geneva, Geneva, Switzerland; [4]Dept. of Radiology, Univ. of Lausanne, Lausanne, Switzerland

Abstract: CRTC1 (CREB-regulated transcription coactivator 1) is a coactivator of the transcription factor CREB, and is predominantly expressed in the brain. CRTC1 plays an important role in brain plasticity, and its dysfunction has been implicated in many neurological disorders, such as neurodegenerative and mood disorders. Mice lacking the *Crtc1* gene, show a depressive-like phenotype and have been proposed as a model for preclinical mood disorder studies. Using *in vivo* metabolic imaging tools (^{1}H-MRS, ^{13}C-MRS and PET), we have shown that these animals have a strong neuroenergetic alteration of the dorsal hippocampus. *Crtc1* KO animals show a reduced glucose entry in the brain as well as lower CMRglc (cerebral metabolic rate of glucose). The resulting drop in pyruvate production is compensated by a higher brain lactate entry allowing a normal mitochondrial energy production. Mitochondrial gene expression profile and ^{13}C-MRS-measured TCA cycle were comparable in both groups as well. ^{1}H and ^{31}P-NMR analysis of dorsal hippocampus metabolic extracts revealed no change in ATP or NADH/NAD^{+} suggesting normal energy homeostasis. A significant drop of phosphocreatine observed *in vivo* and *in vitro* together with higher creatine kinase expression (mtCK and CKB) suggest however that the reduced glycolytic ATP puts the mitochondria under allostatic load.

The altered metabolic profile linked to this mechanism correlated with the depressive-like behavior and followed the behavior change upon social isolation of mice. Together these results suggest that the depressive-like behavior of *Crtc1* KO mice is related to an altered neuroenergetic production efficiency putting the hippocampus under allostatic load.

Title: Chronic social defeat stress induces social avoidance and changes the plasma cytokines levels in mice

Authors: *Y. NAKATAKE[1,2], M. YAMADA[2], H. FURUIE[2], H. KUNIISHI[2], M. UKEZONO[3], K. YOSHIZAWA[1], M. YAMADA[2]

Abstract: Objectives
Chronic social defeat stress (CSDS) models in rodents are often used for researches on stress-related psychiatric disorders. CSDS includes emotional and physical aspects of stress and it is difficult to distinguish these two components. However, in many cases, patients are affected solely by emotional rather than physical distress. Recently, we have established a new stress model focusing on the emotional stress using witnessing the defeat of a conspecific. In this study, we examined the effect of emotional stress on the behavior and the plasma cytokine levels in mice.
Methods
We modified the social defeat witness model reported by the other group (Warren et al., 2013). Male C57BL/6J mice were placed into the home cages of male aggressive ICR mice and exposed to attack of ICR mice (PS mice), while the other cohort of mice could observed it (ES mice). To determine the effect of physical and emotional stress, mice were tested in the social interaction test, the elevated plus-maze, the forced swim test, and the sucrose preference test 24-hour and 1 month after the last stress session. We also measured plasma cytokines levels at the same time point in mice.
Results
PS mice showed decreased social interaction 24-hour after the stress and spent less time in the open arms of the elevated plus-maze 24-hour and 1 month after the stress. Similarly, ES mice

exhibited decreased social interaction 24-hour after the stress and slight decline of time spent in the open arms 1 month after the stress. PS mice, but not ES mice, showed changes in the levels of several cytokines in plasma 24-hour after the last stress session. After 1 month, both ES and PS mice showed decreased levels of plasma chemokine C-X-C ligand 16 (CXCL16), which is a small cytokine belonging to the CXC chemokine family.
Conclusions
In this study, witnessing the defeat of a conspecific induced social avoidance. It is suggested that witnessing the defeat of a conspecific is sufficient to cause stress-related behavioral changes in mice. On the other hand, this behavioral change was not associated with the changes in the level of plasma chemokine, which were found in PS mice. In conclusion, it is suggested that ES mice would be a useful animal model to study neurobiological mechanism of emotional stress and to develop new treatments for stress-related psychiatric disorders.

Title: Ankyrin-G heterozygous conditional knockout mice display increased sensitivity to social defeat stress

Authors: *S. ZHU[1], C. A. ZACHARY, 21287[2], S. KHAMBADKONE[2], J. XIONG[2], C. A. ROSS[3]
[2]Psychiatry, [3]Psychiatry, Neurosci. and Pharmacol., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Genome wide association studies have repeatedly identified ANK3 (encode Ankyrin-G protein) as one of the major risk factors for bipolar disorder. Our previous work on forebrain specific Ankyrin-G homozygous knockout mice found behavioral features reminiscent of human mania, such as locomotor hyperactivity, decreased anxiety and decreased depression-like behavior. Lithium and Valproic acid ameliorated behavioral changes. Patients with Bipolar disorder experience both mania and depression. One trigger of the transition to depression is stress. We have now characterized behavioral phenotype of Ankyrin-G heterozygous knockout mice (Ank-G Het cKO). In behavioral tests, there were only subtle differences from control animals. The behavioral tests include open field (locomotor activity test), elevated plus maze and light/dark box test (test for anxiety) as well as forced swim test (for depression-like behavior). Upon 14 days of chronic social defeat stress, both control and Ank Het cKO mice displayed depression-like behavior: reduced locomotor activity in open field test, lower percent time in

open arm of the in elevated plus maze test, and increased immobile time in forced swim test. Treating both stressed control and stressed Ank-G Het cKO mice with a low dose of fluoxetine rescued the depression-like behavior. When the mice were exposed to only 4 days of social defeat stress, control animals show no deficits, while Ank-G Het cKO mice displayed lower percent time in open arm of the elevated plus maze test, and increased immobile time in forced swim test. These results indicate that Ank-G cKO mice are more vulnerable to sub-threshold stress. Future study will be to study the mechanism of stress vulnerability and effect of anti-depressant. These results indicate Ank-G Het cKO mice could be a valuable model to study mechanisms of depression-like behavior, and to test experimental therapeutics.

Title: Behavioral phenotyping of a Wolfram syndrome transgenic mouse model showed cognitive alteration and anxiety disorder

Authors: *B. DELPRAT[1], L. CROUZIER[1], C. DELETTRE[2], T. MAURICE[1]
[1]Inserm U1198, Montpellier cedex 5, France; [2]Inserm U1051, Montpellier, France

Abstract: Wolfram syndrome (WS) is a rare multisystem neurodegenerative disorder also known as DIDMOAD (diabetes insipidus, insulin-deficient diabetes mellitus, optic atrophy and deafness). WS is an autosomal recessive disease causing degeneration of β cells in the pancreas, ganglion cells in the retina and hair cells in the inner ear. The syndrome is due to mutations in *WFS1*, coding Wolframin, a mitochondria-associated ER membranes (MAM) protein involved in regulation of ER Ca^{2+} homeostasis. This pathology constitutes a genetic model of MAM dysfunction leading to neurodegeneration. MAM are functionalized domains of interaction between organelles, driving local Ca^{2+} transfer. MAM dysfunction contributes to neurodegeneration in numerous pathologies including Alzheimer, amyotrophic lateral sclerosis or Huntington. We characterized the behavioral phenotype of WFS1 KO mice in terms of general activity, learning and memory and anxiety response. Female and male 3-month old wild-type and WFS1 KO mice were compared, in the open-field, spontaneous alternation, passive avoidance, object recognition, water-maze, black-and-white box and elevated plus-maze tests. Results show an hypolocomotor response and short-term memory deficits for both male and female WFS1 KO mice and a deficit in recognition memory only in KO males. Both gender showed increased anxiety parameters but with significant differences measured mainly for WFS1

KO females. These data show that young WFSI KO mice present marked deficits in cognitive abilities and anxiety response in relation with the WS symptomatology. Therefore this model can be useful in the development of new therapeutics approaches targeting neurodegenerative processes due to MAM dysfunction.

[1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Depression is a common, chronic and debilitating disorder. Women are twice as likely to suffer from depression as men, yet the molecular mechanisms contributing to this sex difference remain poorly understood. Long non-coding RNAs (lncRNAs) are a recently discovered class of regulatory transcripts which represent a substantial portion of the human genome. To explore the role of lncRNAs in depression we utilized a comprehensive genome-wide profile of RNAs in six brain regions from both male and female post-mortem depressed and control human subjects. Overall, lncRNAs represent about one-third of the differentially expressed genes in depressed subjects compared to controls, and displayed complex region- and sex-specific patterns of regulation. Next, we carried out bioinformatic genome-wide correlation analysis between lncRNAs and protein-coding genes in our dataset. Using this approach, we identified stronger correlations between lncRNAs and protein-coding genes in females than in males, and specific lncRNAs with potential sex-specific roles in depression. To explore the causal role for two of the identified lncRNAs in depression, each lncRNA was expressed in neurons of the mouse prefrontal cortex (PFC). Such viral-mediated expression mimicked the human sex-specific phenotype: expressing a female upregulated depression-related lncRNA increased depression- and anxiety-related behaviors in female but not male mice, while

expressing a female downregulated lncRNA induced stress resilience in females only. To analyze the molecular mechanism of action of these lncRNAs, we performed RNA sequencing on PFC infected with the target lncRNAs or control viruses. We found that expression of the female specific pro-depressant lncRNA promoted transcriptional changes that resemble the depressed female transcriptome only. In parallel, expressing the female-specific pro-resilient lncRNA blunted the normal transcriptional changes in response to stress that was observed in control mice. Furthermore, electrophysiological recording from PFC pyramidal neurons expressing the pro-resilient lncRNA compared to control indicated changes in synaptic properties in female mice only. Interestingly, the female pro-susceptibility lncRNA is expressed in oligodendrocytes in addition to neurons; therefore, we are utilizing a cell-type specific viral expression system to test the role of this lncRNA in mediating sex-specific effects on mouse behavior and myelin sheaths. These studies provide a fundamentally new view of molecular adaptations in brain that contribute to depression risk and may lead to the identification of novel targets for treatment.

Title: Glutamate-glutamine transfer and chronic stress-induced sex differences in cocaine responses

Authors: *A. SHIMAMOTO[1], T. FARRIS[1], H. MUNJAL[1], C. MOORE[2], C. DAVIS[1], A. WILSON[1], M. EDWARDS[1], C. REYNOLDS[1], V. RAPPENEAU[1], C. K. MESHUL[3,2]

[1]Neurosci. and Pharmacol., Meharry Med. Col., Nashville, TN; [2]Oregon Hlth. and Sci. Univ., Portland, OR; [3]Neurocytology Lab/Bldg 101, Room 520, VA Med. Ctr., Portland, OR

Abstract: Major depression (MD) is one of the common co-occurring mental illnesses in patients with substance use disorders (SUD). The comorbidity of SUD and MD (SUD/MD) is sex-dependent and therefore requires sex-tailored pharmacological intervention. Our previous findings indicate that the sex difference in glutamate (Glu) and glutamine (Gln) transfer between neurons and astrocytes in the nucleus accumbens (NAc) in animals that are chronically exposed to social defeat stress (CSDS), an animal model for MD. Thus, the current study first investigated the role of membrane-expressing transporters for Glu (glutamate transporter-1; GLT-1) and Gln (sodium-coupled neutral amino acid transporter subtype 1/2; SNAT 1/2) on sex differences in CSDS animals. CSDS took place for 21 days using a resident-intruder paradigm in Long-Evans male and female rats. Ten days after the last social defeat, brains from CSDS or non-CSDS animals were collected for western blot analysis. CSDS showed long-lasting behavioral effects on both males and females, as indicated by the prolonged attenuation in intake for sweet-tasting solution, reduced weight gain, and disruption in estrous cycle. Compared to their respective non-CSDS controls, CSDS increased membrane GLT-1 in the NAc and prefrontal cortex (PFC) in females but no change was observed in males. By contrast, CSDS decreased SNAT 1/2 in the NAc in males but not in females. An electron microscopic analysis showed that CSDS males had more Gln localized in outer membrane of mitochondria in glutamatergic neurons in the NAc projecting from PFC. Second, a subset of CSDS and non-CSDS animals were subjected to cocaine repeatedly. Compared to their non-CSDS controls, CSDS females showed a significant increase in locomotor activity while CSDS males showed an attenuated activity. The increased locomotor responses corresponded with a reduction in cytosol fraction of GLT-1 and an increase in membrane SNAT 1/2 in PFC. By contrast, the attenuated locomotor responses in males corresponded with an increase in membrane GLT-1 and SNAT 1/2 and neuronal phosphate-activated glutaminase (PAG) in PFC. Collectively, CSDS impairs both accumbal and prefrontal membrane-expressing transporters that may mediate the sex difference in cocaine-induced locomotor responses.

Title: Sex specific role for slit1 in regulating susceptibility to chronic stress

Authors: *Y. VAN DER ZEE[1], O. ISSLER[1], E. M. PARISE[1], A. TORRES BERRÍO[1], C. J. PEÑA[1], B. LABONTÉ[2], B. P. RUTTEN[3], E. J. NESTLER[1]

Abstract: Major depressive disorder (MDD) is a ubiquitous and disabling disorder that is characterized by mood disturbances, anhedonia, and alterations in cognitive functions. While it has been well-established that women are twice as likely to suffer from MDD than men, the molecular mechanisms of this sexual dimorphism in depression are poorly understood. To explore this, we utilized a recently published RNA-seq expression profile from postmortem tissue from both male and female MDD subjects and healthy controls across six brain regions. We identified the human transcript Slit Guidance Ligand 1 (*SLIT1*), which encodes a secreted molecule essential for axonal navigation and molecular guidance in cellular migration, as a hub gene that drives female-specific gene networks in MDD. Furthermore, we found that *Slit1* mRNA is down-regulated in the ventromedial prefrontal cortex (vmPFC) in postmortem tissue from depressed females, but not depressed males, as compared to healthy controls. We observed a similar sex-specific down-regulation of *Slit1* in the vmPFC of mice exposed to the chronic variable stress (CVS) paradigm. In parallel, we found that early life stress exposure using a maternal separation protocol led to down-regulation of *Slit1* in the vmPFC of female mice compared to controls. To test the potential sex-specific causal role of *Slit1* in depression-related behavioral abnormalities, we used modified Herpes Simplex Viruses (HSVs) to manipulate *Slit1* expression. Our results show that knockdown of *Slit1* in vmPFC neurons, in combination with exposure to CVS, induces an increase in anxiety- and depression-like behaviors in adult female but not male mice. Conversely, HSV-mediated overexpression of *Slit1* has a behavioral sex-specific stress-protective role. Ongoing studies are examining the effects of manipulating *Slit1* expression levels in early life to determine its role in life long sensitivity to stress. Our results propose important sex-specific roles of *Slit*1 in regulating depression- and anxiety-like behaviors selectively in female mice, in both adulthood and early life. Taken together, this is the first study that investigates the role of *SLIT1* in MDD, and provides further insight in understanding novel signaling pathways and molecular factors contributing to sex differences in depression susceptibility.

Title: Sex differences in hippocampal physiology: Circuit-specific mechanisms underlying stress susceptibility

Authors: *E. S. WILLIAMS[1], A. L. EAGLE[2], C. MANNING[3], A. ROBISON[4]
[1]Pharmacol. & Toxicology, [2]Dept. of Physiol., [4]Neurosci., [3]Michigan State Univ., East Lansing, MI

Abstract: Depressive syndromes are a major cause of morbidity, and often arise in response to life stress. Aside from its social and financial burden, a striking characteristic of depression is that it affects women nearly twice as often as men. The impact of depression and the disparity in numbers of affected men and women have been recognized for some time, but the molecular underpinnings of the disease remain unknown. This knowledge gap is critical, as treatments remain ineffective in many patients and no sex-specific therapies are known. Glutamatergic pyramidal neurons that project from the ventral hippocampus (vHPC) to the nucleus accumbens (NAc) are mediators of stress responses, but little is known of the regulation of this circuit at the level of cell function or gene expression. This circuit has gained recent attention in mood disorder research as it has been shown that increased activity in these neurons promotes susceptibility to chronic social defeat stress (CSDS), a validated mouse model of depression. Using whole-cell slice electrophysiology, we show that vHPC-NAc neurons from female mice have heightened excitability compared to those from male mice. Additionally, we show that vHPC-NAc neurons from orchiectomized male mice have similar activity to those from wild-type female mice, suggesting a role for androgens in the regulation of excitability in this circuit. These findings may begin to explain the apparent differences in the number of males and females diagnosed with depression, as the increased activity observed in vHPC-NAc neurons of female mice may indicate increased susceptibility of females to stress. Our group has also shown that the transcription factor ΔFosB is required for hippocampal learning, and its expression is induced in the vHPC by stress or antidepressant treatment. Because of its clear role in resilience in other brain regions, ΔFosB is an exciting prospective target for the differential regulation of vHPC-NAc neuronal activity in male and female mice at baseline as well as in response to stress. To this end, we show that general inhibition of ΔFosB function throughout the vHPC (but not dHPC) promotes susceptibility to subchronic stress, that overexpression of ΔFosB in vHPC reduces cell excitability, and that reduction of *FosB* gene expression in vHPC-NAc neurons

increases cell excitability. We thus hypothesize that stress-induced ΔFosB in vHPC-NAc neurons mediates changes in the function of these neurons and regulates gene expression to promote stress resilience in male and female mice.

Abstract: Rodent differentiation of the sex of human experimenters may influence physiological and behavioral responses. We show that mice manifest aversion to human male odors, and attraction to human female odors, while showing increased susceptibility to stress responses when handled by male experimenters. Administration of the antidepressant drug ketamine to mice by male experimenters reversed stress-mediated behavioral responses, while such responses were absent following injection of the drug by female experimenters. Similar experimenter sex-dependent effects were identified with the ketamine metabolite (*2R,6R*)-hydroxynorketamine, but not with other mechanistically distinct antidepressants. Non-antidepressant behavioral actions of ketamine where present regardless of the sex of the experimenter. We establish that male scent is necessary to induce ketamine's antidepressant effects in our mouse models; however female scent dominantly prevents such an effect in a manner dependent upon production of stress hormones. Moreover, blocking stress responses prior to ketamine administration by male experimenters inhibited ketamine's antidepressant effects. Ketamine administration increased GluA1 AMPA receptor subunit in the ventral hippocampus when injected by male but not female experimenters. Overall, these findings demonstrate that experimenter sex influences the outcome of behavioral and pharmacological assessments,

impacting replicability, and arguing that experimenter sex should be considered as a relevant experimental variable.

Title: A novel cross-species neurophysiological assay of cognitive control: Development of a touchscreen-based rodent Flanker task

Authors: *M. A. ROBBLE, S. NICKELS, B. D. KANGAS, L. WOOLDRIDGE, E. CÁRDENAS, S. PERLO, J. BERGMAN, W. A. CARLEZON, Jr, D. A. PIZZAGALLI

Abstract: Deficits in cognitive function, such as reward sensitivity and cognitive control, are a common feature of virtually all neuropsychiatric disorders. While perturbations in cognitive control have been studied extensively in humans, it has been challenging to examine these complex processes in laboratory animals. In turn, stagnation in the development of animal-based tasks to assess these processes has impeded the identification and development of innovative treatments for neuropsychiatric disorders. As part of a larger effort to create reliable and valid cross-species assays of cognitive function, we are developing a rodent version of the Eriksen Flanker Task to assess cognitive control. Using fading and correction procedures combined with touch-sensitive response technology, we trained Sprague Dawley and Long Evans rats to discriminate between several distinct pairs of visual stimuli including arrows (</>) and letters (H/S) used in traditional (human) versions of the Flanker Task, as well as colored stripes, colored shapes, and more detailed photographic stimuli. Discrimination was deemed successful when the criterion of 80% response accuracy per stimulus-type during the session was observed on two consecutive days. The results of these studies indicated that detailed photographic stimuli (green leaf/violet flower) would be optimal stimuli for use in the Flanker Task and that stimulus control was more likely to be achieved when testing Long-Evans rather than Sprague-Dawley rats. Following training under these final conditions, rats were surgically implanted with skull surface and depth electrodes and neurophysiological data were collected during Flanker Task testing. In parallel, EEG data were collected from human subjects using the stimuli validated in the rodent

task. All human subjects showed the expected Flanker interference effects of reduced accuracy and increased response latency on incongruent trial types. In addition, we observed robust N200 and error-related negativity (ERN) components in humans, as well as increased theta power, when comparing incongruent and congruent trial types. These results indicate that the stimuli chosen for the rodent Flanker Task elicit the expected effects in humans. Preliminary electrophysiological recordings in rodents suggest ERP and spectral findings that have qualitative similarities to those observed in humans. Once behavioral and neurophysiological correspondence between species has been established, the rodent task may provide predictive power to screen potential therapeutics for neuropsychiatric conditions.

Title: Pharmacological and genetic studies of effort-related decision making using mouse touchscreen procedures: Effects of dopamine antagonism and humanized catechol-o-methyltransferase variants

Authors: *J.-H. YANG[1], R. E. PRESBY[1], A. A. JARVIE[1], R. A. ROTOLO[1], R. FITCH[1], M. CORREA[2,1], J. D. SALAMONE[1]

Abstract: Effort-based decision making tasks offer animals choices between a more preferred reinforcer that requires high effort to obtain vs. a low effort/low reward option. The neural mechanisms of effort-based choice have been widely studied in rats, and evidence indicates that a distributed forebrain circuit that includes mesolimbic dopamine (DA) and related neural systems plays a key role. DA antagonism or depletion produces a low-effort bias in rats tested on effort-based choice tasks. However, fewer studies of effort-based choice have been performed in mice, and most of these have involved T-maze choice tasks. The present studies used touchscreen operant procedures (i.e., Bussey-Saksida boxes) to assess effort-based choice in mice. The high-effort component involved rearing up to press an elevated lit panel on the touchscreen in order to receive Ensure strawberry milkshake as the reinforcer. The low effort

choice was a dish of less preferred food pellets (Bio-serv) that was freely available in the box. CD1 mice were tested in a series of experiments in which the mice pressed the panel on a fixed ratio 1 (FR1) schedule. Injections of the DA antagonist haloperidol (0.05-0.15 mg/kg IP) produced a dose-related decrease in panel pressing. Intake of the concurrently available food pellets was not reduced by haloperidol, and in fact, there was a significant quadratic trend, showing that there was a tendency for pellet intake to increase at the low/moderate doses. In contrast, reinforcer devaluation by prefeeding substantially decreased both panel pressing and pellet intake. In free-feeding choice tests, mice strongly preferred the Ensure vs. the pellets, and haloperidol had no effect on food intake or preference. Additionally, humanized catechol-O-methyl transferase (COMT) transgenic mice with two genotypes (Val, and Met variants) as well as wild-type (WT) mice from the S129 background were tested using touchscreen choice procedures. Mice were trained in a FR/choice task with FR requirements varied (FR1, 2, 4, 8, to 16) in an ascending and descending sequence. Results show an inverse relationship between the number of reinforcers delivered by panel pressing and pellet intake across the different FR levels in all three groups. There was a significant group x FR level interaction, with panel presses in the Val group being significantly lower than WT group on FR1, 2, 4, and 8, and lower than Met group on FR4. These studies show that haloperidol did not reduce panel pressing due to decreases in primary food motivation or preference, and illustrate the possible relation between COMT polymorphisms and negative symptoms such as motivational dysfunctions in human psychopathologies.

Title: The novel atypical dopamine uptake inhibitor S-CE-123 partially reverses the effort-related effects of the dopamine depleting agent tetrabenazine

Authors: *R. A. ROTOLO[1], R. SCHWARTZ[1], V. DRAGACEVIC[2], P. KALABA[2], E. URBAN[2], M. ZEHL[3], J. WACKERLIG[2], T. LANGER[2], R. E. PRESBY[1], J.-H. YANG[1], M. CORREA[4,1], G. LUBEC[5], J. D. SALAMONE[1]
[1]Psychological Sci., Univ. of Connecticut, Storrs, CT; [2]Pharmaceut. Chem., [3]Analytical Chem., Univ. of Vienna, Vienna, Austria; [4]Psicobiologia. Univ. Jaume I, Castello, Spain; [5]Neuroproteomics, Paracelsus Med. Univ., Salzburg, Austria

Abstract: Animal studies of effort-related choice behavior are being used to model effort-related motivational dysfunctions in humans. With these procedures, animals are offered a choice between high effort instrumental actions leading to highly valued reinforcers vs. low effort/low reward options. Several previous studies have shown that dopamine (DA) transport inhibitors, including GBR12909, lisdexamfetamine, methylphenidate, and PRX-14040, can reverse the effort-related effects of the vesicular monoamine transport inhibitor tetrabenazine, which blocks DA storage. Because many drugs that block DA transport (DAT) act as major stimulants that also release DA, and produce a number of undesirable side effects, there is a need to develop and characterize novel atypical DAT inhibitors with unique and selective binding profiles. Recent studies have shown that the atypical DAT inhibitor modafinil, which elevates extracellular DA but is not a major psychomotor stimulant, can also reverse the effects of tetrabenazine. Modafinil also has been reported to improve motivational function in depressed patients and non-pathological control subjects, albeit without a strong abuse liability. S-CE-123 is a recently developed analog of modafinil, (S)-5-((benzhydrylsulfinyl)methyl)thiazole, with the biochemical characteristics of an atypical DAT blocker. A recently synthesized and chromatographically separated analog of modafinil, S-CE-123 is highly selective for DAT vs. the norepinephrine and 5-HT transporters. S-CE-123 has been shown to enhance cognitive flexibility and reduce impulsivity in rats. For the present studies, S-CE-123 was assessed for its ability to reverse the effort-related motivational effects of tetrabenazine. Rats were assessed using the fixed ratio 5/chow feeding choice test. Tetrabenazine (1.0 mg/kg) shifted choice behavior, decreasing lever pressing and increasing chow intake. S-CE-123 was co-administered at doses ranging from 6.0-24.0 mg/kg, and the highest dose partially but significantly reversed the effects of tetrabenazine. In summary, S-CE-123 was able to reverse the effort-related effects of tetrabenazine, which suggests that that S-CE-123 or a similar compound could be useful as a treatment for effort-related motivational dysfunction in humans. Future studies should determine the abuse liability of S-CE-123 and other modafinil analogs.

Title: The novel atypical dopamine transport inhibitors CT-005094 and CT-005404 reverse the effort-related motivational effects of the dopamine depleting agent tetrabenazine

Authors: *J. D. SALAMONE[1], R. A. ROTOLO[1], F. MURRAY[2], B. MCNAMARA[1], R. E. PRESBY[1], J.-H. YANG[1], M. CORREA[1,3]
[1]Dept Psychological Sci., Univ. of Connecticut, Storrs Mansfield, CT; [2]Chronos Therapeut., Oxford, United Kingdom; [3]Psychobiology, Univ. of Jaume I, Castello, Spain

Abstract: Motivational symptoms such as fatigue, anergia, and amotivation are seen in depression, multiple sclerosis, Parkinson's disease, schizophrenia, chronic fatigue syndrome, and other disorders. Considerable evidence from basic research and clinical studies implicates brain dopamine (DA) in the regulation of behavioral activation and effort-related aspects of motivation. Animal studies of effort-based choice behavior are being used to provide formal models of effort-related motivational dysfunctions in humans. For assessment of effort-based choice, animals are offered the option of a high effort instrumental action leading to highly valued reinforcer (preferred, or higher magnitude) vs. a low effort/low reward choice. Drugs that block DA transport, such as GBR12909, lisdexamfetamine, methylphenidate, and PRX-14040, are able to reverse the effort-related effects of the vesicular monoamine transport inhibitor tetrabenazine, a drug that blocks DA storage and depletes DA. Many of the existing drugs that are labeled as DA transport (DAT) inhibitors are either classic DA blockers such as cocaine, or drugs that also stimulate release of DA. These drug can produce a number of undesirable side effects, including psychotic symptoms and abuse liability. Thus, there is a need to develop and characterize novel atypical DAT inhibitors that are highly selective and have unique binding profiles. The present studies focused on recently synthesized atypical DAT inhibitors, CT-005094 and CT-005404. These compounds bind to DAT with high selectivity relative to the serotonin and norepinephrine transporters, and can elevate extracellular levels of DA as measured by microdialysis without stimulating DA release. In the present studies, CT-005094 and CT-005404 were assessed for their ability to reverse the effort-related motivational effects of tetrabenazine. Rats were tested using the fixed ratio 5/chow feeding choice test. Tetrabenazine (1.0 mg/kg) shifted choice behavior, decreasing lever pressing and increasing chow intake. CT-005094 was co-administered at doses ranging from 2.0-16.0 mg/kg IP, and the 8.0 mg/kg dose partially but significantly reversed the effects of tetrabenazine. CT-005404 was orally active, and reversed the effects of tetrabenazine in the dose range of 15.0-30.0 mg/kg PO. Atypical DAT inhibitors such as CT-005094 and CT-005404 offer potential as a new avenue for drug treatment of motivational dysfunctions in humans.

Title: Dopamine D1 receptor activation in the dentate gyrus enhances antidepressant effects of an SSRI, fluoxetine in a mouse model of depression

Authors: *T. SHUTO, M. KUROIWA, N. SOTOGAKU, Y. KAWAHARA, Y. OHNISHI, Y. HANADA, A. NISHI
Dept. of Pharmacol., Kurume Univ. Sch. of Med., Kurume-Shi, Japan

Abstract: Major depression is a psychiatric disorder with high lifetime prevalence. Selective serotonin reuptake inhibitors (SSRIs) are commonly used for treatment of depression. However, current pharmacological treatment of depression is insufficient, and development of improved treatments especially for treatment-resistant depression is desired. Recently, chronic administration of SSRI is reported to increase the expression of dopamine D1 receptors in mature granule cells of the hippocampal dentate gyrus, but the mechanisms underlying involvement of D1 receptors of SSRIs to improve symptoms of depression are not fully understood. In this study, we investigated the role of D1 receptors in the dentate gyrus in antidepressant actions of SSRIs. Mice were treated with fluoxetine, an SSRI, chronically by subcutaneous implantation of matrix-driven delivery pellets (15 mg/kg/day, 14 days). The fluoxetine-induced changes in gene and protein expression were analyzed by quantitative real-time PCR and Western blot analysis, respectively. In addition, depression-like behaviors were evaluated with the novelty-suppressed feeding test (NSFT) and tail suspension test (TST) in mice subjected to chronic restraint stress. Chronic treatment with fluoxetine induced the expression of D1 receptor mRNA and protein in the dentate gyrus, but not other subtypes of dopamine receptor mRNA. Regular restraint stress (2 hr/day, 14 days) increased the feeding latency in the NSFT, and chronic treatment with fluoxetine reduced the increased feeding latency. However, in mice subjected to severe restraint stress (4 hr/day, 28 days), chronic treatment with fluoxetine failed to reduce the stress-induced increase in feeding latency in the NSFT and immobility time in the TST. Chronic co-administration of a dopamine D1 receptor agonist, R(+)-SKF81297 (1.5 mg/kg/day, i.p. for 5 days), with fluoxetine resulted in the reversal of the depression-like behaviors. These results suggest that the increase in D1 receptor signaling in the dentate gyrus is essential for the

antidepressant actions, and activation of dopamine D1 receptors in the dentate gyrus enhances therapeutic actions of SSRI under SSRI-resistant stress conditions.

Title: Intracerebral infusion of beta-hydroxybutyrate, an endogenic NLRP3 inflammasome inhibitor, produces antidepressant like effects in a rodent model of depression

Authors: *N. KAJITANI[1], M. IWATA[1], T. YAMANASHI[1], K. TSUNETOMI[1], A. MIURA[1], T. NISHIGUCHI[1], R. S. DUMAN[2], K. KANEKO[1]
[1]Devision of Neuropsychiatry, Tottori Univ., Yonago-shi, Japan; [2]Yale Univ. Sch. Med., New Haven, CT

Abstract: Although the pathology of psychiatric disorders such as depression is unclear, recent studies demonstrate a role for the involvement of intracerebral inflammation, including evidence that the inflammatory cytokine interleukin-1β (IL-1β) causes depressive behavior. Previously we reported that stress increases ATP, which activates the Nucleotide-binding protein, Leucine-rich repeat, Pyrin domain containing 3 (NLRP3) inflammasome, which in turn promotes the formation of mature IL-1β in the rat brain. Thus, we propose a hypothesis that the inhibition of the NLRP3 inflammasome will produce an antidepressant effect by preventing IL-1β production caused by stress. Recently it has been reported that beta hydroxybutyrate (BHB), a ketone body that supports mammalian cell metabolism during states of energy deficiency, such as fasting or exercise, reduces NLRP3 inflammasome-mediated production of IL-1β. We have found that peripheral BHB administration suppressed NLRP3 activation and reduced inflammatory cytokines such as IL-1β and tumor necrosis factor α, and improved anxiety and depressive behaviors in a rodent chronic unpredictable stress (CUS) model of depression. However, whether BHB acts directly on the brain or on peripheral inflammatory NLRP3 responses remains unknown. The brain imaging studies demonstrate altered morphology and blood flow of the prefrontal cortex (PFC) and hippocampus in depressed patients, rodent studies show that chronic stress increase NLRP3 inflammasome and pro-inflammatory cytokines in the these brain regions.

Here, we evaluate the influence of direct infusions of BHB into the PFC and hippocampus. The results show that intracerebral infusion of BHB into medial PFC produces antidepressant like effects in the forced swim test with no effects on locomotor activity. Similar tendencies were observed in the sucrose preference test and the elevated plus maze test. In contrast, infusions of BHB into the hippocampus had no effect on these behaviors. Together, these studies indicate that BHB is capable of producing antidepressant effects by direct actions on the central nervous system and that these effects are specific to the medial PFC. Further studies will be needed to test the contribution of peripheral blockade of NLRP3 on stress-induced antidepressant responses. Nevertheless, these findings are consistent with the hypothesis that inhibiting the NLRP3 inflammasome in brain is a novel effective approach for the treatment of depression.

Title: Beta-hydroxybutyrate ameliorates depressive like behavior induced by social defeat stress

Authors: *K. TSUNETOMI[1], M. IWATA[1], T. YAMANASHI[1], N. KAJITANI[1], A. MIURA[1], M. NAGATA[1], R. MATSUO[1], T. NISHIGUCHI[1], R. S. DUMAN[2], K. KANEKO[1]
[1]Tottori Univ., Tottori, Japan; [2]Yale Univ. Sch. Med., New Haven, CT

Abstract: Stress is known to decrease neurogenesis and synaptogenesis inhippocampus and induces depressive-like behavior in rodent models, but the mechanisms by which stress causes these neuroplasticity deficits is still unclear. Previously, we had reported that a proinflammatory cytokine such as interleukin-1β (IL-1β) is an essential mediator of the anti-neurogenic effects of stress. Recently we have focused on the Nucleotide-binding protein, Leucine-rich repeat, Pyrin domain containing 3 (NLRP3), a cytosolic pattern recognition receptor (PRR), which is considered a key molecule for the stress inflammatory response. NLRP3 recognizes various molecules such as Damage Associated Molecular Patterns (DAMPs) and Pathogen Associated Molecular Patterns (PAMPs), and the activated NLRP3 inflammasome cleaves immature IL-1β to the active form. Thus, we hypothesized that NLRP3 is a novel target for inhibiting stress-related neuroinflammation, which promotes antidepressant actions in rodent models. To inhibit

NLRP3, we applied beta-hydroxybutyrate (BHB), which has recently been reported to reduce NLRP3 inflammasome-mediated production of IL-1β. We have demonstrated that peripheral BHB administration suppresses the activation of the NLRP3 inflammasome, and reduces inflammatory cytokines such as IL-1β and tumor necrosis factor α (TNFα), and improves anxiety and depressive behaviors in a rodent chronic unpredictable stress (CUS) model of depression. In this study, we found that peripheral BHB administration completely prevents depressive like behavior in the forced swim test (FST) induced by the social defeat model of mice. Further studies will be needed to test the contribution of the blockade of NLRP3 on stress-induced antidepressant responses. Nevertheless, these findings are consistent with the hypothesis that inhibiting the NLRP3 inflammasome is a novel effective approach for the treatment of depression.

Title: Age-dependency of effects of enriched environment treatment on depression-like behavior and BDNF expression in normal and promoter IV-BDNF deficient mice

Authors: *S. JHA[1], B. DONG[2], Y. XUE[2], K. SAKATA[2]
[1]Biotech., SASTRA Deemed Univ., Thanjavur, India; [2]Pharmacol., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Enriched environment treatment (EET), a potential intervention for depression, induces expression of brain-derived neurotrophic factor (BDNF), while BDNF deficiency via inactive promoter IV is implicated in the pathophysiology of depression. We previously reported that EET was more effective than antidepressant drug treatment in reversing the depression-like behavior caused by promoter IV-BDNF deficiency in young adult mice (Jha et al., Transl. Psychiatry e40, 2011; Sakata et al., Eur J. Neurosci. 37(11)1863-1874, 2013). However, its age-dependency, i.e., whether EET effects on antidepressive behavior and BDNF expression differ across life stages, remains unclear. Here, we addressed this question by determining EET effects across three life stages—early-life development (ED: 0-2 months), young adult (YA: 2-4 months), and old adult (OA: 12-14 months) in wild-type (WT) and promoter IV-BDNF-deficient

(KIV) mice. KIV mice, at all life stages, displayed reduced exploratory activity in the open field test, stress-induced despair in the tail suspension test, and anhedonia in the sucrose preference test, when compared to WT mice. Two months of EET increased exploratory activity and reduced despair-like behavior in ED and YA, but not OA mice, with the largest effect seen in ED KIV mice. EET normalized anhedonia in KIV age groups. The largest EET-induced increases in BDNF protein levels were observed in ED in the KIV hippocampus and frontal cortex. EET-induced increases in BDNF mRNA levels were similar for all ages in the hippocampus, but were observed only in ED KIV and OA WT mice in the frontal cortex. EET-induced BDNF transcription by promoters I and IV were age dependent in the WT hippocampus with a larger induction of exon IV or I during ED or OA, respectively. EET-induced BDNF transcription by most of the 9 promoters was age dependent in the frontal cortex, mostly observed in ED KIV mice. When mice were housed in standard cages for one month after EET, the EET effects persisted for anti-depressive behavior, BDNF protein expression in the hippocampus, and BDNF transcription in both hippocampus and frontal cortex, but only when EET was provided at ED and particularly in KIV mice. These results suggest that BDNF deficiency causes depression-like behavior regardless of age, but EET during ED can be a potent and lasting intervention against depression caused by BDNF deficiency. Conversely, older adults may require additional treatment.

Abstract: Deep brain stimulation (DBS) of the ventromedial prefrontal cortex (vmPFC) in a chronic mild stress (CUS) model in rats has shown anti-depressant effects. Mostly the infralimbic (IL) and prelimbic (PreL) subregions of the vmPFC have been investigated. The dorsal peduncular (DP) subregion however, has not yet been widely researched. This DP subregion, like the IL and PreL subregions, has direct connections to the dorsal raphe nucleus

(DRN) which indicate a potential role of this DP subregion in mood. Further investigation into this region might therefor be of great value. In our experiments we have stimulated the DP subregion to see if DBS could alleviate 'depressive-like' behavior in an CUS model in rats. To our surprise, 40% (n = 7/18) of our stimulated animals showed severe involuntary movements when applying DBS repetitively. These involuntary movements were not seen in our control groups indicating a direct stimulation effect. To classify these involuntary movements, we acquired EEG and video recordings upon stimulation, showing Racine stage IV-V seizures with typical spike and wave discharges between the implanted electrodes. Both biphasic and monophasic bipolar DBS showed these findings. A trend towards neophobia when conducting the home cage emergence test and a trend towards less sucrose intake when conducting the sucrose intake test was seen in the animals developing seizures later on, considering our CUS sham (n = 4) and non-CUS control group (n = 4) were very small. Due to the severity of the induced seizures upon further stimulation we were unable to continue behavioral testing. Our findings indicate that the DP subregion of the vmPFC in the rat is not a safe brain structure to conduct DBS experiments. A relatively novel finding is that this region is involved in seizure induction and may be an experimental model of frontal epilepsy.

Title: Evaluation of antidepressant-like activity of kiwifruit (actinidia deliciosa) extract in mice

Authors: *C. M. MARZO[1], M. BIANCONI[1], M. COMMISSO[1], C. CHIAMULERA[2], F. GUZZO[1]

Abstract: Antidepressant pharmacotherapies have a slow onset of clinical efficacy which is critical for therapeutic outcome and patient compliance. In recent years, an increasing number of studies suggest that phytochemical compounds activity on mood might be a clinically relevant co-adjuvant to current medications.
Many studies suggest a positive association between fruits and vegetables-rich diet and prevention of depression, therefore the consumption of a whole phytocomplex may increase serotonin bioavailability both at CNS and systemic levels. The aim of this study is to evaluate the activity of kiwifruit (*Actinidia deliciosa*) extracts on mood in murine model of depressive behavior. Indeed, kiwifruit is rich in polyphenols (e.g. ferulic acid, kaempferol, catechin, etc.)

with a known inhibitory effect on both monoamine oxidases A and B.
Naïve male C57BL/6J mice were administered with three increasing concentrations of kiwifruit extracts under chronic or acute regimes. Immobility time was then assessed in forced swimming test (FST) and tail suspension test (TST); additionally, the efficacy of kiwifruit compared to vehicles and selective serotonin reuptake inhibitor fluoxetine (20 mg/kg, i.p.) were investigated. The highest kiwifruit concentration produced a reduction of 40% and 45% in immobility time in FST and TST respectively, without causing hyperlocomotion in the open-field test.
Taken together, these data suggest that kiwifruit may have a mood-improving effect through modulation of the serotonergic system. To support these findings, pharmacokinetic profiles and monoamines detection through chromatographic and mass-spectrometric analyses are in progress on both whole brain homogenate and serum samples.

Title: Peripheral reelin administration rescues neurochemical alterations and depression-like behavior in a preclinical model of depression

Authors: J. ALLEN[1], R. ROMAY-TALLON[1], K. BRYMER[2], M. MITCHELL[2], L. E. KALYNCHUK[1], *H. J. CARUNCHO[1]

Abstract: Chronic stress is a significant risk factor for the onset of depression. This can be studied preclinically using a corticosterone (CORT)-administration paradigm, in which rodents receive daily injections of CORT for several week followed by behavioral testing and post-mortem analyses of biological tissues. We have shown that 21 days of CORT treatment produces a behavioral phenotype of depression that is associated with deficient hippocampal neurogenesis, decreased hippocampal reelin levels, and larger serotonin transporter (SERT) protein clusters in peripheral lymphocytes, all of which parallel changes seen in these parameters in human depression patients. Our most recent data revealed that intrahippocampal infusions of reelin can normalize the behavioral and neurobiological alterations produced by CORT. Here we examined

whether peripheral intravenous administration of reelin may have a similar antidepressant-like effect.
Rats received 21 days of daily CORT or vehicle injections along with either 3µg or 5µg of reelin every 5 or 10 days. Thereafter, they were subjected to the forced swim test to measure depression-like behavior and then sacrificed to permit immunohistochemical analyses of the number of reelin+ cells in the subgranular zone (SGZ) and paraventricular nucleus (PVN) as well as the number and complexity of immature newborn neurons in the granule cell layer. We also analysed the pattern of SERT protein clustering in peripheral lymphocytes. Our results revealed that reelin reversed the CORT-induced increases in FST-immobility, the downregulation of reelin in the SGZ, and the increase in size of SERT clusters. However, only 3µg every 10 days reversed the decreases in reelin expression in the PVN, and all doses failed to reverse the CORT-induced decrease in the number and complexity of dendritic processes of developing newborn neurons.
These novel findings show for the first time that peripheral reelin administration can normalize CORT-induced increases in depression-like behavior and the size of SERT protein clusters in peripheral lymphocytes and the decreases in hippocampal plasticity. Although additional mechanistic and pharmacokinetic studies are necessary, our data also open the possibility of developing reelin peptides with antidepressant activity.

Title: Methamphetamine administration impedes the expected antidepressant-like effect induced by repeated electroconvulsive shock in adult rats

Authors: *R. GARCIA-CABRERIZO, C. BIS-HUMBERT, J. GARCIA-FUSTER
IUNICS. Univ. of the Balearic Islands, Palma, Spain

Abstract: Recent data from our laboratory demonstrated that: (1) binge methamphetamine administration induced hippocampal cell damage (i.e., impaired cell genesis and BDNF regulation) in rats when administered specifically during a window of late adolescence (postnatal day, PND 54-57) and evaluated 24 h later (PND 58), (2) these negative effects persisted in time as measured by a decrease rate in cell survival (41-43 days old cells) observed at PND 91 following prolonged withdrawal, and (3) binge methamphetamine administration enhanced negative affect (i.e., behavioral despair and anhedonia) following prolonged withdrawal. This subsequent study evaluated whether rats with a history of methamphetamine administration in late adolescence (PND 54-57) would benefit from an antidepressant treatment, such as repeated electroconvulsive shock (ECS), in adulthood while being re-exposed to the drug. Rats were treated with BrdU (2 x 50 mg/kg/day, 3 days, i.p., PND 48-50) followed by administration of binge methamphetamine (M group: 5 mg/kg, n=20) or saline (C group: 0.9% NaCl, 1 ml/kg, n=20) (3 pulses/day, i.p., PND 54-57). Rats were exposed to the forced-swim test (FST:15 min pre-test, PND 58, 5 min test, PND 59) to evaluate possible immediate negative effects of drug treatment. Following prolonged withdrawal, rats were re-exposed to daily methamphetamine (5 mg/kg) or saline – accordingly to what they received in late adolescence – and 3 h after injection, treated with a single ECS session (95 mA, 0.6 sec, 100 Hz, via earclip electrodes: C-ECS, n=10 vs. M-ECS, n=10) or connected to earclips eletrodes with no electrical current (C-SHAM, n=10 vs. M-SHAM, n=10) for 5 days (PND 91-95). Rats were then re-exposed to the FST on PND 96 and sacrificed on PND 97. The main result demonstrated that methamphetamine administration (PND 54-57) did not induce changes in behavioral despair (i.e., immobility time in the FST) in adolescence (PND 59) or later on during adulthood following re-exposure to the drug (PND 96). Interestingly, ECS induced the expected antidepressant-like response in C-treated rats (i.e., decreased time spent immobile: -66±17 sec, C-ECS vs. C-SHAM, $p<0.01$) but had no benefitial effect on rats with a prior history of methamphetamine use (+3±19 sec, M-ECS vs. M-SHAM, $p>0.05$). Therefore, these results indicate that methamphetamine exposure during late adolescence and its later re-exposure in adulthood prevents the expected antidepressant-like effects induced by ECS. Current studies are evaluating possible neural correlates (i.e., hippocampal neurogenesis on PND 96) that could help explain this maladaptive behavioral response.

Title: B cell deficiency is associated with depressive-like behavior in mice

Authors: *E. B. ENGLER-CHIURAZZI, J. M. POVROZNIK, X. REN, D. DOLL, H. HU, J. W. SIMPKINS
Physiol. and Pharmacol., West Virginia Univ., Morgantown, WV

Abstract: Major depressive disorder (MDD) is a debilitating mood disorder afflicting 20% of the population. That available pharmacotherapies exert delayed and often insufficient symptom alleviation suggests that the pathology of MDD is more complex than previously appreciated. Neurotransmitters thought to underlie MDD-associated brain pathology may not be the sole contributors to its presentation; as such, monoamine-based therapeutic interventions targeting these systems will remain inadequate at relieving symptoms or treating the underlying dysfunction, thus novel treatments that modulate innovative targets are critically needed. As mounting evidence supports the complex interaction of the brain, endocrine, and immune system (IS), a plethora of findings implicate a pro-inflammatory state and T cell over-activation in MDD. Yet the impact of the B cell on affect is uncertain. Without a clear understanding of the role of the B cell in mood, not only is the IS theory of MDD incomplete, but also potential therapeutic targets are likely being overlooked. Recently, B cell subtype-specific changes were noted in circulation of MDD patients such that while levels of total B cells were not significantly altered, there were reduced levels of IS-regulating B cells. Here, we evaluated the impact of B cell deficiency on depressive-like behavior using male B6.129S2-Ighm^{tm1Cgn}/J homozygous mice (aka muMT$^{-/-}$) that lack mature B cells and have no membrane-bound IgM expression. Depressive-like behavior was assayed using the forced swim and sucrose preference tests. As compared to wild type mice, muMT$^{-/-}$ mice displayed an age-dependent depressive-like phenotype that could not be alleviated with typical antidepressant therapy (20mg/kg desipramine given i.p. 30 min prior to test) but was reversed via immune modulation (adoptive transfer of splenic CD19^{+} B cells). This effect was not explained by locomotor or motivational group differences. These data implicate humoral IS deficiency in MDD, an observation that could contribute to the body of knowledge regarding the IS role in brain disease, inform clinical practice with a paradigm-shifting therapeutic approach, and ease the global mental health burden of MDD.

Title: TMS to LPFC initiates electrophysiological changes in sgACC

Authors: *G. K. ADAMS[1], A. C. DALLSTREAM[1], K. M. SHARIKA[1], N. GOSWAMI[2], A. PETERCHEV[2], J. I. GOLD[3], M. L. PLATT[1]

Abstract: Transcranial magnetic stimulation (TMS) is a therapeutic modality for the treatment of depression and other mood disorders. At present, no a priori detailed mechanism of therapeutic TMS has been validated; such a model would allow researchers and clinicians to predict which patients are likely to respond well, and what stimulation parameters will be most effective. However, previous research has identified some of these factors on the basis of statistical outcomes, and produced a post hoc working model according to which repetitive TMS to lateral prefrontal cortex (LPFC) acts indirectly upon subgenual anterior cingulate cortex (sgACC) via circuit-level effects, working somewhat analogously to deep brain stimulation. This provides a framework for guiding further research into the mechanisms underlying TMS.
To address the need for a mechanistic model, we performed TMS on nonhuman primates in conjunction with awake intracranial electrophysiology. We targeted LPFC (approximately area 9/46) for stimulation, using the theta-burst stimulation (TBS) protocol. To test our working model, we recorded the local field potential (LFP) activity in sgACC (area 24a) before and after LPFC-TBS, to ascertain whether and how sgACC function is affected by LPFC-TBS.
Spectral analysis of sgACC-LFP following LPFC-TBS revealed a transient decrease in power in the >350 Hz band lasting less than one hour, probably reflecting an overall decrease in multiunit spiking activity. By contrast, a narrow band centered at ~80 Hz ("high gamma" frequencies) was elevated, and continued to increase in magnitude over the course of 1 hour after stimulation. Additionally, we observed more modest narrow-band effects in the traditional EEG range. Infraslow (<1 Hz) power also showed a strong decrease in power following LPFC-TBS, recovering nearly to baseline by 1 hour after stimulation.

LPFC-TBS induces dramatic changes in sgACC-LFP, and the dynamics of these effects continue to unfold on the timescale of minutes to hours following stimulation. This effect is consistent with our working model of therapeutic TMS, and further work will explore whether sgACC does indeed play a causal role in alleviating symptoms.

Title: The effects of the antidepressant drugs on matrix metalleoprteinases release and the proteolysis of the perineuronal nets

Authors: *S. S. ALAIYED[1], M. MCCANN[2], M. LARA[2], K. KELLAR[1], K. CONANT[2]
[1]Pharmacol. and Physiol., [2]Neurosci., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: Overall, the underlying pathology of depression is extremely heterogeneous and complex, which makes it difficult to find a treatment that is effective for all depressed individuals. Though a full understanding of the mechanisms that underlie antidepressant efficacy in responsive individuals is not yet fully appreciated, responsiveness correlates with increased volume of select brain regions, particularly the hippocampus. Antidepressant drugs that target monoamines induce structural remodeling in the adult brain, including increasing the volume of selected brain regions, and enhancing excitatory neuronal transmission. Emerging evidence suggests that neuroplasticity and neuronal transmission can be enhanced through modulation of the perineuronal nets (PNN), a lattice like structure that surrounds the parvalbumin (PV) positive interneurons, and by enhancing dendritic arborization and spine formation. Preclinical studies suggest that monoamine modulating antidepressants can reduce the integrity of PNN to potentially facilitate neuroplasticity. However, the specific mechanism of the effects of these medications on the brain plasticity has yet to be determined. Matrix metalloproteinase (MMPs) including MMP-2 and MMP-9, are expressed in neurons, glia and endothelial cells and are involved in the remodeling of the extracellular matrix, PNNs and dendritic plasticity. MMP-9 has been implicated in synaptic plasticity, learning and memory and tissue remodeling in response to enhanced neuronal activity. Herein we show that the monoamine and beta-adrenergic

receptor agonist can significantly increase the release of MMP-3 and -9 from cultured murine hippocampal neurons and astrocytes. We also, demonstrate that mice treated with the antidepressant venlafaxine have increased levels of Pro MMP9 and PSD-95. Golgi staining of pyramidal neurons in cortex showed an increase in the dendritic number of branches at the level of the second order in the Cortex of wild type mice treated with venlafaxine but not in MMP9-KO mice. Evaluation of PNN in venlafaxine treated mice showed reduced PNN intensity and an increase in cleavage fragment of aggrecan, one of the main PNN structural protein. Ongoing studies are evaluating the effect of venlafaxine on the neuronal dynamics by examining sharp wave ripples (SWR), which are population events in the hippocampus that can be increased by disinhibition of pyramidal cell excitability.

Title: Differential effects of monoamine uptake inhibitors on effort-related choice behavior and DARPP-32 phosphorilation patterns

Authors: *C. CARRATALÁ-ROS[1], R. OLIVARES-GARCÍA[2], P. IBÁÑEZ-MARÍN[2], A. MARTÍNEZ-VERDÚ[2], J. D. SALAMONE[3], M. CORREA[2]

Abstract: Vigor, persistence, and work output are fundamental features of normal motivation. Nucleus Accumbens (Nacb) dopamine (DA) regulates behavioral activation and effort-related decision-making in motivated behavior, and DA depletion has been shown to induce anergia and fatigue in effort-based decision tasks in humans and animals. These motivational symptoms are seen in pathologies such as depression and are highly resistant to treatment. In the present work, we evaluate the impact of DA depletion by the administration of Tetrabenazine (TBZ), a VMAT2 blocker that has been reported to induce depression in humans. We also assessed the effect of Bupropion (BUP) that blocks DA uptake and Fluoxetine (FLUOX) that blocks

serotonin (5-HT) uptake. CD1 male mice received TBZ (0, 4, 6 or 8 mg/kg, IP), BUP (0, 5, 10 or 15 mg/kg, IP) or FLUOX (0, 10, 15 and 20 mg/kg, IP). Anergia was evaluated in a mouse T-maze task developed for the assessment of preference between physical activities (running in a RW) in one arm vs. sedentary reinforcers (freely available sucrose pellets) in another arm, as well as, a non-social odor in the third arm. In addition, DA receptor-activity-related markers (pDARPP32-Thr75 and Thr34) in Nacb were assessed using immunoblotting. In the T-maze, control mice spent more time running and less consuming sucrose or sniffing. TBZ produced a shift in the relative preference, reducing selection of the reinforcer that involved vigorous activity, but increasing consumption of a reinforcer that required little effort (sucrose). Although BUP did not have an effect on its own, it was able to reverse the shift in preferences induced by TBZ, restoring normal levels of performance. FLUOX produced a similar shift to TBZ, reducing time running in the RW but increasing time consuming sucrose pellets, moreover, FLUOX was not be able to reverse the effect of TBZ and, in fact, exacerbated it. BUP behavioral effects were parallel to phosphorylation changes in DARPP32, but not FLUOX. These results indicate that drugs acting on DA transmission are effective at reversing the anergia-inducing effects of TBZ, and are consistent with the hypothesis that drugs that enhance DA transmission may be effective to improve depressive symptoms related to reduced behavioral activation.

Title: Pharmacological inhibition of cell proliferation prevents the antidepressant and increased neurogenic effects induced by repeated electroconvulsive shock treatment in rats

Authors: *J. GARCIA-FUSTER, R. GARCIA-CABRERIZO
IUNICS. Univ. of the Balearic Islands, Palma, Spain

Abstract: Electroconvulsive shock (ECS) is an alternative treatment used in psychiatry that offers a safe, rapid and potent therapeutic effect in major depressive disorders. The basis for its

therapeutic effect is still unknown, although a special attention has been given to the role of neuroplasticity markers in the hippocampus, such as hippocampal neurogenesis. Previous data from our research group demonstrated a temporal and parallel course regulation for the antidepressant and increased neurogenetic effects induced by repeated ECS in rats suggesting hippocampal neurogenesis may play a role on the antidepressant-like effect induced by repeated ECS. To corroborate this idea, the present study evaluated whether the pharmacological inhibition of basal cell proliferation with temozolamide (TMZ) would prevent the benefitial effects exerted by ECS on behavior (i.e., antidepressant-like response) and brain function (i.e., increased hippocampal cell genesis). To address this, adult male Sprague-Dawley rats were treated with 2 cycles of TMZ (each cycle: 25 mg/kg, i.p., 5 days, two days rest in between cycles, n=21) or vehicle (V: 1 ml/kg DMSO, i.p., n=19). Every day during the second cycle, 3 hours after the daily injections, rats from each group received a single ECS session (95 mA, 0.6 sec, 100 Hz, via earclip electrodes, 1 session/day, 5 sessions) (TMZ-ECS, n=11 vs. V-ECS, n=11) or were connected to earclips eletrodes but without electrical current (TMZ-SHAM, n=10 vs. V-SHAM, n=8). The possible effect of TMZ on preventing the antidepressant-like effect induced by repeated ECS was evaluated in the forced-swim test in a time-course manner (1, 3 and 7 days after the last ECS session). Repeated ECS induced a temporal antidepressant-like effect by reducing immobility time up to 3 days after the last ECS session (Day 1: -68±23 sec, $p<0.05$; Day 3: -80±23 sec, $p<0.01$; Day 7: -27±23 sec, $p>0.05$; V-ECS vs. V-SHAM). Interestingly, these effects were prevented in animals treated with TMZ (Day 1: -25±20 sec, $p>0.05$; Day 3: -19±20 sec, $p>0.05$; Day 7: -15±20 sec, $p>0.05$; TMZ-ECS vs. TMZ-SHAM). In addition, the expected increase in hippocampal cell proliferation induced by ECS was also reduced in rats treated with TMZ (Day 1: -365±101 Ki-67+ cells, $p<0.05$; V-ECS vs. TMZ-ECS). Current studies are evaluating the regulation of other cell genesis markers (i.e., neuronal survival) in TMZ treated rats and its interaction with the course of ECS antidepressant-like response. So far, these results demonstrate that inhibiting cell proliferation in rats prevents ECS treatment to exert its expected antidepressant and neurogenic effects.

Title: Effects of chronic lithium exposure in a ketamine-induced hyperactivity model of mania

Authors: J. KRUG[1], A. KLEIN[1], E. M. PURVIS[1], K. AYALA[1], M. MAYES[1], L. COLLINS[1], M. P. A. FISHER[2], *A. ETTENBERG[3,1]
[1]Psychological & Brain Sci., [2]Physics, [3]Univ. of California, Santa Barbara, CA

Abstract: Bipolar illness is a psychiatric disease characterized by acute periods of "mania" -- high energy, irritability, and increased psychomotor activation. Unfortunately, there is a paucity of animal models of mania, which are needed for investigations of the underlying neurobiological basis of the disease and to screen for prospective pharmacotherapies. One recent rodent model has been proposed in which motoric hyperactivity is induced over days by repeated administration of sub-anesthetic doses of ketamine – an effect reversed by co-administration of lithium (the primary treatment for bipolar illness). Current applications of this model have, however, employed limited exposure to lithium (typically 15 days), and extremely brief (i.e., 5-min) tests of locomotor behavior. To increase the face validity and translational utility of the test, the current study examined the impact on ketamine-induced hyperlocomotion during extended 30-min test sessions after 80 days of lithium exposure. Male albino rats consumed 2.0mEq/kg of lithium chloride presented daily in a high incentive food source (8 gm of sweetened peanut butter). Control animals ingested peanut butter infused with an equimolar concentration of sodium chloride to control for the salty taste of the food. During the final 11 days of treatment, animals were injected daily with a single dose of 25 mg/kg IP ketamine (in a volume of 1.0 ml/kg). A subset of animals received a comparable volume of IP 0.9% physiological saline and served as vehicle controls. Locomotor testing was conducted during test sessions both before ketamine injections were initiated and on the final day of treatment. The test apparatus consisted of a bank of 10 activity chambers each equipped with infrared sensors interfaced with a desk-top computer running custom software that measured the subjects' movement within the apparatus. Results confirmed that repeated ketamine administration produced a profound increase in locomotor activity relative to non-ketamine controls. Additionally, while lithium did not in and of itself alter locomotor activity, lithium-treated rats exhibited a highly reliable reduction in ketamine-induced locomotion compared to animals on the control diet. Blood samples obtained at the conclusion of testing, confirmed lithium plasma levels of 0.6mEq/L, comparable to low-moderate therapeutic levels in human patients. These data strongly confirm the viability and utility of ketamine-induced hyperlocomotion as a rodent model of mania.

Title: Characterization of corticotropin-releasing hormone expressing cells in the anterior cingulate cortex of human subjects

Authors: *H. OH[1], D. A. LEWIS[2], E. SIBILLE[3]
[1]Neurobio. of Depression and Aging, CAMH, Toronto, ON, Canada; [2]Dept Psychiatry, Univ. Pittsburgh, Pittsburgh, PA; [3]CAMH - Univ. of Toronto, Toronto, ON, Canada

Abstract: *Introduction.* Corticotropin-releasing hormone (CRH) is implicated in a wide range of psychiatric illness. Our recent meta-analysis of 8 transcriptome studies revealed significant downregulation of CRH across 3 corticolimbic brain regions of major depressive disorder (MDD) subjects, suggesting that CRH-expressing cells are affected by disease. It is known that CRH is expressed in subgroups of neurons, mostly GABAergic interneurons in mouse cortex, however, CRH (+) cells are less characterized in human brains. The aim of this study is to investigate the cellular identity of CRH (+) neurons in human cortex. *Methods.* Using fluorescent in situ hybridization, we labeled cells in the human anterior cingulate cortex (ACC, Brodmann area 25) with probes targeting CRH and markers of excitatory (SLC17A7), inhibitory (GAD1) neurons, as well as three major subtypes of inhibitory interneurons (PVALB, SST, VIP). Coexpression patterns of CRH and cellular markers were analyzed. In parallel, CRH expression level was quantified using qPCR in the ACC of MDD subjects and matched controls (n=6/group). *Results.* CRH labeled 27% of GAD1-expressing GABA neurons. 80% of CRH (+) cells were GABAergic and 10% was glutamatergic. CRH (+) GABA neurons coexpressed markers of subpopulation of interneurons: VIP (52%), SST (7%), PVALB (7%). Notably 34% of CRH (+) cells expressed GAD1, but none of three GABA interneuron markers. CRH expression was significantly reduced in the brains of MDD patients compared to control (-24.4%, p=0.018). *Conclusions.* CRH is mainly expressed in GABAergic interneurons with 52% of CRH (+) neurons overlapping with VIP (+) interneurons and 34% expressed in a separate subgroups of interneurons which do not belong to three major interneuron populations. We confirm that CRH expression is significantly reduced in the brains of MDD patients, raising the question as to which CRH (+) GABAergic interneuron population is affected in MDD.

Title: Distinct roles for 5-ht1b and 5-ht2a in antidepressant response

Authors: *Y. SAGI[1], L. MEDRIHAN[2], Z. INDE[2], O. KRUPA[2], C. DANIELS[2], A. PEYRACHE[4], P. GREENGARD[3]

Abstract: Selective serotonin reuptake inhibitors are the most commonly used class of antidepressant drugs, but the cellular and molecular mechanisms by which their therapeutic action is initiated are poorly understood. Here we used a Translating Ribosome Affinity Purification (TRAP) strategy to determine the expression level of serotonin receptors in hippocampal neurons in mice, and found that 5-HT1B and 5-HT2A receptors are highly expressed in cholecystokinin (CCK) inhibitory interneurons of the dentate gyrus. Using conditional knockout strategy, it was found that 5-HT1B receptors in these cells mediate the initiation of the therapeutic response to antidepressants, whereas 5-HT2A receptors in these cells mediate their chronic effects. We describe the mechanisms by which these two receptors regulate CCK cells function and explain how p11, a protein associated with depression and antidepressant response, differentially regulate the function of these two 5-HTR pathways.

Abstract: Altered γ-aminobutyric acid (**GABA**) function is frequently reported in psychiatric disorders, normal aging and neurodegenerative disorders. Reduced function of somatostatin (SST)-expressing GABA interneurons is associated with both mood and cognitive symptoms. SST/GABA-neurons signal in part through α5-subunit containing GABAA receptors (α5-GABAA-Rs) which are localized in brain regions involved in the regulation of emotion and cognition. We hypothesize that enhancing α5-GABAA-R activity has therapeutic potential for both mood and cognitive symptoms in stress-based and aging rodent models. Our group synthesized novel imidazobenzodiazepine (IBZD) amide ligands, tested them for positive allosteric modulation at α5-GABAA-R (α5-PAM), pharmacokinetic properties, and for potential anxiolytic and antidepressant activities in adult mice using escalading doses. Pro-cognitive activity was tested in adult mice submitted to chronic stress and in old mice using a spontaneous alternation task, assessing working memory performances. Diazepam (DZP), with broad PAM activity at GABAA-Rs, was used as a control. Three novel IBZD amide ligands (namely GL-II-73, GL-II-74 and GL-II-76) demonstrated adequate brain penetration, affinity and PAM activity at α5-GABAA-Rs, and metabolic stability for in vivo studies. GL-II-73/74/75 showed significant anxiolytic and antidepressant efficacies in adult mice. Moreover, GL-II-73 and GL-II-75 significantly reversed cognitive deficits induced by stress or occurring during normal aging. This activity was maintained after sub-chronic administration for GL-II-73. In contrast DZP displayed anxiolytic but no antidepressant or pro-cognitive activities. For the first time, our group demonstrated the potential for combined efficacies of newly designed IBDZ amide ligands mediated by efficacy at α5-GABAA-Rs, reducing anxiety and depression and enhancing cognitive performances. These results suggest a novel therapeutic approach targeting both mood and cognitive symptoms in depression and/or aging.

Title: Characterization of high-fat-diet-induced treatment-resistant depressive-like brain state: Neural hyperexcitability and responsiveness to the anticonvulsant retigabine

Authors: *M. FENG, N. A. CROWLEY[1], A. PATEL[1], Y. GUO[1], S. E. BUGNI[1], F. K. MALDONADO[2], B. LUSCHER[3]
[1]Biol., [2]Biochem & Mol, [3]Dept Biol, Dept Biochem & Mol, Penn State Univ., University Park, PA

Abstract: Excessive consumption of fat-rich diet and obesity are associated with neuroinflammation and increased vulnerability to psychiatric disorders including Major Depressive Disorder (MDD), a heterogeneous syndrome caused by both genetic vulnerabilities and environmental factors. Of particular interest are treatment resistant forms of MDD that fail to respond to current antidepressants and may or may not be responding to experimental treatment with subanesthetic ketamine. Increasing clinical evidence suggests that treatment resistance is associated with neuroinflammation and obesity, while obesity is independently linked to neuroinflammation. To start to elucidate possible mechanisms underlying treatment resistant MDD, we here established a High Fat Diet (HFD)-induced mouse model of a depressive like brain state. We exposed C57BL/6J mice to HFD for 18 weeks followed by analyses of glucose tolerance and markers of inflammation. HFD exposure of male mice resulted in glucose intolerance, increased microglial activation and elevated expression of the inflammatory cytokines interleukin-1β, tumor necrosis factor-αand interleukin-6. Similar but insignificant trends were observed in female mice. Behaviorally, the HFD induced inflammation of male mice was associated with anxious-depressive-like phenotypes in the novelty suppressed feeding test, female urine sniffing test, sucrose splash test and Y-maze. Slice recordings of HFD-treated animals revealed increased intrinsic excitability of pyramidal neurons in the medial prefrontal cortex, along with increased hyperpolarization-activated cation currents (I_h). Curiously, HFD-induced behavioral defects were resistant to chronic treatment with the conventional antidepressants, desipramine (40 mg/kg/d) and fluoxetine (18 mg/kg/d) except for the novelty suppressed feeding test, where both drugs elicited anxiolytic effects. Additionally, HFD induced depressive-like phenotypes were largely insensitive to acute treatment with the experimental

antidepressant ketamine (6 mg/kg), except for antidepressant-like effects in the forced swim test. Interestingly, systemic chronic treatment of mice with the anticonvulsant retigabine (1mg/kg/d, 8 d), a voltage-gated K+ channel opener that reduces neural excitability, normalized the $I_h$currents and partially reversed the HFD-induced behavioral defects. Our data suggests that HFD-induced inflammation leads to increased intrinsic excitability that underlies a treatment-resistant depressive-like brain state that can be ameliorated pharmacologically by agents that reduce neural hyperexcitability.

Title: Effects of the serotonin transport inhibitor fluoxetine on effort-related decision making in male and female rats

Authors: *E. HURLEY[1], R. ROTOLO[1], R. PRESBY[1], H. MCMULLEN[1], B. YE[1], M. FLYNN[1], J.-H. YANG[1], M. CORREA[3], J. D. SALAMONE[2]

Abstract: Major depressive disorder (MDD) is characterized by behavioral, cognitive, and mood-related symptoms. In addition, motivational symptoms such as anergia and fatigue are common facets of MDD. Depressed individuals show signs of anergia/fatigue that correlate with overall severity of symptoms, as well as effort-related dysfunctions and amotivation. Inhibitors of 5-HT uptake, known as serotonin transport (SERT) inhibitors, are the most commonly prescribed antidepressants, but treatment with SERT inhibitors is often accompanied by residual motivational symptoms that are resistant to treatment. Moreover, when compared to other antidepressants such as bupropion (Wellbutrin), SERT blockers are more likely to induce symptoms of sleepiness and fatigue. Due to the limitations and adverse effects of SERT blockers, there is a need to establish models for exploring the mechanisms underlying the motivational problems associated with these drugs. Our laboratory has developed behavioral tasks that allow rats to choose between high-effort alternatives that lead to more highly valued rewards vs. low-effort options that lead to less valued rewards. Depressed people show a low-effort bias in human tests of effort-related decision making, and rat studies report that conditions associated with

depression can induce changes in effort-based choice. Importantly, research from our laboratory shows that the SERT inhibitors fluoxetine (FLX; Prozac) and citalopram fail to reverse the effort-related effects of the dopamine depleting agent, tetrabenazine, and in fact tend to exacerbate them. The present studies were undertaken to characterize the effects of FLX on effort-related decision making in male and female rats. FLX (5.0-15.0 mg/kg IP) significantly reduced selection of running wheel activity, and also suppressed lever pressing but not chow intake in males and females tested on a concurrent choice task. Currently, several receptor subtypes are being studied as targets for psychiatric disorders. However, highly selective 5-HT2A and 5-HT2C receptor antagonists were not able to reverse the motivational impairments associated with FLX administration. This indicates the need to study non-selective 5-HT receptor antagonists such as mianserin, or antagonists at other receptors such as 5-HT1B, 3, 6, or 7, for reversing FLX-induced deficits. Elucidating the roles of specific 5-HT receptors could lead to a greater understanding of the neurochemical mechanisms that regulate effort-related aspects of motivation, and ultimately, could foster the development of possible treatments that augment the therapeutic efficacy of serotonin uptake inhibitors.

Title: Sex differences in duloxetine efficacy for depression: Estrogen dependency study in transgenic mouse models

Authors: *R. LI[1], Y. XU[2], L. MA[2], Y. LI[3], G. WANG[2]
[1]Ctr. for Hormone Advanced Sci. and Educ. (CHASE), Roskamp Inst., Sarasota, FL; [2]The Natl. Clin. Res. Ctr. for Mental Disorders,, Beijing Anding Hospital, Capital Med. Univ., Beijing, China; [3]Beijing Inst. for Brain Disorders,Capital Med. Univ., Beijing, China

Abstract: Clinical evidences show sex differences in risk of developing depressive disorders as well as effect of antidepressants in depression treatment. However, whether such a sex-dependent risk of depression and efficacy of antidepressants is dependent on endogenous estrogen level remain elusive. The aim of this study is to explore the molecular mechanisms of

sex differences in antidepressant duloxetine. In the present study, we used genetic knockout or overexpression estrogen-synthesizing enzyme aromatase (Ar) gene as models for endogenous estrogen deficiency and elevation endogenous estrogen, respectively, to examine the antidepressive efficacy of duloxetine in males and females by force swimming test (FST). We also measured the sex-specific effect of duloxetine on dopamine and serotonin metabolisms in frontal cortex and hippocampus. Elevation of brain endogenous estrogen in male and female mice showed a reduction of immobility time in FST compared to control mice. Estrogen deficiency in females showed poor response to duloxetine treatment compared to sex-matched wildtype or aromatase transgenic mice. In contrast, male mice with estrogen deficiency showed same anti-depressive response to duloxetine treatments as aromatase transgenic mice. Our data showed that the sex different effect of endogenous estrogen on duloxetine-induced anti-depressive behavioral change is associated with brain region-specific changes of DA and 5-HT system. Endogenous estrogen exerts antidepressant effects in both males and females. Lacking of endogenous estrogen is responsible for poor response to duloxetine in females only. The endogenous estrogen level alters 5-HT system in female mainly, while both DA and 5-HT metabolisms were regulated by endogenous estrogen levels after duloxetine administration.

Title: Escitalopram in the endoplasmic reticulum

Authors: *A. L. NICHOLS[1], P. M. BORDEN[3], A. V. SHIVANGE[1,3], A. KAMAJAYA[1], A. K. MUTHUSAMY[2], L. LUEBBERT[4], J. S. MARVIN[3], L. L. LOOGER[3], H. A. LESTER[1]
[1]Biol. and Biol. Engin., [2]Chem., Caltech, Pasadena, CA; [3]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [4]Leiden Univ., Institute of Biology, Netherlands

Abstract: Serotonin selective uptake inhibitors (SSRIs) are commonly used and partially effective for major depressive disorder. After SSRIs bind the serotonin transporter (SERT) on the plasma membrane (PM), an incompletely known set of processes generate the anti-depressant

effect. SSRIs also permeate into the endoplasmic reticulum (ER) and *cis*-Golgi, and bind to nascent SERT. Downstream effects, such as pharmacological chaperoning of SERT by SSRIs, may partially underly therapeutic effects of SSRIs. Investigation of this and / or similar actions requires direct proof, quantification, and time resolution of these processes in live cells and brains. We are developing genetically encoded fluorescent biosensors to study the subcellular pharmacokinetics of SSRIs.
OpuBC, a monomeric bacterial periplasmic binding protein (PBP), has (a) a binding site for amines including a cation-π box, and (b) ligand-induced "Venus flytrap" conformational change involving relative motions of two domains. We insert circularly permuted "superfolder" GFP (cpGFP), flanked by several-residue linkers, within inter-domain hinge regions. We apply directed evolution, including X-ray crystallography, to optimize the sensing of drugs, and have achieved the goal of $\Delta F/F0 > 1$ at 1 μM for several drug-biosensor pairs.
Our most detailed studies for SSRIs thus far use "**i**ntensity-based **escitalopram**-**s**e**n**sing **f**luorescent **r**eporters" (iEscitalopramSnFRs). We insert targeting and retention sequences to direct the constructs to the ER or to the PM of clonal mammalian lines and cultured neurons. Live-cell video imaging shows that, after we jump [escitalopram] (increase or decrease) near cells, the drug appears in the ER within < 10 s and leaves within <20 s, reaching a plateau within 20 and 30 s, respectively. Responses are robust, even at the sub-μM steady-state [escitalopram] in the cerebrospinal fluid of human subjects.
We are developing other iDrugSnFRs for other SSRIs including fluoxetine and paroxetine. Further application of these tools will show the initial steps in the pathway of SSRI intracellular pharmacokinetics, allowing study of the role "inside-out" neuropharmacology plays in major depressive disorder.

Title: Effects of selective depletion of CREB in serotonergic neurons on neurotrophin expression after fluoxetine treatment

Authors: *K. RAFA-ZABLOCKA, G. KREINER, M. BAGINSKA, I. NALEPA
Dept. Brain Biochem., Inst. of Pharmacology, PAS, Krakow, Poland

Abstract: Neurotrophins are a family of growth factors consisting of brain derived neurotrophic factor (BDNF), nerve growth factor (NGF) and neurotrophin-3 (NTF-3). They play crucial role in maintaining survival, development and plasticity of neurons. Moreover, according to neurotrophic hypothesis of depression they are thought to be involved in the pathogenesis of illness itself as in the mechanisms of action of antidepressant treatment. In particular, it has been shown that after long-term administration of common antidepressants level of BDNF protein or mRNA expression increases. One of the promoter site of BDNF gene is regulated by cyclic AMP response element binding protein (CREB), so BDNF upregulation can be induced by this transcription factor. On the other hand, BDNF itself can trigger CREB phosphorylation thus creating a positive feedback loop.
In our studies we investigated the role of CREB in the mechanism of antidepressant treatment using novel, inducible transgenic mouse model lacking CREB selectively in serotonergic neurons ($Creb1^{TPH2CreERT2}$). Moreover, animals were depleted of CREM factor to exclude the compensatory effects of its upregulation upon CREB deletion. Our previous research showed no differences in basic behavior between mutant and wild type animals, while their responsiveness to acute fluoxetine was abolished in tail suspension test. In current study we assessed the mRNA synthesis and protein levels of three neurotrophic factors: BDNF, NGF, NTF3 as well as CREB in hippocampus and prefrontal cortex of mutant animals chronically treated with fluoxetine (10mg/kg ip., 1x daily for 21 days).
Our main findings confirmed the observed in other studies fluoxetine-induced upregulation of BDNF in hippocampus (males and females) and prefrontal cortex (only females) in wild type mice. However, in animals deficient in CREB in serotonergic neurons we observed no such changes in BDNF protein after drug. What is more, male mutants show increase in NGF and NTF3 levels in prefrontal cortex after fluoxetine administration, which effect is absent in wild type animals.
In conclusion, we have shown for the first time that BDNF upregulation in hippocampus or prefrontal cortex observed after fluoxetine administration might be dependent on the transcription factor CREB resident not within these particular structures targeted by serotonergic projections, but exclusively in serotonergic neurons. These results may shed a new light on neurotrophic hypothesis of depression linking CREB activity and BDNF level within distinct brain areas.

Title: Comparison between male and female mice in behavioral activation and effort-related decision-making: Involvement of dopamine related markers

Authors: *M. CORREA[1], C. CARRATALA-ROS[1], A. MARTÍNEZ-VERDÚ[1], P. IBÁÑEZ-MARÍN[1], R. OLIVARES-GARCÍA[1], S. PORRU[1], J. D. SALAMONE[2]
[1]Psicobiologia. Univ. Jaume I, Castello, Spain; [2]Dept Psychological Sci., Univ. of Connecticut, Storrs Mansfield, CT

Abstract: Impairments in behavioral activation and effort-related symptoms are commonly seen in people with depression. These motivational symptoms, such as psychomotor retardation and anergia, are highly resistant to treatment. Nucleus Accumbens dopamine (DA) regulates behavioral activation and effort-related decision-making. In the present work, we study, in female and male CD1 adult mice, the impact of DA depletion with Tetrabenazine (TBZ), a vesicular monoamine transporter type 2 blocker, that has shown to induce depression in humans, on preference for activity-based reinforcers in a T-maze-RW-sucrose-task, developed for the assessment of preference between physical activities that require vigor (running in a RW) in one arm vs. sedentary reinforcers (freely available sucrose pellets) in another arm, as well as, a non-social neutral odor in the third arm. In addition, we also evaluated the impact of TBZ in the Forced-Swim-Test (FST). Under vehicle conditions, female and male mice spent the same time in the RW. TBZ reduced RW preference, but increased preference for sucrose in both sexes. In the FST, TBZ increased passive behaviors (immobility) in both sexes, but had a bigger impact on active behaviors (climbing) in male mice. TBZ had a similar impact in both sexes in terms of DARPP-32 phosphorilation patterns. These results indicate that DA is involved in vigorous and sustained behavioral activation, and DA depletion alters effort-related preferences and behavioral activation. Studies in animal models of both sexes are important in order to address potential sex differences in vulnerability to anergia in depression.

Title: Transcriptional coregulators LIM domain-binding protein 1(Ldb1) and LIM-domain-only protein 1(LMO1) modulate Lmx1b-mediated activation of the human tryptophan hydroxylase-2 promoter

Authors: H. KANEKO[1], Y. NAWA[1], M. TSUBONOYA[1], T. HIROI[1], R. TAKAHASHI[2], *H. MATSUI[3]
[1]Inst. RI Res, St. Marianna Univ. Grad Sch. Med., Kawasaki, Japan; [2]Dept Biochem, Fac Pharm Sci, Toho Univ., Funabashi, Japan; [3]Dept Mol Behav Neurosci, St. Marianna Univ. Grad Sch. Med., Kawasaki, Kanagawa, Japan

Abstract: Tryptophan hydroxylase-2(TPH2) plays an essential role in the regulation of 5-HT neurotransmission and is thus a promising therapeutic target for the treatment of neuropsychiatric disorders. The mechanism by which TPH2 gene expression is regulated still remains an open question. Lmx1b, a member of LIM-homeodomain (LIM-HD) family of transcription factors, contains two N-terminal LIM domains, a central DNA-binding homeodomain, and a C-terminal transactivation domain. Lmx1b is required for regulation and maintenance of normal functions of 5-HT neurons including transcriptional regulation of the TPH2 gene. LIM domain-binding proteins (Ldb1 and Ldb2) were discovered because of their ability to bind to LIM-HD proteins and LIM-domain-only (LMO) proteins (LMO1 to 4). It is conceivable that Ldbs bind to LIM domains of Lmx1b, thereby modulating Lmx1b-mediated regulation of the TPH2 gene expression. Moreover, it is postulated that LMOs modulate the transcriptional activity of Ldb-Lmx1b complexes by competing with Lmx1b for binding to Ldbs. In this study, to address these questions more directly, we examined how the human TPH2 (hTPH2) promoter activity changes by Lmx1b, Ldbs and LMOs. A 2-kb promoter region of the hTPH2 gene (-1850/+141) was cloned into pGL4-Basic (TPH2-55) and a mutant having deletion of its 5'-untranslated region (+10/+121; a region containing potential repression elements) was constructed (TPH2-100). Promoter activities were assessed by transient transfections into RN46A cells, a cell line derived from rat raphe neurons. Sequence analysis revealed two potential Lmx1b binding sites (-1418/-1409 and -950/-945) in the hTPH2 promoter. To facilitate analysis of the transactivation function of Lmx1b, an expression vector for the VP64 (promiscuous activator domain derived from HSV)-Lmx1b fusion protein was prepared. Overexpression of VP64-Lmx1b fusion protein increased promoter activity of TPH2-100. Mutation analysis revealed that both Lmx1b binding sites were critical for Lmx1b-mediated activation of the hTPH2 promoter. Quantitative real-time RT-PCR analysis revealed the expression of Ldb1, Ldb2, LMO1, LMO2 and LMO4 genes in RN46A cells. Co-expression study demonstrated that Ldb1 was more potent than Ldb2 in enhancing Lmx1b-mediated activation of the hTPH2 promoter. In turn, Ldb1-mediated enhancement was remarkably attenuated by co-expression of LMO1, LMO2 or LMO4. Among tested, LMO1 was the most potent. Altogether, these results imply that Ldb1 and LMO1 modulate Lmx1b-mediated activation of the hTPH2 promoter and ultimately regulate 5-HT synthesis in the brain.

Abstract: Anxiety is a debilitating disorder with high prevalence and co-morbidity across multiple psychiatric diseases. Evidence from both clinical and preclinical studies suggest that the biological bases of anxiety and depression are associated with chronic exposure to stress. To identify the biological bases of anxiety-like behavior, rodent models have either studied the acute response to stress or acutely measured the effect chronic stress exposure. Little is known about the longitudinal progression of anxiety-like behavior. Most commonly used tests such as the open field test (OFT), elevated plus maze (EPM), novelty suppressed feeding (NSF) require a novelty component that undermines their ability to be used repetitively. Additionally, they measure behavior over a short duration, rely highly on housing and testing conditions and are subject to experimenter bias. Here, we have designed and validated a novel behavioral assay to measures anxiety-like behavior devoid of these limitations. Using a home cage-like apparatus (Noldus Phenotypers) we monitored baseline behavior by measuring time spent in designated zones (food and shelter zones) for a 12h period overnight. To assess anxiety-like behavior a 1h light challenge was applied over the food zone, 4h into the night. In this study, C57Bl/6 and Balb/c (n=12/group 50%♀) mice were subjected to chronic restraint stress (CRS) or unpredictable chronic mild stress (UCMS) for 5 weeks. Weekly assessments using the phenotyper plus a series of classical tests (OFT, EPM, and NSF) were performed at the end of the 5 weeks of stress exposure. Both literature and work in our lab have found that animal performances in classical behavioral tests show high heterogeneity not only across stress paradigm, strain and stress but also across test. Across experimental conditions and experiments (UCMS vs CRS, Balb/c vs C57Bl/6, male vs female) it was evident every week during the stress exposure that the phenotyper test could detect anxiety-like behavior (avoid the food zone, favor

the shelter during/after challenge). We also confirm baseline and anxiogenic response. Ongoing experiments will identify whether this assay can detect the potential reversal of induced anxiety-like behavior in control and stress conditions with treatment of diazepam. Altogether this new assay provides consistent and robust results as exhibited across different stress models, sexes and strains and can potentially be used to measure anxiety-like behavior repetitively. This novel tool should be instrumental in the design of longitudinal studies aiming to better understand the biological bases of chronic anxiety disorders and others stress-related illnesses.

Title: Investigating the neurobiological correlates of antidepressant treatment response: Findings from a novel rat model of treatment resistant depression

Authors: *C. AYDIN, P. BLANDINO, E. HEBDA-BAUER, H. AKIL
molecular and behavioral neuroscience institute, Universty of Michigan, Ann Arbor, MI

Abstract: According the World Health Organization (2017) depression is the leading cause of disability worldwide affecting over 300 million people. Despite the availability of multiple modalities of antidepressant (AD) medications, fewer than half of depressed patients achieve full remission with a first line of treatment. Moreover, a significant percentage of patients are resistant to all available AD treatments. In an effort to understand the neurobiological mechanisms of antidepressant response versus resistance, we created an animal model of treatment-resistant depression using the bred High Responder-Low Responder (bHR, bLR) rats. These animals are selectively-bred in our laboratory, and differ in their emotional reactivity to environmental manipulations. In order to induce a depressed-like state in these rats, we employed a multiple-hit (MH) regimen starting in adolescence. Our data showed that this stress regimen induced affective resilience in bLRs, but vulnerability in bHRs to a stress challenge in adulthood, suggesting that environmental challenges encountered in adolescence interact with genetic background to alter affective behavior later in life. Interestingly, our data showed that

genetic background determined antidepressant response as well; a 2-wk treatment with a selective serotonin reuptake inhibitor, fluoxetine (FLX), following the MH regimen was effective in control bLRs, but ineffective in control bHRs. Moreover, FLX failed to reverse the depressed-like state observed in bHRs following multiple hits, whereas treatment with a tricyclic AD, desipramine (DMI), was successful in this measure. Using hippocampi from the FLX-resistant, and DMI-responsive bHRs we performed an RNA sequencing (RNAseq) experiment to identify the molecular correlates of AD treatment response versus resistance. Key findings from our analyses of the RNAseq data will be presented.

Abstract: The hippocampal CA1 pyramidal cells (CA1PCs) play an important role in fear memory formation. These cells associate aversive stimuli conveyed by the entorhinal cortex to their distal dendrites, with the multisensory environmental contextual information conveyed by CA3 pyramidal cells to their proximal dendrites. However, the direct entorhinal input has to be excluded from most of the CA1PCs at the moment of fear conditioning to ensure precise contextual memory encoding. Oriens-lacunosum molecure (OLM) interneurons can exclude those direct entorhinal inputs, by inhibiting the distal dendrites of CA1PCs and they are activated by salient sensory information via glutamatergic and cholinergic inputs from the basal forebrain. However, for certain events, memory encoding is unnecessary, and OLM cells may need to be inhibited. It was unknown whether OLM cells receive any extrahippocampal inhibitory input that could fulfill this role. Using vesicular GABA transporter (vGAT)-Cre mice, here, we show that the GABAergic cells of the pontine nucleus incertus (NI) selectively inhibit OLM cells directly

and also indirectly via the inhibition of basal forebrain cholinergic and glutamatergic cells. Contextual fear conditioning experiments showed that optogenetic activation of NI GABAergic cells during aversive inputs can effectively disrupt, while their optogenetic inhibition can excessively enhance contextual fear memory formation. Using Cre-dependent monosynaptic rabies tracing, we also show that NI GABAergic cells receive inputs from forebrain areas related to the processing of salient environmental information. Two-photon calcium-imaging in head-restraint behaving mice showed that in vivo, NI GABAergic fibers are preferentially activated by salient sensory stimuli. Furthermore, in vivo optogenetic stimulation of NI changed the properties of the hippocampal theta-rhythm in freely moving mice. Finally, in vitro optogenetic stimulation of NI fibers decreased the frequency of sharp-wave ripple events in hippocampal slices suggesting a role of NI in the regulation of memory consolidation. These results suggest that by specifically controlling the activity of OLM cells, NI GABAergic cells can heavily influence the right balance between hippocampal contextual memories that needs to be formed and kept and those that are unnecessary.

Abstract: The goal of our study was to investigate neuronal specializations in the retrosplenial cortex to a new environment and objects in it. To this end, we used in vivo two-photon calcium

imaging in mice during object-in-place recognition task. As two-photon imaging requires head fixation of animals, we used the Mobile Home Cage (MHC, Neurotar Ltd) setup - an air-lifted mobile cage, where a head-fixed animal can move around and explore the environment. First, we developed the object-in-place recognition task in the MHC on C57 Bl/6 mice with implanted headposts (Neurotar Ltd). Mice were habituated to the MHC conditions during 14 days with session time increasing from 10 to 50 min. The object-in-place task consisted of 7 sessions. During sessions mice explored empty MHC, MHC with new proximal cues, MHC with two novel objects, MHC with one of the familiar objects displaced (place recognition task), and MHC with a familiar and a novel object (object recognition task). We showed that mice actively explored MHC with cues and objects. In the place recognition task, mice spent more time exploring and sniffing the familiar object in the new location, demonstrating place recognition memory. In the object recognition task, animals preferentially explored and sniffed the novel object, demonstrating object recognition memory. After we successfully developed the MHC-based object-in-place task, we performed two-photon calcium imaging using GCaMP6 in the retrosplenial cortex during task sessions. We showed the responses of the retrosplenial neurons to different objects and locations through the imaging sessions.

Title: Permanent damage or chemogenetic inactivation of the postrhinal cortex impairs two forms of higher order conditioning

Authors: *T. L. CHAKOMA, E. K. DONAHUE, A. E. DENNEY, S. ROBINSON
Psychology Dept. and Neurosci. Program, Hamilton Col., Clinton, NY

Abstract: The postrhinal cortex (POR) provides a major source of visuospatial information to the hippocampal memory system and, similar to the retrosplenial cortex, is involved in a number of cognitive processes that require the formation of associations among environmental stimuli. To investigate the role of the POR in learning situations that require the formation of stimulus-stimulus associations, the effect of permanent electrolytic lesions or transient chemogenetic inactivation of the POR was evaluated in higher order sensory preconditioning studies that included either appetitive or aversive unconditioned stimuli. In Experiment 1, POR-lesioned or sham rats were exposed to two contexts that contained distinct visual, olfactory and auditory stimuli. In a subsequent classical conditioning phase, the salience of one of the auditory stimuli

was paired to an aversive footshock in a novel context while the other was not. Freezing behavior was analyzed upon re-exposure to the contexts and to the auditory stimuli in the absence of footshock. In separate cohorts of rats, higher order conditioning was evaluated following either permanent (Experiment 2) or transient (Experiment 3) inactivation of the POR. Specifically, during an initial learning phase, presentation of one auditory stimulus was paired with presentation of a visual stimulus whereas a second auditory stimulus was presented alone. Next, during a classical conditioning phase, the visual stimulus was paired with food. During a subsequent probe test, both auditory stimuli from the initial phase were presented individually and the amount of time spent in the food cup was assessed. The results from Experiment 1 and 2 revealed that the POR is necessary for rats to higher-order condition successfully, whereas the ability to form Pavlovian associations remained intact in the absence of POR signaling. Employment of a chemogenetic approach extended these findings by revealing that POR function is required for acquisition of stimulus-stimulus associations, but not for expression of higher order conditioning.

Title: The social context is a cognitive enhancer for episodic-like memory in Wistar rats

Authors: *P. E. MARINHO[1], M. A. S. FRANÇA[2], R. V. C. B. MOURÃO[2], F. F. BARBOSA[2]
[1]Dept. de Sistemática e Ecologia, [2]Univ. Federal da Paraíba, Joao Pessoa, Brazil

Abstract: Episodic memory is our capacity to recall when and where a specific event occurred, initially addressed as a unique human cognitive ability. However, some studies have provided evidence that other species, such as birds and mammals, are capable of some sort of encoding, consolidation and retrieval of episodic information. Nevertheless, the social nature of the non-human species investigated has been often under-emphasized or ignored in the design and interpretation of experiments. Thus, considering that the laboratory rat strains are domesticated forms of the species *Rattus norvegicus* – a highly social species –, we aimed to investigate the effect of the social environment on the performance of Wistar rats in an episodic-like memory task. We used a three-trial "what", "when" and "where" object exploration task, based on the novelty preference paradigm. Our protocol comprised 2 samples and 1 test. In the first sample, 4 equal objects (A) were arranged in the experimental apparatus. The second sample was carried out 1 hour later, in which 4 equal objects (B), different from those already presented to the

animals, were provided. Of these, 2 remained at spatial coordinates already occupied by A objects. After a delay of 24 hours, the subjects performed a test session containing 4 objects, all of which were already presented in the previous sessions. In this session, 2 objects maintained stationary positions in the apparatus (A1 and B1) and 2 were displaced (A2 and B2). Episodic-like memory integration can be inferred when the subjects explore “A1” more than “A2". We analyzed the behavior of 26 male individuals, allocated into 3 groups: the control group (GC), the co-habituated dyad group (HD), and the co-tested dyad group (TD). The GC group went through the processes of habituation to the experimental apparatus individually and carried out the episodic-like memory task individually. The HD group was subjected to habituation to the apparatus in dyads, but performed the task individually. As for the TD group, the rats went through all the experimental procedures in dyads. The results showed that only the TD group presented episodic-like memory. Also, the co-tested dyad rats explored for a longer period the objects used in the task. In addition, the behavioral analysis applied showed that the rats in dyads spent a long time together, expressed social behaviors and exhibited fewer anxiety-like responses. Putting together, these results stand out the importance of investigating the cognitive processes in a more naturalistic setting, as well as to explore ethologically-relevant parameters related to information processing and allocation of attention.

Title: VGlut1-expressing hippocampal neurons mediate stress-induced generalization of context memories

Authors: *L. Y. REN[1], J. M. RADULOVIC[2]
[1]Northwestern Univ. - Chicago, Chicago, IL; [2]Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Episodic memories must be encoded and maintained with specificity so that information about different environments is not generalized to unrelated novel environments. Stress promotes inappropriate generalization of memories, and mechanistic study of this may provide insight into the generalization of negative memories commonly seen in major depressive

and anxiety disorders and PTSD. While it is well established that excitatory transmission in the dorsal hippocampus is crucial for associating aversive events with the environmental contexts in which they occur, the role of hippocampal excitatory neurotransmission in stress-induced generalization of memories is less understood. As dorsal hippocampus excitatory efferents contain either vesicular glutamate transporter 1 (VGlut1) or 2 (Vglut2), we used Vglut1- and Vglut2-Cre mice to investigate their roles in stress-induced generalization of context memories. After training mice to associate a context with a fear-provoking stimulus, we exposed mice to social defeat stress. Under these conditions, mice that normally acquired fear responses begun to show generalization during testing in a novel context. We found that chemogenetic inhibition of vGlut1-expressing neurons in the dorsal hippocampus before memory tests prevented generalization of context fear. These results suggest that fear generalization is enhanced by social defeat stress, and this effect is mediated through vGlut1-positive hippocampal neurons. These results suggest that fear generalization is enhanced by social defeat stress, and this effect is mediated through vGlut1-positive hippocampal neurons.

Title: SUVN-502: A pure and selective 5-HT_6 antagonist alleviates phenytoin and topiramate induced cognitive impairments

Authors: *R. ABRAHAM, J. FERNANDES, V. REBALLI, R. NIROGI
Suven Life Sci., Hyderabad, India

Abstract: Anti-epileptics such as topiramate and phenytoin are known to induce memory deficits in epileptic patients. These anti-epileptics affect acquisition more adversely than retention. This is further worsened in aged population. In the current investigation we examined the effect of SUVN-502, a pure, potent and selective 5-HT_6 antagonist in conditions of cognitive deficits induced by topiramate and phenytoin. Doses of topiramate or phenytoin which disrupts acquisition was determined. The effect of SUVN-502 on cognitive deficits induced by topiramate or phenytoin was investigated. SUVN-502 was administered 60 minutes prior to trial and topiramate or phenytoin was administered 30 minutes before the trial. It was observed that SUVN-502 alleviated topiramate and phenytoin induced memory deficits in adult rats. A similar effect was observed in aged rats as well. Doses of SUVN-502 which reversed memory deficit did not affect the anti-convulsant properties of phenytoin or topiramate. Hence SUVN-502 can

alleviate learning deficits induced by anti-epileptics without adversely affecting their anti-epileptic property

Title: SUVN-D4010 (5-HT_4 receptor partial agonist) shows promising therapeutic potential for aged post-menopause state associated dementia and Alzheimer's disease

Authors: G. VENKATA RAMALINGAYYA, J. TADIPARTHI, N. GANUGA, H. TALAKANTI, P. JAYARAJAN, S. PANDRINKI, N. PATIBANDLA, *N. MUDDANA, A. RASHEED MOHAMMED, R. NIROGI
Suven Life Sci. Ltd., Hyderabad, India

Abstract: Evidence shows that post-menopausal women are highly susceptible to dementia and Alzheimer’s disease (AD) which will have great negative impact on quality of life (QOL). Although acetylcholine esterase (AChE) inhibitors, viz. donepezil or hormonal replacement therapy (HRT) were tried clinically, the outcome was not satisfactory. Moreover there could be potential risk of ovarian and breast cancers with HRT. No effective intervention is available or approved till date for cognitive deficits associated with post-menopause population. In our continued efforts in discovering new medications for the treatment of cognitive related ailments, the 5-HT_4 receptor partial agonist SUVN-D4010 was evaluated for its potential to alleviate the cognitive deficits associated with post-menopause state. Menopause state was induced in 7-8 weeks old female Wistar rats by surgical removal of ovaries (bilateral ovariectomy). At the age of 12 months, overiectomized rats were subjected to novel object recognition task (NORT) and social recognition task (SRT) for evaluation of episodic and social memories respectively. SUVN-D4010 was administered for 6-9 days prior to testing. Exploration towards object or juvenile rats and also discriminative indices were assessed. Following the cognitive evaluation, exposures of SUVN-D4010 in plasma, brain and CSF were assessed. Sub-acute treatment (6-days) with SUVN-D4010 reversed surgical menopause induced object memory deficits. Sub-acute treatment (9-days) of overiectomized rats with SUVN-D4010 reversed social memory deficits in a dose dependent manner. Significant improvement in discriminative index was observed. Efficacy was correlated with SUVN-D4010 exposures. SUVN-D4010 could be a

potential future promising therapeutic medication in post-menopause women associated dementia and AD so as to improve their health related QOL

Title: Resting-state functional connectivity is correlated to memory performance in the developing brain

Authors: A. BOUYEURE[1], D. BEKHA[1], R. CHAUVIN[2], D. GERMANAUD[1], V. DELATTRE[1], G. VAROQUAUX[3], C. CHIRON[4], L. HERTZ-PANNIER[1], *M. NOULHIANE[5]
[1]UMR1129/UNIACT, Neurospin CEA-Saclay & INSERM, Gif-sur-Yvette, France; [2]Donders Institute, Radboud Univ., Nijmegen, Netherlands; [3]Parietal, INRIA, Palaiseau, France; [4]UMR1129, INSERM, Paris, France; [5]INSERM U663 LBIOM / Neurospin I2BM DSV CEA, Gif Sur Yvette, France

Abstract: Introduction The medial temporal lobe (MTL) plays a pivotal role in memory. In adults, resting-state functional connectivity (FC) predicts memory performance [1] but little is known about this relationship in children and adolescents [2]. Here, we propose to fill this gap by examining if FC is correlated to memory performance in the developing brain. We focused our analyses on intra-MTL FC as the functional maturation of the MTL network is yet to be fully described. **Methods** Functional images of 30 subjects aged 7-17yo were acquired on a Siemens 3T. On a separate day, subjects underwent a battery of 11 memory tests covering episodic, working and semantic memory. After preprocessing of functional data, we built FC connectomes

using an atlas of manually-defined ROIs of MTL regions. Dimensionality of raw memory scores was reduced using PCA. Subjects' coordinates on each component were correlated to the edges between each nodes of the connectome using linear regression. Multiple comparisons were corrected with FDR at p=0.05. **Results** We retained 3 PCA components explaining 70.48% of the variance. Each component was mainly representative of a specific type of memory (Fig. 1a,b). Correlations between FC and age showed several significant age-dependent FC diminutions. Correlations between FC and PCA components evidenced negative correlations for the two first components. Adding age as a covariate of non-interest, no major changes were observed for the episodic memory component while there were no more significant correlations for the working memory component (Fig. 1c-e). **Discussion** We described age-dependent diminution of FC between MTL regions and showed that FC was negatively correlated to episodic memory at constant age as well as for age-related improvements. Hence, diminution of FC in the MTL could be linked to memory development. The extent of this diminution may explain episodic memory efficiency in children and adolescents at a given age. Future work will have to pinpoint the role of FC on memory development. 1. Wang et al. (2010), *Hippocampus*. 2.. Riggins et al. (2016). Dev. Cog. Neurosci.

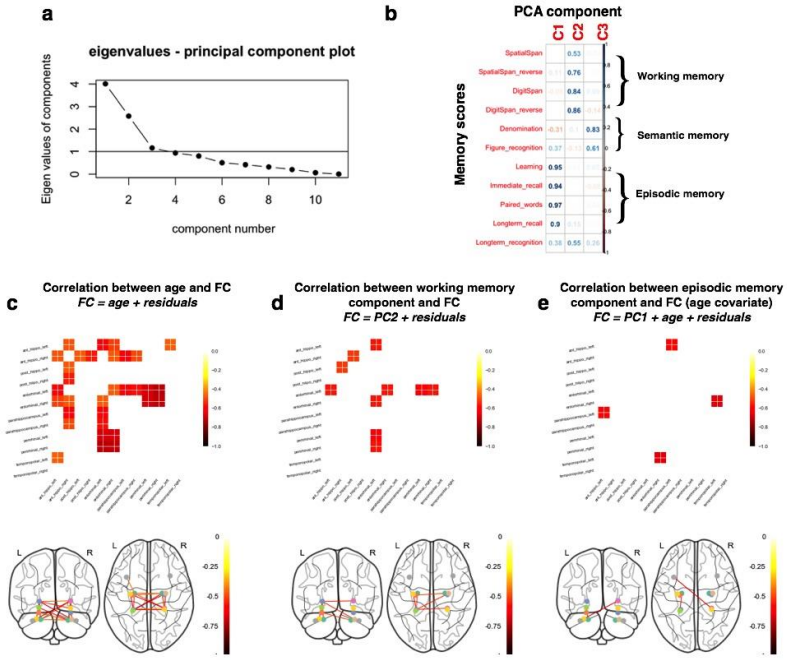

Figure 1: PCA and Regression results. a. Kaiser rule on the eigenvalues of PCA components retains 3 components. **b.** Loadings of memory scores on PCA components : component 1 is mainly representative of episodic memory variables, C2 of working memory variables and C2 of semantic memory variables. **c.** Significant correlations between age and FC of MTL ROIs after FDR correction. The correlations are represented as a matrix (top) or plotted on a glass brain (bottom). In both cases, the values of the significant correlations are plotted after conversion of the t-values to r-values. Only negative correlations were observed. **d.** Correlations between MTL FC and the second component of PCA (accounting for working memory), without age as a covariate. Only negative correlations were observed. **e.** Correlations between FC and the first component of PCA (accounting for episodic memory), with age as a covariate (results without age as a covariate are similar for this component). Only negative correlations were observed.

Title: Identification of hippocampal subfields responsible for components of episodic memory

Authors: *B. M. COX[1], A. A. LE[1], B. G. GUNN[1], C. D. COX[1], N. R. HADIDI[1], J. QUINTANILLA[1], G. LYNCH[2], C. M. GALL[1]
[1]Anat. and Neurobio., [2]Psychiatry, Univ. California Irvine, Irvine, CA

Abstract: Failure to properly encode episodes is a common feature of numerous neuropsychiatric and congenital intellectual disability disorders and is likely related to other cognitive problems. The hippocampus plays a central role in episodic memory formation by building codes needed for organizing sequences into a narrative about what happened, where particular features occurred, and the order in which they appeared ('what', 'where', and 'when'). Human and animal research indicates that the dentate gyrus, the first stage of hippocampal circuitry, receives semantic information ('what') via the lateral perforant path (LPP) projections from lateral entorhinal cortex, and spatial cues ('where') from the medial perforant path (MPP), which arises in the medial entorhinal cortex. However, it remains unclear how temporal information is processed or how the diverse information is integrated within the subfield(s) of hippocampus. To examine these questions, we used novel sequential olfactory tasks for mice that, as with human episodic memory, do not include explicit rewards or past training. Chemogenetic technology (i.e., DREADDs) was used to transiently silence discrete regions and pathways in hippocampal circuitry. The results point to a larger than expected role for the lateral entorhinal cortex and its LPP efferents to the dentate gyrus, and indicate that other subsystems have more specific involvement in encoding spatial information and temporal ordering.

Title: Hippocampal replay of distinct contextual versions of the same sensory experience

Authors: *B. R. LUSTIG[1,2], Y. WANG[1], A. K. LEE[1], E. PASTALKOVA[1], S. ROMANI[1]
[1]Janelia Res. Campus, Ashburn, VA; [2]Univ. of Chicago, Chicago, IL

Abstract: The same experience can result in very different memories depending on the context the experience was embedded in. For instance, the experience of driving home on the same road after a concert versus after a meeting at work is an example where internal states, shaped by the recent past, can color similar sensory experiences as very distinct episodic memories. Previously, most demonstrations of replay during sharp wave ripples (SWRs) in hippocampus have been replays of different sensory experiences, such as replay of the inbound or outbound traversal of a maze arm. Here we leverage a task design in which rats, undergoing the same sensory experience in a delay period, internally generate different sequential activity determined by the context shaped by recent arm choice. Analysis of population activity during SWRs found replay of the distinct contextually specific delay period sequences. These data provide a clear demonstration for replay of specific contextually differentiated experiences in rat hippocampus, a signature of episodic memory.

Title: Replay of episodic memories in the rat

Authors: *D. PANOZ-BROWN, V. IYER, L. M. CAREY, IV, A. G. HOHMANN, J. D. CRYSTAL
Psychological & Brain Sci. | Program in Neurosci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: Vivid episodic memories in people have been characterized as the replay of multiple unique events in sequential order. The hippocampus plays a critical role in episodic memories in both people and rodents. Although rats remember multiple unique episodes, it is currently unknown if animals *replay* episodic memories. Therefore, we developed an animal model of episodic memory replay. Here we show that rats can remember a trial-unique stream of multiple episodes and the order in which these events occurred by engaging episodic memory replay. We document that rats rely on episodic memory replay to remember the order of events rather than relying on non-episodic memories. Replay of episodic memories survives a long retention-interval challenge and interference from the memory of other events, which documents that replay is part of long-term episodic memory. Elsewhere, we show that episodic memory replay in rats is hippocampal dependent. Our approach provides an animal model of episodic memory replay, a process by which the rat searches its representations in episodic memory in sequential order to find information. Our findings support the view that rats can be used to model fundamental aspects of human episodic memory to both explore the biological mechanisms of memory disorders (e.g., Alzheimer's disease) and validate therapeutic approaches.

Title: Hippocampus-dependent acquisition and rapid systems consolidation of new learning through elemental second-order conditioning during remote retrieval of contextual memories

Authors: *A. SINGH, S. KUNDU, V. SINGH, S. SAUMITRA, J. BALAJI
Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: Second-order conditioning (SOC) plays a vital role in developing indirect associations between unconditional stimulus (US) and novel stimuli (conditioned stimulus, CS) encountered afterwards even in the absence of US. Sometimes a similar CS may be encountered long after the occurrence of primary conditioning between original CS and US and such delay could range from hours to weeks. In such cases when SOC occurs through remote retrieval of generalized primary conditioning memories while animals are exposed to a similar CS, it is not yet clear how does SOC take effect. To understand more about remote SOC, we perform experiments with C57/B6 mice (young adult males) in contextual fear conditioning paradigm. We find that SOC that occurs during remote configural retrieval of contextual memories has elemental nature and requires hippocampus for its manifestation. We also find that retrieval-based new learning resulting from SOC undergoes rapid systems consolidation even in absence of hippocampus. In our study, we incorporate three contexts A, B and C with more common elements between context A-B and B-C while there are less elements common between context A-C. Using discrimination paradigm, we establish the extents of feature overlap across the three contexts A, B and C. Further, using generalization paradigm with different orders of context exposure for testing remote retrieval, we demonstrate that ability to retrieve specific details and discriminate similar context could be intact post systems consolidation even after a month of training. Such remote retrieval with discrimination between training context A and similar context B is observed only when context A is tested before B. Notably, when animals are tested in a third context C, they show higher freezing in C for ABC testing order as compared to BAC testing order (control). We hypothesize that our observation of retrieval-associated new learning occurs in ABC testing order due to second order conditioning. We further explore the properties of such retrieval-associated new learning using hippocampal lesions at different time points along its acquisition. Based on our observations, we propose a theory to explain the occurrence of retrieval-associated new learning for specific testing orders during remote retrieval and identify neural correlates of such learning using immunohistochemistry. We also perform longitudinal in vivo imaging of dendritic spines in retrosplenial cortex to provide evidence for structural correlates of SOC based new learning in neocortex.

Abstract: It is currently thought that acquisition of related contextual memory does not require NMDAR activation. This phenomenon has been demonstrated in the water maze and contextual fear conditioning behavioural paradigms in mice. It has been shown that contextual learning induces spine clustering in the retrosplenial cortex (RSC).We used in vivo longitudinal imaging to visualize spine dynamics in RSC as the mice undergo contextual and related contextual learning across multiple days. Here, we contrast the spine clustering parameters between the novel and related contextual learning within individual mice.

Abstract: Consistent related memories are stored in memory associative networks also known as “mental schema”. Neocortical structures have been shown to be involved in such cognitive processes, but no mathematical/statistical model has been tested to explain evolution of mental schema and its role in memory acquisition. In order to address this, we trained mice to learn same sets of flavour place associations (paired associates) in two different ways viz., i) Solitary Learning: Two sets of association are presented independently one after the other ii) Relational Learning: Second set is presented in relation to first set and. We discovered that only the animals that underwent relational learning were able to acquire both set of flavors. We have shown that older memories help in acquisition of new memories only if presented in a relational manner. Further we tested Bayesian based modelling approach on our acquired data and have gathered evidence that the memory acquisition in mice for our task follows Bayesian inference. We have also conducted additional experiments and found that only large sets of memories act as mental schema at remote time point while small sets of memories face interference and make animals performance worse.

Abstract: Two-photon microscopy is an experimental tool to investigate neural correlates of brain function. Recently high dynamic range laser scanning microscopy using multiple detector channels has been demonstrated. However, such a setup is limited by shot noise and will not utilize the entire photon flux because of several emission optical elements in the path. Here, we report high dynamic range two-photon microscopy in-vivo using single detector by utilizing the entire photon flux. Two amplifier channels with low and high sensitivity were employed to obtain the scaling factor under a non-saturated regime. This improvement in image quality will be useful in depth imaging of neurons in-vivo.

Title: Generalization of temporal memory

Authors: *S. SHRIDHAR[1], V. P. SINGH[2], S. KUNDU[2], R. BHATT[2], J. BALAJI[1]
[1]Ctr. for Neurosci., Indian Inst. of Science, Bengaluru, Bengaluru, India; [2]Ctr. for Neurosci., Indian Inst. of Sci., Bengaluru, India

Abstract: Systems Consolidation is a process in which episodic memories which are dependent on the Hippocampus for acquisition and retrieval, gradually gain the ability to be retrieved independent of it. In this process, memories might lose richness of detail, and generalize the stimuli and contextual information. However, little is known about the nature of the temporal aspects of episodic memories and to what extent they are preserved or generalized during systems consolidation.Our current research aims to understand the consolidation of temporal memory, specifically that of temporal order memory. To this end, we have designed novel tasks where we can probe for temporal memory in mice. These paradigms include an Order-Place

association task, performed in an event arena and a compound tone fear conditioning task involving Tone-Order discrimination. These paradigms are designed such that they can be contrasted with comparable, established paradigms that lack an explicit temporal component. Further, these comparisons are important, since in the non-temporal version of these tasks, the precise time scales of consolidation are known. Using these tasks we have been able to quantitatively establish order learning in male C57BL/6 mice, by measuring their performance during probe trials. By probing for temporal-order memory at various time-points during the training/learning phase and after, where we attempt to quantify how much of the memory persists, we have been able to observe how this temporal-order memory evolves with time. Since the mice have been taught a sequence containing 4 events, and later, a 5-event sequence in a subsequent iteration, we are able to quantify, using their errors, how the well they discriminate events closer together in time and how their strategies evolve with subsequent training sessions. Further tests, with and without 'reminder' training sessions have also been performed to observe the effects of minimal re-training and priming on order memory. We have been able to show that a 'reminder' session is able to rescue a significantly deteriorated remote temporal order memory.

Title: Chemogenetic inhibition of episodic memory replay in rats

Authors: *V. IYER, D. PANOZ-BROWN, L. M. CAREY, IV, A. G. HOHMANN, J. D. CRYSTAL
Prog. in Neurosci. and Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Episodic memories have been characterized as the replay of multiple unique events in a sequential order. Profound impairments in episodic memory are a significant disabling

complication of several neurological diseases and disorders. Currently, there is a great need for accurate pre-clinical models that mimic these memory deficits observed in humans. Most existing methods used to create such models use lesions, toxins and gene knockouts which lack the ability to inactivate specific neuronal populations both selectively and reversibly. Therefore, we used chemogenetic inhibition of the hippocampus to temporarily impair episodic memory replay in rats. Rats first underwent extensive training on an episodic memory task where they were presented with a list of trial-unique odors, and reported, via their behavior, items that occupied multiple positions within the list. Next, a recombinant viral vector containing an inhibitory chemogenetic actuator (AAV8-hSyn-hM4Di-mCherry) was injected bilaterally into the hippocampus in all rats. After recovery, memory assessments were repeatedly conducted in all rats after receiving a dose of the chemogenetic activating drug, clozapine N-oxide (CNO, 10mg/kg i.p.) or a vehicle that served as the within subject control. Chemogenetic silencing of the hippocampus reversibly impaired episodic memory replay ($p<0.05$) while sparing other non-hippocampal dependent measures of memory and general odor detection, showing selectivity of this hippocampal-dependent impairment. Immunohistochemical analysis of all rats confirmed the presence of hM4Di-mCherry positive neurons in the dorsal hippocampus. The distribution of anti-mCherry immunofluorescence showed prominent labeling of the dentate gyrus and the mossy fiber pathway. Major labeling appeared in the dentate gyrus granule cell layer, hilus, mossy fibers, and CA3 stratum lucidum, which is the site of dense termination of mossy fibers. This experimental approach demonstrates for the first time a reversible model of episodic memory replay. It represents a unique paradigm for manipulating episodic memory that is currently unavailable in the field and could help further explore the role of hippocampal dysfunction in memory disorders like Alzheimer's disease.

Title: Patterns of axonal collateralization of single neurons in layer III of the rat presubiculum

Authors: *Y. HONDA[1], T. FURUTA[2]
[1]Dept. Anatomy, Tokyo Women's Medical.Univ., Tokyo, Japan; [2]Dept. of Oral Anat. and Neurobiology,, Grad. Sch. of Dentistry, Osaka Univ., Suita-Shi, Japan

Abstract: Connections among the hippocampal formation (DG, CA, subiculum), presubiculum (PreS) and entorhinal cortex (EC) are crucial for memory formation. Layer III cells of PreS provide strong projections to the superficial layers of the medial entorhinal cortex (MEC) in the rat. We have investigated that presubicular projections terminated in a band-like zonal area of MEC. The transverse axis of these zones was disposed parallel to the rhinal fissure. In the present study, we visualized the entire axonal processes of single presubicular layer III neurons in the rat, using in vivo injection of a viral vector expressing membrane-targeted green fluorescent protein (GFP). Anesthesia was performed with ketamine and xylazine. All experimental procedures were conformed to the guidelines for the case and use of laboratory animals (NIH). To facilitate the analysis, the hippocampal formation with adjacent cortices were flattened which allowed sections to be cut perpendicular to the septotemporal axis of them. By 3D-reconstruction of the axonal structures of presubicular layer III neurons in MEC, we found that there were several types of axonal branching patterns with some morphological features of their terminal arborization. Several layer III neurons (including both pyramidal and nonpyramidal neurons) provided two major axonal branches to MEC and each of them formed elaborate terminal arbors that seemed to face each other within layer III of MEC. To find the positional relationship between the soma and axon terminals, we represented them on the unfolded map of the entire PreS and EC. The width and axis of the area of terminal distribution resembled that of the band-like terminal field seen with massive-scale observation. Our results suggest that inputs from a single presubicular layer III neuron can directly affect each band-like zone in MEC.

Title: Identification and segregation of neuronal ensembles of multiple memories using temporal expression dynamics of a single immediate early gene shows related memories are encoded in overlapping population

Authors: *M. PRABOD KUMAR[1], S. KUMAR[2], J. BALAJI[3]
[1]Indian Inst. of Sci., Bengaluru, India; [2]Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India; [3]Neurobio., Indian Inst. of Sci. Malleshwaram Bangalore, Bangalore, India

Abstract: Immediate early genes (IEGs) are widely used as a marker for neuronal plasticity. Yet, techniques to identify the temporal coupling of IEG expression to different behaviours or events (e.g. cellular compartment analysis of temporal activity by fluorescence in situ hybridisation (catFISH), Fos-tTA Tet-tag transgenic mice) are limited to in vitro applications and provide a snapshot of the different neuronal populations that were activated during behaviour. However, if one were to follow these populations in vivo then it amounts to several imaging sessions that are interspersed between behavioural tasks. This leads to anesthetizing the mice several times for identifying these neurons. Further, if one were to investigate the synchronous IEG activation of the neurons in an ensemble, it is harder and in many instances, not viable. Here, we model the dynamics of an IEG expression in vivo and experimentally show that this approach can be used to identify distinct neuronal subsets. The rationale is to use the kinetics of expression to estimate when the activity of the neuron was induced. We present a generalised theoretical framework of such a dynamical system. We show that the fluorescence measurement of cFOS-shGFP protein in the transgenic mice over time, from the onset of stimulus, is well fit to an analytical expression derived to describe the above model. Using this approach we obtain the general method by which we are able to distinguish between neurons that took part in multiple events that are separated in time, by looking at the level of fluorescence of individual neurons.

Title: Negative emotion disrupts the coherence of episodic memories

Authors: *J. A. BISBY[1], N. BURGESS[2]
[1]UCL Inst. of Cognitive Neurosci., London, United Kingdom; [2]UCL, London, United Kingdom

Abstract: Events are thought to be stored in episodic memory as coherent representations, in which the constituent elements are bound together so that a cue can trigger re-experience of all elements via hippocampal pattern completion. Negative events can influence memory in

complex ways, strengthening memory for emotional content whilst impairing associations between the content and its surrounding context, and in some situations resulting in severe memory disturbances as seen in posttraumatic stress disorder (PTSD). Here we examined the neural structures supporting the disruptive effects of negative emotion on memory coherence. During fMRI, participants viewed a number of person-location-object events encoded as overlapping pairwise associates. Half of the events including a negative element (e.g., an injured person), and memory was tested across all within event associations (e.g. present person, recall location). We show that the presence of a negative element at encoding reduces memory for associations between event elements, a reduction also seen for associations between two neutral elements that formed part of a negative event. Whilst neutral events were remembered in a holistic way, the presence of a negative element at encoding was found to reduce the coherence with which the multimodal event is remembered. In fMRI, we saw greater hippocampal activity for neutral but not negative events on the final encoding trial when events would be bound together, consistent with pattern completion and its disruption by negative elements. Further, we found that amygdala activity at encoding negatively correlated with subsequent associative memory accuracy and predicted reduced memory coherence. Our results highlight how the experience of negative events can disrupt both memory formation and the holistic manner in which they are remembered via opposing effects on amygdalar and hippocampal systems. These findings support a dual representation model (see e.g. Bisby & Burgess, 2017) and have important implications for the development and maintenance of memory disruptions in PTSD.

Title: The ontogeny of spatial memory consolidation during sleep

Authors: L. MUESSIG, M. LASEK, F. CACUCCI, *T. WILLS
Univ. Col. London, London, United Kingdom

Abstract: The ability of humans to encode and retrieve long-term episodic memories for past events does not develop until late childhood. It remains unknown whether the neuronal basis for such early-life amnesia lies with deficits in encoding, consolidation or retrieval. In rats, hippocampus-dependent learning emerges late, being absent before 3 weeks of age, and emerging slowly thereafter. Importantly, hippocampal place cells develop spatially localised firing before 3 weeks of age, leaving open the question of which changes in hippocampal circuits underlie the emergence of memory.
In this study, we aim to understand how the consolidation of spatial memories develops, using the offline 'reactivation' of place cell activity of previous experiences in population events (sharp wave ripples, SWR) during slow wave sleep (SWS), which is thought to be a candidate mechanism for memory consolidation. Reactivation is the increased tendency of neurons which fire together during experience to also be co-active during SWRs in post-experience sleep: reactivation following learning has been shown to correlate with performance on spatial memory tasks.
We recorded the activity of place cells in CA1 during exploratory behaviour in familiar and novel environments and their subsequent reactivation during SWRs in post-experience sleep, in young rat pups (aged 2.5-4 weeks) as well as in adult controls. Even the youngest animals show reactivation of previous place cell activity during SWS. However, the extent of reactivation was equal in both familiar and novel contexts, in contrast to adults, where exposure to a novel environment causes a significant increase in reactivation.
Because memory requires the association of sequences of events, in a second experiment we sought to investigate the emergence of place cell 'replay', defined as an ordered activation of a place cells during an SWR, tracing out a trajectory through the environment. We find that up to 3 weeks of age, firing during single SWRs does represent locations on the track, though less frequently than in adults. Importantly, the speed of replay trajectories was also significantly lower in pups, with most events representing static locations rather than trajectories through the environment.
These results indicate that while the basic mechanisms of consolidation in the hippocampus might already be present in young animals (i.e. offline reactivation of a previously active cell ensemble), the enhancement of reactivation by novelty, and the organisation of offline firing into sequences representing trajectories, may emerge later in development.

Title: After watching traumatic videos, wakeful rest and hippocampal activity have opposing effects on subsequent intrusive thoughts vs deliberate memory

Authors: L. D. HORLYCK[1], J. A. BISBY[2], *N. BURGESS[3]
[1]ICN, Univ. Col. London, London, United Kingdom; [2]UCL Inst. of Cognitive Neurosci., London, United Kingdom; [3]UCL, London, United Kingdom

Abstract: Immediately following an event, offline processing is thought to support its integration into memory. Changes to these processes in the aftermath of trauma might lead to the occurrence of intrusive imagery, as in posttraumatic stress disorder (PTSD). According to dual representation theories this reflects an imbalance between weak explicit contextual processing and strong sensory/affective processing (e.g. reviewed in 1). To test this, we investigated the effects of brief wakeful rest following encoding of traumatic material on subsequent intrusive and explicit memory. Participants watched negative video clips immediately followed by wakeful rest or a working memory task, recorded any intrusive memories for 1-week using a diary and then returned for a recognition test for the clips. Brief wakeful rest reduced intrusive memory frequency but did not alter explicit memory performance.
In a second experiment, participants watched short negative clips (~30sec) in an fMRI scanner, with each clip followed by a wakeful rest period of similar duration. Participants again kept a diary to record intrusions of the footage and returned for a surprise recognition memory test. Results showed that subsequent explicit memory was associated with greater activity in entorhinal cortex and hippocampus both when viewing the clips and immediately following clip offset. In contrast, subsequent intrusive memory frequency correlated with increased amygdala activity, again seen during both viewing and rest periods. Further analysis showed a clear post-encoding increase in hippocampal activity at clip offset, which was greater for explicitly remembered clips (see also 2) but lower for clips that later intruded.
Our findings highlight the importance of post-encoding activity in facilitating memory formation and the way in which negative events might attenuate this process. The results further support a dual representation account in which intrusions are supported by amygdala-dependent strengthening of sensory/ affective representations and weakening of hippocampal processing to disrupt associative and contextual binding. The use of wakeful rest to boost hippocampal contextual processing might complement strategies aimed at interfering with consolidation of sensory representations (e.g. 3).

Title: Functional populations in the pyramidal cell layer of hippocampal area CA1

Authors: *D. M. GRIJSEELS[1], K. SHAW[1], C. BARRY[2], C. N. HALL[1]
[1]Univ. of Sussex, Brighton, United Kingdom; [2]Univ. Col. London, London, United Kingdom

Abstract: A wide range of functional and physiological diversity has been reported among pyramidal cells in region CA1 of the hippocampus. The most widely studied subtype of pyramidal cells are place cells, neurons that respond in discreet spatial locations[1]. In the absence of spatial cues, some pyramidal cells show sequential firing during periods of locomotion[2]. Other cells have been identified as responding specifically to reward[3] and different frequencies of sound[4]. Currently it is unclear how these distinct functional types relate to one another - are they encoded by a single plastic population of cells, or by distinct subpopulations? Recent advances in two-photon (2P) calcium imaging allow concurrent recording of neural activity in large cell populations, with the additional advantages of precise spatial localisation and long-term stability. We used 2P microscopy to examine the activity of CA1 pyramidal cells in awake, behaving mice navigating through distinct virtual reality (VR) environments. Based on their activity profiles we classified cell as place cells, sequence-encoding cells, and other cell types. Using traditional and machine learning approaches we then investigate the relationship between the different cell types. Specifically, examining the extent to which individual cells predicted the firing of others in the population and their information content with respect to spatial location and sequence position. We were able to identify independent populations of place cells and sequence-encoding cells concurrently in CA1. Similar proportions of cells from both categories occurred as has been previously reported. However, contrary to previous reports, sequence-encoding cells in our experiment occurred in the presence of spatial cues. Additionally, we identified a third population of cells that were preferentially active during rest but did not encode repeatable sequences. The three types were not spatially clustered within dorsal CA1. In all cases, the interaction within functionally-defined populations was greater than between these populations. These data suggest that sub-populations of hippocampal pyramidal cells with distinct functional properties exist. *1. O'Keefe, J., and Dostrovsky, J. Brain research (1971). 2. Villette, V., et al. Title: Recall memory in the object recognition task is dependent of the care given by the mothers

Authors: *L. DÍAZ[1], M. D. DORANTES-NIETO[2], A. UGARTE[2], A. TRUJILLO[3], C. CORTES[4], J. EGUIBAR[5]
[1]Benemérita Univ. Autónoma De Puebla, Puebla, Mexico; [2]Inst. de Fisiologia, [3]Facultad de Ciencias Biologicas, Benemerita Univ. Autonoma de Puebla, Puebla, Mexico; [4]B. Univ. Autonoma de Puebla, Puebla, Mexico; [5]Benemerita Univ. Autonoma De Puebla, Puebla, Pue., Mexico

Abstract: We selectively bred two sublines from Sprague-Dawley (SD) rats in base of their spontaneous yawning frequency. High-yawning rats (HY) yawn 22 times/h and low-yawning rats yawn two times/h. These sublines also differ in their maternal care, because HY dams build nests of poor quality and perform atypical retrieving respect to SD and both sublines spent less time with their pups compared with SD dam. The mother, siblings and nest have great impact in the development of the newborn. In this sense cross-fostering is an adequate technique to evaluate the role of maternal care on behavioral traits in adulthood. We employed female rats from HY, LY and SD at three months of age that were reared by their natural mother (controls), and by the other two types of mother (cross-fostered groups), from these combinations we obtain seven groups with 6 subjects (Ss) in each group. All Ss were maintained under standard animal room conditions and with free access to rodent pellets and purified water. All experiments were done between 1000 to 1600. Using the object recognition task in an open-field arena, in the first trial Ss were freely allowed 5 min to explore two objects of the same form and weight (marble cube); after 30 min delay period one of the objects was changed with a different form: a triangle pyramid or a cylinder of marble with the same size and weight as the cube. All Ss allowed to explore the arena by 5 min, and 6 h later one of the objects changed and an additional 5 min free exploration allowed. Our results showed that in the short-term memory (30 min) LY females reared by SD (SD-LY) dams explored 70% more than LY raised by their natural mother (χ^2 = 50.4, $P \leq 0.001$), and if a HY dam was raised by SD dams their exploration scores decreased 42%

(χ^2= 18.4, $P \leq 0.001$). In long-term memory SD-LY dams increased 23% their exploration respect to control (χ^2 = 53.2, $P \leq 0.001$). On the other hand, SD produced in LY dams showed a reduction of 50% respect to the control (χ^2 = 25, $P \leq 0.001$). We conclude that the type of maternal care given is capable to induce changes in the memory capacities of the female rats in adulthood probably due to epigenetic mechanisms given by nest conditions.

Title: Orbitofrontal cortex lesions disrupt anticipatory autonomic responses to reward magnitude in macaque monkeys

Authors: *J. HWANG, P. L. NOBLE, E. A. MURRAY
Section on Neurobio. of Learning and Memory, Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Neurons in the macaque orbitofrontal cortex (OFC) encode the sensory properties, magnitude and subjective value of expected and received outcomes, typically foods and fluids. Subjective value is reflected not only in neural activity, but also in autonomic responses. Indeed, both neural activity and pupil diameter changes, a measure of sympathetic autonomic arousal, are correlated with magnitude of expected reward (Mitz et al., J. Neurosci. Methods, 2017). However, previous research has not identified how the value coding in OFC is linked with autonomic arousal. To answer this question, we compared rhesus monkeys with bilateral excitotoxic lesions of OFC (N = 4) and unoperated controls (N = 4) on a reward magnitude task in which five visually presented images were assigned to five different fluid reward amounts (0, 0.2, 0.4, 0.8 and 1.6 ml). Monkeys were required to maintain fixation at the center of a monitor screen for the duration of each trial, which consisted of image presentation (cue period), an unfilled interval with no cue (delay period), and reward delivery. Monkeys received the amount of reward assigned to the single image displayed on that trial. Pupil size, which was continuously measured while the monkeys performed the task, served as our measure of autonomic arousal. To test whether the monkeys' pupillary responses differed based on anticipated reward amounts, we performed one-way ANOVA and calculated Spearman's rank correlation coefficients. The groups did not differ in the number of sessions required to exhibit a significant autonomic

response during the cue period within a single daily session or across 4 consecutive days. In addition, the pupil size change during both the cue period and delay period was positively related to the reward magnitude in both groups. Compared to the controls, however, monkeys with OFC lesions showed a late onset of differentiated pupillary responses during the cue period and a significant impairment in sustaining arousal during the delay period. At the same time, autonomic responses to unsignaled reward and to changes in luminance were intact, demonstrating that OFC lesions did not affect the basic physiology of the pupil. Our findings show that OFC is necessary for acquiring the normal pattern of autonomic arousal in anticipation of different reward magnitudes. In particular, the data suggest that subjective value representations in OFC sustain autonomic arousal for biologically significant events.

Title: Orbital cortex activity encoding of associative information underlying goal-directed actions

Authors: *C. CAZARES[1], C. GREMEL[2]
[1]Neurosciences Grad. Program, [2]Dept. of Psychology, Univ. of California San Diego, LA Jolla, CA

Abstract: The orbitofrontal cortex (OFC) is necessary for performance of goal-directed decision-making, with deficits observed in disorders such as alcohol dependence. However, whether OFC circuit activity contributes to associative information necessary for goal-directed control is not clear. Goal-directed actions are by definition under a strong action-outcome contingency control; actions are continually adjusted using feedback from prior actions until they are successful. Hence, OFC circuit activity may contribute to prior action history, confidence in the current decision, and successful execution of the appropriate decision. To investigate representation of goal-directed associative information within OFC, we developed a self-paced, un-cued modified version of the rodent Progressive Hold Down (PHD) task that requires a mouse to make a sustained single lever press response to earn a valued outcome. This allowed us

to observe ongoing action feedback behaviorally in a trial-by-trial manner, as both expected and delivered outcomes dictate adjustments in future lever-press duration. Using in vivo photometry to measure calcium activity in OFC projection neurons during behavior, our preliminary data show increased calcium transients prior to action onset. These OFC calcium transients prior to action onset were often of a higher magnitude when the future action performance was successful. In addition, we also observed increases in OFC calcium transients that were dependent on outcome delivery, but not outcome expectancy. Single unit in vivo recordings via chronic indwelling multi-channel electrodes showed up modulation and down modulation of single putative OFC neurons during the lever-press initiation and offset, as well as periods of sustained modulation throughout the duration of the action. This suggests that sub-populations of OFC neurons encode separate aspects of action-contingency information. Importantly, it appears that alcohol dependence modulates putative single unit encoding of action properties. Thus far, our results suggest the OFC encodes associative information including action feedback, and that alcohol dependence may disrupt such processing thereby hindering goal-directed decision-making.

Title: Nodal perturbation disrupts value representations and coherent neural dynamics across the fronto-striatal network

Authors: *J. I. SEDILLO, S. QIAO, B. PESARAN
NYU, New York, NY

Abstract: The orbital frontal cortex (OFC) is anatomically interconnected with sensory, limbic, and motor-association areas. It has been shown to participate in multiple operations regarding valuation, reinforcement learning, and flexible cognitive function**.** We implanted two rhesus macaques with large-scale semi-chronic microdrives capable of simultaneous extracellular recording and intracortical microstimulation (ICMS) from multiple brain areas in the fronto-striatal network (FSN). We tested the hypothesis that the OFC encodes action-outcome value associations with effector-specific representations as part of the FSN. We trained two male monkeys to perform a reward-driven reinforcement learning choice task using a reward drift

model to assign reward magnitudes to two different stimuli with different shapes. This task assesses the monkey's ability to decode the varying reward signals and respond with either reach or saccadic effectors to implement a choice towards the target with optimal value**.** Choice performance using either reach or saccade consisted of immediate and delayed trials (1-1.5s) that were randomly interleaved (1:3) for each effector block. We used open-loop bipolar continuous tetanic ICMS to perturb multiple sites within the OFC to investigate its role in effector-specific valuation during behavior. We found that multiple sites in the OFC are involved with action-outcome value representations. For example, bipolar continuous 100 Hz tetanic ICMS (biphasic, charge-balanced 20 µA, 100 µs/ phase) in the medial OFC decreased reaction times ($P = .0170$, Wilcoxon rank sum test) for the delayed-reach condition and decreased reward sensitivity indicated by choice performance on the psychometric curve. In comparison, increased reaction times ($P < .0001$) and reward sensitivity was observed for the delayed-saccadic condition during stimulation in the same area. These perturbations indicate disruptions/enhancement of effector-specific value representations possibly encoding decision variables related to recent experience and response outcomes. Our evidence also shows topographically distinct value representations decoded from the beta band of local field potentials (LFP) in the lateral OFC and caudate. Furthermore, adaptive and flexible goal-directed behavior involves temporally precise coordination within task-relevant distributed neural networks. Our large-scale coverage allows the analysis of interactions between frontal and striatal networks during decision making. These analyses provide insight into coherent neural dynamics distributed across the FSN during a decision-making task.

Title: Value based decision making across ventro-medial Prefrontal Cortices in monkey

Authors: *E. C. LEVY[1,3], E. CHAVRET-RECULON[2], C. I. JAHN[4], S. BOURET[4,5]

Abstract: All species adjust their behaviors by optimizing the ratio between costs and benefits. In complex species, action selection involves comparing the value associated with distinct

courses of actions, which rely upon the prefrontal cortex. More specifically, recent studies in humans have identified the ventromedial prefrontal cortex (VMPFC) as a key node for value-based decision making, but the underlying physiological processes remain unclear. Here, we used an electrophysiological approach in behaving monkeys to further understand the dynamic relation between neuronal activity in the vmPFC, evaluation and decision processes. We trained one monkey to perform a sequential cost-benefit choice task involving sequences of actions. Each trial starts with a visual cue indicating how many actions (bar presses) the monkey must perform on a given lever (left or right) in order to obtain a given reward (volume of juice). In a fraction of these trials, the monkey is offered a choice before the end of the sequence. The animal can choose to complete the initial sequence to obtain the associated reward (default option) or to switch to the alternative lever to perform the alternative options, defined by a given number of squeeze and a given reward size. This choice is indicated by explicit visual cues indicating the costs and benefits associated with each option, which the monkey selects by squeezing the corresponding lever. We conducted a preliminary analysis on 74 single VMPFC units (area 14). In agreement with previous studies most VMPFC neurons (59/74, 80%) encoded the monkeys willingness to work. The relation between VMPFC firing and engagement in the task encompassed several trials, reflecting a slow state function rather than an event-related function. In addition, many VMPFC neurons encoded the monkeys choice in the default vs alternative frame. Indeed, 27 neurons responded at the time of the choice cue (requiring the monkey to choose between default vs alternative option), vs only 16 at the cue signaling sequence onset, and requiring the monkey to engage in the sequence, or not. Moreover, half of VMPFC neurons (n=37) encoded the monkey's decision in the default vs alternative frame, especially around the time of the decision itself. Thus, the firing of VMPFC neurons is strongly associated with both the internal changes in willingness to work and with value-based decision making. Altogether, this data supports the idea that vmpfc activity is strongly related to a subjective and internal component of value based decision making and can predict choices. Future analysis will enable us to further charatcerize the nature and the dynamic of this relation.

Title: Optogenetic inactivation of medial orbitofrontal cortex fails to affect economic choice in well-trained rats

Authors: *M. P. GARDNER[1], J. C. CONROY[1], C. V. STYER[1], T. HUYNH[1], G. SCHOENBAUM[2]
[1]Cell. Neurobio. Res. Br., NIDA IRP, Baltimore, MD; [2]Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD

Abstract: How humans and animals make choices when confronted with complex and diverse options remains an active area of research within neuroscience. One attractive hypothesis is that particular brain regions compress the complex feature space of each of the available offers to a single dimension of utility in order to make rational decisions between options. There has been considerable evidence that several frontal brain regions, in particular the orbitofrontal cortex (OFC), contribute to this process of value determination, yet much of this evidence arises from neural correlates measured through fMRI or single-unit recordings in humans and monkeys. To directly address whether OFC is necessary for making decisions between biologically relevant goods which differ across features and size, we inactivated the OFC of rats using halorhodopsin during the choice period of an economic choice task. The task was developed to mimic those used in primate single-unit recording studies showing neural correlates of value in OFC. We previously showed that lateral OFC is not necessary for successful behavior on the task. In fact, rats were able to continue to make decisions based not only on the amount of food available but on the type of food as well. There is also considerable evidence that the medial portion of the OFC (mOFC) is a critical region for computing the value of different offers. Here we show that inactivation of mOFC in rats (n = 6) using the light-sensitive hyperpolarizing protein halorhodopsin does not impact behavior on the task in well-trained rats. We further found successful manipulation of mOFC using halorhodopsin in the same rats as their behavior was disrupted on the progressive ratio task, a task previously shown to be mOFC dependent. This result, combined with our prior findings of lateral OFC inactivation, suggests that economic choices between offers with multiple different features likely depends on a value computation distributed across a network of several brain regions encoding a variety of pertinent associative information. We are currently looking at how OFC is involved in economic choice behavior when confronted with these choices for the first time under different conditions. Preliminary results suggest that normal OFC function becomes critical when rats are confronted with choices between offers which have never been experienced in the particular paired arrangement. This finding suggests that OFC might be necessary for determining the relationship between goods within a goods space, yet only during the initial exposure of the comparison.

Title: Functional influence of mediodorsal thalamic projections onto mouse lateral orbitofrontal cortex

Authors: *E. YALCINBAS[1,2], C. GREMEL[3,2]
[1]UCSD, LA Jolla, CA; [2]Neurosciences Grad. Program, UCSD, La Jolla, CA; [3]Dept. of Psychology, UCSD, LA Jolla, CA

Abstract: Across species, different anatomical divisions of the mediodorsal thalamus (MD) project to and receive input from distinct prefrontal cortical regions implicated in different executive functions. While MD projections onto more medial and dorsal prefrontal areas have been studied in the context of various cognitive tasks, the functional influence of excitatory MD relay neurons that project to the lateral orbitofrontal cortex (lOFC) has not been explored in depth. We investigated the functional role of MD input onto the mouse lOFC during a decision-making task shown to be dependent on the OFC. This incentive learning task involves mice learning to leverpress for a rewarding outcome, experiencing a shift in motivational state and - importantly -- updating outcome value in the new motivational state through experience with the outcome. During an extinction test the following day, mice are expected to infer and use the updated representation of outcome value to control their leverpress actions. An intersectional virus strategy was used to chemogenetically attenuate MD --> lOFC projection neurons during the value updating epoch of the incentive learning task. Compared to fluorophore controls, mice with prior MD --> lOFC attenuation were impaired in their performance on the extinction test, suggesting an impairment in value updating following a state change. Thus, we hypothesized that excitatory MD --> lOFC input's influence over local lOFC circuit activity changes depending on motivational state. To examine this, we probed whether different motivational states alter presynaptic release from MD terminals onto lOFC neurons in a cell-type specific manner. Channelrhodopsin-2 (ChR2) was injected into the MD of transgenic mice that express a fluorescent reporter in parvalbumin-positive (PV) interneurons. Following chronic food restriction of experimental mice or free feed in control mice, whole-cell voltage-clamp recordings were performed from both pyramidal neurons and PV interneurons in the lOFC while MD terminals were photostimulated. Our preliminary data using paired-pulse or asynchronous release protocols suggest that there are state-dependent changes at the level of MD --> lOFC synaptic physiology. These studies contribute to our understanding of how distinct MD projections may be important for state-dependent decision-making.

Title: Inactivation of the orbitofrontal cortex, basolateral amygdala, or mediodorsal thalamus during training impairs performance on a multiple-response/multiple-reinforcer operant devaluation task in rats

Authors: *H. FISHER, A. PAJSER, S. FOX, C. LONG, S. GILBERT, C. L. PICKENS
Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: Devaluation is a task often used to model flexible goal-directed behavior, the ability to adaptively modify behavior when the value of a reinforcer changes. In rodents, there are many simplified versions of the devaluation task and the brain regions involved can differ depending on the task demands. We chose to use a multiple-response/multiple-reinforcer devaluation task that should require the basolateral amygdala (BLA), orbitofrontal cortex (OFC), and mediodorsal thalamus (MD). In order to determine the role of these brain areas in the learning the necessary associations, we inactivated each of these three brain regions during operant training and then tested the rats on devaluation without the brain areas inactivated. We implanted bilateral cannula into the BLA, OFC, or MD of male Long Evans rats. The rats then were trained on a multiple-response/multiple-reinforcer operant devaluation task. Five minutes prior to beginning each cued-trial training session, the rats were infused with either muscimol/baclofen (n= minimum of 6/group) or PBS (n=minimum of 8). We gave cued-trial operant training with lever-light compounds available during 40-sec trials. Two lever-light compounds were each associated with a different food pellet (earned for lever-pressing on an intermittent reinforcement schedule). Only one lever-light-food pellet combination was available during each training session. After the rats received four days of cued operant training, two days for each lever, each of the two reinforcers was devalued through selective satiety in two separate tests (one pellet sated in each test) and devaluation was assessed through choice tests in extinction. The control rats (PBS) showed a devaluation effect, but there was no devaluation in the BLA, OFC, or MD inactivation groups. These results show that the BLA, OFC, and MD regions are involved in learning the necessary associations to guide behavior after reward devaluation in our task. Future studies will determine how these brain regions communicate to support goal-directed behavior.

Title: Noradrenergic modulation of the orbitofrontal cortex mediates flexibility of goal-directed behavior

Authors: *J.-C. CERPA[1,2], A. R. MARCHAND[1,2], M. WOLFF[1,2], S. L. PARKES[1,2], E. COUTUREAU[1,2]
[1]Univ. de Bordeaux, Bordeaux Cedex, France; [2]CNRS, UMR 5287, Bordeaux, France

Abstract: For an organism, knowledge of the consequences of its actions and the ability to assign a value to these consequences are both crucial processes allowing an appropriate goal-directed response. The major role of prefrontal regions, e.g. insular and medial prefrontal cortices, for these processes has been very well described. However, the mechanism by which the organism quickly adapt this goal-directed response to unexpected environmental changes remains unknown. It is possible to study this ability using instrumental learning. Typically, during an initial phase, an animal must associate voluntary actions with the delivery of rewarding outcomes. Then, during a reversal phase, the animal must respond flexibly to a modification of these associations. Using this task and chemogenetic tools allowing specific inhibition of cerebral regions, we have recently demonstrated a crucial role of the ventrolateral orbitofrontal cortex (vlOFC) for flexible response adaptation during the reversal phase (Parkes et al., 2017). In the present study, we focused on the noradrenaline (NA) input to the vlOFC which has been commonly implicated in flexibility-requiring tasks. In a first experiment, using a toxin (anti-DβH saporin) we selectively depleted noradrenergic fibers in the vlOFC and showed a deficit of behavioral flexibility. Notably, this effect was not only specific to the reversal phase but also to vlOFC input since a similar depletion restricted to the medial portion of the prefrontal cortex had no effect. Using an intersectional chemogenetic approach aiming at selectively targeting the locus cœruleus (LC) input to the vlOFC, we are deciphering the time course of the involvement of this pathway during behavioural flexibility. Taken together, these results demonstrate a central role for noradrenaline input to the vlOFC in behavioural flexibility and reinforce the idea that the LC exerts a strong modulation of OFC functions.

Abstract: Every decision we make is accompanied by a sense of confidence about its likely outcome. This sense informs subsequent behavior, such as investing more ―whether time, effort, or money― when reward is more certain. We previously showed that the firing of many orbitofrontal cortex (OFC) neurons encode statistical confidence about olfactory-discrimination decisions and OFC inactivation specifically impairs the ability of rats to optimally invest time waiting for reward. However, it is unknown if these neurons predict time investments and whether these neurons represent confidence across sensory modalities consistent with a metacognitive notion of confidence. Here we show that single OFC neurons represent abstract decision confidence and predict confidence-guided time investments. We trained rats to make choices based on evidence from two different sensory modalities (auditory discriminations or olfactory discriminations). After making a choice, rats had to wait in a choice port to obtain an uncertain, randomly delayed reward. The time rats were willing to wait for a potential reward provided a time investment, which reflected their decision confidence. Single OFC neurons encoded decision confidence and predicted rats' time investment trial-by-trial, seconds in advance of giving up on waiting. Furthermore, the same OFC neurons signal confidence and predict time investment irrespective of whether the sensory discrimination was olfactory or auditory. Orbitofrontal cortex thus contains a sensory-modality-general metacognitive representation of confidence useful for mediating confidence-guided economic decisions.

Title: Influence of DLPFC on OFC representation during decision-making

Authors: *Z. BALEWSKI[1], J. D. WALLIS[2]
[1]UC Berkeley, Berkeley, CA; [2]Univ. of California Berkeley, Berkeley, CA

Abstract: Dysfunction of frontal cortex, including orbitofrontal (OFC) and dorsolateral (DLPFC) regions, has been implicated in many neuropsychiatric disorders, including mood disorders, obsessive-compulsive disorder, and addiction; many of these involve impaired decision-making. Pharmaceutical treatments, which broadly alter neural function, are often ineffective in reducing the prevalence or severity of mental illness. Brain-machine interfaces (BMIs) provide a more targeted manipulation of complex behaviors, for example to give paralyzed patients control of a computer or robotic arm. To implement these tools in the cognitive domain we first need to identify the computational processes implemented in frontal cortex. Specifically, we aim to understand how reward-predictive cues are translated into decisions. Previously our lab (Rich and Wallis, Nat Neuro 2016) trained a decoder to identify reward predictive cues on four value levels from ensembles of on average 10 primate OFC neurons. The decoder flip-flopped between the two available options while the subject made a decision. While the frequency and duration of these flips were predictive of choice behavior, there was no evidence of gradual ramping up toward the ultimately chosen option. OFC is anatomically connected to DLPFC, which may play a role in translating these vacillations into a decision. Using multi-site array electrodes in one subject, we simultaneously recorded OFC and DLPFC neurons while he selected between pairs of 16 cues using a lever. We trained multiple decoders on value and choice direction separately for both regions. With a more complex stimulus set, we continue to see flip-flopping in OFC based on value and no evidence of action information. In DLPFC we observe similar switching between the available options using either the value or action decoders. We are currently investigating whether DLPFC influences the vacillations in OFC, for example as an attention modulator, or instead “reads out” OFC serving as an accumulator for the ultimately chosen option.

Title: Orbitofrontal-hippocampal interactions underlying reinforcement learning

Authors: *E. B. KNUDSEN[1], J. D. WALLIS[2]
[1]Helen Wills Neurosci. Inst., [2]Univ. of California Berkeley, Berkeley, CA

Abstract: The orbitofrontal cortex (OFC) is critical for learning and exploiting reinforcing stimuli in the environment. Orbitofrontal neurons exhibit responses to reward-predictive cues, but it is unclear how these responses arise. Recent experimental and theoretical work has positioned OFC as a computational substrate for modeling the abstract state-space underlying value-based tasks, much in the same vein as hippocampus' theorized role for spatial learning and memory. Despite this common theoretical underpinning, the interrelationships between these two distant regions remain poorly understood.

Using a simple reinforcement learning (RL) task, we identified a strong presence of theta phase resetting in OFC around critical events in the task. This resetting, prominent throughout a session, displayed a bistability, such that the degree of phase resets was significantly increased when subjects were required to update stimulus-outcome associations. To test the functional relevance of this signal, we disrupted it via temporally-linked, closed-loop microstimulation. This had the net effect of drastically reducing our subjects' ability to update value estimates for optimal task performance. There was no effect of stimulation on behavior if it was a) delivered during epochs when values were previously learned, b) delivered open-loop, or c) delivered at beta frequency.

We then recorded from hippocampus and OFC to determine if this theta signal had a common function. Indeed, the hippocampus and OFC showed a significant synchronization within the theta frequency band coincident with optimal behavioral performance and the emergence of stable value representations in OFC. Theta-linked hippocampal stimulation interrupted theta synchronization and disrupted behavior in an identical fashion to OFC stimulation. These results provide a causal link between OFC, hippocampus, and reinforcement learning, and provide crucial evidence for the role of hippocampal model-building in even the simplest RL behaviors.

Title: Value representations in the orbitofrontal cortex drive learning, not choice

Authors: *K. J. MILLER[1], M. M. BOTVINICK[2], C. D. BRODY[3]
[1]Princeton Univ., Princeton, NJ; [2]DeepMind, London, United Kingdom; [3]Princeton Neurosci. Inst. and Dept of Mol. Biol., HHMI / Princeton Univ., Princeton, NJ

Abstract: Humans and animals make predictions about the rewards they expect to receive in different situations. In formal models of behavior, these predictions are known as "value representations", and they play two very different roles. Firstly, they drive choice: expected values of available options are compared to one another, and the best is selected. Secondly, they support learning: expected values are compared to rewards actually received, and future expectations are updated accordingly. The orbitofrontal cortex (OFC) is well established as a key region for representing and using value information, but its particular role remains the subject of heated debate. Does the OFC play a role in choice, in learning, or in both? Resolving this question has been difficult, because both ideas make similar predictions for typical laboratory tasks, in which the items to be learned about are identical to the items to be chosen between. In recent work (Miller, Botvinick, & Brody, 2017), we have adapted for rats a two-stage decision task from the human literature (Daw, et al., 2011) which breaks this identity, cleanly separating learning from choice. Electrophysiological recordings and optogenetic perturbations indicate that, contrary to prominent theories, the OFC does not directly drive choices. Instead, it supplies value information to a learning process that updates choice mechanisms elsewhere in the brain.

Title: Adolescent exposure to THC alters mean diffusivity in adult rat brain regions associated with learning and emotion

Authors: *R. J. DRAGONE[1], S. L. BLAES[1], S. C. WALL[1], M. M. BRUNER[5], L. M. COLON-PEREZ[2], A. W. BRUIJNZEEL[3], B. SETLOW[2], M. FEBO[4]
[2]Dept. of Psychiatry, [3]Psychiatry, [4]Psychiatry Dept., [1]Univ. of Florida, Gainesville, FL; [5]Neurosci., UF, Gainesville, FL

Abstract: Cannabis use among adolescents is expected to increase as its use becomes legal in a growing number of states and countries. Despite this growth, little is known about the lasting impact of its chemical constituents on brain development. In this study, we sought to determine the impact of daily exposure to Δ9-tetrahydrocannabinol (THC) during adolescence on adult brain structure using a variety of MRI approaches.
Beginning on post-natal day 32, male and female Long Evans rats were given twice daily injections of vehicle or 2.5 mg kg^{-1} THC (i.p.) for three days, 5.0 mg kg^{-1} for 4 days, and 10.0 mg kg^{-1} for 4 days, for a total of 11 treatment days (as per Rubino et al. 2008, *Neuropsychopharmacology*). The treatment groups were the following: vehicle (n=8 females, 8 males); THC (n=8 females, 8 males). At 178 days of age, rats were sacrificed and brain tissue prepared for *ex vivo* imaging. Imaging data were collected at 4.7 Tesla using a two-shell 36 direction (6 low b value and 30 high b value) high angular resolution diffusion MRI (HARDI) sequence. Diffusion tensor images (DTI) were constructed using FMRIB software library (FSL), using DTIFIT. ROIs were selected a priori based on their known roles in various reward and cognitive functions. These were analyzed for estimates of fractional anisotropy (FA) and Mean Diffusivity (MD).
The results indicate prominent and sex-dependent effects of THC on DTI measures. In females, THC treatment during adolescence resulted in reduced MD values in hippocampal subregions and major white matter tracts, which suggest alterations in memory processing. In males, THC did not affect these regions, but instead reduced MD in nucleus accumbens and prelimbic cortex, which suggest effects related to reward seeking and substance use. In addition, ongoing work is taking advantage of the HARDI parameters used in the scans to conduct Neurite Orientation Dispersion and Density Imaging (NODDI) analyses.
The results of this work indicate that adolescent THC exposure alters brain developmental trajectories, which appear to differ between females and males. These imaging-based findings will help guide future behavioral assessments directed at memory and reward circuitry, and how these are differentially affected by THC in male and female rats.

Abstract: In order to optimize outcomes in the face of uncertainty, one must recall past episodes and extrapolate to the future by assigning values to different choices. This behavior requires an interplay between memory and reward valuation, functions carried out by activity across all brain regions. At the anatomical nexus of this interplay is the perirhinal cortex (PRC), in theory a hub integrating memory, reward, and prediction. The perirhinal cortex is densely directly connected to the amygdala and orbital frontal cortex (Burwell RD, Witter MP, & Amaral DG, 1995), regions that have been implicated in reward-based decision making. However, the PRC's role in value-based decision making, to our knowledge, has not been explored. Therefore, we tested the role of the PRC in a spatial delay discounting task, which allowed rats to choose between a 1-second delay for a small food reward and a variable delay for a large food reward, with the delay to the large reward increasing after delivery of each large reward and decreasing after each small reward. Thus, the rat could alternate sides to stabilize the delay or adjust the delay by consecutively choosing the same side (Breton YA, Seeland KD, Redish AD, 2015; Papale AE, Stott JJ, Powell NJ, Regier PS, Redish AD, 2012). When the PRC was bilaterally inactivated with the GABA(A) agonist muscimol, rats completed the task with a higher proportion of adjustments relative to controls (32% vs 8%; $P<.01$), indicating less stability in the time they were willing to wait for the large reward, and increased reaction times at the choice point of the maze. These results indicate that the PRC is required for stable valuation of reward and should be the target of further research on decision making.

Title: Sex differences in the relationship between risk-taking preference and escalation of cocaine self-administration in rats

Authors: *C. A. ORSINI[1], S. L. BLAES[1], J. L. BIZON[3], B. SETLOW[2]
[2]Dept. of Psychiatry, [1]Univ. of Florida, Gainesville, FL; [3]Neurosci., Univ. of Florida McKnight Brain Inst., Gainesville, FL

Abstract: Impaired decision making is known to be strongly associated with substance use disorders (SUDs). Previous work from our laboratory has shown that cocaine self-administration alters risky decision-making behavior, causing an increase in risky choice (risk taking). Furthermore, pre-existing individual differences in risk-taking behavior are positively correlated with subsequent cocaine intake. These studies are limited, however, in that only male subjects were used. Given the well-established sex differences in both risk taking and substance use, it is conceivable that the relationship between risk taking and cocaine self-administration may differ in females relative to males. To begin to address this hypothesis, male and female Long-Evans rats were first trained in the "Risky Decision-making Task" (RDT), in which they made discrete trial choices between a small, "safe" food reward and a large, "risky" food reward accompanied by increasing probabilities of mild footshock punishment.
After reaching stable performance, males and females underwent jugular catheter surgery followed by long-access cocaine self-administration (6 h, 0.5 mg/kg/infusion) for 14 days. There were no sex differences in total cocaine intake or in change in cocaine intake over days (escalation). There were also no significant correlations in males between risk taking and either total cocaine intake or escalation of cocaine intake. In contrast, although risk taking in females was not correlated with total cocaine intake, it was positively correlated with escalation of cocaine intake such that females who displayed greater risk taking (greater preference for the large, risky food reward) showed greater escalation of cocaine intake. The sex difference in this relationship between risk taking and escalation of intake is consistent with evidence that women progress from casual drug use to drug dependence more rapidly than males, but it also suggests that, at least at some doses, pre-existing risk taking may be a stronger predictor of the development of substance use problems in women than in men. Future experiments will extend these findings by examining whether cocaine self-administration causes similar increases in risk

taking in females as it does in males. Collectively, results from these experiments will have significant implications for understanding and treatment of impaired decision making in individuals with SUDs.

Title: Development of the spatial gradient along the dorsal-ventral axis of the hippocampus

Authors: *S. H. NEAL[1], D. T. GUENTHER[2], S. D. LOVETT[3], B. A. SULAMAN[1], K. N. LUBKE[1], M. V. GUEVARA[1], S. N. BURKE[3], A. P. MAURER[4]
[2]McKnight Brain Inst. - Dept. of Neurosci., [3]Neurosci., [4]Evelyn F. McKnight Brain Inst., [1]Univ. of Florida, Gainesville, FL

Abstract: The size of hippocampal place fields progressively increases from the dorsal to ventral region of the hippocampus (Jung et al., 1994; Maurer et al., 2005; Kjelstrup et al., 2008), leading to the hypothesis that there is a spatial gradient along the long axis of the hippocampus. Small place fields in the dorsal hippocampus are associated with spatial representation while broader fields in the ventral hippocampus facilitate emotional and homeostatic processing (Bannerman et al., 2004). Although the dorsal-ventral axis of transcription is differentiated at birth (O'Reilly et al., 2015), place cells and spatial selectivity do not appear for approximately 2 more weeks. Therefore, to understand the developmental trajectory of the spatial selectivity along the long-axis of the hippocampus, we characterized the expression of the activity-regulated immediate early gene, Arc, at ages P14 to P21. Pups underwent a two-epoch object exploration task, in which the position of two out of the four objects are swapped (Ramsaran, Westbrook, & Stanton, 2016). This design provides the capability to assess spatial selectivity as well as any potential correlates to object-place selectivity. Our preliminary data demonstrates that at P14, there is no significant difference in Arc activity between the dorsal and ventral regions of CA1, however by P21 a gradient is evident. In addition, this gradient is a result of increased expression of Arc in the dorsal region, as the activity in the ventral region remains relatively stable. Ongoing experimentation will seek to focus on the development of the spatial gradient in the CA3 region in addition to the previously studied CA1.

Abstract: The link between age-related cellular changes within brain regions and larger scale neuronal ensemble dynamics critical for cognition has not been fully elucidated. The current study measured neuron activity within medial prefrontal cortex (PFC), perirhinal cortex (PER), and hippocampal (HPC) subregion CA1 of young and aged rats by labeling expression of the immediate-early gene Arc (Guzowski et al., 2001). 4- and 24-month old male Fisher 344 x Brown Norway rats were trained on an object-place paired association (OPPA) task that is dependent on this PFC-PER-HPC circuitry as well as an alternation task within the same testing apparatus. Although aged animals required more training to learn the object-in-place rule (Hernandez et al., 2015), all animals were trained to equivalent performance. The proportion of cells expressing Arc was quantified at baseline in a subset of rats sacrificed directly from the home cage, and following the OPPA and alternation behaviors in another subset. Additionally, the retrograde tracer cholera-toxin subunit B was injected into the prelimbic (PL) and infralimbic (IL) cortices within the PFC to identify cells within PER and CA1 that project to the medial PFC. Baseline Arc expression did not differ across age groups within CA1 or PER, but was elevated in aged rats relative to young within the PL and IL regions of the PFC. Within the CA1 of task-performing rats, no age-related differences in neuronal activity were observed in the entire neuron population or within CA1 pyramidal cells that project to PFC. Although behavior was comparable across age groups, behaviorally driven Arc expression was higher in the deep layers of both PER and PFC, and lower in the superficial layers of these regions in aged rats. Moreover,

age-related changes in activity levels were most evident within PER cells that project to PFC. These data suggest that the PER-PFC circuit is particularly vulnerable in advanced age.

Title: Female rats show greater impulsive choice than males in an intertemporal choice task

Authors: *A.-R. WHEELER[1,2], C. M. HERNANDEZ[1,2], C. A. ORSINI[1,3], T. W. TEN EYCK[1,2], C. C. LABISTE[1,2], B. SETLOW[1,3], J. L. BIZON[1,2]
[1]Univ. of Florida, Gainesville, FL; [2]Neurosci., Gainesville, FL; [3]Psychiatry, Gainesville, FL

Abstract: Intertemporal choice involves decisions among options that differ in both reward magnitude and delay to reward delivery. All other things being equal, individuals prefer large over small rewards; however, individuals tend to more readily choose small over large reward options the longer they have to wait for the large reward (i.e., the value of the large reward is "discounted" by the delay to its delivery). Marked individual differences in intertemporal choices exist across the population, with preferences for small, immediate rewards (greater "impulsive choice") associating with many psychiatric disorders. While data from our lab (Orisini et al, 2016) and others strongly implicate sex and gonadal hormones in other aspects of decision making, such differences are poorly elucidated in the context of intertemporal choice. The goal of the current study was to characterize adult (4 mo.) male and female Fischer 344 × Brown Norway F1 hybrid (FBN) rats on an intertemporal choice task in which rats make discrete trial choices between a small, immediate reward and a large, delayed reward using a block task design. Estrous cycle was evaluated in female rats after stable baseline performance was achieved. Choice preference (% choice of the large, delayed reward) was used as the primary performance measure, and latency to respond during intermixed forced choice trials was analyzed as a measure of motivation to obtain the rewards. Compared to males, female rats

showed significantly greater preference for the small, immediate over the large, delayed reward (i.e., females showed greater "impulsive choice" than males). Consistent with less incentive motivation for the large, delayed reward, females also showed longer latencies to choose this option relative to males. Overall task motivation was not affected by sex, however, as males and females completed similar numbers of trials. These sex differences in intertemporal choice were also not secondary to differences in reward magnitude perception, as males and females showed equivalent preference for the large reward when there was no delay to its delivery. Finally, choice behavior in females was not altered across the estrous cycle. Considered together, these data demonstrate that female rats show greater impulsive choice than males, and suggest that sex differences in decision making may be a contributing factor to gender disparities across a range of neuropsychiatric disorders.

Title: Altered $GABA_B$ receptor signaling in basolateral amygdala may contribute to age-associated differences in intertemporal choice

Authors: *T. W. TEN EYCK[1], C. M. HERNANDEZ, III[2], J. A. MCQUAIL[2], M. M. BRUNER[2], S. GHAY[2], C. C. LABISTE[2], A.-R. WHEELER[2], B. SETLOW[3], J. L. BIZON[2]
[2]Dept. of Neurosci., [3]Dept. of Psychiatry, [1]Univ. of Florida, Gainesville, FL

Abstract: The ability to choose adaptively among options that vary in time to arrival (i.e., intertemporal choice) is critical for navigating many aspects of everyday life. Most individuals will choose a large over a small reward in the absence of delays, but reliably "discount" the subjective value of the large reward if there is a delay imposed between the choice and its delivery. Greater discounting of large, delayed rewards (i.e., greater impulsive choice) is a hallmark of several neuropsychiatric disorders. In contrast, older adults exhibit less discounting

of delayed rewards compared to young adults (i.e., less impulsive choice). Impulsive choice is mediated by a network of limbic cortico-striatal brain structures, and recent findings indicate that the basolateral amygdala (BLA) and medial prefrontal cortex (mPFC) are particularly critical for regulating impulsive choice in young adults. Previous optogenetic and biochemical studies from our lab and others implicate altered excitability of BLA and mPFC in age-associated changes in intertemporal choice. The objective of the current study was to investigate specifically how changes in signaling at the extrasynaptic $GABA_B$ receptor contribute to age differences in intertemporal choice in Fischer 344 × Brown Norway F1 hybrid rats. In a first cohort of young and aged behaviorally naïve rats, RNA was extracted from tissue punches of the BLA and mPFC in order to evaluate expression of transcripts associated with excitatory and inhibitory signaling molecules using RT-qPCR. Transcripts for $GABA_B$ receptor subunits were significantly reduced in the aged BLA but not the aged mPFC relative to young adults. In additional experiments, cohorts of young and aged rats received surgically implanted guide cannulae targeting either the BLA or mPFC. After recovery from surgery, rats were trained on the intertemporal choice task. Using a within-subjects design, choice performance was evaluated following intra-cerebral infusion of either the $GABA_B$ receptor agonist, baclofen (0.03, 0.1, 0.3 µg/0.5 µl/hemisphere), or the $GABA_B$ receptor antagonist, CGP55845 (0.05, 0.15, 0.5 µg/0.5 µl/hemisphere). Baclofen infused into the BLA increased impulsive choice in both young and aged rats, whereas CGP did not alter choice performance in either age group. The effects appeared specific to the BLA as neither baclofen nor CGP55845 targeted to mPFC altered choice performance in either age group. Taken together, these data suggest that reduced $GABA_B$ receptor expression, particularly in the BLA, may contribute to age-associated decreases in impulsive choice.

Abstract: Cognitive flexibility is a core prefrontal cortical-dependent neurocognitive process that enables modification of one's behavioral strategy in response to a change in environmental contingencies. Reversal learning is a form of cognitive flexibility in which the learned reinforcement contingencies associated with a two choice discrimination are reversed (e.g., A+/B- becomes A-/B+). Therapies to enhance cognitive flexibility may have broad functional benefit to individuals engaged in some forms of learning (e.g., acquiring a new language) and may attenuate maladaptive behavior in conditions in which cognition is compromised. Based on previous work from our laboratory and others that implicates prefrontal cortical GABAergic signaling as critical for cognitive flexibility, the overarching goal of this study was to assess the efficacy of multiple approaches for modulating cortical GABAergic signaling on reversal learning. Adult male Brown Norway rats were trained in a novel reversal learning task in "touchscreen" operant chambers, in which visual stimuli are projected on a touch-sensitive video screen. In this task, rats initially received training sessions consisting of intermixed presentations of two pairwise visual discrimination problems (W+/X- and Y+/Z-). For each problem, touching the correct stimulus in each pair (W+ and Y+) earned a food pellet reward. Once rats learned to perform accurately on both problems (>80% correct on each), the contingencies were reversed for the stimuli in one of the problems, whereas they remained consistent for the other (W-/X+ and Y+/Z). In naïve rats, initial performance accuracy was markedly lower on the reversed problem in comparison to the consistent problem, but improved over the course of subsequent training. Rats were then tested in a within-subjects comparison of acute, systemic administration of 0, 1.0, and 2.5 mg/kg of the GABA(B) receptor agonist baclofen. Baclofen (2.5 mg/kg) significantly enhanced performance accuracy on the reversed problem compared to vehicle administration, with minimal effects on the consistent (non-reversed) problem. These results show that activation of GABA(B) receptors can enhance reversal learning, and in combination with previous findings from our laboratory (Beas et al., 2016, 2017), suggest that increasing cortical GABAergic activity can promote cognitive flexibility. Current experiments are evaluating whether electrical stimulation of the vagus nerve, which is an approved treatment for epilepsy, can similarly enhance reversal learning.

Title: Acute vagus nerve stimulation attenuates novelty-induced arc transcription in dorsal CA1

Authors: *S. N. BURKE[1], A. CRIDER[2], K. P. OLCZAK[3], E. W. DIRR[3], K. N. LUBKE[1], J. NICK[1], B. MCLAURIN[1], E. ATKINSON[1], K. J. OTTO[4], A. P. MAURER[5], D. G. LAMB[7], B. SETLOW[6], J. L. BIZON[8]

Abstract: Vagus nerve stimulation (VNS) is currently an FDA-approved treatment for drug-resistant epilepsy, major depressive disorder, and migraine. Moreover, recent data have indicated that VNS may be beneficial for treating stroke (Kilgard et al., 2018), tinnitus (Tyler et al., 2017), and post-traumatic stress disorder (Noble et al., 2017), as well as for enhancing auditory discrimination (Engineer et al., 2017) and other cognitive functions (see Lamb et al., 2018). While the mechanisms of the clinical utility of VNS are not yet known, it is well established that VNS paired with sensory stimuli enhances cortical plasticity (e.g., Porter et al., 2012; Hulsey et al., 2016; Engineer et al., 2017; Borlan et al., 2018). Thus, it is likely that a potential mechanism of VNS efficacy is the ability of this treatment to modulate the expression of immediate-early genes, which are implicated in plasticity and known to be induced by behaviors associated with new learning. One such immediate-early gene is activity-regulated cytoskeletal (*Arc*) protein, which is involved in homeostatic synaptic scaling and hypothesized to be a nexus point for synaptic dysfunction in cognitive disorders (for review, see Shepherd and Bear, 2011). The current experiment investigated the extent to which VNS can modulate behaviorally-driven *Arc* transcription during two distinct epochs of novel object exploration in adult (4-months old) Brown Norway rats. Critically, because the distribution of *Arc* mRNA in the nucleus versus the cytoplasm occurs at distinct time points following neuron spiking, its subcellular location can reveal the activity history of neurons during two different epochs of behavior 20 min apart. This cellular compartment analysis of temporal activity by fluorescence *in situ* hybridization (catFISH; Guzowski et al., 1999) therefore enables distinct VNS parameters to be compared within an individual animal. Within the CA1 subfield of the dorsal hippocampus, high frequency VNS (60μs pulse width, 500mA, 50Hz, 0.8s train duration) paired with object exploration resulted in a significant decrease in the proportion of *Arc* positive cells following exploration when compared to animals that received no stimulation. This reduction in *Arc* expression was not observed when animals received low frequency stimulation during the behavioral epoch (60μs pulse width, 500mA, 2Hz, 20s train duration). These data suggest that VNS paired with salient behavioral events may operate to enhance plasticity by promoting the sparsification of active neural ensembles to increase signal-to-noise ratios.

Title: Hippocampal, perirhinal, and lateral entorhinal contributions to mnemonic discrimination in young and aged rats

Authors: *S. A. JOHNSON[1,4], S. M. TURNER[1], K. N. LUBKE[1], K. E. FERTAL[1], A. P. MAURER[1,2], J. L. BIZON[1,4], S. N. BURKE[1,4,3]
[1]Dept. of Neurosci., [2]Dept. of Biomed. Engin., [3]Inst. on Aging, Univ. of Florida, Gainesville, FL; [4]Evelyn F. McKnight Brain Inst., Gainesville, FL

Abstract: Memory requires that similar episodes be represented distinctly. Notably, many symptoms of age-related memory loss appear to derive from a decreased ability to distinguish between similar events (e.g., Stark et al. 2013). In a rodent version of the mnemonic similarity task that tests this ability, we have shown aged rats are selectively impaired in distinguishing a learned target object from similar lure objects (Johnson et al. 2017), and that disrupting neural activity in the dorsal CA3 in young adult rats impairs mnemonic discrimination. Given work in animal models and, more recently, human functional neuroimaging studies, implicating the perirhinal and entorhinal cortices in age-related decline in mnemonic discrimination (Berron et al. 2018; Maurer et al. 2017; Reagh et al. 2018; Ryan et al. 2012), the present study investigated activation of neural ensembles across medial temporal lobe and hippocampal regions during mnemonic similarity task performance in young and aged rats. F344 x Brown Norway F1 hybrid rats (young adult 6-8 m, aged 26-30 m) were behaviorally characterized and trained on a target-lure LEGO object discrimination task in which feature overlap of a well-learned target object (S+) to lures (S-) was systematically varied (Johnson et al. 2017). To assess neural ensemble activation as it relates to mnemonic discrimination performance, rats completed two behavioral epochs with distinct versus similar objects, then brain tissue was rapidly extracted and prepared

for fluorescent in situ hybridization (FISH) against the immediate early gene Arc. The proportion of neurons expressing Arc was systematically counted from regions of interest across the lateral entorhinal cortex (LEC), perirhinal cortex (PRC), CA3, and CA1. Consistent with previous studies, aged rats showed a reduction in the proportion of neurons active during mnemonic discrimination in superficial layers of PRC. This effect was also observed in output layers of LEC. In contrast to medial temporal lobe regions, aged rats showed a greater proportion of neurons active in hippocampus, particularly in CA3 and the proximal portion of CA1. Of note, while the size of neural ensembles active across regions did not correlate with performance on behavioral epochs immediately prior to tissue collection, a greater proportion of neurons active in the proximal CA1 was observed in rats that showed better abilities discriminating similar objects over the course of initial behavioral training. Our results directly parallel findings from older adults and support the emerging view that circuit level dysfunction across the medial temporal lobe and hippocampus contributes to age-related memory loss.

Title: Laminar differences in velocity modulation of hippocampal local field potential

Authors: *S. D. LOVETT[1], J. P. KENNEDY[2], Y. ZHOU[3], Y. QIN[4], S. N. BURKE[5], A. SHEREMET[6], A. P. MAURER[7]

Abstract: Local field potential oscillations, which arise from large-scale synaptic activity over a population of neurons, are hypothesized to play a fundamental role in the organizing the timing of single neuron action potentials to promote the formation of cogent cell assemblies (Lisman & Idiart, 1995). During active behavior and REM sleep, the hippocampal LFP is dominated by gamma oscillations (50-120 Hz) and the 4-12 Hz theta rhythm (Vanderwolf, 1969; Bragin et al., 1995). As the frequency and power of both these oscillations are modulated by running speed and other behaviors (Montgomery and Buzsaki, 2008; Ahmed and Mehta, 2012; Zheng et al., 2015), and theses oscillations are primarily generated by ionic flux related to synaptic activity,

then it stands to reason that increases in power are a consequence of more afferent input into the hippocampus.. While there is a well-defined organization of afferent input across the hippocampal laminae (Amaral and Witter, 1993), to our knowledge, there has yet to be an explicit investigation of changes in local-field potentials across layers of the hippocampus as a function of velocity. A simple hypothesis is that increased running velocity is associated with a uniform increase in all synapses independent of afferent location (e.g., radiatum power increases as much with velocity as the lacunosum-moleculare). Alternatively, the entorhinal cortex containing path integration-related information may eclipse the CA3 input field. These mutually exclusive hypotheses were tested in the current study.

Title: Aged rats do not use basolateral amygdala during outcome evaluation in an intertemporal choice task

Authors: *C. M. HERNANDEZ, III[1], C. A. ORSINI[2], C. C. LABISTE[1], A.-R. WHEELER[1], T. W. TEN EYCK[1], M. M. BRUNER[1], S. M. SINGHAL[3], C. J. FRAZIER[3], B. SETLOW[2], J. L. BIZON[1]
[1]Neurosci., [2]Psychiatry, [3]Pharmacodynamics, Univ. of Florida, Gainesville, FL

Abstract: Intertemporal choice involves decisions among options that differ in both reward magnitude and delay to reward delivery. Such decisions require integration of existing reward representations (prior experience) with valuation of the organism's current wants and needs (incentive motivation). Moreover, evaluation of the outcome received (is it more or less than expected) is critical for driving future choices. Prior studies in both humans and rodents show that relative to young adults, aged subjects are better able to delay gratification, and generally prefer large, delayed over small, immediate rewards. While the neural circuit changes that mediate these age differences in intertemporal choice are unknown, lesion and

electrophysiological studies consistently implicate the basolateral amygdala (BLA) in motivation and affective decision making. The current experiments used optogenetic approaches to determine the effects of temporally discrete BLA inactivation on choice behavior during an intertemporal choice task. Young adult (6 mo) and aged (24 mo) Fischer 344 x Brown Norway F1 hybrid rats were surgically implanted with guide cannulae targeting BLA through which pAAV-CaMKIIa-eNpHR3.0-mCherry (halorhodopsin) was delivered and optic fibers were implanted. Rats were subsequently trained on an adjustable-delay intertemporal choice task in which preference for small vs. large rewards was evaluated in the presence of increasing delays to large rewards. Upon reaching stable performance, light-induced BLA inactivation was performed using a within-subjects design such that BLA was inactivated at discrete phases of the task: the period before choice (deliberation), the delay interval prior to large reward delivery (delay), a 4 s period during reward (outcome) or the intertrial interval (ITI). BLA inactivation during the ITI, delay interval or large reward delivery had no effect on behavioral performance. In contrast, BLA inactivation during deliberation *increased* young rats' choice of the large, delayed reward, whereas BLA inactivation during the small reward outcome *decreased* their choice of the large, delayed reward. The effects of BLA inactivation during deliberation were replicated in aged rats, while there was no effect of BLA inactivation during the outcome phase of the task in aged rats. These data indicate that in young adults, there are multiple BLA circuits that exert opposing influences on decision making. Importantly, however, aged rats fail to use the BLA to process information about outcome to guide future choices. These data may help explain the robust age-associated differences in intertemporal choice evident across aging populations.

Abstract: Selective attention is a prefrontal cortical-mediated executive function that serves as a building block for many aspects of higher-order cognition. Enhancement of selective attention may offer broad functional benefits across a range of cognitively challenging circumstances and for the treatment of cognitive disorders. Prefrontal cortical acetylcholine and norepinephrine have been particularly implicated in attentional processes, and vagus nerve stimulation (VNS) can modulate cortical levels of these neurotransmitters via projections through the nucleus tractus solitarius. In the current studies, the effects of VNS were tested in Brown Norway rats (~4 mo.) using a 5-choice serial reaction time task in which rats had to respond to brief presentations of visual stimuli in a touchscreen operant chamber. Within each test session, five stimulus durations (ranging from 0.7-0.05s) were presented in a randomized fashion. Under baseline conditions, rats showed a systematic reduction in accuracy with decreasing stimulus durations. On test days in which VNS (60μs pulse width, 500μA, 50Hz, 0.8s train duration) followed correct choices, rats showed a reliable improvement in accuracy at short stimulus durations compared to baseline (no stimulation) conditions. VNS further produced a reduction in trial omissions as well as an increase in premature responses, consistent with greater task vigilance. In contrast to these enhancing effects on performance, VNS impaired accuracy at long stimulus durations relative to baseline. The effects of VNS were compared with those resulting from systemic administration of either donepezil (an acetylcholinesterase inhibitor, 0.1, 0.3, 1.0 mg/kg) or atomoxetine (a noradrenergic transporter blocker, 0.3, 1.0, 3.0 mg/kg), which were assessed using a within-subjects design. In agreement with previous literature, both drugs enhanced accuracy relative to vehicle conditions, suggesting that the beneficial effects of VNS may act through these modulatory neurotransmitter systems. Title: Perforant path fiber loss results in mnemonic similarity task deficits in rats

Authors: *S. M. TURNER[1], S. A. JOHNSON[1], J. J. FLINT[1], K. L. ROBERTSON[1], J. A. NICK[1], S. D. LOVETT[1], J. L. BIZON[2], S. N. BURKE[1], A. P. MAURER[1]
[1]Neurosci., Univ. of Florida, Gainesville, FL; [2]Neurosci., Univ. of Florida McKnight Brain Inst., Gainesville, FL

Abstract: The observation that entorhinal input into the hippocampus declines in old age is well established across human studies and in animal models (Barnes and McNaughton, 1980; Yassa et al., 2011; Rogalski et al., 2012; Bennett and Stark, 2016). This loss of perforant path fibers is exaggerated in Alzheimer's disease and Mild Cognitive Impairment (Gómez-Isla et al., 1996; Kordower et al., 2001; Stoub et al., 2005), with additional research suggesting that perforant path integrity in cognitively normal adults is predictive of progression to Alzheimer's Disease and more generally of episodic memory impairment (Stoub et al., 2014). Together, this suggests that, at least in the early stages, diseases of pathological cognitive aging are cortical disconnection disorders (Hyman et al., 1984). However, evidence linking perforant path changes to cognitive decline has been largely correlational, as invasive mechanistic studies in humans are not feasible. Thus, the current project aimed to 1) Replicate the finding perforant path fiber loss in aged rats in the same data modality as used in humans - DTI, and 2) Test the causative role of perforant path fiber loss in behavioral decline by performing a unilateral knife cut to disconnect the entorhinal cortex from the hippocampus in the right hemisphere. Our preliminary data suggest a decline in perforant pathway fractional anisotropy between 6 and 28 months of age in Fischer 344 x Brown Norway F1 hybrid rats. When young male rats received a right hemisphere perforant path knife cut and were tested on the rat variant of the mnemonic similarity task (Johnson et al., 2017), there was a significant impairment in the abilities of lesioned animals to discriminate between objects with high levels of feature overlap. This deficit was not observed in the sham group that received a cut to cortex that did not involve white matter. Interestingly, a significant difference in mnemonic similarity task performance between the perforant path knife cut and sham group was not observed in female rats. Together these data support the view that perforant path fiber loss is a consequence of normal aging that is ubiquitous across species. Moreover, the integrity of perforant path fibers is critical for an animal's ability to resolve mnemonic interference.

Title: Normal aging increases susceptibility to human wild type tau in transentorhinal cortex

Authors: *J. A. MCQUAIL[1], S. A. JOHNSON[1], M. N. LITENSKI[1], S. GHAY[1], S. L. ROSSI[2], P. CHAKRABARTY[1], B. I. GIASSON[1], S. N. BURKE[1], P. R. RAPP[2], J. L. BIZON[1]
[1]Dept. of Neurosci., Univ. of Florida, Gainesville, FL; [2]NIH, Natl. Inst. on Aging, Baltimore, MD

Abstract: Intracellular inclusions comprised of hyperphosphorylated tau are among the earliest pathological features of Alzheimer's disease (AD), the most prevalent age-associated neurodegenerative disorder. Initially manifesting in area 35 of the transentorhinal cortex, tau pathology has been described as progressing in an anatomically directed manner, propagating to synaptically interconnected regions throughout the medial temporal lobe. Distinct from AD, these same neural circuits are highly sensitive to the effects of normal aging, exhibiting neurophysiological and synaptic changes that associate with memory loss. The overarching goal of the current study is to directly investigate interactions between aging and tau pathology using approaches that model the anatomical specificity of the human disease. Young adult (6 mo) and aged (24 mo) Fischer 344 × Brown Norway rats received a stereotaxic delivery of an AAV containing human wild type tau-eGFP (AAV-hWTtau) or eGFP alone (AAV-CON). Two months after surgery, sections from one hemisphere were processed for immunofluorescence to evaluate phosphorylation and conformational alterations in tau, using antibodies to AT8 and Alz50. Expression of eGFP was robust in area 35 across all groups and did not differ with age. In both young and aged rats that received AAV-hWTtau, immunoreactivity for AT8 and Alz50 was reliably detected in both area 35 and the monosynaptically connected CA1 subfield of hippocampus. In the AAV-hWTtau condition, eGFP neurons in area 35 of aged rats showed

increased AT8 in somatodendritic compartments, less AT8 in axons and markedly reduced soma size relative to young rats. The other hemisphere of each brain was cleared using iDISCO procedures and processed for immunohistochemistry to localize hyperphosphorylated tau (AT8). Using volume imaging, AT8 immunopositive cell bodies were visualized within area 35 and monosynaptically interconnected structures, including CA1. Consistent with observations from traditional histological sections, qualitative observations of cleared tissue confirmed that aged rats receiving AAV-hWTtau showed overall less AT8-immunoreactivity in axons compared to young rats in the same condition. Together, these observations indicate that aged neurons appear to have increased susceptibility to the deleterious effects of human wildtype tau and establish the methodology to detect 3-dimensional spread of tau pathology in the medial temporal lobe of aged rats. Ongoing work will apply quantitative anatomical and biochemical methods to compare abnormal tau species and synaptic integrity in area 35 and CA1 in this model.

Title: Effects of inactivation of the lateral habenula on risky decision making

Authors: *S. L. BLAES[1], C. A. ORSINI[1], H. HOLIK[1], J. L. BIZON[3], B. SETLOW[2]
[2]Dept. of Psychiatry, [1]Univ. of Florida, Gainesville, FL; [3]Neurosci., Univ. of Florida McKnight Brain Inst., Gainesville, FL

Abstract: Cost-benefit decision making is critical for adaptive behavior, and impairments in decision making are associated with a range of psychiatric disorders. The lateral habenula (LHb) is a brain region thought to play a key role in some forms of cost-benefit decision making, potentially through its role in signaling “negative prediction errors” (which occur when the consequence of an action or event is less optimal than expected). Lesions or inactivation of the LHb cause alterations in some forms of decision-making, but its role in decisions involving risk of explicit punishment is unclear. To address this question, male Long Evans underwent surgery to implant bilateral cannulae targeting the LHb and were then trained in a Risky Decision Making Task (RDT) in which they made discrete trial choices between a small, “safe” food reward and a large, “risky” food reward accompanied by varying probabilities of footshock

punishment. Once stable performance was achieved, rats received microinfusions of baclofen/muscimol or vehicle into the LHb followed by testing on the RDT, using a randomized, within-subjects design. While inactivation of the LHb with baclofen/muscimol had no effect on choice of the large, risky reward in the group as a whole, rats' performance under vehicle conditions revealed a strong bimodal pattern of choices; some rats showed a strong preference for the large, risky reward ("risk-taking"), whereas others showed a strong preference for the small, safe reward ("risk-averse"). Separate analyses of the effects of LHb inactivation on choice performance in these two subgroups of rats revealed opposing effects on choice performance. Specifically, LHb inactivation reduced choice of the large, risky reward in the risk-taking subgroup, but increased choice of the large, risky reward in the risk-averse subgroup. Ongoing experiments are further evaluating whether these distinct effects of LHb inactivation reflect inherent differences in the recruitment of neural circuits during decisions that involve risk in "risk-taking" versus "risk-averse" subpopulations.

Title: A mechanistic model of memory and schema consolidation for preventing catastrophic interference in neural networks

Authors: *T. J. HWU[1], J. L. KRICHMAR[1,2]
[1]Dept. of Cognitive Sci., [2]Dept. of Computer Sci., Univ. of California, Irvine, Irvine, CA

Abstract: Humans and other animals develop mental schemas of their environments, allowing them to recognize different scenarios and behave appropriately according to the situation. The complementary learning systems theory suggests that schemas are acquired through a gradual learning system in the neocortex combined with a fast learning system via the hippocampus to consolidate episodes of experience (McClelland, McNaughton, and O'Reilly, Psych Review, 1995). However, it has been shown that information matching a preexisting schema can be learned very rapidly (Tse et al., Science, 2007). Although there exist theories of how schemas are stored and processed, we have an incomplete understanding of the neural mechanisms that achieve this. To address this, we created a systems level computational model of schema consolidation that examines the interactions of several brain areas. Replicating the experiment

from Tse et al., our model uses a multi-layer contrastive Hebbian network (CHN) to train paired associations (PAs) between food cues and their corresponding locations. We show that the representation of spatial layouts as schemas in the medial prefrontal cortex (mPFC) supports the retrieval of different PAs according to context. The model also suggests that the indexing behavior of the ventral hippocampus (vHPC) gates neurons in intermediate layers of the CHN depending on their involvement within the current schema. This causes the learning of a new schema to not interfere with the storage and recall of prior schemas. Furthermore, oscillations in the dorsal hippocampus (dHPC), which alternate between clamping and unclamping the output layer of the CHN, are necessary to drive learning. Finally, our simulations show the vital role of neuromodulation, as the locus coeruleus detects uncertainty in the mPFC according to how strongly information fits within a prior schema. It uses this to consolidate new information into an existing schema when consistent with a prior schema, and drive the encoding of this information into a new schema when it is inconsistent. The present work provides a mechanistic explanation of how schemas are formed and recalled. Moreover, the model provides inspiration for creating context-dependent memories and avoiding catastrophic forgetting in artificial neural networks.

Title: Systemic administration of 5-HT_6 receptor agonist and antagonists at active and sub-active doses during memory consolidation and amnesia

Authors: *A. MENESES, L. APARICIO-NAVA
Cinvestav - IPN, Mexico, Mexico

Abstract: Serotonin or 5-hytryptamine (5-HT) $_6$ receptor antagonists have pro-memory and/or anti-amnesic effects. Certainly, not all researchers report pro-memory and/or anti-amnesic effects of 5-HT_6 receptor antagonists and agonists. These inconsistencies might be due to drug administration timing, memory task or memory phase used. To our knowledge serotonergic 5-HT_6 receptor tone remains little explored; hence, we are addressing it by testing systemic administration of 5-HT_6 receptor drugs with differential intrinsic activity. Thus, the antagonists SB-399885 (SB-399) and SB-357134 (SB-357) as well as the agonist EMD 386088 (EMD) at active and sub-active doses are tested in autoshaping Pavlovian/instrumental short- (STM) and long-term memory (LTM) and amnesia. Automatized autoshaping is bridging translational testing between rodents and humans, measuring memory, neural markers and pharmacological

effects. Both SB-399 (10.0 mg/kg) and SB-357 (10.0 mg/kg) increased CR% in STM and LTM and prevented decrements of scopolamine- or dizocilpine-induced. EMD at 1.0 mg/kg had did not affect STM but increased CR in LTM (24-h) and reversed STM induced-amnesia by scopolamine or dizocilpine. SB-399 (10.0 mg/kg) or SB-357 (10.0 mg/kg) prevented LTM (24-h)-amnesia. Systemically sub-active doses of SB-399 or SB-357 (both at 5.0 mg/kg) plus EMD (2.5 mg/kg) had no effect on STM but facilitated LTM (24-h) and prevented scopolamine-induced STM amnesia. SB-EMD co-administration di not alter the scopolamine- or dizocilpine-induced decreased CR; thus indicating that both drugs exerted their effects via 5-HT_6 receptor.

Title: Neural activity suppression in the mediodorsal thalamus precedes the occurrence of hippocampal ripples

Authors: *M. YANG, N. LOGOTHETIS, O. ESCHENKO
Max Planck Inst. For Biol. Cybernetics, Tuebingen, Germany

Abstract: Highly synchronized oscillations, or ripples (~200Hz), are generated in the hippocampus (HPC) during awake immobility or non-REM (NREM) sleep and has long been suggested to mediate the hippocampal-cortical communication underlying memory consolidation. The medial prefrontal cortex (mPFC) receives direct input from the HPC and many mnemonic processes depend on these two brain regions. The HPC-mPFC pathway is considered critical for consolidation of declarative memory and is currently one of the most studied memory-related pathways. A memory-supporting network is, however, not limited by the HPC and the mPFC. The thalamic mediodorsal (MD) nucleus is likely a part of an extended memory network. The MD is reciprocally connected with the mPFC and has long been implicated in different mnemonic functions. Our fMRI-based mapping of the whole brain activity associated with ripples occurrence suggested that silencing of a subset of subcortical regions, including thalamus, may reduce interference for hippocampal-cortical communication (Logothetis et al., 2012).
We characterized neural activity in the MD around times of the hippocampal ripples in spontaneously behaving rats. Generally, the MD population activity was strongly suppressed around ripples. A substantial reduction of the MD firing occurred 0.4 - 2.4 sec (mean: 1.1 ± 0.1

sec) before the ripple peak and lasted for 2.1 ± 0.2 sec. Moreover, the degree of MD activity suppression correlated with the ripple amplitude. The ripple-associated decrease of the MD firing rate was the strongest and the most consistent during awake immobility. In contrast, during NREM sleep bidirectional modulation of the MD activity was observed: the MD firing was actually enhanced around ripples that were temporally coupled with sleep spindles, while it was decreased around spindle-uncoupled ripples. Our results suggest possible competitive interaction between the hippocampal-cortical and thalamo-cortical networks supporting 'off-line' and 'on-line' information processing, respectively.

Title: Triggering k-complexes and spindles during NREM sleep in rats by electrical stimulation of deep cortex

Authors: *K. IYER, M. J. ECKERT, M. TATSUNO, D. R. EUSTON
Canadian Ctr. For Behavioural Neurosci., Lethbridge, AB, Canada

Abstract: Non-rapid eye movement (NREM) sleep is thought to play a key role in memory consolidation. Evidence suggests that the offline replay of memories occurs during oscillatory events in NREM sleep, specifically slow oscillations and sleep spindles. Previous studies have shown that transcranial direct current stimulation in both humans and rats results in better memory consolidation. However, the exact stimulus parameters which lead to the strongest memory enhancement have not been fully explored. Here, we tested whether pulsatile stimuli might be useful for triggering consolidation-related oscillations in the cortical local field potential (LFP) and how evoked responses varied as a function of sleep state. We delivered stimulation via bipolar electrodes located in deep layers of dorsal medial frontal cortex (Paxinos and Watson areas Cg1 and M2) and recorded electrical potentials via bipolar electrodes located

in M1 motor cortex for cortical LFP and just above CA1 for hippocampal LFP. Stimulation consisted of brief biphasic electrical pulses (500uA square pulse with 0.2 msec per phase, delivered every 3-sec) during slow-wave sleep (SWS) in four male Fisher Brown Norway rats. EMG (electromyogram) electrodes in the neck muscle were used to identify rest and waking states. LFP recordings obtained from the frontal cortex and hippocampus were used to divide the sleep periods into NREM sleep and REM sleep, based on theta(5-10 hz)/delta(1.5-4 hz) power ratio. LFPs were recorded during three epochs, a one-hour stimulation period and two one-hour no stimulation periods before and after ('pre-stim' and 'post-stim' periods). The pulsatile stimulation reliably triggered an evoked response in the cortical LFP. During slow-wave sleep, the stimulation-evoked LFP was visually similar to naturally occurring k-complexes followed by spindle activity. Quantitatively, we found that the rate of spindle occurrence during stimulation periods was significantly higher than during equivalent slow-wave periods in the pre-stim period before stimulation began. Qualitative observations suggested that the evoked response are state-dependent in that stimulation during waking states did not trigger spindles while stimulation during the transition from waking to SWS occasionally triggered high-amplitude spindles, a separate phenomenon from the low-amplitude spindles associated with memory consolidation. In sum, the results show that stimulation over frontal cortex with brief pulses can increase spindle density in a state-dependent manner. This method may be useful for future studies which attempt to boost memory via transcranial or intracranial stimulation.

Title: Modelling the influence of reward on offline activity: Replay of hippocampal-accumbens activity supports learning in a stochastic reinforcement learning task

Authors: *E. ROSCOW, N. F. LEPORA, M. W. JONES
Univ. of Bristol, Bristol, United Kingdom

Abstract: Experience-dependent patterns of neural activity are replayed during periods of quiet rest and sleep. Replay is best-characterised in CA1 of the hippocampus, where substantial evidence shows that memory consolidation depends on this offline activity. Preferential hippocampal replay of activity related to rewarding experiences is reported to be coordinated with reactivation of reward-responsive cells in the nucleus accumbens following learning. This

distributed offline activity may underlie the integration of reward into memory, potentially improving learning efficiency.
To test this, we developed a stochastic, spatial reinforcement learning task for rats, in which rewards are delivered at each of three goal locations on a Y-maze with different probabilities. Successful learning depends on acquiring reward probability distributions by integrating reward information over many trials, as well as learning to alternate between goal locations rather than revisit one successively. The stochastic nature of the task allows reward outcome (delivery or withholding of reward) to be distinguished from reward prediction (high, medium or low expectation of reward).
6 adult male Lister hooded rats were trained daily on the task, and began performing significantly above chance after 33 trials ($p = 0.03$). With a moderate difference between reward probability at goal locations (75%, 50% and 25% respectively), rats reached a peak of 64% optimal behaviour after 6 hour-long training sessions. With a bigger difference in reward probability (87.5%, 50% and 12.5%), rats reached a peak of 74% optimal behaviour.
Behaviour was modelled using a Dyna-Q reinforcement learning algorithm, which updates estimates of the value of state-action pairs based on expected reward. The algorithm was trained to predict rats' actions on each upcoming trial based on the complete history of actions taken and rewards obtained up to that point, and parameters were optimised for each individual rat. The Dyna-Q model showed strongest predictive accuracy when endowed with replay between trials and between sessions, consistent with offline activity biased by reward contributing to learning in the face of uncertain outcomes.
We are now testing model predictions using chronically recorded multiple single-unit activity from dorsal CA1 of the hippocampus and the nucleus accumbens, during Y-maze training sessions and surrounding periods of rest and sleep.

Title: Effects of optogenetic activation of the locus coeruleus during sleep on hippocampal replay

Authors: *B. A. GROSS[1], K. SWIFT[2], M. FRAZER[1], M. MAHONEY[3], G. R. POE[1]
[1]Dept. of Integrative Biol. and Physiol., UCLA, Los Angeles, CA; [2]Univ. of Michigan, Ann Arbor, MI; [3]Univ. of Vermont, Burlington, VT

Abstract: The locus coeruleus (LC), the main source of norepinephrine (NE) throughout the brain, is silent during rapid eye movement (REM) sleep and just before non-REM sleep spindles. We posited that these periods of LC silence are required for the incorporation of new memories into preexisting memory circuits. We have previously shown that preventing these sleep silent periods, via optogenetic stimulation of the LC, after a hippocampal-dependent altered learning task led to reductions in CA1 spindle density and REM theta power and a decrease in ripple-spindle coupling, which were correlated with poorer task performance. In addition, this LC stimulation resulted in CA1 spatial mapping abnormalities, i.e. lower place field stability and abnormal place field expansion. Here, we investigated the effects of our LC stimulation paradigm on sleep replay. Using variable length Markov chain (VLMC) models trained on firing sequences during sleep of identified place cells, we found that LC stimulated animals had approximately half the number of significant sequences during non-REM sleep compared to controls. In the control animals, roughly half of the significant sequences were forward or reverse replay of the run sequence—greater than 20 times the proportion of ordered replay occurring in the LC stimulated animals. These results provide further support for the importance of sleep-specific LC silent periods in accurate memory consolidation.

Title: Parahippocampal feedback input to layer 1 gates dendrite-dependent learning in cortex

Authors: *G. DORON, J. SHIN, C. BOCKLISCH, M. VON HEIMENDAHL, M. BRECHT, M. LARKUM
Humboldt Univ. of Berlin, Berlin, Germany

Abstract: The hippocampus (HPC) and related parahippocampal structures play a vital role in transforming experience into long-term memories that are then stored in the cortex, however the cellular mechanisms which designate single neurons to be part of a memory trace remain unknown. In order to examine associative cortical memory formation we developed a behavioral paradigm using cortical microstimulation in which rats and mice were trained to report the direct stimulation of somatosensory cortex (S1). Pharmacogenetic inhibition of perirhinal cortex (PRh) projections to Layer 1 (L1) of S1 as well as optogenetic activation of dendritic targeting interneurons during behavioral training resulted in learning deficits, suggesting a critical role of L1 in memory formation. We further investigated the cellular mechanisms of information transfer between PRh and S1 using juxtacellular recordings in PRh in awake head-restrained rats during learning. We found that firing and burst rates in deep layers of PRh is increased a few seconds after microstimulation in S1. Spectral analysis of local field potential (LFP) at a similar time window after microstimulation revealed an increase in theta frequency in PRh and S1 during this time window, suggesting a mechanism for information transfer between these regions during memory formation. Finally, we examined the role of feedback activity on microstimulation-learned engrams retrieval by generating somatic & dendritic input patterns in a single-neuron detection task following microstimulation learning. We found that simulated dendritic input was sufficient for memory retrieval. Overall, our data are consistent with dendritic-dependent information transfer and memory formation via cortical L1.

Title: Ca^{2+} imaging of network mechanisms of long-term memory consolidation

Authors: *A. D. GROSMARK[1], F. T. SPARKS[2], M. J. DAVIS[3], J. ZHANG[1], A. LOSONCZY[1]
[1]Neurosci., Columbia Univ., New York, NY; [2]Ctr. for Neural Sci., New York Univ., New York, NY; [3]Inst. for Neurosci., The Univ. of Texas At Austin, Austin, TX

Abstract: The mechanisms by which SWR-related activity lead to stable or unstable spatial-coding outcomes remains little understood. Moreover, limits on the sensitivity and speed of Ca^{2+}-imaging techniques, as well as the absence of well-defined Ca^{2+}-analogues of established biomarkers of 'offline' activity such the LFP-detected SWRs, have restricted the accessibility of

'offline' activity to Ca^{2+}-imaging. We have successfully developed and implemented combined chronic CA1 LFP recordings with simultaneous fast (60 Hz) two-photon Ca^{2+} imaging to stably track the activity of genetically identified mouse CA1 principal neurons over weeks of 'online' spatial behavior and 'offline' resting. I employ a behavioral paradigm designed to test the cross-day stability of CA1 'online' spatial representations as well as test for evidence of 'offline' replay. This project aims to predict the diverging cross-day spatial-coding stability outcomes of place cells by their recruitment to and replay in SWR events - to link long-term spatial memory to the 'offline' SWR-related replay activity thought to underlie memory consolidation. Our preliminary results recorded under this paradigm demonstrate: 1) that joint LFP recording and Ca^{2+}-imaging is an effective tool for studying fast neural dynamics, such as SWR-related responses, 2) stable and unstable cross-day spatial coding of CA1 place cells, 3) the first reported Ca^{2+}-imaging of SWR-associated place cell replay of a recent non-local spatial experience, and 4) that SWR-recruitment predicts long-term spatial stability outcomes. Ongoing work will directly relate the replay of memory ensembles to their spatial coding stability during treadmill running, and in turn relate these to various behavioral variables including memory performance and proximity to reward.

Title: CA1 maintains working memory representation of stimulus identity during trace conditioning

Authors: *J. L. KLEE[1], F. P. BATTAGLIA[2]
[1]Neuroinformatics, HG00.813, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [2]Donders Inst. for Brain, Cognition and Behavior, Radboud Univ., Nijmegen, Netherlands

Abstract: Establishing associations between stimuli that are discontinuous in time is a central element of intelligent behavior but also poses a complex problem for neural networks. While a multitude of lesion studies have pointed towards the hippocampus as a key entity in enabling trace conditioning, a form of classical conditioning during which CS and US are non-overlapping, very little is known about the underlying neurophysiology. In this context, we

combine an appetitive auditory trace conditioning paradigm in head fixed mice with high density silicon probe electrophysiological recordings from the hippocampus CA1 region. We find that single cells in CA1 exhibit robust sensory evoked responses to sounds and reward as well as CS+ specific and learning dependent sustained responses during the trace interval. In addition, we find a learning dependent and CS+ specific increase in CA1 theta and gamma power during the trace period. Finally, we employ template matching to show that patterns of evoked responses after CS presentations are replayed during Sharp Wave Ripples and that this replay is stronger for templates representing the CS+. In combination, these results suggest that the hippocampus contributes to trace conditioning by maintaining working memory representations of stimulus identity, possibly enabled by increased replay of task relevant information during Sharp Wave Ripples.

Title: Dissecting brain plasticity patterns of alcohol-memory dynamics - Formation, reconsolidation and extinction

Authors: *S. BARAK[1], H. LAUFER[2], Y. ASSAF[3,2]
[2]Sagol Sch. of Neurosci., [3]Dept. of Neurobio., [1]Tel Aviv Univ., Tel Aviv, Israel

Abstract: Alcohol relapse is often driven by cue-alcohol associative memories, thus, disruption of cue-alcohol memories is a potential therapeutic strategy for alcohol relapse prevention. Extinction of the cue-alcohol association by prolonged or repeated exposure to cues alone reduces craving temporarily, but the memory often recovers, evoking relapse. Current memory theories hold that memories undergo a transient instability period through a process termed reconsolidation, during which they become labile. Reconsolidation is triggered by memory reactivation, typically via a brief exposure to the cue alone. Therefore, procedural resemblance between extinction and reconsolidation may lead to non-effective relapse treatments. Here, we dissociated between the brain mechanisms underlying extinction and reconsolidation of alcohol-related memories. We used diffusion tensor imaging (DTI), which is considered a microstructural probe that identifies learning-induced structural changes. Mice were scanned

before and after the formation of a context-alcohol associative memory in an alcohol-conditioned place preference (CPP) procedure, followed by scans after a short (reconsolidation) or long (extinction) exposure to the context alone. DTI analysis revealed that the formation of alcohol-associated memories led to changes in the cortex and mesolimbic system, which was different between mice that learned the association and preferred the alcohol-associated compartment, compared to non-learners. Strikingly, extinction and reconsolidation processes led to differential brain plasticity profiles in several brain regions, which also displayed differential synaptic density and expression of plasticity-related genes. Our findings suggest that formation and extinction of alcohol-associated memories induce similar changes in brain plasticity. In contrast, reconsolidation affects brain plasticity in a fashion similar to non-learning. These results provide critical neurobiological evidence for the difference between formation, reconsolidation and extinction of memories.

Abstract: Mammalian sleep contains rapid eye movement (REM) and non-REM sleep, both could employ different mechanisms for memory consolidation. Previous reports showed that memory-associated odor stimulation during non-REM sleep enhanced memory consolidation[1]. In addition, boosting slow oscillations or inhibiting sharp wave-ripples during non-REM sleep potentiated or interfered with memory consolidation[2,3]. On the other hand, REM sleep deprivation inhibited memory consolidation[4]. However, the memory circuit that is responsible for memory consolidation during each sleep stage has not been clearly shown. We have shown that hippocampal adult-born neurons are incorporated in memory circuits after learning[5]. Therefore, we silence the activities of the adult-born neurons during specific stages of sleep after learning using optogenetics, which provides reversibility in intervention with higher time resolution and target specificity. The intervention reveals that the activities of the adult-born neurons is necessary for memory consolidation during specific stage of sleep.

Title: Memory interactions across wakefulness and sleep: Consolidation and reconsolidation of auditory classification learning in a songbird

Authors: *T. P. BRAWN[1], H. C. NUSBAUM[2], D. MARGOLIASH[3]
[1]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [2]Psychology, Univ. of Chicago

Dept. of Psychology, Chicago, IL; [3]Organismal Biol. and Anat., Univ. of Chicago Dept. of Organismal Biol. and Anat., Chicago, IL

Abstract: Memory consolidation strengthens and stabilizes new memories, a process that benefits from sleep. We have shown sleep-dependent consolidation in starlings operantly trained to classify novel starling songs. Classification accuracy improved after sleep but not after waking retention. Learning two similar classification tasks produced interference that impaired performance on both tasks after waking retention but recovered after sleep. Here, we examine how memories are maintained in the presence of multiple interfering stimuli encountered over one or more days as well as the relationship between learning, sleep structure, and post-sleep memory. In the first study, starlings were trained and tested on one or two auditory memory classification tasks and retested at later times in the day. Starlings that only learned one task exhibited stable performance across the day. In contrast, starlings that learned both tasks showed impaired performance on both, but with asymmetrical effects such that retroactive interference developed during the learning of the second task whereas proactive interference developed subsequent to learning the second task. Next, we examined whether sleep-consolidated memories could be destabilized by memory reactivation and reconsolidated by sleep. Starlings were trained on one task and retested at multiple time points over the next 3 or 5 days. Starlings were also trained on additional classification tasks on the subsequent days. We found that sleep-consolidated memories were destabilized and impaired if the interference was encountered after, but not before, the memory of the first task was reactivated by retrieval, and that sleep reconsolidated the impaired memory. Finally, we examined the structure of starling sleep in relation to task performance. Starlings were trained on one or two classification tasks and retested after waking and sleeping retention. We implanted starlings with EEG electrodes and chronically recorded EEG and infrared videos for 56 hours during each experimental session. Starlings expressed a mammalian-like pattern of sleep characterized by initially high levels of SWS that decreased across the night and initially very low levels of REM sleep that increased. Critically, classification training led to an increase in SWS during the first hour of sleep that correlated with post-sleep performance improvements. This series of studies indicates that long-term memory formation involves a dynamic process of sleep-dependent consolidation, use-dependent destabilization, and sleep-dependent reconsolidation.

Title: Targeted memory reactivation during sleep facilitates spatial memory consolidation in rats

Authors: *E. E. HOWARD, M. CONTRERAS, B. HARPER, E. ARMSTRONG, R. PADGETT, J.-M. FELLOUS
Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Following acquisition, new memories undergo a time-dependent consolidation process. Many human and animal studies suggest that consolidation involves spontaneous memory reactivation during specific phases of sleep. Recent studies have focused on the selective reactivation of memories by exposing subjects to learning-associated cues, such as auditory or olfactory stimuli, during non-rapid eye movement sleep. However, the mechanism by which targeted memory reactivation modulates memory consolidation is not fully understood. In this study, we investigated whether auditory cueing during post-learning sleep influenced spatial memory consolidation and recall performance in rats. Adult male Brown Norway rats were chronically implanted with 14-tetrode hyperdrives targeted to dorsal CA1 of the hippocampus with local field potentials in the medial prefrontal cortex. We trained rats to receive rewards from peripheral feeders on an open-field maze. During the learning phase, a subset of feeders was rewarded, and a sound was played at these locations. After the animals learned the cued locations, the sound was played again during sleep. Rats completed a distractor task on the maze, followed by another sleep session, and memory was tested during a subsequent recall phase. Conditions with no sound or a different sound played during post-learning sleep were used as controls. Preliminary findings show that the same sound condition facilitated memory consolidation compared to the other conditions. This finding suggests that playing the same learning cue during sleep strengthened the spatial memory for the particular set of locations associated with this cue. We investigate the effect of this targeted reactivation on sharp-wave ripple and sleep spindle densities, as well as cue- and oscillation-associated cell activity. These results may provide insights into potential applications of targeted memory reactivation to normal and pathological memory consolidation.

Title: Can we erase fearful memories? A role of sleep

Authors: *R. SHARMA, P. SAHOTA, M. THAKKAR
Truman VA Med. Center/University of Missouri, Columbia, MO

Abstract: Purpose: Newly formed memories are labile initially, but through the process of consolidation, they can enter permanent stores and become resistant to disruption or interference. Permanently stored memories can be again made labile through a process of reactivation. Reactivated memories can again become resistant to disruption or interference through the process of reconsolidation. Sleep is a requisite for memory consolidation. Is sleep necessary for reconsolidation? **Methods:** To address this question, we used male C57BL/6J mice and exposed them to contextual conditioning [conditioned stimulus (CS) = Context A; unconditioned stimulus (US) = foot shock)] followed by fear reactivation on Day 2. During reactivation, a set of mice were exposed to paired (Context A; CA group) or neutral (Context B; CB group) context without any US for 2 min. Percent time spent in freezing behavior was measured. Subsequently, one subset of mice, from each group (CA-SD and CB-SD groups), underwent sleep deprivation. The second subsets (CA-NSD and CB-NSD groups) of mice were allowed to sleep. On the following day (Day 3) fear memory recall testing was performed by exposing all four groups to CS (without US) for 12 min. Percent time spent in freezing behavior was monitored. **Results:** Two-way ANOVA suggested a significant main effect of context and sleep deprivation. Subsequent Bonferonni's post-hoc test suggested that only mice in the CA-SD group showed a significant reduction in freezing during fear memory recall testing. **Conclusion:** These results suggest that sleep is necessary for reconsolidation.

Title: The effects of sleep deprivation on stress granules in *Caenorhabditis elegans*

Authors: *M. K. DOUGHERTY, C. SAUL, M. NELSON, J. C. TUDOR
St. Joseph's Univ., Philadelphia, PA

Abstract: Stress granules (SGs) are non-membrane bound aggregates of messenger ribonucleoprotein. It has been shown in cells *in vitro* that suppression of the mammalian target of rapamycin (mTOR) pathway and its non-mammalian orthologue target of rapamycin (TOR) is associated with an increase in SG formation. It has also been shown that the mTOR pathway is suppressed in response to sleep deprivation in mice. Despite the possible connection via the TOR/mTOR pathway, there has not been any previous evidence directly linking sleep deprivation with SG formation. Our present investigation uses the microscopic, transparent, and genetically tractable nematode, *Caenorhabditis elegans* as a model for examining SG formation in response to sleep deprivation. *C. elegans* experience two different types of sleep, developmentally-timed sleep and stress-induced sleep. Developmentally-timed sleep occurs between the different larval stages of the worm, while stress-induced sleep occurs in response to a stressor, such as heat or UV shock. These different types of sleep are mediated by different mechanisms, and mutant strains have been developed that are deficient in the mediators of each type of sleep. We developed two novel strains of *C. elegans* that model sleep deprivation that have GFP-labeled TIA-1 protein, a key component of SGs. Through analysis and quantification of SG levels in the sleep-deprived mutant and the sleeping wildtype, we analyzed the impact of sleep deprivation on SG formation. Preliminary imaging shows an increase in SG formation after UV stress, and current work involves imaging sleep-deprived animals. This work will explore novel mechanisms by which sleep deprivation affects neuronal function.

Title: Low acetylcholine during early sleep is crucial for motor memory consolidation: Support for the synaptic homeostasis theory

Authors: *S. INAYAT, .. QANDEEL, M. NAZARIAHANGARKOLAEE, S. SINGH, I. Q. WHISHAW, M. MOHAJERANI
Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: The study investigated the contributions of Acetylcholine (ACh) synaptic activity in relation to the synaptic homeostasis theory of sleep-related memory storage. We hypothesized that during the early phase of sleep, characterized by slow wave electroencephalographic activity and reduced ACh tone, a downscaling of overall synaptic strength happens that improves synaptic signal-to-noise ratio and facilitates motor memory consolidation. Therefore, upregulation of ACh levels during early sleep would disrupt the consolidation of motor

memories. To test this hypothesis, mice were trained and then evaluated on two motor tasks; rotarod and skilled-forelimb reaching. For the rotarod task, 58 C57 Black/6J (wild-type, WT) and 17 transgenic mice were used. Mice were trained on rotarod on day 1 and immediately after motor training, ACh was either upregulated or downregulated for the subsequent post-learning sleep period. In WT mice, physostigmine was used to increase ACh levels while a combination of scopolamine and mecamylamine was used for decreasing ACh levels. In transgenic mice clozapine-N-oxide was used to decrease ACh levels. A memory test given on Day 5 following training showed that increasing ACh for post-learning sleep was associated with poorer performance while decreasing ACh levels resulted in normal motor performance. As a control, increasing ACh levels in post-learning sleep 24 hours after training also did not disrupt performance. Oxotremorine and nicotine were used to selectively activate muscarinic and nicotinic ACh receptors during post-learning sleep and showed a relatively larger involvement of muscarinic ACh receptors compared to nicotinic ones on motor performance. For the skilled-forelimb reach task, 21 WT mice were trained/tested for 9 days and each day either saline (n=10) or physostigmine (n=11) was given immediately after training. Physostigmine slowed learning and diminished success scores as compared to mice given saline. Home-cage filming and electrophysiology showed that increasing ACh levels with physostigmine altered sleep structure and decreased slow-wave activity duration and power in the first hour of post-learning sleep. These results suggest that post training slow-wave sleep, associated with low cholinergic levels, is optimal for motor memory consolidation. The early phase of sleep therefore may contribute to motor memory consolidation by providing a homeostatic state that is optimal for the selective synaptic formation required to establish motor memory.

Title: A single episode of binge alcohol drinking causes sleep disturbance, disrupts sleep homeostasis and downregulates equilibrative nucleoside transporter 1

Authors: *M. M. THAKKAR[1], P. SAHOTA[2], R. SHARMA[1]
[1]Neurol., HSTMV Hospital/University of Missouri, Columbia, MO; [2]Neurol., Univ. of Missouri Columbia Sch. of Med., Columbia, MO

Abstract: Binge alcohol drinking, a risky pattern of alcohol consumption, has severe consequences toward health and well-being of an individual, his family and society. Although, binge drinking has detrimental effects on sleep, underlying mechanisms are unknown. We used adult male C57BL/6J mice and exposed them to a single, four-hour session of binge alcohol self-administration, in stress-free environment, to examine neuronal mechanisms affecting sleep. We first verified binge pattern of alcohol consumption. When allowed to self-administer alcohol in a non-stressful environment, mice consumed alcohol in a binge pattern. Next, effect of binge drinking on sleep-wakefulness was monitored. While sleep-wakefulness remained unchanged during drinking session, significant increase in non-rapid eye movement (NREM) sleep was observed during 4 hours of active period post-binge, followed by increased wakefulness, reduced sleep during subsequent sleep (light) period; although the timing of sleep onset (at lights-on) remained unaffected. Next, electrophysiological and biochemical indicators of sleep homeostasis were examined using sleep deprivation-recovery sleep paradigm. Mice exposed to binge-drinking did not show an increase in cortical theta power and basal forebrain adenosine levels during sleep deprivation; NREM sleep and NREM delta power did not increase during recovery sleep suggesting that mice exposed to binge alcohol do not develop sleep pressure. Our final experiment examined expression of genes regulating sleep homeostasis following binge drinking. While binge drinking did not affect adenosine kinase and A1 receptor, expression of equilibrative nucleoside transporter 1 (ENT1) was significantly reduced. These results suggest that binge alcohol consumption-induced downregulation of ENT1 expression may disrupt sleep homeostasis and cause sleep disturbances.

Abstract: Memory re-consolidation is the process of update or modification of consolidated memories after their reactivation. Sleep is well-known to play a role in memory consolidation, but no information is given on whether reconsolidation of memories after their reactivation also occurs during sleep or whether sleep somehow affects memory reactivation. Studies of fear memory conditioning showed a theta synchronization between amygdala and hippocampus, and theta-gamma cross-frequency coupling in hippocampal CA1 area during reactivation. Although hippocampus and basolateral amygdala (BLA) are involved in appetitive memory reactivation as shown by Wells et al (2011), however it is not known their reciprocal functional and temporal connectivity modes during this stage.
The aim of the current study is to assess differences in memory reconsolidation when appetitive memory reactivation is performed during the sleep or awake phases, at both behavioural and electrophysiological levels. Particularly, we focus on the study of Local Field Potential (LFP) patterns in dorsal CA1 and BLA and their modulation during awake/sleep phases.
LFPs were recorded in freely moving rats exposed to a behavioural protocol of appetitive memory reactivation (or no reactivation). Briefly, we used a sucrose self-administration paradigm with the following stages, 1), training, 2), forced abstinence, 3), reactivation (RET) or no-reactivation (NORET), and, 4), relapse test. All the stages were performed during the awake phase, except for memory reactivation which took place either during awake or sleep phases. Behaviour and theta-gamma powers in CA1 and BLA were assessed.
Behavioural data showed a significantly different responding measured as Inter Response Time (IRT, seconds) between RET-awake and RET-sleep groups, with the former showing lower mean IRT compared to the latter, i.e. faster responding. However, no difference in responding was observed at relapse test.
LFPs from CA1 and BLA were analysed by extracting theta and gamma powers from each subject during stage 3) and by comparing their means. Two-way ANOVA showed a main effect of RET/NORET condition (but not of sleep/awake), with greater theta and gamma powers for NORET compared to RET. However, this effect was observed for each frequency band in the spectrum, thus suggesting that the observed differences are possibly due to methodological differences between RET/NORET groups.

Title: Early consolidation window is vulnerable to induction of state dependent memory by amnesic drugs

Authors: *A. HERNANDEZ-MATIAS, D. OSORIO-GÓMEZ, F. BERMUDEZ-RATTONI
Neurociencia Cognitiva, Inst. de Fisiología Celular - UNAM, Mexico City, Mexico

Abstract: Memory consolidation refers to the post-learning processes by which the information is stabilized and strengthened into long-term memory. In general, newly formed memories are labile and susceptible to many amnesic agents that disrupts long-lasting memory establishment. This consolidation hypothesis has been recently challenged by a memory integration hypothesis, which suggests that new memories are liable to incorporation of the neurobiological state induced by amnesic drugs in a state-dependent memory manner. In this study, we evaluated the effects of a protein synthesis inhibitor, a RNA synthesis inhibitor, or an NMDA receptor antagonist infused into the insular cortex of male Wistar rats on object recognition memory. Our results revealed that administration of a protein synthesis inhibitor, the RNA elongation inhibitor and an NMDA antagonist generated a state-dependent recognition memory when infused after a specific period of time and before retrieval. Interestingly, all amnesic drugs used in this study could not generate state-dependent memory when infused outside the early consolidation window. Therefore, we suggest that there are sensitive windows when drugs effects could become an attribute of the recognition memory from the period of time that recognition memory is impaired. In general, state-dependent memory is produced by amnesic drugs only for a specific period of time, and not outside that period, whereas memory consolidation impairments rely on sensitive windows and time of administration.

Title: Simultaneous assessment of cognitive function, circadian rhythm and spontaneous activity in aging mice

Authors: *S. LOGAN[1], D. OWEN[1], S. CHEN[2], W.-J. CHEN[2], Z. UNGVARI[1], J. FARLEY[1], A. CSISZAR[1], A. SHARPE[3], M. LOOS[4], B. KOOPMANS[4], A. RICHARDSON[1], W. E. SONNTAG[1]
[1]Reynolds Oklahoma Ctr. on Aging/Geriatric Med., [2]Dept. of Biostatistics and Epidemiology, [3]Col. of Pharmaceut. Sci., Univ. of Oklahoma HSC, Oklahoma City, OK; [4]Sylics, Amsterdam, Netherlands

Abstract: Cognitive function declines substantially with age in both humans and animal models. In humans, this decline is associated with decreases in independence and quality of life. Although the methodology for analysis of cognitive function in human models is relatively well-established, similar analyses in animal models have many technical issues (e.g. unintended experimenter bias, motivational issues, stress, and testing during the light phase of the light dark cycle) that limit interpretation of the results. These caveats, and others, potentially bias the interpretation of studies in rodents and prevent the application of current tests of learning and memory as an overall healthspan assessment in rodent models of aging. The goal of this study was to establish the methodology to assess cognitive function in aging animals that addresses many of these concerns. Here, we use a food reward-based discrimination procedure with minimal stress in C57Bl/6J male mice at 6, 21 and 27 months of age, followed by a reversal task to assess behavioral flexibility. Importantly, the procedures minimize issues related to between-experimenter confounds and are conducted during both the dark and light phases of the light dark cycle in a home-cage setting. During cognitive testing, we also were able to assess multiple measures of spontaneous movement and diurnal activity in young and aged mice including distance moved, velocity, and acceleration over a 90h period. Both initial discrimination and reversal learning significantly decreased with age and, similar to rats and humans, not all old

mice demonstrated impairments in learning with age. These results permitted classification of animals based on their cognitive status. Analysis of movement parameters indicated decreases in distance moved as well as velocity and acceleration with increasing age. Based on these data, we developed preliminary models indicating that, as in humans, a close relationship exists between age-related movement parameters and cognitive ability. Our results provide a reliable method for assessing cognitive performance with minimal stress and simultaneously provides key information on movement and diurnal activity. These methods may represent a novel approach to developing non-invasive healthspan measures in rodent models that can be standardized across laboratories.

Title: A memorytrace built in conjunction with a stressor is privileged: Reconsolidation-resistant memories in the crab neohelice

Authors: *A. DELORENZI[1], V. A. MOLINA[2], P. N. FERNÁNDEZ LARROSA1[1], F. J. MAZA[1], L. BLOISE[1], H. GONZALEZ[1]
[1]Dept. de Fisiología y Biología Mol. y Celular, Lab. De Neurobiología De La Memoria, Buenos Aires, Argentina; [2]IFEC-CONICET, Dept. de Farmacología, Facultad de Ciencias Químicas,, Univ. Nacional de Córdoba, Córdoba, Argentina, Córdoba, Argentina

Abstract: The dynamics of memory processes are conserved throughout evolution, a feature based on the hypothesis of a common origin of the high-order memory centers in bilateral animals. Reconsolidation is just one example where, for instance, in crabs and humans both expressed or unexpressed memories can enter reconsolidation only if a surprise is presented during reactivation sessions. Our view is that, during reconsolidation, endogenous

neuromodulators determine the probability of the memory to guide behavior by decreasing or increasing its behavioral expression, disturbing neither its persistence nor its capacity to be reactivated. The possibility to interfere long-term memory expression during reconsolidation has been proposed as a potential clinical approach to treat traumatic memories. However, several pieces of evidence in humans and rodents show that both robust fear memories or stressful events applied before acquisition promote reconsolidation-resistant memories, i.e., memories that are resistant to the interfering effect of drugs on memory reconsolidation. Is the induction of reconsolidation-resistant memories part of the dynamics of memory processes conserved throughout evolution? In the semiterrestrial crab Neohelice, memory reconsolidation is triggered by a short reminder without reinforcement since the onset of reconsolidation depends on errors in outcome prediction. Here, we showed that an increase in the salience of the aversive stimulus boosts memory strength; nonetheless, the proteins synthesis inhibitor cycloheximide still disrupted the reconsolidation process. However, crabs stressed by a water-deprivation episode before a strong training session build up a memory that was reconsolidation-resistant. We tested whether these reconsolidation-resistant effects can be challenged by changing the parametric conditions of memory-reactivation sessions; multiple (three) memory reactivations without reinforcement were not able to trigger the labilization-reconsolidation of this apparent resistant memory. Overall, the present
findings suggest that reconsolidation-resistant memories can be another feature of the dynamics of memory processes conserved throughout evolution. Memories built in conjunction with stressors are privileged. Consequently, its ability to guide behavior should not be put at risk after each memory reactivation episode.

Title: Behavioural tagging: A general approach to understand the mechanism of long term memory formation

Authors: *M. NASEEM[1], S. PARVEZ[2]
[1]Jamia Hamdard, New Delhi, India; [2]toxicology, Hamdard Univ., New Delhi, India

Abstract: Aim: We aimed to investigate the novel mechanism of “Behavioural Tagging” which is thought to be involved in long term memory (LTM) formation and to find the key factors playing role in consolidation of LTM.

Methods: Behavioural tagging is a process which explains how to stabilizeshort-term memory induced by a weak stimulus and transforms it into long lasting memorieswhen exposed to a novel environment in a critical time window. Here we have shown thathow the process of "Behavioural Tagging" provides both setting of learning tags as well assynthesis of plasticity related proteins (PRPs) to stabilize LTM in adult Wistar rats. Thereforethe expression of these LTP specific PRPs at the cellular as well as molecular level have beenshown to play a significant role in both maintaining long term potentiation (LTP) andmemory storage. Furthermore to confirm the relationship between behavioural tagging, PRPsand LTM, we investigated the effects of PRPs inhibitor.
Results: The results here indicated that memory consolidation-like events take place in various regions of the brain including prefrontal cortex and these LTP-specific PRPs are critical for the consolidation of an abiding plasticity and memory storage which are the essential components in LTM formation.
Conclusion: In conclusion our findings provide evidences for the possible role of LTP-specific PRP i.e., PKM-ζ, activated by the process of behavioural tagging in long term memory formation.**Keywords:** LTP-Specific-Plasticity Related Proteins, Prefrontal Cortex, Behavioural Tagging, long term memory

Title: Experience-specific anterograde amnesia: Impairment of memory consolidation prevents its subsequent reacquisition in young chicks

Authors: *K. ANOKHIN[1,2,3], D. BEZRIADNOV[2], D. GAEVA[1], A. TIUNOVA[2]
[1]Dept. of Neurosci., NRC Kurchatov Inst., Moscow, Russian Federation; [2]P.K.Anokhin Inst. of Normal Physiol., Moscow, Russian Federation; [3]Lomonosov Moscow State Univ., Moscow, Russian Federation

Abstract: Memory can be experimentally disrupted by a variety of ways, for example by NMDA receptor antagonists or inhibitors of protein synthesis administered prior to memory consolidation or reconsolidation. It is natural to assume that once the effects of such drugs vanish it should be possible to reacquire the initially impaired experience. In this study we tested an

opposite hypothesis - that damage to a specific memory prevents its subsequent reacquisition. Here we examined this possibility in a model of long-term memory formation in young chicks. Day-old chicks were trained in the one-trial passive avoidance task (Cherkin, 1968) by presenting them a 2-mm white bead dipped in a bitter-tasting substance, methylanthranilate. Training was preceded by administration of protein synthesis inhibitor anisomycin (80 mkg intracranially), or NMDA receptor antagonist MK-801 (0.4 mg/kg intraperitoneally or 5 mkg intracranially). Both drugs caused amnesia which was permanent, and no spontaneous recovery of memory was observed. Next, the second training was given to amnestic animals either using the same object ("Retraining" group) or a novel one - a bead of a red color ("Novel training" group). Interval between the first and second training was 2 or 24 h, and the retention test was given from 30 min to 48 h after the second training. During the test chicks were presented for 10 s with a dry bead identical to the one used for training. Chicks were also presented next with a dry metal bead which was used as a neutral (discriminating) stimulus. Pecking or avoidance of the aversive bead was recorded, and a percentage avoidance score was calculated for each group. The second training of the amnestic chicks for the same stimulus failed to produce avoidance memory for all the between-training and training to test intervals. We call this phenomenon an experience-specific anterograde amnesia (ESAA) and discuss its possible neural bases.

Title: Maintenance of contextual fear memories and context discrimination acquired in the absence of the hippocampus

Authors: D. C. GIDYK, R. J. MCDONALD, *R. J. SUTHERLAND
Univ. Lethbridge, Lethbridge Alberta, AB, Canada

Abstract: One prominent view of the hippocampus is that it is essential for acquisition and initial maintenance of certain long-term memories. In particular, it has been hypothesized that the longevity and precision of episodic memory both require the hippocampal participation at the time of learning. We tested these ideas by damaging the rat hippocampus before contextual fear conditioning. We showed that after one contextual fear conditioning episode, non-hippocampal networks can acquire, maintain, and express context memory, apparently normally, for up to 30 days[1]. In a separate previous experiment using our discriminative fear conditioning to context

procedure, we discovered that context discrimination is supported by non-hippocampal networks for up to three days[2]. These findings confirm earlier reports that non-hippocampal networks can acquire and express a version of context memory. However, the discovery that non-hippocampal context memory exhibits normal longevity and is not lacking detail requires further investigation. In the present experiment, rats with or without damage to the hippocampus were exposed to a single contextual fear conditioning episode, then tested for context discrimination 1, 7, or 15 days later. To ensure damage to the hippocampus completely disrupted hippocampal function, rats were also trained and tested on the spatial cue version of the Morris Water Task (MWT). The results are: 1) damage to the hippocampus was very extensive and caused a large disruption of spatial learning in the MWT; 2) similarly extensive hippocampal damage did not affect the maintenance of contextual fear memory at any retention interval; 3) rats with extensive hippocampal damage exhibited intact context discrimination ability at all retention intervals. The present findings do not support the ideas that the longevity or details of contextual fear memory depend upon the hippocampus. Moreover, further exploration of the mnemonic capacities of non-hippocampal networks may help resolve recurrent theoretical questions about memory consolidation, its dependence on the hippocampus and its importance in remote long-term memory[3,4]. Title: Role of the posterior parietal cortex in fear recovery after extinction

Authors: *B. JOO, S. LEE, J. KOO
Korea Brain Res. Inst., Daegu, Korea, Republic of

Abstract: Relapse of extinguished fear is a major challenge to clinical treatments of fear-related anxiety disorders (e.g., exposure therapy). The extinction of conditioned fear does not eliminate

fear memory itself. For example, presentation of conditioned stimulus (CS; e.g., tone) can induce fear response again with outside of an extinction context ('renewal') or re-experience of aversive shock ('reinstatement'). Considerable researches have suggested that the posterior parietal cortex (PPC) mediates visual and spatial information processing and the recognition of context, such as novel object placement task. However, its role in the context-dependent relapse of extinguished fear response has not been explained. Accordingly, we investigated whether the PPC plays a role in fear renewal and reinstatement which are differentially elicited by context alternation. In Experiment 1, the effects of the reversible inactivation of PPC on the fear renewal were examined. It is known that the fear renewal is occurred in the original fear acquisition context (ABA renewal) or in a context distinct from the conditioning and extinction contexts (ABC renewal). Inactivation of PPC attenuated the ABC renewal but not ABA renewal. In Experiment 2, fear reinstatement was not affected by the inactivation of PPC. In experiment 3, optogenetic inhibition of PPC (Light-ON) selectively blocked ABC renewal but this effect was not shown in Light-OFF trial. The results revealed that inactivation of PPC prevented ABC renewal, but not ABA renewal and reinstatement. In conclusion, the PPC is critical for the fear recovery in the new context, but not for the return of fear in the old context that previously have been explored.

Title: Overtraining transforms the role of the perirhinal cortex in object recognition memory

Authors: *H. LEHMANN, J. MACKENZIE
Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Evidence from lesion and neural activation studies suggest that the perirhinal cortex (PRH) plays a critical role in object recognition memory. The neural network supporting a memory, however, can be altered with many learning reinstatements (overtraining), to the extent that a given structure may no longer be required for it. This raises the possibility that overtraining may reduce the contribution of the PRH to an object recognition memory. The current study examined this issue by assessing PRH activation in the novel object preference test, which is commonly used to assess object recognition. Specifically, rats were given either 5 or 30 daily learning sessions during which they were allowed to investigate two identical sample objects. The rats were then given a recognition test in which a novel object replaced one of the

sample objects. Regardless of the reinstatement extent, the rats showed a significant preference for the novel object, but this preference was significantly greater in the 30-session group. Thus, overtraining produced a stronger object recognition memory. Ninety minutes following this recognition test, the rats were sacrificed, their brains removed, sectioned, and finally processed for the expression of the immediate early gene c-Fos, a marker of neural activity. Unbiased stereological quantification of c-Fos+ cells in the PRH revealed that, in contrast to control rats that did not receive any experimental manipulations, rats tested for novel object preference showed increased c-Fos expression in the PRH. Importantly, however, the 30-session group showed significantly fewer c-Fos+ cells in the PRH than the rats that only received five sample sessions. Hence, the overtrained rats, which showed the strongest object recognition memory, had less PRH activation. A second experiment examined the retrograde amnesic effects of PRH lesions on object recognition memory in rats that received the same training parameters as the rats in the immediate early gene experiment. The lesions impaired memory in the group that was limited to five learning session, whereas the memory was intact in the rats that received the overtraining (30 sessions). Combined, these findings suggest that overtraining or repeated learning reinstatements of an object memory causes neural reorganization of the memory and that this plasticity includes PRH disengagement.

Title: Effect of classical music on the extinction of fear memory in rats

Authors: *P. H. OLIVEIRA[1], D. H. PIETROBON[1], L. L. S. LEMOS[1], A. C. D. DE ANDRADE[1], C. M. F. TRZESNIAK[1], C. R. SARTORI[2], D. A. R. MOREIRA[1], R. S. FARIA[1]
[1]Faculdade de Medicina de Itajubá, Itajuba, Brazil; [2]Univ. Estadual de Campinas, Campinas, Brazil

Abstract: INTRODUCTION: The memory process is divided into acquisition, consolidation, persistence and extinction. Studies suggest that the exposure to music is beneficial in acquiring and consolidating memory. However, little is known about how music could affect the extinction of memory. OBJECTIVE: To analyze the influence of the exposure to the Mozart's Sonata K448 and Classical Music on the extinction of fear memory in rats. METHODS: Sixteen pregnant Wistar rats were daily exposed to music or ambient sound, subdivided into the following groups:

G1-Mozart; G2-Classical; G3-Ambient sound and G4-Control (ambient sound). After delivery, offspring male rats were separated into the respective groups: G1-Mozart (n=24); G2-Classical (n=15); G3-Ambient sound (n=15); G4-Control (n=15), remaining the musical exposure according to the gestational period. On the 39th day, a Fear Conditioning test was performed, in which the groups G1-Mozart, G2-Classical and G3-Ambient sound were submitted to 3 shocks. On the 67th-71th days, the Extinction Test was performed, in which all animals were individually placed in the same shock chamber for 5 consecutive days (D1, D2, D3, D4, D5), but not receiving shock, being collected freezing time data. Statistical analysis was performed with one-way ANOVA, followed by the Tukey test, being significant $p<0.05$. RESULTS: On the D1-D2 days, G1-Mozart, G2-Classical and G3-Ambient sound groups presented higher freezing time compared to controls ($p<0.001$). On the D3, both G1-Mozart ($p=0.074$) and G2-Classical ($p=0.052$) in relation to control already tended to a shorter freezing time, while G3-Ambient sound still had a longer freezing time compared to controls ($p<0.001$). On the D4-D5 days, there were no differences between G1-Mozart or G2-Classical compared to G4-Control ($p>0.05$). On the D5, there was a longer freezing time in G3-Ambient sound compared to the other three groups ($p<0.05$). CONCLUSION: The results point to significant benefits of the exposure to music for more efficient extinction of fear memories. The positive effect of the exposure to Classical Music on the extinction of implicit aversive memory may contribute to the current knowledge about the environmental modulation of memory process. In psychopathological terms, this could help in cases of posttraumatic stress disorder.

Title: The effects of diet manipulation on learning, memory and anxiety

Authors: *K. PEDEMONTE, C. M. HERNANDEZ, J. M. FLINN
George Mason Univ., Fairfax, VA

Abstract: This study looks at the effects of autoclaving lab feed as well as the levels of soy content in lab feed. Autoclaving sterilizes and cleans equipment through heat and steam. However, autoclaving animal feed can not only affect key nutrients, but also increase the “hardness” of food pellets and produce toxic and carcinogenic products. An additional dietary factor that is often overlooked is soy (phytoestrogen) content. Evidence has found that

phytoestrogens have anxiolytic effects in both males and females when assessed in an elevated plus maze (Lephart et al., 2002) and open-field testing (McCarthy et al., 1997). Therefore, it is important to consider both autoclaving and soy content in animal feed when conducting behavioral neuroscience research. Ninety-six C57BL/6J male and female mice were assigned to one of four diet groups prenatally: (1) a non-autoclaved standardized Teklad 7012 (containing soy); (2) an autoclaved standardized Teklad 7012; (3) soy-free Teklad 2020SX; and (4) low-soy Teklad 2018SX. Neither the soy-free nor the low-soy diets were autoclaved. At 4 months of age, the mice were examined on behavioral tests including: Morris water maze (MWM), fear conditioning (FC), nesting, elevated zero maze (EZM), open field (OF), and grooming. Collapsed across sex, there were no significant differences in MWM, EZM, and OF between dietary groups. However, animals on Teklad 7012 and autoclaved Teklad 7012 extinguished the learned tone/shock pairing in FC significantly slower than animals on low-soy and soy-free diets. Animals on the standard Teklad 7012 diet created significantly better nests than the animals on any other diet. Additionally, animals on standard Teklad 7012 diet groomed less than the animals on low-soy and soy-free, but more than the animals on the autoclaved Teklad 7012. These data show that the dietary effects including autoclaving feed and amount of soy in diet have a significant effect on behavior and is therefore an important factor for behavioral researchers to consider.

Title: Laparoscopic sleeve gastrectomy induced structural connectivity changes between dorsolateral prefrontal cortex and anterior cingulate cortex

Authors: *Y. HU[1], G. LI[1], M. XU[1], L. LIU[1], Q. JIN[1], Y. NIE[2], G. JI[2], G.-J. WANG[1], Y. ZHANG*[1]

Abstract: Laparoscopic-sleeve-gastrectomy (LSG) is one of the most effective ways to treat obesity, and neuroimaging studies showed alterations in frontal-mesolimbic circuitry in obese patients after LSG, which included attenuated activation in mesolimbic/mesostriatal reward

circuits and diminished activation in dorsolateral prefrontal cortex (DLPFC). However, LSG-induced structural connectivity (SC) changes in the circuitry have not been studied yet. We tested the hypothesis that LSG-induced alterations in SC of frontal-mesolimbic circuitry were associated with improved functional connectivity (FC) in obese patients. Diffusion tensor imaging (DTI) and functional-magnetic-resonance-imaging (fMRI) cue-reactivity task with high- (HC) and low-calorie (LC) food cues were used to investigate brain structural and functional connections changes in 28 obese patients, who were tested before and 1 month after bariatric surgery (BS), and in 22 obese controls (Ctr) without surgery but tested at baseline and 1 month later. ANOVAs showed there were significant interaction effects (group × time) on fractional anisotropy (FA) between the right DLPFC-ACC tract due to significantly increased SC in LSG group (Fig 1), and its changes were correlated with changes in psychophysiological interaction (PPI) connectivity of right DLPFC-ACC (Fig 1). Both increases in SC and FC were associated with decreases in BMI (Fig 1). In addition, the relationship between weight-loss and increases in SC of right DLPFC-ACC can be fully mediated by increases in FC of right DLPFC-ACC (Fig 1). These findings suggest that LSG-induced weight-loss may alter SC of DLPFC-ACC by influencing its FC, reflecting a strengthening of top-down control post LSG.

Title: The histone chaperone Anp32E regulates H2A.Z eviction and turnover and regulates memory formation in the hippocampus

Authors: *G. STEFANELLI[1], M. BRIMBLE[4], K. NARKAJ[2], A. M. DAVIDOFF[4], B. J. WALTERS[5], I. B. ZOVKIC[3]
[1]Dept. of Psychology, [2]Cell and Systems Biol., [3]Psychology, Univ. of Toronto Mississauga, Mississauga, ON, Canada; [4]St. Jude research Hosp., Memphis, TN; [5]Neurosci. and Mental Hlth., Hosp. For Sick Children, Toronto, ON, Canada

Abstract: H2A.Z is a highly conserved variant of histone H2A, whose role as a memory suppressor we recently discovered (Zovkic et al. 2014). Specifically, H2A.Z is removed from chromatin after learning, and AAV-mediated H2A.Z depletion results in enhanced memory, suggesting that H2A.Z eviction promotes memory formation. However, the molecular mechanism underlying learning-induced H2A.Z removal remains uncharacterized. Studies in non-neuronal tissue recently identified Anp32E as an H2A.Z-specific histone chaperone that removes H2A.Z from nucleosomes, leading us to hypothesize that Anp32E-mediated removal of H2A.Z is crucial for memory formation. Here, we show that Anp32E and H2A.Z are simultaneously bound to several H2A.Z-enriched genes in the mouse hippocampus. In response to fear conditioning, H2A.Z and Anp32E are concurrently evicted from sites in which they co-localize. Moreover, Anp32E is functionally relevant for memory formation, as AAV-mediated knock-down of this chaperone in the hippocampus results in impaired memory, whereas Anp32E overexpression results in enhanced memory. Notably, manipulating Anp32E levels in cultured neurons and in the hippocampus results in altered gene expression of H2A.Z-regulated genes and altered accumulation of H2A.Z in different chromatin fractions. In addition, knock-down of Anp32E in primary hippocampal neurons results in impaired dendritic branching. Strikingly, simultaneous knock-down of Anp32E and H2A.Z results in rescue of altered gene expression, impaired dendritic branching and memory formation seen in Anp32E knock-down. Overall, our data suggest that Anp32E is a functional component of the molecular machinery regulating H2A.Z eviction during learning and turnover in neurons.

Title: Targeting dna methylation to treat intellectual disability

Authors: H. SMITH, A. H. HOWARD, A. R. BOITNOTT, A. REDA, B. MALACHOWSKY, *A. J. KENNEDY
Bates Col., Lewiston, ME

Abstract: Haploinsufficiency of transcription factor 4 (Tcf4) leads to the extremely rare learning disability known as Pitt-Hopkins Syndrome (PTHS). We have recently shown that Tcf4-deficient hippocampal tissue from a mouse model of PTHS has altered expression of critical plasticity-related genes. Importantly, these genes were overexpressed in Tcf4-deficient tissue, correlating with a significant decrease in DNA methylation at these loci. Thus, the hypomethylation of genes activated after learning may be a key molecular phenotype of PTHS. Here, we determine the genome-wide sites of altered DNA methylation in Tcf4 (+/-) mice, a mouse line we have already developed that exhibits deficits in learning and memory, social interaction, ultrasonic vocalizations, and have altered synaptic plasticity. Then we test the hypothesis that these deficits can be ameliorated by increasing DNA methylation via the deletion of Tet1, a DNA demethylase that regulates learning and memory. These experiments test the overarching hypothesis that Tcf4 regulates synaptic plasticity, that its deficiency causes cognitive dysfunction, and that epigenetic mechanisms, specifically DNA methylation, can be utilized for the treatment of PTHS.

Title: Memory reconsolidation requires de novo synthesis of PKMζ

Authors: *M. BERNABO[1], K. NADER[2]
[1]Psychology, [2]McGill Univ., Montreal, QC, Canada

Abstract: Following retrieval, many memories become temporarily labile and must be restabilized through the process of reconsolidation. Reconsolidation is widely recognized as a protein synthesis-dependent process but specifically which molecules are necessarily synthesized remains largely unknown. Research has demonstrated that PKMζ, an atypical protein kinase C isoform, is essential for maintaining long-term memories by preventing the endocytosis of GluA2-containing AMPA receptors from the postsynaptic membrane. Given this role of PKMζ in maintaining memory stability, we investigated whether disruption of PKMζ occurs during memory labilization and if de novo synthesis of PKMζ is necessary for reconsolidation. We trained rats in an auditory fear conditioning task. Following a retrieval test the next day, rats were sacrificed and their brains collected for Western blotting. Rats sacrificed 1h post-retrieval showed a significant decrease in PKMζ compared to those sacrificed 24h post-retrieval. In a second experiment, rats were trained in the same task. Immediately following retrieval, they were bilaterally infused with antisense oligodeoxynucleotides (ODNs) specific to PKMζ or a scrambled control into the basolateral amygdala. Rats were tested 24h following retrieval to determine the effect of these ODNs. Rats infused with PKMζ-antisense ODNs showed a significant impairment in memory performance at test compared to scrambled controls. These data suggest that during labilization, there is a reduced amount of PKMζ protein and failure to synthesize new PKMζ during reconsolidation prevents the restabilization process, significantly impairing long-term memory.

Title: The induction of a labile state during memory reconsolidation requires beta-adrenergic signaling

Authors: *C.-S. LIM[1,2], J.-I. KIM[3], C. KWAK[2], J. LEE[2], E. JANG[2], J. OH[2], B.-K. KAANG[2]
[1]Dept of Pharmacol, Wonkwang Univ. Sch. of Med., Jeonbuk, Korea, Republic of; [2]Sch. of Biol. Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Sch. of Life Sci., Ulsan Natl. Inst. of Sci. and Technol. (UNIST), Ulsan, Korea, Republic of

Abstract: Memory reconsolidation is the process by which previously consolidated memories reenter a labile state through reactivation of the memory trace and are actively consolidated through *de novo* protein synthesis. Although extensive studies have shown that β-adrenergic signaling plays a critical role in the restabilization of reactivated memory, its role in the destabilization of long-term memory is not well-studied. In this study, we found that membrane excitability increased in hippocampal CA1 neurons immediately after the retrieval of contextual fear memory. Interestingly, this increase in membrane excitability diminished after treatment with propranolol (a β-adrenergic receptor antagonist), an NMDA receptor antagonist, and a PKA inhibitor. In addition, we found that administration of propranolol prior to, but not after, the retrieval of fear memory ameliorated the memory impairment caused by anisomycin, indicating that inhibition of β-adrenergic signaling blocks the destabilization of contextual fear memory. Taken together, these results indicate that β-adrenergic signaling via NMDA receptors and PKA signaling pathway induces a labile state of long-term memory through increased neuronal membrane excitability.

Title: Deletion of PDE11A improves remote long-term social memory despite blocking recent long-term memory for that same event

Authors: *K. N. PILARZYK[1], J. KLETT[1], M. P. KELLY[2]
[2]Pharmacology, Physiol. & Neurosci., [1]Univ. of South Carolina- Sch. of Med., Columbia, SC

Abstract: System consolidation (SC) is a process by which certain types of information (e.g., social experiences) require the hippocampus for recent long-term memory (LTM) but then become increasingly independent of the HIPP and more dependent on the cortex for remote LTM. Here, we identify the first molecular manipulation—namely deletion of the phosphodiesterase 11A (PDE11A)—capable of *enhancing* remote LTM despite *blocking* recent LTM for that same event. PDE11A4, which degrades cAMP/cGMP and regulates glutamate signaling and protein synthesis, is selectively expressed in neurons of the subiculum, the superficial layer of CA1, and the adjacently connected amygdalohippocampal region. Thus, PDE11A4 is biochemically and anatomically positioned to regulate SC of social memories. In social odor recognition and social transmission of food preference (STFP), PDE11 mutant mice show normal short-term memory 15 minutes to 1 hour after training, no recent LTM 24 hours after training, and spontaneously improved remote LTM 7 days after training relative to WT littermates. At least in the case of STFP, the impaired recent LTM observed in adult PDE11A KO mice appears to correspond to weaker activation of ventral CA1; whereas, the improved remote LTM corresponds to stronger activation of SC-related extrahippocampal brain regions. An upregulation of NR1 and NR2A subunits in prefrontal cortex of PDE11A KO mice vs WT littermates, yet a downregulation of NR2A subunits in HIPP of KOs. We discuss our findings in the context of a working hypothesis: deletion of PDE11A produces transient amnesia by virtue of temporarily "misplacing" the memory (i.e., PDE11A deletion strengthens SC within the cortex ahead of schedule at the expense of prematurely erasing the memory from the HIPP).

Title: c-Fos expression in amygdala after moderate and intense inhibitory avoidance training

Authors: *C. X. RUIZ-LOPEZ, A. C. MEDINA, P. BELLO-MEDINA, G. L. QUIRARTE, R. A. PRADO-ALCALA
Neurobiologia Conductual y Cognitiva, Inst. de Neurobiología-UNAM, Queretaro, Mexico

Abstract: Long-term memory formation is thought to depend on long-lasting changes in synaptic efficacy involving structural rearrangement of synapses. These processes are likely to require *de novo* protein synthesis. One of the first targets of plasticity-inducing stimuli appears to

be the activation of transcriptional factors, such as c-Fos. This protein has been used as a marker to identify brain regions that are activated in response to learning. On the other hand, several experimental findings suggest that typical amnestic treatments are ineffective when administered to subjects that have been over-trained or subjected to high foot-shock intensities in aversively learning. This protective effect has been found in a variety of learning tasks when treatments that disrupt normal activity are administered in several regions of the brain, including the amygdala. However, the mechanisms of this protective effect are unknown, and we do not know what regions are activated with this type of training, nor whether moderate and intense training recruit the same number of cells. In the present work we analyzed the number of c-Fos positive cells in amygdala after moderate and intense training. Rats were trained in a inhibitory avoidance task using different intensities of foot-shock (0.0, 1.0, and 3.0 mA). We also studied three controls groups: a cage group (rats that did not experience the inhibitory avoidance task), a 0.0 mA group (rats "trained" in the task, but the foot-shock was not delivered), and a shock-only group (rats that were placed in the shock compartment and received a non-contingent 3.0 mA foot-shock). The rats from each group were sacrificed 90 min after training for immunohistochemical c-Fos protein detection in the anterior basolateral (BLa) and lateral (LA) amygdala. A significant high number of neurons expressed c-Fos in BLa, but not in LA, in the 3.0 mA group compared with the rest of groups. In particular, the BLa has been suggested to play modulatory roles in fear memory. We conclude that long-term neuroplastic changes in the amygdala, which are dependent upon c-Fos expression, may be required for the formation of memory of intense training; the fact that there were no significant changes in c-Fos expression in the 1.0 mA group does no exclude the possibility that this protein is involved, within a different time-window in the amygdala, in the formation of memory of moderate aversive training. We thank Norma Serafín, Bertha Islas, Leonor Casanova, Nydia Hernández, Omar González, and Ramón Martínez for technical assistance.

Title: Model and remodel the trace: Actin cytoskeleton's role in different memory processes

Authors: *C. MEDINA, V. DE LA FUENTE, A. ROMANO
IFIBYNE - CONICET, DFBMC - UBA, Buenos Aires, Argentina

Abstract: Memory consolidation is the process by which new information is encoded in a stable form in neural circuits. Once a memory is already consolidated, certain types of reminders of the learning event (i.e. a short re-exposure to the training context) might induce memory labilization and a process of reconsolidation is required to re-stabilize the memory trace. When the reminder of the learning event is prolonged in time, an extinction memory may form, consisting in a new memory trace which temporarily inhibits the expression of the original one. Long-term memory has been associated with morphological changes in the brain, in strict correlation with changes in synaptic efficacy. Such plasticity is proposed to rely on dendritic spines as a sort of neuronal canvas on which these changes can take place. These small actin-rich protrusions from dendrites provide a suitable biochemical compartment to locally control and integrate different inputs, due to spatial confinement. Therefore, spine number, morphology and underlying actin polymerization level can modulate synaptic efficacy in many different ways. Depolymerization of actin cytoskeleton is mainly regulated by a family of actin-binding proteins termed ADF/cofilin, becoming an attractive target to study processes underlying dendritic plasticity. Using a contextual fear conditioning paradigm in mice, we have found that pharmacological induction of depolymerization of actin filaments through an intra-hippocampal injection of BMS-5 –a potent inhibitor of LIM kinase, which is in turn an inhibitor of ADF/Cofilin activity– causes an impairment in memory consolidation and reconsolidation. On the other hand, when favoring stabilization of actin filaments by intra-hippocampal injection of Jasplakinolide immediately before a reminder session that usually elicits reconsolidation of memory, the consolidation of an extinction memory was facilitated. Moreover, extinction was impaired when direct actin cytoskeleton depolymerization was induced by intra-hippocampal administration of Latrunculin-A immediately after a prolonged reminder session. In addition, western blot analysis of synaptoneurosome-enriched hippocampal fraction obtained after a short reminder session that leads to reconsolidation showed an increased P-Cofilin/Cofilin ratio, implying a diminished depolymerization activity by this factor, therefore favoring stabilization of actin filaments. All of these results support the role of actin cytoskeleton dynamics in the morphological changes which underlie different memory processes.

Title: Effects of garcinol administration on microtubule dynamics following cocaine-cue memory retrieval

Authors: *M. S. MONSEY[1], A. N. FRANKLIN[3], S. G. RUIZ[3], T. T. LAM[2], A. C. NAIRN[4], J. R. TAYLOR[5]
[1]Mol. Psychiatry, [2]Mol. Biophysics and Biochem., Yale Univ. Sch. of Med., New Haven, CT; [3]Psychology, [4]Psychiatry, Yale Univ., New Haven, CT; [5]Psychiatry, Yale Univ. Sch. Med., New Haven, CT

Abstract: Sustained abstinence from cocaine use is frequently compromised by exposure to stimuli that have previously been associated with drug taking. Such cues trigger drug-associated memories leading to craving and relapse. Our previous work has shown that altering cocaine-cue memories by interfering with the reconsolidation process is a potential therapeutic tool to prolong abstinence. We have previously shown that the histone acetyltransferase (HAT) inhibitor, garcinol, can impair the reconsolidation of cocaine-cue memories in a manner that is reactivation specific, temporally constrained, and long lasting. Here, we examined the neuroproteomic profile of the lateral nucleus of the amygdala (LA) following cocaine-cue memory retrieval and systemic garcinol administration. Rats underwent 12 d of cocaine self-administration where lever presses resulted in an i.v. infusion of cocaine that was paired with a cue. Next, rats underwent lever extinction for 8 d followed by cue reactivation and were sacrificed 90 m later. LA tissue was collected for proteomic analysis using a label free quantitative approach (LCMS/MS) with a significance cutoff of $p<0.05$ and False Discovery Rate of 1% or less. Our results showed significant regulation of 14 proteins, half of which were identified as regulators of microtubule dynamics. One of these proteins, Rho guanine nucleotide exchange factor 2 (ARHG2), was significantly upregulated in the LA following garcinol administration ($p<0.05$) and is associated with changes in α-tubulin acetylation. This led us to investigate whether in addition to being a HAT inhibitor, garcinol might also be inhibiting acetylation on other proteins, such as α-tubulin. To test this we used primary cortical and striatal cell cultures. Cells were grown for 14 d and then treated with garcinol (5uM) or vehicle and collected at 5 or 15 m after application. Cells were then processed for Western blotting. Results show that garcinol significantly decreased levels of α-tubulin acetylation (K40) at 5 m ($p < 0.05$) but not at 15 m in cortical and striatal cultures. These data indicate that not only is garcinol a HAT inhibitor but it may also exert effects by changing levels of α-tubulin acetylation. Future experiments will assess garcinol's effect on human neuroblastoma (SH-SY5Y) and cortical (HCN-2) cell lines. Behavioral studies will use specific inhibitors of α-tubulin acetylation following cocaine-cue memory retrieval to reduce reinstatement. Collectively, these data support the hypothesis that garcinol may be used as a novel tool to interfere with the reconsolidation of cocaine-cue memories possibly through altering microtubule dynamics.

Title: Glutamate NMDA receptors in thalamic nucleus reuniens have a subtype-specific role in memory destabilization and reconsolidation

Authors: *F. TROYNER, L. J. BERTOGLIO
Pharmacol., Univ. Federal de Santa Catarina, Florianopolis, Brazil

Abstract: Glutamate NMDA receptors are essential for plasticity that supports memory processing in several brain areas, including the amygdala, the hippocampus (HPC) and the medial prefrontal cortex (mPFC). Two NMDA receptor subtypes have received attention due to their roles in memory destabilization (the NR2B-containing subtype) and reconsolidation (the NR2A-containing subtype). The nucleus reuniens (NR) of the thalamus is reciprocally connected with the HPC and the mPFC and has been identified as a hub for functional integration between them during memory processing. Therefore, we hypothesized that glutamatergic activity through NMDA receptors in the NR would be essential for memory destabilization and reconsolidation, both processes dependent on the functional connectivity between HPC and PFC, and that NR2B and NR2A-containing NMDA receptors would have different roles. Male Wistar rats were fear conditioned to a context A and 24 h later submitted to a memory reactivation session in the same context. In the subsequent days, they were re-exposed to context A (Test A) and exposed to a novel unpaired context B (Test B). In the first experiment, infusing a selective antagonist of NR2B-containing NMDA receptors into the NR before reactivation prevented fear memory destabilization, since animals which received a reconsolidation blocker (clonidine) right after the session did not show a decrease in freezing behavior during Test A. Animals infused with vehicle or a selective NR2A-containing NMDA receptor antagonist presented a significant reduction in the time spent freezing during Test A when compared with that respectively expressed in the reactivation session, indicating that the reconsolidation blocker had an effect on fear memory. Neither NR2B nor NR2A antagonist interfered with memory expression during reactivation session or Test B. In the second experiment, animals were contextually fear conditioned and then systemically administered with the alpha-2 adrenoceptor antagonist yohimbine to induce a more generalized fear memory, which has been shown to be less prone to destabilization and reconsolidation. Infusing a selective NMDA receptor agonist into the NR immediately after reactivation induced fear memory updating, since animals presented a

reduction in freezing behavior during Test B when compared to vehicle-treated animals. Collectively, present results indicate a subtype-specific role of NR NMDA receptors in memory destabilization and reconsolidation.

Title: Insular cortex glutamatergic NMDA receptors participate in the maintenance of addictive memory

Authors: *E. GIL LIEVANA[1], J. LUIS ISLAS[2], R. GUTIERREZ[2], A. BONCI[3], R. A. MCDEVITT[4], F. BERMUDEZ-RATTONI[5], P. MORENO-CASTILLA[5]

Abstract: The insular cortex (IC) is a brain structure that has been related mainly to visceral control, stimuli salience and recognition memory. Recent studies indicate that IC is also related to addictive behaviors, however, little is known about its participation in the formation and maintenance of addictive emories. Therefore, in this work, we study the cellular mechanisms in the IC involved in the acquisition and maintenance of addictive memory associated with a context. Using the in vivo optogenetic technique in a transgenic TH-cre mouse, we studied the VTA-IC dopaminergic pathway. We observed that the stimulation of the dopaminergic neurons in the VTA produced strong conditioning place preference (PP), while the stimulation of the dopaminergic terminalsin the IC did not. In addition, we determined using the in vivo microdialysis technique the extracellular concentration of different neurotransmitters during the acquisition and retrieval of PP task. Our results indicated that during the acquisition of PP, only the extracellular concentration of dopamine increased in the CI. Interestingly, during the retrieval of PP, the extracellular concentrations of glutamate, dopamine and norepinephrine increased in the IC. Given these results, we performed pharmacological manipulations with different receptor antagonists involved in the maintenance of the PP in the IC. We found that one intracortical injection of an NMDA receptor antagonist just after the first post-test trial impaired PP

maintenance and start to induce an accelerated extinction process. Conversely, injections of glutamate AMPA, D1 and D2 dopaminergic and β-adrenergic receptors antagonists in the IC did not affected the maintenance of the addictive memory generated by optogenetic stimulation in the VTA.

Title: Developmental features of AMPAR trafficking-dependent memory

Authors: M. OPENDAK, 10016[1], R. ZANCA[2], *R. M. SULLIVAN[3], P. A. SERRANO[4]
[1]Child and Adolescent Psychiatry, New York Univ., New York, NY; [2]Psychology, Hunter College, CUNY, New York, NY; [3]Emotional Brain Inst., NKI & NYU Sch. of Med., New York, NY; [4]Dept of Psychology, Hunter Col. and City Univ. of New York, New York, NY

Abstract: Although infants are able to learn and remember, infant memory processes are attenuated compared to the adult, including the phenomenon of infantile amnesia. However, mechanisms for this attenuated infant memory have remained elusive. The existing literature has identified intracellular molecular events that are critical in memory formation, although this has yet to be described for infants. To fill this gap, we explored the molecular substrates of memory using a rat model of threat/fear learning and describe a complex, dynamic cascade that shows at least 3 mechanistic transitions as pups approach independence from the mother. In Experiment 1, pups underwent amygdala-dependent odor-shock (0.5mA) conditioning in early life during three distinct phases of threat learning: 1) Early infancy (<postnatal day PN10), when pups do not learn threat; 2) Transitional (PN10-15), when pups learn amygdala-dependent fear learning but it can be switched off by maternal presence via social buffering of the shock-induced corticosterone (CORT) stress hormone response; 3) Adult-like, when pups learn threat and it cannot be switched off by maternal presence or CORT blockade. Our results show that, amygdala memory molecules were not engaged in pups too young to exhibit fear learning. As pups reach a developmental age of amygdala-dependent fear conditioning, some aspects of the molecular memory cascade emerge, including PKMz-dependent upregulation of GluA2 and downregulation of GluA1. A more adult-like molecular cascade was seen in the oldest pups (PN17), with PKMz-dependent upregulation of both GluA1 and GluA2. In Experiment 2, we dissociated age and molecular events by shutting off the amygdala-dependent learning during odor-shock conditioning, where memory mechanism were also shut down. Specifically, at PN12

but not PN17, we shut down learning with pharmacological CORT blockade during conditioning and memory mechanisms were similarly shut off. Taken together, these results identify unique features of memory processes across early development: we provide novel evidence that GluA1/2 expression is differentially utilized and is sensitive to PKMζ inhibition for an amygdala-dependent avoidance memory. The partial recruitment of adult molecular mechanisms in the infant may help provide one explanation of why memories are not as well retained in early life.

Title: Overexpression of GluN2B(E1479Q) within the basal and lateral amygdala enables the modification of a strong fear memory via reconsolidation

Authors: *C. A. DE SOLIS[1], M. GALDAMEZ[3], C. U. GONZALEZ[3], S. W. WOODARD[3], C. E. SALINAS[3], J. N. MILLER[3], J. M. PERISH[4], O. H. PINEDA[3], R. HOLEHONNUR[5], A. SANDOVAL[3], J. E. PLOSKI[2]

Abstract: Memory retrieval does not initiate the reconsolidation process for some memories rendering pharmacotherapies designed to disrupt reconsolidation ineffective, in particular, strong memories have been shown to be difficult to disrupt via reconsolidation blockade and this is likely due to the inability of these memories to destabilize upon retrieval. In an effort to understand the molecular basis for why weak and strong fear memories differ in their requirements to initiate reconsolidation, we recently determined that training-dependent changes in the N-methyl D-aspartate receptor (NMDAR) subunit composition occur at basal and lateral amygdala (BLA) synapses that correlate with a strong memory's inability to be modified upon retrieval. We then demonstrated that genetically increasing the NMDAR GluN2A/GluN2B ratio is sufficient to block retrieval-induced memory destabilization and this prevents an existing memory trace from being modified via reconsolidation updating. Now we would like to determine if increasing the GluN2B/GluN2A ratio via overexpression of GluN2B or

GluN2B(E1479Q) mutant might enhance the initiation of reconsolidation. GluN2B(E1479Q) contains a point mutation in the PDZ domain of GluN2B which leads to higher surface levels of the subunit by inhibiting phosphorylation-driven endocytosis (Sanz-Clemente et al., 2010). In order to examine these questions, we generated lentiviruses designed to express these subunits from a TRE3G promoter. Injecting these viruses into the BLA of α-CaMKII-tTA mice allows us to restrict expression of the GluN2B transgenes to excitatory neurons and also enables expression of the transgene to be selectively expressed before or after fear conditioning training using doxycycline (Dox) (Holehonnur et al., 2015). Here, we examine how the overexpression of GluN2B and GluN2B(E1479Q) influences the consolidation, extinction and the initiation of reconsolidation of weak and strong Pavlovian auditory fear memories. We found that overexpression of GluN2B or GluN2B(E1479Q) within BLA neurons prior to fear conditioning led to an increase in LTM freezing levels. STM was not affected in either condition. Extinction was not affected due to overexpression of GluN2B(E1479Q) or GluN2B(WT) at the time of extinction learning. Increasing GluN2B at the time of reconsolidation with GluN2B(E1479Q), but not GluN2B(WT), allowed for pharmacologically induced amnesia of a strong fear memory. This amnesia was found to be dependent on retrieval. Increasing GluN2B(E1479Q) at the time of reactivation did not affect the initiation of reconsolidation for a weak fear memory.

Title: The pre- and postsynaptic compartments of *Aplysia* sensorimotor neuron synapses form positive feedback loops and act as one functional unit during consolidation of learning-related facilitation by 5HT

Authors: *I. JIN, E. R. KANDEL, R. D. HAWKINS
Dept. of Neurosci., Columbia Univ., New York, NY

Abstract: Intermediate- and long-term synaptic plasticity generally require coordinated pre- and postsynaptic mechanisms. Thus, the transition from presynaptic short-term facilitation (STF) to

intermediate-term facilitation (ITF) induced by 5HT at *Aplysia* sensory-to-motor neuron synapses requires the recruitment of postsynaptic mechanisms and activation of protein synthesis in both neurons. We previously found that presynaptic ApNT acts on ApTrk autoreceptors to form a self-perpetuating presynaptic positive feedback loop that is sufficient to drive the synapses from STF to ITF (Jin et al., 2016, 2017). Presynaptic ApNT also recruits postsynaptic mechanisms of facilitation by enhancing spontaneous release of glutamate, which acts on postsynaptic mGluR5 receptors. In addition, ApNT acts through both anterograde and retrograde signaling to form a trans-synaptic positive feedback loop (Jin et al., 2017). The presynaptic feedback loop appears to be the main self-perpetuating force driving consolidation: (1) activation of presynaptic PKA produces an increase in the signal intensity of ApNTpHluorin in the presynaptic neuron that grows over time ($p < 0.01$) without any clear growth over time in the postsynaptic neuron ($p > 0.05$); (2) Selective activation of presynaptic ApTrk receptors produces an increase in the signal intensity of calcium orange in the presynaptic neuron that grows over time ($p < 0.001$), without any clear growth over time in the postsynaptic neuron in analogous experiments ($p > 0.05$). On the other hand, the trans-synaptic feedback loop acts to orchestrate cellular activity in both the presynaptic and the postsynaptic neurons. For example, activation of protein synthesis by ApTrk receptor signaling in each synaptic compartment also depends on signaling from the other synaptic compartment: (1) activation of presynaptic protein synthesis by presynaptic ApTrk receptor signaling is reduced by injection of siRNA against ApNT into the postsynaptic neuron; (2) activation of protein synthesis in the postsynaptic neuron by postsynaptic ApTrk receptor signaling is reduced by bath application of MPEP, a potent inhibitor of mGluR5 ($p < 0.01$). These results suggest that protein synthesis in the presynaptic neuron depends on postsynaptic mechanisms and protein synthesis in the postsynaptic neuron requires presynaptic mechanisms, so that the pre- and postsynaptic compartments act as one functional unit. In summary, a presynaptic feedback loop acts as the driving force while a trans-synaptic feedback loop coordinates cellular activity in the pre- and the postsynaptic neurons during the consolidation of learning-related facilitation induced by 5HT.

Title: Behavioral tagging and capture: Memory persistence and memory-activated neuronal ensembles in old age

Authors: *S.-H. WANG, A. GROS, A. LIM, V. HOHENDORF, N. WHITE
Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Our daily memories of insignificant events fade away quickly. However, when a memory-modulating event is introduced before or after memory encoding, memories can persist longer. Using a rodent spatial task that mimics human daily experience of locating objects, we found that a novel event can facilitate the persistence of spatial memory (Wang et al., 2010). This phenomenon shares the same principle of facilitating long-term potentiation in synaptic tagging and capture (Redondo and Morris, 2011). Using this spatial task, we recently showed that the memory decline in middle age (c.a. 12 months) is associated with an impaired encoding or synaptic tagging mechanism (Gros and Wang, 2018). This study aims to: characterise memory impairment in older age (c.a. 20 month) by using this task; investigate if training in young protects memory impairment; visualise the cellular signature in the hippocampus for memory representation. We trained male Lister-Hooded rats to find rewards in an open arena in a sample trial and to search for more rewards among multiple locations in a choice trial. Their memory was probed in a test trial with multiple locations no rewards and the time spent searching in previous rewarded, correct location or incorrect locations were scored blindly. The results showed that memory declined in old age, which was not facilitated by a novel modulating event. Encoding and modulating with high level of rewards were required to keep the memory in old age. Prior training of this task in young and in mid-age was partially effective at delaying the memory decline. Finally, we used fluorescence in situ hybridization (FISH) to explore the activation of neuronal ensembles in the hippocampus in this task. We found that in young rats, the neurons activated by the encoding overlapped with neurons activated by the memory-modulating event in CA1.

Title: Dorsal hippocampal kappa opioid receptors modulate contextual fear memory reconsolidation in rats

Authors: *F. VANZ, V. F. LINARTEVICHI, M. GIACHERO, T. C. M. DE LIMA, L. J. BERTOGLIO
Dept. of Pharmacology, Biol. Sci. Centre, Block D/CCB, Univ. Federal De Santa Catarina, Florianopolis, Brazil

Abstract: Reconsolidation is a dynamic and adaptive process allowing the incorporation of new information into consolidated memories. Kappa opioid receptors (kORs) are expressed in brain regions involved in fear memory reconsolidation, including the dorsal hippocampus (DH). The present study sought to investigate the contribution of DH kORs to contextual fear memory reconsolidation. Male Wistar rats were fear conditioned to context A (3 shocks 1.0 mA, 3s). On the next day, they were briefly reexposed to the context A to reactivate the established memory and then bilaterally infused into the DH with vehicle (VEH), a selective kOR antagonist *nor*-binaltorphimine (*nor*-BNI; 0.3, 1.0, 3.0 or 10 nmol/hemisphere) or a selective kOR agonist GR 89696 (0.1, 0.3 or 1.0 nmol/hemisphere) 0 or 6 h later. To investigate the treatment effects on reconsolidation animals were reexposed to the paired context A on days 1 and 8 (Tests A1 and A2). The potential treatment effects on memory generalization were assessed by exposing the animals to a novel and unpaired context B on days 2 and 9 (Tests B1 and B2). Freezing behavior was measured as an index of memory in both cases. In experiment 1, infusing *nor*-BNI 1.0 nmol immediately after reactivation session increased the time spent freezing in both Tests B1 and B2 when compared with respective VEH groups (Test B1: VEH = 15 ± 3% *vs. nor*-BNI 1.0 = 48 ± 10%; Test B2: VEH = 27 ± 3% *vs. nor*-BNI 1.0 = 55 ± 7%). On the other hand, no effect was observed when *nor*-BNI 1.0 nmol was infused 6 h after reactivation session (experiment 2) (Test B: VEH = 11 ± 2% vs. *nor*-BNI 1.0 = 14 ± 1%). In experiment 3, infusing GR 89696 1.0 nmol immediately after reactivation session reduced the time spent freezing time in both Tests A1 and A2 when compared with respective VEH groups (Test A1: VEH = 82 ± 2% *vs.* GR 89696 1.0 = 43 ± 6%; Test A2: VEH = 78 ± 3% *vs.* GR 89696 1.0 = 39 ± 5%). However, this effect was no longer observed when GR 89696 1.0 nmol was infused 6 h after the reactivation session (experiment 4; Test A: VEH = 74 ± 3% *vs.* GR 89696 1.0 = 78 ± 3%) or when animals were pretreated with *nor*-BNI in a sub-effective dose (experiment 5) (Test A1: VEH ± GR 89696 1.0 = 51 ± 7% *vs. nor*-BNI 0.3 ± GR 89696 1.0 = 82 ± 3%; Test A2: VEH + GR 89696 1.0 = 48 ± 6% *vs. nor*-BNI 0.3 + GR 89696 1.0 = 72 ± 4%). Altogether, present results suggest the DH kORs play an important negative modulatory role in contextual fear memory reconsolidation.

Title: Protein kinase C activity in prelimbic cortex is necessary for reconsolidation and persistence of a reactivated contextual fear memory in rats

Authors: *T. R. DA SILVA[1], A. SEGANTINE[1], A. RAIMUNDY[1], L. BERTOGLIO[2], R. ANDREATINI[1], C. STERN[1]
[1]UFPR, Curitiba, Brazil; [2]UFSC, Florianopolis, Brazil

Abstract: An expanded time-window to mitigate reactivated fear memories has been shown, however, the mechanisms underlying the reactivation-induced memory persistence are not understood. Considering the role of protein kinase C (PKC) in the late stages of long-term memory formation, and the prelimbic cortex (PL) role in fear memory persistence and reconsolidation, this study sought to investigate whether PKC activity in PL could be important for reconsolidation and/or persistence of a reactivated fear memory. Male Wistar rats with bilateral implant of guide cannulas aimed at the PL underwent contextual fear conditioning that consisted of familiarization to the Context A on day 1, fear conditioning (Context A-shock pairing) on day 2, a brief Context A reexposure to memory reactivation on day 3, and subsequent Context A reexposures to estimate the drug effects on days 4 and 11 (TestsA1 and A2). Independent groups of rats received vehicle (VEH) or the selective PKC inhibitor cheleritrin (CHE; 1 or 3nmol/0,2µL/side) immediately, 6, 9, 12 or 18 hours after memory reactivation. A control group had the memory retrieval, or its reactivation omitted by the i.p. administration of nimodipine 16mg/kg, and after 6 hours they received VEH or CHE 3nmol. Freezing behavior was assessed as an index of fear memory. Data was analyzed using repeated measures ANOVA followed by Newman-Keuls test ($p \leq 0.05$). When infused into the PL immediately after memory reactivation, CHE (1nmol) significantly reduced the time spent freezing during TestA1 and A2, indicating a role for PKC in memory reconsolidation. VEH-treated animals presented a similar percentage of freezing during reactivation, Test A1 and A2. The groups treated with CHE 1 or 3 nmol intra-PL 6, 9 or 12 hours after memory reactivation presented less freezing behavior than controls during TestA2, indicating a role for PKC in memory persistence. No changes in the levels of freezing behavior during Test A1 were observed in the groups treated with CHE (1 or 3nmol) 6, 9 or 12 hours after memory reactivation. CHE 18 hours after reactivation presented no changes in freezing expression.When the memory retrieval or its reactivation were omitted, the

infusion of CHE 6 hours after did not change the freezing expression during Test A1 or Test A2.These results corroborate the role of PL in fear memory reconsolidation, indicating the PKC activity as a mechanism involved in this process. Moreover, the present findings indicate that the PKC activity in PL until 12 hours after memory reactivation and reconsolidation is involved in memory persistence, confirming the existence of an expanded time-window to selectively impair the persistence of reactivated fear memories.

Abstract: Background
Pro-inflammatory cytokines are known to play a role in the bidirectional communication between brain and immune system. Recently, anti-inflammatory cytokines have been shown to also be expressed in the central nervous system (CNS), and to be essential for cognitive function. We recently showed that IL-13—possibly from immune cells—plays a role in the regulation of cognitive functions by stimulating astrocytes to produce brain derived neurotrophic factor that is known to play a significant role in memory formation.
In this study we aim to address the role of type 2 cytokine signaling via IL-4Rα on cognitive functions, in order to define IL-13 target cells involved, as well as the underlying molecular mechanism. We further address the consequence of inhibited signaling of IL-13 via IL-4Rα, leading to impairment of reference memory, but not learning.
Materials and Methods
To investigate immunological-relevant genes influencing cognitive function, mouse models

deficient of IL-4Rα, IL-4/IL-13, and IL-4Rα/IL-13 were analyzed for their influence on learning and memory using the Morris water maze (MWM) as described by Brombacher et al. Data were recorded using the EthoVision XT 8 automated tracking system (Noldus Information Technology, Leesburg, VA). Statistical analysis was performed using ANOVA and Bonferroni post hoc test or Student t test. Groups were run in alternating order on successive training days, and animal protocols were approved by the independent Animal Ethics Research Committee at the University of Cape Town. To gain insight into cellular infiltrates, Flow cytometry and histological analyses were conducted from brain parenchyma. qPCR and ELISA were employed to investigate local cytokine environment to assess systemic upregulation of cytokine production.
Results
We show that IL4Rα or IL4Rα/13 deficiency does not impair learning in comparison to wild type control mice—whether simple or complex—however, reference memory is impaired. From loss of function approach, using the MWM, we demonstrate that IL-13 signaling via IL-13RαII is not the cause for observed impairment of memory formation.
Conclusions
While both IL-4 and IL-13 are known to be required for learning and memory, failure to signal via the common receptor IL-4Rα, impairs only reference memory, but not learning. This suggests that possible compensatory mechanisms and pathways employed in the absence of IL-4Rα are effective to uphold the processes of learning, but not sufficient to support reference memory, indirectly suggesting that IL-13 is critical for the process of memory formation.

Title: Examining the role of AKT isoforms on spatial learning and memory in AKT mutant mice

Authors: *D. J. PETERSON[1], J. LEVENGA[2], H. WONG[2], C. HOEFFER[2]
[2]Inst. for Behavioral Genet., [1]Univ. of Colorado - Boulder, Boulder, CO

Abstract: AKT is a protein kinase involved in synaptic plasticity and behavior and is often implicated in neurological disorders in which memory and cognition are impacted, such as

schizophrenia and Alzheimer's disease (AD). Behavior and memory formation involve activity-dependent changes that ultimately strengthen or weaken specific neuronal connections, and these activity-induced changes are commonly referred to as synaptic plasticity. Importantly, dysregulation of these activity-dependent changes has been implicated in schizophrenia, AD, and intellectual disability. There is ample evidence that links AKT signaling and protein synthesis in these processes; however, AKT is expressed in the brain by three distinct isoforms. The specific role each isoform may play in regulating memory, behavior, and synaptic plasticity remains unknown. Previous work from our lab found three major findings: 1) AKT isoforms demonstrate different patterns of regional and cellular expression in the brain; 2) removal of specific AKT isoforms differentially regulate the expression of hippocampal synaptic plasticity and protein synthesis; 3) AKT isoforms serve differential roles in cognition and memory formation. In the present study, we sought to further delineate the roles of each isoform by examining the effects of specific isoform removal in both floxxed and knockout mouse strains under various working memory tasks. Then, using a Cre/lox system, we examined whether the observed deficits in AKT1 mutants were due to the removal of AKT1 from the brain or the absence of AKT1 during development. To generate mice that have a conditional *AKT1* or *AKT2* removal in excitatory neurons in the forebrain, we bred $Akt1^{loxP/loxP}$ or $Akt2^{loxP/loxP}$ with *Camk2α*-Cre mice on a C57/BL6 background. We found that the removal of AKT isoforms differentially effects spatial learning and memory, and likely contribute to the cognitive impairments in disease states in an isoform specific function.

Title: Seizure-induced cognitive impairment in pregnancy and preeclampsia: Effects of prolonged seizures and anti-seizure treatments

Authors: *A. C. JOHNSON, M. J. CIPOLLA
Neurolog. Sci., Univ. of Vermont Larner Col. of Med., Burlington, VT

Abstract: Preeclampsia (PE), a hypertensive disease of pregnancy, can result in de novo seizures known as eclampsia. Eclamptic seizures, including generalized tonic-clonic seizures and status epilepticus (SE), often result in amnesia lasting days. While a brief seizure may cause minimal

injury, recurrent and prolonged seizures such as during SE can impair memory and cognition. Whether PE increases the susceptibility to seizure-induced memory impairment remains unclear. Magnesium sulfate (MgSO4) is more effective at reducing the incidence of recurrent eclamptic seizures than anti-convulsants such as diazepam (Dz); however, whether MgSO4 or Dz treatments are protective from SE-induced memory impairment in PE is unknown. Here, we tested the hypothesis that SE would cause greater memory impairment than a single seizure in PE versus the normal pregnant and nonpregnant states, and compared the protective effects of MgSO4 and Dz on seizure-induced cognitive dysfunction. Female Sprague Dawley rats (n=6-8/group) were either virgin, nonpregnant (NP), normal pregnant (Preg; d19-20) or with PE (induced by a high cholesterol diet gestational d7-20). The chemoconvulsant pentylenetetrazol (PTZ; i.p.) was used to compare the effect of one tonic-clonic seizure versus SE on cognition. Rats received one PTZ injection (60mg/kg) to induce a single seizure, multiple PTZ injections (5-40mg/kg; 10 min intervals) to induce SE including multiple tonic-clonic seizures lasting 30 mins, or vehicle (CTL). Rats having seizures received MgSO4 (270mg/kg i.p.) or Dz (10mg/kg i.p.) 20 min after PTZ or SE. Short-term memory was tested 24 hours post-seizures using a novel object recognition task and recognition index calculated: (novel object time)/(total object time). Data are mean ± SEM and comparisons made using a one-way ANOVA with post hoc Bonferroni test. SE impaired short-term memory in Preg and PE rats, demonstrated by decreased recognition indices compared to CTL (0.49 ± 0.04 vs. 0.69 ± 0.06, $p<0.05$ and 0.46 ± 0.07 vs. 0.70 ± 0.05, $p<0.05$) that was unaffected by MgSO4 or Dz in PE rats (0.49 ± 0.12 and 0.42 ± 0.08, respectively) and Preg rats (0.46 ± 0.08 and 0.51 ± 0.04, respectively). A single seizure did not affect short-term memory in either group, and short-term memory was unaffected by seizures in NP rats. In conclusion, short-term memory impairment after SE in Preg and PE, but not in NP rats suggests pregnancy increases the susceptibility to seizure-induced cognitive dysfunction. Neither MgSO4 nor Dz treatment improved cognition after prolonged and recurrent seizures, highlighting the importance of prevention of eclampsia and seizure cessation to maternal cognitive health.

Title: Structural and functional reorganisation in the brain of macaques following fornix transection

Authors: *V. PELEKANOS[1], S. CHAKRABORTY[2], S. MASON[1], E. PREMEREUR[3], D. J. MITCHELL[4], A. H. BELL[1], A. C. LEE[5], A. S. MITCHELL[1]

Unit, Univ. of Cambridge, Cambridge, United Kingdom; [5]Dept. of Psychology (Scarborough), Univ. of Toronto, Toronto, ON, Canada

Abstract: The fornix, the white matter pathway in the primate brain that connects the extended hippocampal system to the limbic thalamus, mammillary bodies, and frontal cortex, has a critical role in episodic memory, as revealed by monkey lesion (Gaffan, 1994; Buckley et al., 2008) and human neuroimaging studies (Metzler-Baddeley et al., 2011; Rudebeck et al., 2009). In the present study, we used monkey neuroimaging combined with lesions to investigate the role of the fornix, and anatomically related structures, in rapid learning of episodic-like information. Eight age-matched young adult male macaques were scanned using diffusion-weighted magnetic resonance imaging (MRI) and resting-state functional MRI. Four animals underwent surgeries to receive selective bilateral fornix transections. Before and after the surgeries, these animals were scanned after extensive training on the object-in-place scene discrimination (OIP) task which measures episodic-like memory in monkeys. The other four animals, trained on a passive fixation task for an independent experiment, remained as unoperated controls. We employed diffusion tensor imaging to quantify white matter properties, which, preoperatively, showed increased fornix microstructural integrity in the OIP-trained monkeys compared to controls. Postoperatively, we found lesion-related structural and functional connectivity changes. Specifically, microstructural integrity in alternative major white matter pathways, like the cingulum bundle, was associated with learning on the OIP task, whereas the resting-state results suggested marked changes within the default-mode network (Mantini et al., 2011). Together, our results solidify the contribution of the fornix in episodic-like memory, and further demonstrate lesion-induced neural reorganisation in the primate brain, underlying its capacity for plasticity.

Title: Behavioral strategies and source of directional signal for reorientation in sighted and blind animals

Authors: *C. M. GAGLIARDI, M. R. LOPEZ, M. C. GARZA, T. I. ERESANARA, I. A. MUZZIO
Univ. of Texas At San Antonio, San Antonio, TX

Abstract: Reorientation - regaining one's bearings after becoming lost - is a fundamental problem of navigation. In lost animals the internal sense of direction is unreliable; therefore, disoriented navigators must reorient only using external cues. Across sighted species it has been shown that spatial geometry, i.e. the shape of a navigable space, plays a critical role in reorientation, even when other directionally informative cues, such as landmarks and objects, are present. Since vision allows a navigator to quickly and precisely process the external layout, it is unknown if blind navigators, who rely on sequential exploration to form detailed representations of space, use the same strategies and neural mechanisms as sighted subjects to reorient. Here we investigated how blindness affects behavioral strategies and the source of directionality during reorientation. First, we used a classic reorientation paradigm where disoriented animals have to find a reward in a rectangular environment containing a polarizing tactile cue. We found that both sighted and blind animals search equally often in the rewarded location and the symmetrically opposite corner, indicating the use of geometry for reorientation, disregarding the tactile cue. Then, we investigated whether the use of geometry during reorientation is contingent upon the area that the animal can explore or it merely requires the presence of tactile surface boundaries using the classic paradigm. We found that sighted mice could reorient using both the affordable navigable space and surface boundaries, but showed better performance in the later condition. Conversely, blind animals could only reorient using the affordable navigable space, suggesting that two-dimensional surface boundaries are not efficient for disoriented blind mice. We are now investigating if the directional signal necessary for reorientation arises from the same brain region/s in sighted and blind animals. To this end, we are using chemogenetic silencing to determine the role of the retrosplenial cortex and postsubiculum, two areas that are critical for landmark control of head direction. These results will be critical to understand the cognitive architecture of reorientation and determine the role of vision in this process.

Title: Hippocampus-retrosplenial cortex interaction for memory formation and retrieval

Authors: *A. N. OPALKA[1], J. LIU[1], H. LIANG[2], D. V. WANG[1]
[1]Neurobio. and Anat., [2]Sch. of Biomed. Engin., Drexel Univ., Philadelphia, PA

Abstract: The hippocampus and retrosplenial cortex (RSC) both play important roles during memory acquisition, consolidation and retrieval. However, it is unclear how the two brain structures may interact at each of these memory processes. Anatomically, there is a dense reciprocal connection between the dorsal hippocampus and RSC, suggesting a potential two-way communication between them. Here we employed in vivo electrophysiology and optogenetic approaches to study hippocampus-RSC interaction in freely-behaving mice. We first recorded neural activity from the dorsal hippocampus and RSC simultaneously and confirmed coordinated activity between the two brain regions at both the local field potential (LFP) and single-neuron levels. Hippocampal LFP displayed discrete fast ~200 Hz oscillations, known as sharp-wave ripples that are believed to be important for memory consolidation. On the other hand, the RSC LFP displayed a characteristic broad-band oscillation. This RSC oscillation shifted sequentially from fast (~300 Hz) to slow (~30 Hz) frequencies immediately prior to hippocampal ripples, signifying an orchestrated and controlled influence on hippocampal ripples. Consistently, most of the RSC neurons exhibited increased activity, which was phase-locked to the RSC oscillation. Immediately after hippocampal ripples, a small percentage of the RSC neurons, most likely interneurons, also increased their activity after a short latency of ~5 ms, suggesting a monosynaptic connection from the hippocampus to RSC. In contrast, the remaining RSC neurons, most likely pyramidal neurons, decreased their activity after ~25 ms, which are likely suppressed by the local interneurons. These above results indicate a two-way communication between the hippocampus and RSC during memory consolidation: the RSC influences hippocampal ripple activity through a coordinated fast-to-slow oscillation, while the hippocampus mainly inhibits RSC activity through direct activation of RSC local interneurons. In a second set of experiments, we trained mice with a contextual or trace fear conditioning procedure and optogenetically silenced the hippocampal projection to the RSC. Preliminary results revealed that the hippocampus-to-RSC pathway is required for retrieval of long-term (1 month) but not short-term (1 day) fear memory. Our ongoing effort is to determine the role of hippocampus-RSC connections at different stages of memory formation processes and advance our current understanding of memory associated circuits.

Title: Optogenetic silencing of retrosplenial cortex disrupts sensory associative memory

Authors: *A. BOTTURA DE BARROS[1], T.-Y. LEE[2], V. SAMBORSKA[2], M. PANAYI[3], T. AKAM[3], D. M. BANNERMAN[3], M. M. KOHL[2]

Abstract: Numerous studies implicate the hippocampus and neocortex in associative memory. Still, it is unclear if and/or how sensory and contextual information is stored in these regions. The retrosplenial cortex (RSC) is known to reciprocally connect to the hippocampal formation and to sensory areas. Although RSC has been previously described as important for processing spatial information, this connectivity suggests that the RSC might be involved in hippocampus-neocortex interplay and more generally required in the formation and storage of sensory associative memory. This notion is supported by RSC-lesion and -inactivation studies that produced impairments in associative memory.
Here, we aimed to develop an associative memory task in mice and performed precise optogenetic manipulations of RSC activity to understand its role in facilitating the association of neutral sensory stimuli. We developed an aversive preconditioning behavioural paradigm in mice which allows us to test associations between neutral stimuli. We used the red-shifted opsin, Jaws, to inactivate the RSC during different phases of the task to investigate the role of this structure in sensory associative learning.
Our results show that control mice successfully learn the preconditioned association in our task. Optogenetic silencing of the RSC at the time when the mice form associations between neutral stimuli reduces performance to chance levels.
In summary, we establish a new sensory preconditioning task for mice allowing us to probe associative memory between neutral stimuli. Optogenetic silencing of RSC enables us to demonstrate the necessity of the RSC in this type of memory.

Abstract: The retrosplenial cortex (RSC) is a part of association cortex and has extensive interconnections with both sensory and limbic structures. The RSC is bidirectionally connected with the visual cortex and also receives substantial inputs from the hippocampal formation (specifically from CA1 and the subiculum). Functionally, the RSC is involved in visuospatial processing and memory, and lesions of the RSC lead to impairments in both fear conditioning and spatial learning. RSC neurons have been shown to encode both allocentric and egocentric spatial locations, as well as the head-direction of animals. To understand the detailed functional connectivity supporting this kind visuospatial encoding by cells in the RSC, we used large-scale simultaneous tetrode recordings from the visual cortex, CA1 and RSC in male Long-Evans rats. Here, we report on the neuronal activity patterns and cross-correlations seen among these three brain regions during distinct sleep-wake states. We compare our results to recent reports suggesting that RSC neurons are most likely to show maximal firing rates selectively during REM sleep.

Abstract: The ability to remember and to navigate to safe places is necessary for survival. Place navigation is known to involve connections from medial entorhinal cortex (MEC) to the hippocampus. However, learning-dependent changes in neuronal activity in distinct circuits remain unknown. Two pathways could be involved in visual place navigation. Here, we demonstrate that the MEC layer II - dentate gyrus (DG)-pathway is crucial for visually cued spatial navigation, while the connections from MEC layer III to hippocampal CA1 are not. In this study, we were able to record bulk calcium activity from the axon bundle of specific pathways in freely behaving mice. This was achieved by using an improved version of optic fiber photometry together with the layer-specific expression of the genetically encoded calcium indicator GCaMP5G in different spatial learning paradigms. We discovered the experience-dependent induction of a persistent task-associated (PTA) activity in the axons from MEC layer II to DG. This activity started at the onset of the task and terminated immediately after the localization of the target place. PTA activity followed place learning and its amplitude and duration strongly correlated with task performance. Moreover, PTA activity depended on continuous visual input and was elicited by visually guided navigation in a morris water maze or a radial eight-arm maze but not by locomotion in general. Electrophysiological tetrode

recordings in MEC layer II revealed that PTA population activity, on a single cell level, was created by both an increase in intermittently active neurons and by the de-novo development of persistently active neurons. Optogenetic inhibition of the MEC layer II - DG pathway completely and reversibly disrupted spatial navigation in trained animals, while it had no effect on different learning paradigms like fear conditioning. The MEC-Layer III - CA1 pathway, on the other hand, did not show activity patterns comparable to the experience-dependent PTA activity. Moreover, the optogenetic disruption of this pathway had no effect on spatial memory performance. Together, these findings suggest that the visual system, the MEC layer II and the dentate gyrus are essential hubs of a memory circuit for visually guided navigation. Also, the newly found PTA activity in MEC layer II neurons that project to DG is essential for successful visually cued navigation.

Title: The basal forebrain may provide a link between locomotion and learning

Authors: *K. SVIATKÓ[1], A. SZÉLL[2], P. HEGEDÜS[1], A. BÁNHIDI[1], B. HANGYA[1]
[1]Inst. of Exptl. Med. Hungarian Acade, Budapest, Hungary; [2]Dept. of Measurement and Information Systems, Budapest Univ. of Technol. and Econ., Budapest, Hungary

Abstract: Cortical processing depends on brain states that influence animal behavior. Brain states are controlled by the coordinated activity of multiple subcortical neuromodulatory centers. Among these the basal forebrain has widespread cholinergic, GABAergic and glutamatergic projections thought to mediate multiple cognitive functions including learning, memory and plasticity. From these, the GABAergic projection has been implicated in controlling the locomotion-related theta oscillation in the hippocampus and the glutamatergic projection can directly control animal speed. On the other hand, cholinergic cells respond rapidly and reliably to reinforcement that is likely important for learning. Therefore we hypothesize a relationship between basal forebrain neuronal activity, locomotion and learning.

To directly test this, head-fixed mice were placed on a wheel and trained on an auditory Pavlovian cued outcome task in which two pure tones of different frequency predicted likely reward (water) or likely punishment (air puff). We quantified how well mice learned the task by measuring anticipatory licking after the tone predicting likely reward. This experimental design allowed mice to run or stay still voluntarily during the task. Additionally, stress levels induced by head-fixation and water restriction were tested by measuring corticosterone and adrenocorticotropic hormone levels from the blood. We monitored neuronal activity in the medial septum of the basal forebrain using tetrode electrodes. Therefore it was possible to examine whether there were correlated changes in basal forebrain neuronal activity, behavioural performance and learning across 'standing still' and running states, potentially influenced by differential levels of stress hormones.
We found that mice initially trained on a fixed wheel learned faster. When allowed to run freely, mice tended to run after reinforcement delivery, which could reflect approach (water) or escape (air puff) responses. Neurons displayed a diversity of responses to behaviourally relevant events with dominant subpopulations showing activation or suppression after air puff delivery. These medial septal cell types may convey locomotion-dependent learning signals via the septo-hippocampal pathway.

Title: Distinct ripple-triggered cortical activity during natural sleep and wakefulness

Authors: *J. KARIMI ABADCHI[1], M. NAZARIAHANGARKOLAEE[2], T. KNOPFEL[3], B. L. MCNAUGHTON[4], M. H. MOHAJERANI[5]
[1]CCBN/University of Lethbridge, Lethbridge, AB, Canada; [2]CCBN, Univ. of Lethbridge, Lethbridge, AB, Canada; [3]Imperial Col. London, London, United Kingdom; [4]Dept. of Neurosci., The Univ. of Lethbridge, Lethbridge, AB, Canada; [5]Dept. of Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Hippocampal sharp-wave ripple (SWR) events, the transient high frequency (100 - 250 Hz) oscillations in the hippocampal local field potential (LFP), are the main candidate for

facilitating reactivation of recently acquired memories in the hippocampal circuits. SWRs occur during both slow-wave sleep (SWS) and quiet wakefulness. Their co-occurrence with cortical slow oscillation (up- and down-states) and thalamocortical spindles during SWS is believed to mediate coordinated memory replay in the hippocampus (HPC) and the cortex (CTX). Coordinated reactivation of memory traces in the hippocampal-cortical circuits, mediated by SWR events, also occurs during periods of awake quiescence and immobility, particularly, during the pauses that animals make while they are performing a spatial task. However, there are major differences between SWS and awake reactivations. These differences probably stem from the different ways by which HPC and CTX communicate during different behavioral states. Recent research indicates that SWR-correlated activity of prefrontal cortex neurons equally shows both inhibitory and excitatory modulation. However, it is mainly biased toward excitation during SWS. It has also been shown that the hippocampal-cortical coordination is stronger during awake ripples compared to sleep ones, even though it seems there is no global synchronizing mechanism like slow-oscillation during quiet wakefulness. To further probe the differences in hippocampal-cortical interaction during sleep and wakefulness, we chronically monitored cortical activity in a large portion of the dorsal CTX in mice using wide-field optical imaging and simultaneously recorded hippocampal LFP from the pyramidal layer of the dorsal CA1 during both quiet wakefulness and natural sleep. We also collected and analyzed the same data under urethane anesthesia as a model of sleep. In line with the previous reports, we found an extensive ripple-triggered activation in the cortical areas during natural sleep and anesthesia. This activation was strongest in the retrosplenial cortex (RSC) compared to other dorsal cortical regions. Moreover, this activation was preceded by a period of silence, which probably reflects cortical down-states. In contrast, we found that RSC shows an abrupt inactivation during awake ripples, and we did not observe preceding down-states. Interestingly, this inactivation was mainly localized in the RSC and not in other cortical regions. Our data implicate RSC as one of the principal contributors to the ripple-triggered hippocampal-cortical interactions and support the idea that these interactions are state-dependant.

Title: Coherent theta and respiratory oscillations between sensory systems and the hippocampus

Authors: *A. SHERIFF[1,2], S. ZHENG[3], V. NGUYEN[2], L. M. KAY[1,2]
[1]Dept. of Psychology, The Univ. of Chicago, Chicago, IL; [2]Inst. for Mind and Biol., Chicago, IL; [3]Mathematics, Univ. of Chicago, Chicago, IL

Abstract: Spatial navigation provides an important window into understanding how neural activity gives rise to several components of cognition (e.g., attention, decision-making, sensorimotor processing, learning and memory). A recent proposal suggests that olfaction evolved primarily in the context of spatial navigation. Therefore, the rodent spatial learning and memory (SLM) model may be more ethologically valid when adding olfactory-spatial cues rather than using solely visual-spatial cues. The respiratory rhythm, arising from brainstem central pattern generators, is tracked by olfactory bulb respiratory oscillations (2-12 Hz in rodents) and recently shown to be capable of widespread coordination of neural activity implicated in cognition. The respiratory rhythm could be serving functions attributed to hippocampal theta, as it has been shown to coexist with theta in the hippocampus and olfactory bulbs at similar but separate frequencies. In this study, behavioral and electrophysiological methods were used with aims of 1: comparing spatial navigation and SLM in rodents across visual and olfactory modalities; and 2: assessing the roles of theta and respiratory oscillations in coordinating widespread neural activity during SLM and other related behaviors. Recordings of the local field potential (LFP) were obtained from the olfactory bulb, dorsal CA1 and DG of the hippocampus, piriform cortex, and primary visual cortex, concurrently with measures of respiratory rhythm in the nasal cavity, in freely behaving rats performing several tasks. Power and coherence spectral analyses and Granger causality are used to address cooperativity and causal relationships between areas. Spatial tasks included a four-arm radial maze, as well as navigation in an open field, with both tasks including phases with either visual or olfactory spatial cues present. Odor tasks involve passive odor sampling and a Go/No-Go odor discrimination task. Preliminary data suggest globally high coherence during spatial tasks between most areas measured with fluctuating patterns of theta and respiratory dominance over training and between areas. Odor tasks show high respiratory coherence within the olfactory circuit throughout, extending to the hippocampus during more difficult phases (e.g., rule reversal). Collectively, these studies aim to further characterize the potentially distinct yet complementary roles of hippocampal theta and olfactory bulb respiratory rhythms in the context of cognition.

Title: Renewal following extinction of remotely acquired conditioning depends on the postrhinal cortex

Authors: *N. E. DEANGELI, D. J. BUCCI, T. P. TODD
Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The postrhinal cortex (POR) is part of a network of posterior cortical regions involved in learning and memory. POR is critical for recent and remote context fear memory retrieval (Burwell, Bucci, Sanborn, & Jutras, 2004), but not for recent or remote cue fear memory retrieval (Bucci, Phillips & Burwell, 2000; DeAngeli et al., in preparation). Despite evidence that POR is not necessary for the retrieval of these cue fear memories, it may play a role in the context-specific expression of a cue fear memory after extinction (i.e renewal). Renewal, the recovery of responding to an extinguished conditioned stimulus that occurs when the CS is presented outside the extinction context, is impacted by hippocampal damage in some cases, but not others, suggesting that context encoding and retrieval might also depend upon other brain areas. As a parahippocampal structure, POR is well positioned to provide hippocampus with processed sensory information necessary for renewal.
In the present studies, rats received infusions of either inhibitory or control DREADDS into POR. Upon recovery, subjects were exposed to a single 8 min conditioning session in Context A, with three tone-shock pairings. Following a 28-day retention interval, rats were placed back in Context A for 20 min for a context retrieval test. The next day, the tone retrieval session occurred in Context B (different visual, olfactory, and tactile cues than Context A) with 20 presentations of the tone alone. Rats then underwent 7 days of extinction with 20 presentations of the tone alone in Context B each day. Following the last day of extinction training, rats were re-exposed to Context A for 20 min. On the next two days, renewal of extinguished fear was tested via 5 presentations of the CS each day. Each rat received one test session in Context A and one test session in Context B (counterbalanced). Freezing behavior was measured throughout the sessions as an indicator of conditioned fear. For Experiment 1, all rats received an IP injection of clozapine-n-oxide (CNO) 30 min prior to behavior on each extinction day. For Experiment 2,

rats received CNO injections prior to the renewal tests. Both manipulations resulted in impaired renewal in rats with temporary inactivation of POR versus controls. Thus, temporary inactivation of POR during extinction of a remote tone fear memory impairs renewal of that extinguished fear cue. Furthermore, temporary inactivation of POR during the renewal test also disrupts renewal of the extinguished fear cue.

Title: The retrosplenial cortex is necessary for contextual fear memory even when rats are over-trained

Authors: *D. FOURNIER[1], M. EDDY[2], T. TODD[2], D. J. BUCCI[2]
[1]Program of Exptl. and Mol. Med., [2]Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: It has been consistently shown that damaging the rodent hippocampus soon *after* Pavlovian fear conditioning (e.g., 24 hr later) produces severe retrograde amnesia for contextual fear memories. In contrast, hippocampal damage that occurs *prior* to conditioning only impacts contextual fear memory when relatively weak fear conditioning procedures are used (e.g., 1-3 trials, weak shock); if rats receive strong conditioning (i.e., over-training) procedures, hippocampal lesions are without effect (Wiltgen et al., 2006). This supports the long-standing view that alternate brain pathways and structures can 'compensate' for the absence of the hippocampus under certain conditions. To date, these alternate regions and systems remain unidentified. Moreover, an important, yet unstudied corollary of this hypothesis is that there may be brain regions that are essential for context fear memory regardless of the training parameters or timing of the damage. One such structure may be the retrosplenial cortex (RSC), based on its position at the interface between hippocampal/parahippocampal memory structures and the sensory cortical regions that provide essential information about the context. Consistent with this idea, we and others have previously shown that RSC lesions or inactivations impair context fear memory regardless of whether damage occurs soon after conditioning, or at distal time points

(e.g., 28 days after conditioning). In addition, damage to RSC prior to conditioning impairs the expression of contextual fear memories. However, most of the pre-training RSC lesion studies to date have used relatively weak conditioning procedures. If RSC is essential for contextual fear memory, we would expect that RSC lesions, unlike hippocampal lesions, would impact context fear memory even when rats are over-trained. To test this, rats were conditioned using the identical overtraining procedures and experimental designed used by Wiltgen et al. (2006) to demonstrate that the effects of pre-training hippocampal lesions could be overcome with strong conditioning. Like hippocampal lesions, neurotoxic lesions of RSC carried out 24 hours after conditioning abolished contextual fear memory. Unlike the hippocampus, however, RSC lesions also impaired context fear memory when damage took place *prior* to strong conditioning. This pattern of results suggests that RSC has an essential role in contextual fear memory regardless of the strength of training or timing of the damage.

Title: Effects of retrosplenial cortex damage on negative and positive patterning discrimination tasks

Authors: *A. TAVAKKOLI[1], D. I. FOURNIER[2], T. P. TODD[3], D. J. BUCCI[3]
[1]Dartmouth Col., Lebanon, NH; [2]Program in Exptl. and Mol. Med., [3]Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The retrosplenial cortex (RSC) is a polymodal association area that is highly interconnected with hippocampal, parahippocampal and cortical sensory regions. This pattern of connectivity suggests that RSC may contribute to variety of forms of learning and memory, particularly those that involve linking together two more sensory cues. Consistent with this, previous research has demonstrated that lesioning or temporarily inactivating the RSC impairs contextual fear memory, which is thought to involve forming a configural representation of the collection of stimuli that define the environment. Similarly, RSC lesions impair several forms of discrimination learning, including serial and compound feature negative discriminations. As a

result, we predicted that RSC lesions would also impact so-called negative and positive patterning discriminations, which arguably provide a strong test of the hypothesis that RSC is important for forming associations between multiple sensory cues. In this study, we used electrolytic lesions of the RSC specifically to produce extensive damage and to maximize the likelihood of observing an effect on behavior. Rats were trained in one of two discrimination tasks. In the negative patterning procedure, two individual cues (click, C and light, L) were each paired with food reward on separate trials, while on a third type of trial, the cues were presented in simultaneous compound and non-reinforced. Conversely, in the positive patterning procedure, presentation of the compound stimulus was followed by food, but presentations of the individual cues were non-reinforced. We hypothesized that the RSC- lesioned animals would be impaired in both discrimination tasks if the RSC is needed to learn the meaning of the compound stimulus and successfully discriminate between the trial types. To our surprise, the pre-training lesions of RSC did not impair the ability of rats to learn the negative patterning or positive patterning discriminations. Subsequently we tested the efficacy of the lesions by testing rats in a spatial object-in-place task that is known to depend on RSC. Consistent with prior studies, the lesioned rats were impaired in this procedure, suggesting that the lack of effects on negative and positive pattering was not due to insufficient damage to RSC. The implications of these findings for understanding the functional contributions of RSC to learning and memory are discussed.

Title: Characteristics and interactions in the local field potential of the perirhinal and postrhinal cortices

Authors: *S. G. TRETTEL[1], I. TOMAS PEREIRA[2], V. R. HEIMER-MCGINN[1], R. D. BURWELL[1]
[1]Dept. of Cognitive, Linguistic, and Psychological Sci., [2]Brown Inst. for Brain Sci., Brown Univ., Providence, RI

Abstract: Local field potential oscillations appear to play an important role in coordinating the activity of ensembles of neurons located in different brain regions. Previous studies have shown that in the hippocampus and its connected cortical regions, theta (6-12 Hz), slow gamma (25-55

Hz), and fast gamma (65-100Hz) oscillations all appear to play a role in temporarily synchronizing cell ensembles to perform computation. In the parahippocampal region, the perirhinal and postrhinal cortices are integrally related to structures in the hippocampal formation and play roles in hippocampal memory functions. What is less understood, however, is how the local field potential correlates across the two regions and how the field potential patterns change across layers and rostral-caudal position within these areas. By examining the pattern of field potential oscillations, we can better understand how perirhinal and postrhinal cortices communicate with each other and other structures of the parahippocampal region. We used local field potential data recorded simultaneously from the perirhinal and postrhinal cortices of Long-Evans rats as they traversed a familiar environment to examine oscillations in the theta and gamma ranges. We compared the oscillations between these two regions, and we investigated how these oscillations changed across cortical layers. We found that the theta oscillation in postrhinal cortex is phase-reversed from the weaker theta oscillations of the perirhinal cortex. We also found that, while transient fast-gamma epochs appear to occur concurrently in perirhinal and postrhinal cortex, slow gamma epochs were not coherent between the two regions. Our findings indicate that, like other regions of the hippocampal memory system, perirhinal and postrhinal oscillations in different frequency bands may be coordinating temporary increases in synchrony between sub-regions of the hippocampal formation. This temporary synchrony allows for a flexible set of sub-circuits to be set up to perform different but related computations.

Title: Neuronal correlates in the rat retrosplenial cortex and the postrhinal cortex during performance on a visuospatial attention task

Authors: *E. HWANG[1], F.-C. YANG[3], T. K. JACOBSON[1], R. D. BURWELL[2]

Abstract: Recent work in both primates and rodents has addressed the role of the retrosplenial cortex (RSC) in spatial and non-spatial information processing. These studies show that the RSC

is implicated in navigation, spatial memory, processing of contextual information, sensory integration, cross-modal information processing, and the representation of stability or reliability. While most studies of the RSC address hypothesis about the spatial functions, the findings of non-spatial studies provide compelling evidence that cannot be explained by a purely spatial hypothesis. An open question is what core function of the RSC could support this wide variety of functions in both the spatial and non-spatial domains. Rodent studies show that the RSC and the postrhinal cortex (POR) are functionally and anatomically interconnected (Burwell & Amaral, 1998, Burwell et al, 2004, Keene & Bucci, 2008). We have shown that the POR exhibits object-location conjunctive coding (Furtak, Ahmed, & Burwell, 2012). Previous work also shows that the POR plays an important role in spatial information processing. We hypothesize that the RSC integrates information across multiple information processing domains that include both spatial and non-spatial information. Here we report a study in which we compare neuronal activity in the rodent RSC and POR during performance on a visuospatial attention (VSA) task in the Floor Projection Maze (Jacobson et al., 2014). The VSA task is a purely visual task that was adapted from the five choice serial reaction time task (Bari, Dalley, Robbins, 2008) for a double-sided, bowtie shaped enclosure. The VSA task allows assessment of top-down and bottom-up visuospatial attention as well as multiple spatial reference frames. Detailed analyses of neuronal correlates for both RSC and POR will be presented. In addition, the patterns of neuronal activity in RSC and POR will be compared with those of the PPC recorded in rats performing the same VSA task.

Title: Control of perirhinal-dependent novelty exploration in rats by optogenetic modulation of prefrontal cortex

Authors: *A. E. IOANNOU[1], D. L. POETA[2], R. D. BURWELL[3]
[1]Biomed. Engin., [2]Cognitive, Linguistic and Psychological Sci., [3]Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: The perirhinal cortex (PER) has a well-established role in the identification and recognition of individual items and objects (reviewed in Ho and Burwell, 2014). Animals and

humans with perirhinal damage are unable to distinguish familiar from novel objects or images in recognition memory tasks. Our lab previously found that neuronal activity in PER appears to signal novelty and familiarity through synchronous activity at specific frequencies (Ho et al., 2015), with novelty signaled at 30Hz and familiarity signaled at 11Hz. Whereas many animals have a propensity to explore novel objects, it is sometimes necessary to suppress that activity when exploration is not optimal, e.g. a hungry animal may avoid exploring a novel item when navigating toward a food source. Evidence indicates that such cognitive control relies on prefrontal cortex (PFC) (reviewed in Lehky and Tanaka, 2016). Medial prefrontal cortex (mPFC) is known to be involved in processing information about novelty (Dias and Honey, 2002;). The secondary motor cortex (MOs, also known as medial agranular cortex, AGm) in the rodent plays an important role in processing sensory information in order to guide appropriate goal-directed behavior (Sul et al., 2011). Based on this evidence, it is reasonable to suggest that the PER interacts directly with the mPFC and the MOs to provide the necessary cognitive control over this novelty exploration. In this study we employ optogenetics to address the hypotheses that PER-PFC interaction is necessary for novelty guided exploration and that these interactions are modulated by synchronous neuronal activity in specific frequency bands. Rats were bilaterally injected with an adeno-associated viral vector (AAV) containing channelrhodopsin (ChR2) and bilaterally implanted with an optical fiber in either the MOs or in the infralimbic cortex (IL), located in the mPFC. During a Spontaneous Object Recognition (SOR) task, rats underwent optical stimulation in a within subject design. Conditions were 30Hz, 11Hz, 8Hz (theta frequency), and a no-stimulation control (optical fiber was physically blocked). Based on our hypotheses, we expect that pairing a familiar object with a 30Hz stimulation in either the MOs or IL, will increase exploration of that object, as if it were novel. Further, pairing a novel object with 11Hz stimulation in either the MOs or IL, will decrease exploration of that object, as if it were familiar. The 8Hz condition was intended to determine how stimulation in the theta frequency band might impact exploratory behavior.

Title: Characterizing representations in the postrhinal cortex during a location bi-conditional spatial memory task

Authors: *V. J. ESTELA[1], R. D. BURWELL[2]
[1]Neurosci., [2]Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: Episodic memory, or the recollection of events in time and space, requires the ability to fully represent and recall context. Context-dependent cognitive processes are disrupted in a number of neuropsychiatric and neurological disorders such as schizophrenia, depression, PTSD, and Alzheimer's disease. These disruptions are associated with changes to the parahippocampal region of the medial temporal lobe, specifically the parahippocampal cortex (PHC, human homologue of the rodent postrhinal cortex, POR) and the hippocampus (HC). The contribution of each of these areas and the mechanisms underlying the representation of these context-dependent memories is still unknown. My laboratory showed that the POR, situated upstream of the HC, has neurons that respond to a particular item only when it is in a particular location (Furtak, et al., 2012). In the HC, this type of object-location conjunctive coding emerges with the learning of an association (Komorowski, et al., 2009), and is proposed to be a signature of episodic memory. The temporal characteristics of these conjunction cells in the POR have yet to be defined, nor has the relationship between the conjunction cells in the POR and the HC. Further, initial data indicates that oscillations in the theta frequency in the POR might signal error (Furtak, et al., 2012), but this function should be studied further. Finally, the POR appears to have cells that represent both egocentric and allocentric reference frames, indicating another integrative function of the region. Based on this preliminary data, we hypothesize that the POR integrates object information from the PER with spatial information from the posterior parietal and retrosplenial cortices to represent the spatial layout of objects, patterns, and features in the local environmental context. Further, we hypothesize that the HC relies on contextual representations from the POR for associative learning and episodic memory. Based on this, we predict that object-location conjunctions should be present in the POR before they emerge in the HC, and that we will recapitulate the results showing error signaling via theta in the POR. To test these predictions, we will record in the POR and HC during performance on the Location Biconditional Discrimination task in the floor projection maze. In this task, a pair of objects is presented alternatingly on the east or west side of a bowtie-shaped maze. The east-west location determines which of the two objects is correct. Finding object-location conjunctions in the POR prior to the HC would be consistent with the interpretation that object-location conjunctive coding in the HC relies on POR representations of context.

Title: Impaired spatial reorientation and amyloidosis in the dorsal hippocampus of the 3xTg-AD mouse model of Alzheimer's disease

Authors: *A. C. STIMMELL[1], S. C. MOSELEY[1], V. LAPOINTE[2], L. MESINA[2], L. F. SANTOS-MOLINA[1], B. N. CRAFTON[1], B. L. MCNAUGHTON[2,3], A. A. WILBER[1]
[1]Dept. of Psychology, Florida State Univ., Tallahassee, FL; [2]Dept. of Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [3]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: In early Alzheimer’s disease (AD) spatial navigation is impaired; however, the precise cause of this impairment is unclear. Recent evidence suggests that getting lost is one of the first impairments to emerge in AD. It is possible that getting lost represents a failure to use distal cues to get oriented in space. Therefore, we set out to look for impaired use of distal cues for spatial orientation in a mouse model of amyloidosis (3xTg-AD). To do this, we trained male and female mice to shuttle to the end of a track and back to an enclosed start box to receive a water reward. Then, mice were trained to stop in an unmarked reward zone to receive a brain stimulation reward. The time required to remain in the zone for a reward was increased across training, and the track was positioned in a random start location for each trial. Finally, we compared performance on the spatial reorientation task to pathology marker density (e.g., 6e10, M22, M78) measured across the whole brain. We found that 6-month female, but not 6-month male, 3xTg-AD mice were impaired at the spatial reorientation task. However, 3-month female and 13-month male 3xTg-AD mice were not impaired. Male and female mice had only intracellular amyloid pathology and male mice had less pathology, particularly in the dorsal hippocampus. Phosphorylated tau was present but in such a small proportion of neurons that it was not quantified. Thus, AD may cause spatial disorientation early in the disease progression as a result of impaired use of landmarks and this impairment may be a related to intracellular amyloid accumulation in the dorsal hippocampus.

Title: Parietal contributions to context-dependent spatial sequence learning

Authors: *C. SIMMONS, H. BOWLEY, M. KIRLAN, M. BAIAMONTE, A. A. WILBER
Florida State Univ., Tallahassee, FL

Abstract: A preponderance of evidence suggests that the internal map of the environment is represented in world-centered (allocentric) coordinates; however, movements and perception of the environment are in body-centered (egocentric) coordinates. Therefore, to navigate in space, it is essential to translate between egocentric and allocentric coordinates. Cell activity in the parietal cortex (PC) and hippocampus suggests a PC-hippocampal network for transforming landmark representations from egocentric to allocentric coordinates (Wilber et al., 2014), consistent with theoretical modeling work (McNaughton et al., 1995). More recent computational modeling studies predict bi-directional coordinate transformation (Byrne et al., 2007; Oess et al., 2017). Finally, PC is organized in a modular fashion with each module tuned to specific action states (Wilber et al., 2017). Thus, PC is uniquely positioned to interface between allocentric spatial location and action. This suggests that PC could be part of a brain network involved in assigning the appropriate action at a redundant spatial location. For example, on the way to the grocery store I turn right at an intersection, but on the way to the library I turn left from the same intersection. We set out to test this hypothesis by training rats to learn complex sequences that require disambiguating a common spatial location associated with two distinct actions. Specifically, rats were trained to run through an 8-zone, complex sequence that contains repeating zones (similar to: Bower et al., 2005). After each pass through the repeated zones, the correct path diverges toward two reward locations (i.e., 1-2-3-**4**-1-2-3-**5**). To receive an immediate reward, the rat needed to go toward zone 4 after the first pass through the repeated zones (1-2-3), and toward zone 5 after the second. To investigate its role in this disambiguation, PC was inactivated using bilateral infusions of muscimol, a $GABA_A$ receptor agonist, during learning and after acquisition of the complex sequence task. Saline infusions were performed either in the session immediately before or after each muscimol infusion session,

and this order was counterbalanced. Performance during inactivation showed an increase in path distance toward the two disambiguation zones (zones 4 and 5) compared to saline controls during learning and after acquisition. However, performance was not impaired for the other items of the complex sequence (1-2-3), or with muscimol infusions for an 8-zone simple sequence that did not contain any repeating segments (i.e., 1-2-3-4-5-6-7-8). Thus, PC may be particularly important for disambiguating place and action.

Abstract: In preclinical Alzheimer's disease (AD), spatial navigation is impaired (Allison et al., 2016). We recently found impaired spatial orientation and increased pathology in the dorsal hippocampus of 6-month female 3xTg-AD mice compared to male 3xTg-AD and non-Tg controls of the same age (Stimmell et al., 2018). This finding suggests that impaired use of landmarks may underlie navigation impairments in AD. Theoretical, computational and recording studies of parietal cortex (PC) and hippocampal activity patterns suggest a PC-hippocampal network for transforming landmarks from egocentric (body-centered) to allocentric (map-like) coordinates for spatial orientation. Thus the spatial orientation deficit in female 3xTg-AD mice could be a consequence of AD related changes to the PC-hippocampal network for coordinate transformation. Recent findings suggest that in preclinical AD a functional deficit

emerges in PC, as a consequence of entorhinal cortex pathology (Kahn et al., 2014). Therefore, to look for evidence of dysfunction in the PC-hippocampal network related to impaired spatial orientation, we assessed modular (multi-unit activity) memory reactivation in 6-month female 3xTg-AD mice that were learning a spatial orientation task. The spatial orientation task requires use of distal cues to locate an unmarked reward zone (Rosenzweig et al., 2003). Mice were implanted with a 16 tetrode recording arrays targeting right PC and hippocampus and then underwent daily recording sessions of rest-task-rest as they learned to locate the unmarked reward zone. To assess memory reactivation we took advantage of a new approach using template matching to compare multi-unit activity patterns from the approach to the reward zone to activity patterns observed during slow-wave sleep (Wilber et al., 2017). Female 6-month 3xTgAD mice had impaired memory reactivation within the PC compared to age-matched non-Tg controls. Further, temporal correlations between markers of memory reactivation in hippocampus (sharp wave ripples) and parietal cortex (delta waves) were reduced in 6-month 3xTg-AD female mice. Thus, AD may cause PC-hippocampal network changes which impair spatial orientation as a consequence of impaired learning related plasticity during sleep.

Title: Head-scan firing cells in hippocampal subregion CA3 of aged rats

Authors: *G. RAO[1], H. LEE[1], N. LUKISH[1], A. TILLEKERATNE[1], M. GALLAGHER[2], J. J. KNIERIM[1]

Abstract: CA3 hippocampal place cells in aged rats fail to rapidly encode spatial changes (Wilson et al., 2005), but this study did not isolate forward locomotion from head-scanning epochs, in which the animal pauses to inspect the environment with head movements (Whishaw et al., 1994). Hippocampal cell firing during scanning is correlated with the formation or potentiation of place fields in adult animals (Monaco et al., 2014). To address how head scanning behavior and hippocampal firing is affected by aging, we examined CA3 cells that fired during

scanning in 8 Long-Evans male rats [3, young (YG, 5-7 mos.), 3 aged-unimpaired (AU, 25-26 mos.), and 2 aged-impaired (AI, 25-26 mos.)] pretested in the Morris water maze to assess their cognitive status. The rats were then trained to run on a circular track, consisting of 4 textured quadrants, located in a curtained room with peripheral objects. Multiple tetrode recordings consisted of 3 sessions with a standard cue configuration identical to training, interleaved with 2 mismatch sessions in which global cues were rotated CW and local cues CCW. All groups exhibited scanning: the mean scanning rate (scans/min) ± s.e for DAY 1, session 1, prior to any cue manipulation, was YG: 6.78 ± 1.89, AU: 8.01 ± 1.00, AI: 5.56 ± 0.04. A significant effect of group on normalized scan rate was observed for the first cue mismatch session [YG: 1.47 ± 0.23; AU: 0.74 ± 0.03; AI: 1.06 ± 0.02; $F(2,5) = 6.2$, $p = .023$], indicating a heightened response to environmental change in the YG group. Spikes were recorded from 110 YG, 152 AU, and 93 AI CA3 pyramidal cells. Cells with at least 30 scanning-related spikes but no place fields in a given session (n = 33 YG, 50 AU, 38 AI) were analyzed. Scan firing rates (number of scan spikes/time spent scanning) showed a significant increase with age [YG: 0.39 ± 0.23; AU: 0.74±.09 ; AI= 1.00 ± 0.17; $F(2,118) = 5.65$, $p < .005$]. The mean vector length of the angular locations around the circular track where scanning spikes occurred (measuring dispersion) was not significantly different across groups [YG: 0.75 ± 0.04; AU: 0.68 ± 0.03, AI: 0.61 ± 0.03; $F(2,118) = 2.61$, $p = .08$], but tended to decrease with age. Significant increases in scan firing rate in the absence of spatially focused firing may explain prior reports of larger CA3 place fields with aging (Wilson et al., 2005). Interestingly, we have observed scan-firing cells in all groups that fire robustly solely during scanning, but not during forward movement, particularly at locations on the track near cues. It is possible that the function of these cells is to punctuate the hippocampal spatial code and segment the representation of space (McKenzie and Buzsaki, 2016; Wang et al., 2017, SFN Abstracts).

Title: Aged rats with intact memory show additional recruitment in cortical regions relative to young adults in a cue mismatch task

Authors: *R. P. HABERMAN, A. BRANCH, A. MONASTERIO, M. GALLAGHER
Dept Psychol & Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Functional neuroimaging studies of cognitively normal older adults demonstrate greater activation of cortical regions relative to younger adults during memory tasks. Determining the implications of such enhanced cortical activation is difficult because this cognitively normal older population exhibits variability in long term outcomes and progression to cognitive decline. Here we asked if greater cortical recruitment also occurs in aged memory intact rats, which perform on par with young rats in hippocampal dependent memory tasks and show phenotype stability lasting many months. Using in situ hybridization, we measured a marker of neural activation, Zif268 (Egr1), in the hippocampus and select cortical regions of memory intact aged and young rats in response to a cue mismatch task that engages hippocampal functions critical to memory formation. After being trained to run on a circular track with local and global cues arranged in a fixed position, half the rats experienced a cue rearrangement on test day such that local and global cues were rotated for a 180-degree mismatch. A control group of rats experienced the familiar cue orientation. Behavioral measures assessing recognition of the cue mismatch were similar across. Previously presented work demonstrated similar increases in hippocampal activation in young and aged intact rats in the mismatch group relative to the familiar group. In a new extended analysis, we found elevated Zif268 expression across several cortical regions, including retrosplenial cortex, perirhinal cortex, and lateral entorhinal cortex in the mismatch relative to the familiar group only in aged intact rats. No differences between mismatch and familiar Zif268 expression was found in these regions for young rats, and no differences were found for either age group in the medial entorhinal cortex. Increased expression in parietal association cortex in mismatch relative to familiar occurred in both young and aged rats, demonstrating some consistency across age. These mismatch-induced increases occurred in addition to an overall increase in Zif268 expression in all rats that completed track running (mismatch and familiar combined), relative to home cage rats, for all five cortical regions. These data suggest that, similar to cognitively normal older humans, aged rats with intact memory show greater recruitment of cortical regions than younger rats in a hippocampal activation paradigm. Furthermore, these results are consistent with accumulating data that suggest that aged intact rats recruit adaptive mechanisms, that differ from typical young neurobiological activity, to preserve cognitive function during aging.

Title: Age does not increase the magnitude of afterhyperpolarization in CA1 pyramidal cells of a behaviorally characterized Long-Evans rat model of aging

Authors: *A. KIRKWOOD[1], D. SEVERIN[2], M. GALLAGHER[3]
[1]Mind Brain Inst., [2]Zanvyl Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD; [3]Dept Psych & Brain Sci., Johns Hopkins Univ. Dept. of Psychological and Brain Sci., Baltimore, MD

Abstract: Recent studies in aging rodents and humans have identified an excess of hippocampal neural activity as an attractive candidate mechanism contributing to age-related cognitive decline. In aged individuals with impaired learning hyperactivity is prominent in the dentate gyrus/CA3 subfields, but not so prominent in the CA1 subfield. This raises the question of how neural activity is maintained in CA1 in the face of excess input from CA3 pyramidal cells. One possible mechanism is a reduced intrinsic excitability of CA1 cells. Indeed, previous studies in Fisher-344 rats, a model of accelerated aging, report an age-related increase in the slow afterhyporlarization (AHP) evoked by a burst of action potentials. This prompted us to test the possible relationship between AHP magnitude and learning performance in a Long-Evans model of cognitive decline. The experiments were conducted in slices prepared from young 6-month adult rats (Y) and ~24-month rats characterized in the Morris water maze as aged impaired (AI) or aged unimpaired (AU). Whole-cell current clamp recordings were made from CA1 pyramidal cells and the AHP was evoked by bursts of somatically induced action potentials (8 AP at 50 Hz) as in previous studies. Our measurements indicate that AHP does not increase with aging in the Long-Evans rat model. Indeed, we found that the peak AHP in the AI group (5.50±0.41 mV; 6 rats, 31 cells) was smaller than the peak AHP measured in the AU group (7.50±0.54mV; 6 rats, 46 cells), which in turn was comparable to the peak AHP measured in the Y group (7.05±0.47; 6 rats, 42 cells). The statistical significance of these findings was confirmed with a Kruskal-Wallis test (KW=6.944) followed by a Dunn's test. These results indicate that reduced intrinsic cellular excitability is not a universal compensatory mechanism to maintain neural activity within optimal ranges. In the CA1 region of Long-Evans rats this function might be accomplished by changes in synaptic inhibition as we have reported previously.

Title: Local-global reference frame control in the CA3 region of aged rats

Authors: *H. LEE[1], N. LUKISH[1], A. TILLEKERATNE[1], M. GALLAGHER[2], J. J. KNIERIM[1,3]

Abstract: Hippocampus-dependent spatial memory declines with age, and aged rats showed reduced changes in their spatial representations in response to environmental manipulations (Tanila et al., 1997). To address altered hippocampal processing in aging when local and global reference frames are in conflict, young rats and aged rats were trained to run around a circular track containing salient local cues (textures on the track) in a curtained room containing salient global cues (landmarks along the curtains). Three standard sessions were interleaved with two mismatch sessions, in which the local cues were rotated counterclockwise (CCW) and the global cues were rotated clockwise (CW) by an equal amount. Total mismatch angles between the local and the global cue sets varied between 45°, 90°, 135°, or 180°. We recorded neurons from the CA3 region in 3 young, 3 aged-impaired, and 5 aged-unimpaired male, Long-Evans rats. Young (Y) rats were 5-7 months old and aged rats were 25-26 months old at the time of recording. Aged rats were pretested in the Morris water maze and categorized as learning impaired (AI) or learning unimpaired (AU). Comparing the rate maps between a standard and the following mismatch session, cells were classified as "rotating" if their place fields rotated CCW with the local cues or CW if their place fields rotated with the global cues in the mismatch session. They were classified as "remapping" if the place fields appeared or disappeared in either the standard or the mismatch session. Approximately 58% of CA3 neurons (59/101) in young rats and 58% of CA3 neurons (176/301) in AU rats had rotating place fields, while 73% of CA3 neurons (78/107) in AI rats had rotating place fields (X^2=7.4, p = 0.02). All other cells remapped their place fields. Individual cell rotation amounts showed significant angular clustering in all three groups (Rayleigh test, all *p* values < .007). In all combinations of mismatch angles (n = 4) and age groups (n = 3), the mean angle rotated in the CCW direction (binomial test, p < .001), showing control by the local cues. The higher proportion of rotating cells in the AI rats suggests that the spatial representations remained more coherent in the conflict situations than the young and the AU rats. These data are in agreement with the results of Tanila et al. (1997), with the exception that the CA3 cells were more controlled by the local frame of reference compared to the global frame. It is possible that the functional differences observed in the AI rats may be CA3 subregion specific (Lee et al., 2015; Lu et al, 2015). Further analyses will examine the population coherence differences along the CA3 transverse axis (proximal vs distal) in the young and the aged groups.

Title: Firing rate modulations may encode surface texture cues within the place cell map of hippocampal CA1 neurons

Authors: *W. HOCKEIMER[1,2], J. J. KNIERIM[1,2]
[1]Zanvyl Krieger Mind/Brain Inst., [2]Solomon Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: An influential theory asserts that episodic memories are stored within a framework of the location where they occurred [1]. The hippocampus has been suggested as a neural substrate of this "cognitive map." It has further been proposed that spatial information is encoded in the set of neurons that are active in an environment and nonspatial information in the distribution of those neurons' firing rates [2]. To provide a direct test of this hypothesis, pilot data was collected from a 20-month old, male, Long-Evans rat implanted with a tetrode array in hippocampal CA1. The animal was trained to perform a match-to-sample task on a T-maze using textured floor plates as stimuli. On each trial, the rat traversed a textured plate on the stem and chose the arm of the T-maze that contained a matching copy of that texture, ignoring the nonmatching distractor placed on the opposite arm. Average performance was 64.3% across 11 days of recording, providing single-unit data from 94 pyramidal neurons. To test the hypothesis that texture identity is encoded in rate modulations of place field activity, data was compared across trials from periods during which the animal occupied the same location but different textures were present underneath. This analysis revealed a subset of place cells exhibiting field modulation as a function of texture present. To assess the significance of these findings, we performed a permutation test with a family-wise error rate of 0.05 to identify location bins in which a cell fired more strongly to one of the textures over another. We further required that there be a set of contiguous bins of > 5 cm that pass the 0.05 familywise criterion and that the firing rate of the cell be > 1 Hz in at least one of these bins. These criteria resulted in 18/94 cells displaying firing rate modulations to at least one of the texture pairs. Further, a random forest classifier trained on the population firing rates was able to correctly predict texture identity with 50% accuracy, compared to 33% chance performance, suggesting that the population contains information about texture identity. These preliminary data support the rate-remapping hypothesis that hippocampal

neurons encode specific nonspatial cues present within the cell's place field by modulating the firing rate of the cell when the rat occupies the place field.

Title: Spatial firing properties of the lateral entorhinal cortex on a one-dimensional track

Authors: *C. WANG[1], H. LEE[1], G. RAO[1], J. J. KNIERIM[1,2]
[1]Zanvyl Krieger Mind/Brain Inst, Johns Hopkins Univ., Baltimore, MD; [2]Solomon H Snyder Dept of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Decades of research have established the role of the hippocampus and its neighboring areas in spatial navigation as evidenced by the presence of numerous spatially selective cell types, such as place cells in the hippocampus and grid cells and head direction cells in the medial entorhinal cortex (MEC), one of the primary input areas to the hippocampus. Neurons of the lateral entorhinal cortex (LEC), which is the other major input pathway to the hippocampus, are much less spatially selective, even in cue rich environments. Instead, when objects are present in an environment, LEC neurons fire at the location of the objects and a small proportion develop spatial firing fields away from the objects. Even though many studies of the hippocampus employ tasks in which rats run on one-dimensional tracks (e.g., linear or circular tracks), few studies have examined the responses of LEC cells during goal-oriented tasks on such tracks. We recorded 242 LEC neurons from 4 male Long-Evans rats (5-6 months old) while they performed a shuttling task on a linear track (5 feet long) or a circular track (radius 46 cm) between fixed goal locations. A majority of LEC cells showed weak but significant spatial tuning for at least one running direction (shuffling test, $\alpha = 0.05$, linear track: 131/194; circular track: 134/199), with a small percentage of cells having strong (information score > 0.5) and significant spatial

information (linear track: 28/194; circular track: 24/199). In addition, a significant number of cells showed direction selectivity on the track (88/227 on linear track, 90/231 on circular track), especially around the goal locations (Monte Carlo simulation test against uniform distribution, linear track, $P < 0.001$, circular track, $P = 0.004$). When we recorded the cells in the dark on the circular track, the number of cells that showed significant direction selectivity did not change significantly (dark, 65/140; $\chi 2(1) = 2.00$, $P = 0.16$), although the correlation of spatial firing patterns between light and dark sessions showed a significant difference from the correlation between the two light sessions ($t(243) = 3.92$, $P < 0.001$). Previously we reported that many LEC neurons encode egocentric bearing relative to certain external locations or objects (Wang et al., SFN Abstracts 2017). Thus, the direction-dependent firing of LEC neurons on the 1-D apparatus could be a demonstration of egocentric bearing selectivity relative to the goal locations at the ends of journeys. These results further suggest that under naturalistic behaviors involving behaviorally relevant items or locations, LEC neurons show rich dynamics, which may be related to the encoding of the contents of episodic memory.

Title: Responses of granule cells, mossy cells, and proximal CA3 cells to local/global cue mismatch indicate a shared role in pattern separation

Authors: *D. GOODSMITH[1], H. LEE[1], J. P. NEUNUEBEL[3], J. J. KNIERIM[1,2]
[1]Krieger Mind/Brain Inst., [2]The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: The processes of pattern completion and pattern separation are thought to be essential for memory storage and recall. Neunuebel & Knierim (2014) provided evidence for the hypothesis that CA3 and the dentate gyrus (DG) are involved in pattern completion and pattern separation, respectively. In a “double rotation” task, where local texture cues on a circular track and global cues at the perimeter of the room were rotated in opposite directions (for total cue mismatch amounts of 45°, 90°, 135°, or 180°), there was a relatively coherent population

response in CA3, despite disrupted input from the DG. Furthermore, Lee et al. (2015) found that the response of cells in the proximal part of CA3 (pCA3) was similar to the DG response, while more distal regions of CA3 were involved in pattern completion.
Although most cells in the DG are granule cells, mossy cells in the hilus may be recorded on tetrodes located throughout the DG and in pCA3. It is uncertain how the responses of mossy cells compare to granule cells and pCA3 cells. We used a random forests classifier to classify pCA3 recordings from Lee et al. (2015) and DG recordings from Neunuebel & Knierim (2014) to examine the responses of granule cells, mossy cells, and pCA3 cells in the double rotation task.
Out of 272 active cells from 14 Long-Evans rats (male, 4-7-months old), 124 were classified as mossy cells (21/114 from tetrodes in pCA3, 103/158 from tetrodes in DG). For all three cell types, most cells gained or lost place fields (i.e., remapped) following the cue mismatch sessions > 45° (number of remapping cells/total: granule 18/30, mossy 78/140, pCA3 101/126). These proportions were significantly different (chi-square = 18.4, p = .0001), demonstrating that pCA3 cells were less likely to maintain their place fields in the mismatch session compared to the granule and mossy cells. We further investigated whether the subset of cells that maintained place fields between the standard and > 45° mismatch sessions rotated their place fields as a coherent ensemble in the same direction, as has been reported for distal CA3 (Lee et al. 2015). For all 3 areas, ~60% of the rotating place fields followed the local cues and ~40% followed the global cues (local cue cells divided by total number of rotating cells: granule 6/10; mossy 28/49; pCA3: 16/24; chi-square = 0.61, p = .74). Analyses of population vector correlations demonstrated very small correlations between standard and mismatch sessions in all 3 classes of cells. These data show that mossy cells resembled the pattern observed previously in the DG and pCA3 regions and suggest that all components of the DG/pCA3 circuit may work together as a computational unit to support pattern separation.

Title: Hippocampal place fields from modular and distorted entorhinal grid inputs via synaptic plasticity in environments of varying size: A model

Authors: *F. SAVELLI[1], J. J. KNIERIM[1,2]
[1]Zanvyl Krieger Mind/Brain Inst., [2]Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: How entorhinal grid cells contribute to the generation of stable place fields in the hippocampus is poorly understood. Hippocampal cells can produce place fields in the absence of these inputs, but several studies indicate that this ability may be limited to place fields expressed by CA1 neurons near environmental boundaries. These studies thus suggest that grid inputs become increasingly relevant in the earlier stages of the trisynaptic loop, or while the animal ventures farther into open space. We previously described a spiking model of place-field formation based on a Hebbian plasticity rule applied to grid inputs, which were simulated from real animals' trajectories recorded during foraging sessions. The momentary firing rate of the inputs determined the direction of synaptic weight changes, which were gated postsynaptically by the place cell activation—consistent with later experimental observations that intrinsic excitability is correlated with a cell's propensity to form a place field. Very high learning rates were necessary for place fields to form, sometimes causing their abrupt emergence, also consistent with experimental observations. Here, we updated this model by (A) revising some of the original assumptions in light of the richer experimental characterization of grid cell properties currently available and (B) testing the model in larger environments, where grid inputs may become increasingly important to the expression of place fields. (A) We modeled grid distortions (elliptical compressions and shearing); clustered grid orientation and scale following a modular organization; and varied peak firing rates across different vertices of the grid. These modifications to the inputs did not compromise the model's ability to produce spatially selective and stable place fields. (B) As larger environments were tested (and more grid modules could be accommodated), we found that more place fields were typically produced per place cell, consistent with experimental observations. Some of these fields, however, were the result of remapping episodes that could occur after tens of minutes from the beginning of the session. In sum, our theoretical proposal that place fields can form autonomously from grid cell inputs via a fast, postynaptically gated, Hebbian plasticity rule holds up to observed deviations of the grid representation from a continuum of purely periodic patterns. Moreover, our simulations highlight the need for experiments characterizing how place field properties may change in large 2D environments away from their boundaries.

Title: Robust tracking of neuronal spatial dynamics enables discovery of recalibration of the path integrator in hippocampal place cells

Authors: *R. P. JAYAKUMAR[1], M. S. MADHAV[2], F. SAVELLI[2], H. T. BLAIR[3], J. J. KNIERIM[2], N. J. COWAN[1]
[1]Dept. of Mechanical Engin., [2]Zanvyl Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD; [3]Dept Psychology, UCLA, Los Angeles, CA

Abstract: Path integration, the ability to update an internal estimate of position by integrating over time a movement vector representing speed and direction, is critical for survival across taxa. This computation requires a finely tuned gain factor that relates the animal's self-motion to the update of position in the internal representation. We investigated how visual landmarks can calibrate this gain factor using a novel, augmented reality system that puts these landmarks in continuous conflict with nonvisual self-motion cues. An estimator of spatial coding was required to determine the effect of these manipulations on hippocampal place cells. Standard Bayesian decoding techniques can estimate a rodent's position from a population of place cells. However, visual cue manipulations can trigger extensive reorganization (remapping) of place cells, causing these population decoders to become less accurate or fail entirely. Using an experimental paradigm where the animal traverses a closed 1D curve, we took advantage of the periodicity of place fields as the animal runs laps to develop a spectral algorithm to track the hippocampal gain by estimating the spatial frequency of a place cell's firing pattern. Each cell's gain was tracked independently, allowing detection of subpopulations that might have different spatial tuning characteristics. The gain of interneurons could also be tracked. This technique is robust to remapping: such events cause phase shifts in a cell's spatial tuning which only induce a localized effect on the gain estimate. In a coherent population of cells, the estimated gain trajectory can be integrated to estimate the animal's position. We used this novel spectral estimation technique to analyze CA1 place cell ensembles recorded from 5 male, Long-Evans rats (5-9 months old) as the rats ran circular laps while an array of visual landmarks under feedback control was rotated in directions the same as, or opposite to, the rats' movement. In all 5 rats, the gain of the hippocampal path integration system could be recalibrated quickly (30 laps or less) and the recalibrated gain was sustained over extended periods. Thus, the path integration gain is a plastic variable that is fine-tuned through experience. This fine-tuning may be required to (a) maintain accuracy of the path integration signal under different behavioral conditions; (b) synchronize the different types of self-motion signals (e.g., vestibular, optic flow, motor copy, or proprioception)

thought to underlie path integration; and (c) coordinate the discrete set of different path integration gains thought to underlie the different scales of grid cell modules in the medial entorhinal cortex.

Title: Is theta a traveling wave in the medial entorhinal cortex?

Authors: *J. HERNÁNDEZ, K. COOPER, E. NEWMAN
Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Though it is well known that the entorhinal-hippocampal system supports spatial navigation and memory, how these circuits interact to support adaptive behavior remains poorly understood. Both regions exhibit prominent 6-12 Hz rhythmic fluctuations in the LFP (i.e., theta activity) during exploratory behaviors and REM sleep. In the hippocampus, theta activity is not synchronous. Rather, it precesses steadily across the long axis to span a total of 180 degrees phase offset. At dorsal sites, it is well known that the entorhinal activity is phase locked to the hippocampal theta rhythm. For these areas to communicate in a similar fashion across their long-axes, theta activity in the entorhinal cortex must also precess across the long-axis. Whether this is the case remains unknown. To understand how the hippocampus and entorhinal cortex functionally interact, it is essential to know whether theta also precesses along the long axis of the medial entorhinal cortex. To resolve this, we built custom electrode arrays designed to simultaneously record across the entire long axis of the rat medial entorhinal cortex (spanning >4.5 mm) at regular fixed intervals (~580 um). We then recorded theta activity as rats performed a variety of tasks. We found a systematic theta phase shift along the length of medial entorhinal cortex. As previously reported for the hippocampus we found that there is a 180-degree total shift indicating that the two areas are likely to be synchronized across the long axis. The phase shift is attributable, in part, to a shift in the theta waveform across the axis. The theta wave recorded from dorsal sites was a leftward shifted asymmetric wave while the theta wave recorded ventrally was largely symmetric. This shift, however, did not account for the full phase precession across the axis. To understand if the phase shift across the axis reflects a traveling

wave, we computed the temporal cross-correlation of theta power across electrodes with the rationale that changes in power should propagate along with phase if it is a traveling wave. Notably, however, across all electrodes, the peak correlation occurred at zero-lag indicating that theta activity in the entorhinal cortex is a phase-shifted standing wave, increasing in power synchronously across the axis rather than propagating along the axis. These results suggest that the entorhinal cortex and hippocampus are likely synchronized across the long-axis and provide new insights into the nature of theta phase shifts along the long-axis constraining our understanding of how these areas work together to support spatial navigation and memory.

Title: Dorsal hippocampus not necessary in a delayed spatial win-shift radial arm maze task

Authors: *D. M. LAYFIELD[1], N. SIDELL[1], A. ABDULLAHI[1], E. L. NEWMAN[2]
[1]Indiana Univ., Bloomington, IN; [2]Dept. of Psych. and Brain Sci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: Effective foraging and navigation depend upon spatial working memory. However, spatial working memory is not well understood at a systems level. The hippocampus is well known for its role in spatial coding and involvement in spatial memory (Buzsaki & Moser., 2013) and prior inactivation studies in rodents have suggest that the dorsal hippocampus is necessary to perform spatial working memory tasks as the temporal delay increases from seconds to minutes (Lee & Kesner., 2003; Churchwell & Kesner., 2011). This dependency is widely understood to persist independently of the amount of training animals receive. Here we describe data which demonstrates that the dorsal hippocampus is not always necessary for spatial working memory at intermediate delays, particularly when animals become overtrained. Procedurally, rats were trained to visit all arms of an 8-arm radial maze in a delayed spatial win-shift task across two trials. In the first trial (i.e., study trial), only four arms were open. In the second trial (i.e., test trial), run 8 minutes later, the rat was challenged to remember which four arms they had not yet visited when all arms were opened. A unique configuration of arms was used for each study-test trial pairing. Rats received bilateral infusions of either 4 % w/v lidocaine or phosphate buffered saline prior to the test phase such that with the lidocaine, the dorsal hippocampus could

be expected to be inactivated throughout the test trial. Compared to saline infusions, lidocaine infusions produced no difference in the number of correct arm entries or the number of total arm entries in the test trial. These results indicate that spatial working memory was largely preserved despite the 8-min delay between trials. Importantly, these rats were overtrained on the task before infusions began. Thus, the role of the dorsal hippocampus in spatial working memory may be attenuated in contexts with extensive training. The discrepancy of these result with prior literature and the roles of the dorsal and ventral hippocampus are discussed.

Title: Decoding the elements of neural computation

Authors: *S. P. FABER[1], N. M. TIMME[2], J. M. BEGGS[1], E. L. NEWMAN[1]
[1]Indiana Univ., Bloomington, IN; [2]IUPUI, Indianapolis, IN

Abstract: Understanding how networks of neurons process information is a major objective of systems neuroscience. In particular, the determinants of how information is modified through successive interactions between neurons is poorly understood. Information theoretic analyses are useful for quantifying information propagation and modification in networks of spiking neurons and have revealed important new insights into how cortical networks process information. Yet, the results of information theoretic analyses do not address what types of propagation (e.g., excitatory vs. inhibitory) or modification (e.g., ‘and-gate,’ ‘x-or,’ etc.) occur between neurons. The goal of this project was to reveal the types of information propagation and modification that take place in cortex. To do this, we recorded the spiking activity of 98 - 594 well isolated neurons simultaneously from organotypic cultures of mouse somatosensory cortex using a high-density 512-channel microelectrode array. We then identified functionally connected pairs of neurons using an information theoretic approach (i.e., those with significant transfer entropy in the 1.6–14 ms range), across which we could evaluate the types of information propagation. We further identified triads, sets of three neurons, where the output of two transmitting neurons

converged on a third receiving neuron and, for each triad, used partial information decomposition to quantify neural computation within that triad. We then asked: how does neural computation depend on the spiking patterns of interacting neurons? The analyses revealed three clear patterns. First, information modification by a receiving neuron is greatest when there is greater information transfer between the upstream neurons. Second, information modification is greatest when the information transfer from the upstream neurons to the downstream neurons is unidirectional (i.e., the receiving neuron does not transfer information back upstream). Third, excitatory interactions lead to increased amounts of information transfer and neural computation relative to inhibitory interactions. These findings inform our understanding of how network topology and neural activity shape neural computation. We discuss these results in the context of learning and memory by considering the role of neural computation in memory encoding and retrieval.

Title: A nonspatial auditory task to investigate the memory for sequences of events across timescales

Authors: *S. M. GIL[1], G. A. ELIAS[2], S. MESA[3], R. METHERATE[4], N. J. FORTIN[5]

Abstract: The ability to temporally organize information is fundamental to many perceptual, cognitive, and motor processes. To investigate the neural basis of this capacity, we previously

developed a cross-species sequence memory task, using olfactory stimuli in rodents and visual stimuli in humans, in which sequences of stimuli are presented over a timescale of seconds. Importantly, we found that the two versions show strong behavioral parallels and depend on similar circuits across species, including the hippocampus and prefrontal cortex. Here we developed an auditory version of the task, which involves repeated presentations of pure tones of different frequencies and requires subjects to correctly identify each tone as presented "in sequence" (e.g., ABC···) or "out of sequence" (e.g., ABD···). Since the auditory modality allows for greater control over the timing of stimuli, this approach will allow us to more systematically investigate the neural mechanisms underlying the memory for sequences of events across timescales. In addition, this approach may help determine how this capacity relates to other forms of temporal integration performed by the auditory system.

Title: Prefrontal neurons represent task-relevant information about upcoming events

Authors: *G. A. ELIAS, S. MESA, M. GIRCZYC, M. MCDERMOTT, A. T. GUDMUNDSON, J. D. LUONG, G. G. K. GOLLA, N. J. FORTIN

Abstract: A defining feature of episodic memory is its sequential organization. The hippocampus and prefrontal cortex have been identified as key regions in a network supporting memory for sequences of events. In a recent study, we recorded neural activity in hippocampal region CA1 as rats performed a nonspatial odor sequence memory task. A significant proportion of CA1 neurons fired differentially to odors based on their temporal context, i.e. whether the

odor was presented “in sequence” or “out of sequence” (Allen et al., 2016, *JNeurosci*). Here, we recorded prefrontal neurons (prelimbic region) in rats performing the same task to determine how task-relevant coding differs in prefrontal cortex. Briefly, rats were trained to identify whether each delivered odor was presented in or out of sequence. Preliminary results show the activity of prefrontal neurons is influenced by the ordinal position of a trial (odor presentation) within the sequence. This modulation was observed prior to the start of a trial, suggesting it might serve to track the current sequence position or store a short-term memory trace of the previously presented odor. To distinguish these alternatives, we determined the degree to which the pre-trial activity of each neuron was explained by the identity of the *previous* odor or the *upcoming* sequence position. Pre-trial activity was significantly explained by both the previous odor and the upcoming position on trials identified correctly, but not on errors. Notably, activity explained by the previous odor was present only ~200ms prior to trial start whereas activity explained by upcoming position was present during the entire pre-trial period. Interestingly, on trials following an odor presented out of sequence (when the identity of the previous odor is not informative about the upcoming odor), pre-trial activity was significantly explained only by the upcoming position, not the preceding odor. These results suggest the prefrontal cortex plays a key role by representing different forms of task-relevant information, but can also selectively activate the correct, task-critical representation when necessary.

Title: Sequential activation of upcoming nonspatial item representations in hippocampal activity

Authors: *N. J. FORTIN[1], G. A. ELIAS[1], L. LI[2], F. AGOSTINELLI[3], P. BALDI[3], B. SHAHBABA[2]

Abstract: The hippocampus plays a key role in the memory for sequence of events. Considerable research suggests this applies to both spatial and nonspatial memories; however, our understanding of the fundamental neuronal mechanisms is limited by the fact that electrophysiological studies almost exclusively focus on spatial information. It therefore remains to be determined whether sequence coding properties observed in hippocampal neurons, including the reactivation of experienced or predicted sequences of locations, extend to nonspatial information. To address this important issue, we recorded CA1 activity in rats performing a nonspatial sequence memory task. Briefly, the task involves repeated presentations of sequences of odors at a single port and requires rats to identify each item as "in sequence" or "out of sequence". We then used statistical machine learning methods to quantify the information represented in CA1 ensemble activity during odor presentations. First, we used an unsupervised deep learning model to identify the structure in population activity vectors at different moments within trials. As expected, the model did not clearly differentiate among population vectors before trial-specific information was present (i.e., immediately after the rat enters the port; 0-50ms time period). However, during the same odor presentations, the model then strongly differentiated among the different odors (200-250ms time period) and whether odors were presented in or out of sequence (400-450ms time period). Second, we used the output of this model to quantify the degree to which each odor representation was decoded (predicted) during individual trials. As expected, we found that the representation of the currently presented odor could be accurately decoded when the animal is sampling the odors (~250ms). Importantly, within the same odor presentation, we also found that the representations of upcoming odors were then activated in the correct sequence, and that this coding property was linked with performance. These results provide compelling evidence that reactivation of experienced sequences of events in hippocampal neurons extends beyond the domain of spatial trajectories, and thus represent a fundamental role of the hippocampus in memory.

Title: Optimising a behavioural protocol for an animal model of everyday memory

Authors: *T. TAKEUCHI[1,2], N. J. BROADBENT[3], B. MASATSUGU[3], M. CORCOLES-PARADA[2], A. AYRES[2], D. TSE[2], M. PETERS[3], R. G. MORRIS[2]

Abstract: Aim: Better animal models of 'everyday memory' are required beyond tests of novelty-recognition or spatial memory. A behavioural protocol in the 'event arena' in rats (Bast et al., J. Neurosci., 2005) was recently revised (Nonaka et al., Eur. J. Neurosci., 2017); it shows overnight forgetting, retention sensitive to novelty and other relevant properties. We have recently found, however, that a subset of animals use ideothetic path integration rather than allocentric representations. Our aim was to optimise the protocol whereby rats demonstrably use allocentric representations.
Methods and results: The core concept is that regular training takes place over weeks or even months, with new memory traces encoded each day. During encoding, rats find a rewarded food pellet hidden in a different daily location. Instead of carrying the rewarded pellet back to the startbox (permissive for path integration), they are trained to always carry it to a specific goal box (in the north). Memory retrieval after a delay consists of the rats being released from the different startbox (East, South or West) either (a) to find more food at the same place from a choice of 6 locations (choice test), or (b) to dig freely in these 6 locations with no accessible food available (probe test). We found that rats initially prefer to return to their start location (Whishaw et al., Behav. Brain. Res., 2001) but soon overcome this, thereby abandoning path-integration, and display good performance with the properties of everyday memory.
Conclusion: The protocol is reliable and absolutely requires use of allocentric cues. Current work is checking beneficial effects of novelty and optogenetic manipulations in the locus coeruleus that was shown in mice (Takeuchi et al., Nature, 2016).

Title: Biphasic hippocampal activation by unconditional stimulus shapes contextual memory and memory generalization

Authors: *J. GUO[1], D. TRUONG[2], A. SAMUEL[1], A. BARREIRO[2], E. KAVALALI[1], D.-T. LIN[3], W. XU[1]
[1]Neurosci., UT Southwestern Med. Ctr., Dallas, TX; [2]Mathematics, Southern Methodist Univ., Dallas, TX; [3]Behavior Neurosci., NIH NIDA IRP, Baltimore, MD

Abstract: To apply what has been learned from experience to new situations, memories need to be generalized based on the similarity among circumstances. Failing to generalize can lead to failure to recognize danger. On the other hand, over-generalization leads to ambiguity in memory retrieval and is implicated in neuropsychiatric disorders such as post-traumatic stress disorder, depression and schizophrenia. To understand how the level of generalization is determined, we conducted functional imaging of neuronal activity at the CA1 region of the hippocampus, a brain region critical for encoding and generalizing contextual memories, during contextual fear conditioning training and tests. We found that CA1 neurons showed specific activities in reaction to the contexts and unconditional stimulation - the electric foot-shocks. Interestingly, the responses to foot-shocks were biphasic, consisting of an early phasic phase and a delayed tonic phase. The neurons active in the delayed phase showed high activity when the mice were learning the context and when the contextual memory was retrieved, suggesting that they encoded contextual information. Moreover, their activity during context exploration predicted the level of memory generalization. The results indicate that the hippocampus, in contrast to what has been described in the traditional models of conditioning, reacts to unconditional stimulation and this reaction may determine the precision and generalization level of memories. Future work will focus on using temporal-specific optogenetic silencing to examine the causal roles of foot-shock-related neuronal activity in memory generalization and on elucidating the neuronal mechanisms underlying the biphasic activation.

Francisco, San Francisco, CA; [3]Dept Neurolog Surgery, Univ. California San Francisco, San Francisco, CA

Abstract: Hippocampal theta (6-12 Hz) oscillations are implicated in different aspects of behavior and are correlated with running speeds. Recent research has highlighted the effect of time on hippocampal processing (Colgin et al 2018), however it is unknown how speed and time interact to modulate theta rhythm within the hippocampal sub-regions (CA1, CA3, DG) when the animal is exposed to the same environment. We hypothesized that hippocampal theta is affected by both speed and time independently, and, depending on the cognitive state of the animal, observed theta will be disproportionally affected by one process more than the other. To test this hypothesis, we studied hippocampal theta oscillations in mice while performing open field navigation. Specifically, we used 32-channel silicone probes with recording electrodes distributed across different regions of the hippocampus (area CA1, CA3 and DG) to record *in vivo* local field potential signals in wild-type mice (n = 6) while freely moving in an open field task. Mice were exposed to three different environments for two 25-min sessions per day. We analyzed how time and running speed effected theta power within each hippocampal sub-region across sessions. In general, we present two major findings: (1) the previously reported positive correlation of running speed on hippocampal theta power is present only in the first exposure trial, and habituates across both time and session, and (2) there is an overall tendency for theta power to decrease in amplitude across time and sessions (holding speed constant). These results suggest that speed effects theta power in the earlier stages of encoding. However, after the environment is well known, time plays a larger role in theta modulation.

Abstract: Activation of the basolateral amygdala (BLA) by both arousal and direct brain stimulation can modulate hippocampal activity. Prior work has assessed the impact of direct BLA stimulation on memory performance, plasticity, and oscillatory activity in the hippocampus. Here, we optogenetically stimulated the BLA in awake rats over a large parameter space to determine the extent of and the quality of effect that stimulation has within and between those brain regions. Specifically, we recorded local field potentials and single units in the BLA and in the CA1 and CA3 subregions of the dorsal and intermediate hippocampus. The design allowed us to record the changes in neural activity during and after BLA stimulation, with focus on oscillatory power and coherence between regions. Given the ability of the BLA to induce remapping of place cells in the hippocampus, we also stimulated the BLA while rats ran on a fixed path to investigate the effect of stimulation on place cell dynamics. We recorded activity before, during, and after stimulation throughout a continuous block of activity. We hypothesized that hippocampal ensembles that were active concurrently with BLA stimulation would be disproportionately represented in subsequent activity. Finally, we repeated the running task after 24 hours to assess the stability of any changes to place cell properties. Our results demonstrate the effects of optogenetic stimulation on the communication between the BLA, CA1, and CA3.

Title: Intracellular dynamics of hippocampal CA3 pyramidal cells in relation to brain state in awake head-fixed mice

Authors: *A. L. KEES, M. MALÉZIEUX, C. MULLE
UMR 5297 Interdisciplinary Inst. for Neurosci., Univ. de Bordeaux, Bordeaux Cedex, France

Abstract: Different behavioral states are associated with distinct brain states. Each brain state is associated with characteristic oscillatory patterns in the local field potential (LFP), which reflects different patterns of coordinated neuronal activity. Studies from several brain areas show that changes in single cell properties correlate with and possibly result in these changes in brain state. While much work has characterized different brain states and their LFP signatures, the underlying cellular mechanisms are less known.

Area CA3 of the hippocampus, important in rapid encoding of one-trial memory, is of particular interest for this line of research because of its unique function and network structure. CA3 is the site where information from the entorhinal cortex, dentate gyrus, and CA3 itself (via extensive recurrent connections and local inhibition) is compared and integrated before output to CA1. During quiet wakefulness, the hippocampal LFP displays large irregular activity punctuated by short oscillations known as sharp-wave ripples, which play a role in memory consolidation. During exploratory behaviors, hippocampal LFP oscillates at both theta and gamma frequencies. CA3 pyramidal cells play an important role in each of these brain states; they are involved in the generation of both sharp waves during quiet wakefulness, and gamma during exploratory behavior.

To explore the changes that occur in the intracellular dynamics of CA3 pyramidal cells during changes in brain state, we made whole-cell patch-clamp recordings from CA3 pyramidal cells in awake head-fixed mice. In order to characterize brain states, we combined those recordings with measurements of pupil diameter and CA3 LFP.

We find that during running, CA3 pyramidal cells reduce their firing rate. Additionally, as the mouse transitions between resting and running, there is an overall change in the membrane potential, either a hyperpolarization or a depolarization, which can be partially explained by the membrane potential of the cell before the start of the run. Finally, the variance of the membrane potential is different during running and rest, which may have ramifications on the integration of synaptic inputs as well as indicate changes in the function of the CA3 network as a whole. Taken together, these findings indicate that changes in behavioral state are accompanied by changes on the single-cell and network levels in area CA3 of the hippocampus; these changes may underlie the ability of this area to switch between different stages of memory processing.

Title: Stability and disruption of hippocampal spiking sequences encoding odors and time during working-memory

Authors: *J. TAXIDIS[1], A. L. MYLAVARAPU[1], E. PNEVMATIKAKIS[2], P. GOLSHANI[3]
[1]UCLA, Los Angeles, CA; [2]Simons Ctr. for Data Analysis, Simons Fndn., New York, NY; [3]UCLA Dept. of Neurol., Los Angeles, CA

Abstract: Working memory (WM) allows for active retention of information during a short period of time. Even though its neurophysiological hallmark is persistent neuronal firing across a delay period in prefrontal cortical areas, WM is thought to incorporate a larger network, including the hippocampus (Sreenivasan et al. 2014). Instead of persistent firing, hippocampal ensembles typically fire in sequences during delayed-response tasks (Pastalkova et al. 2008, MacDonald et al. 2011). These sequences may be critical for task performance, but their link to WM is not understood. Are they associated with the memory of the stimulus? Are they causally linked with learning the task? How do they evolve over time? To gain more insight in these questions, we applied two-photon calcium imaging *in vivo* in the dorsal CA1 pyramidal layer of head-fixed mice while they performed an olfactory delayed non-match-to-sample task (DNMS) requiring WM activation (Liu et al. 2014). We recorded activity from hundreds of neurons over multiple days and a variety of delay periods (5-10 seconds). We observed two distinct classes of pyramidal cells: (i) neurons that were active during the presentation of specific odor stimuli ('odor-cells') and (ii) neurons that were active during given time points in the delay following specific odor stimuli ('delay- cells'). These collectively formed odor-specific spiking sequences that covered the entire odor presentation and delay period and encoded odor identity and delay time. When extending the delay, odor-cells remained stable whereas delay-cells shifted their fields. Similarly, by tracking the same neurons over multiple days, we observed that odor-cells retained their representation for multiple days, whereas delay-cells remapped their activity, yielding overall unstable sequences. Moreover, we conducted optogenetic manipulation experiments, disrupting these sequences during (i) learning the task, (ii) in the well-trained phase and (iii) when extending the delay, but found no significant effects in any of these conditions. However, performing the same manipulation in the medial entorhinal cortex (MEC), resulted in slower learning curves and adaptation to extended delay duration. This work indicates that two distinct neural codes coexist in CA1. A stable stimulus-driven and an internally-generated unstable one encoding task-relevant time. Activation of MEC, plausibly shaping these dynamics, is required for efficient learning of the task or adapting to increased memory load. Untangling the mechanisms that generate these representations is crucial for understanding population encoding in the hippocampus and its role in memory formation.

Title: Phase decoding of replay events in the rodent hippocampus

Authors: *S. MACKESEY[1], F. T. SOMMER[2]
[1]Univ. of California Berkeley, Berkeley, CA; [2]Univ. California, Helen Wills Neurosci Inst., Helen Wills Neurosci. Inst., Berkeley, CA

Abstract: Over the last decade, the local field potential (LFP) has been shown to encode high-fidelity behavioral information. In particular, the phase structure of theta-filtered recordings from rat hippocampal area CA1 robustly encodes the position of a navigating rat. Application of dictionary learning to a demodulated version of this signal reveals the presence of place-tuned phase-distortion signal components distributed across a broad swath of CA1. One possible explanation for this phenomenon is that upstream spiking place cells generate a downstream distributed field potential signature due to postsynaptic EPSPs. Here we investigate hippocampal replay events to test this hypothesis. Replay events are temporally compressed "replays" of earlier sequential place cell activity. They take place both during sleep and during periods of rest (i.e. non-locomotion) during activity. While the spiking activity during replay corresponds closely to that during navigation, the extracellular environment is markedly different in that theta-band power is low but higher-frequency "sharp-wave ripple events" are common. Our hypothesis predicts that spiking place cells should produce field potential phase distortions during replay just as they do during navigation. We test this hypothesis by comparing phase-decoding performance of replay events (during momentary pauses) and location during locomotion) from the same linear-track recording sessions in rodent CA1.

Abstract: The mammalian hippocampus participates in a variety of behavioral and cognitive functions. It has been postulated that parallel circuitry, embedded within the serial architecture of

the hippocampus, may give rise to such functional diversity. We aimed to identify, delineate, and manipulate such putative parallel architecture in the dorsal subiculum, the primary output subfield of the dorsal hippocampus. Population and single-cell RNA-seq revealed that the subiculum could be divided into two spatially adjacent subregions that exhibited prominent differences in pyramidal cell gene expression. We found that these two regions varied in their long range inputs, local wiring, projection targets, and electrophysiology. Leveraging the gene-expression differences between these regions, we used region-specific neuronal silencing to show that they provide distinct contributions to spatial working memory. This work provides a coherent molecular-, cellular-, circuit-, and behavioral-level illustration that the hippocampus embeds structurally and functionally dissociable streams within its serial architecture.

Title: GABAergic inhibition coincident with sharp wave-ripples broadcasts within and beyond the hippocampal formation

Authors: *G. G. SZABO[1], I. GULSEVER[1], B. DUDOK[1], C. VARGA[3], M. OIJALA[1], I. SOLTESZ[2]

Abstract: Information processing in the hippocampal formation involves the reception and transmittance of activity patterns of ensembles of excitatory neurons in the dentate gyrus, CA3 and CA1 subfields. At each of these subfields, the information flow is efficiently regulated by GABAergic inhibition in a spatio-temporal manner by specific subsets of GABAergic cells that fire at preferred time windows during ongoing network oscillations. For example, during the hippocampal theta rhythm, a prominent oscillatory pattern that occurs during running, GABAergic cells typically increase their firing rates and show preferential spiking activity at distinct theta phases. During sharp wave-ripples, another prominent hippocampal oscillatory activity pattern that occurs during rest, the discharges of most GABAergic cells in the hippocampal formation are also modulated in distinct cell type-specific manners in terms of

frequency and phase of firing. Here we introduce a special population of GABAergic cells that markedly differ from the known GABAergic neurons in the hippocampal formation. Unlike other GABAergic neurons, these cells reduce their firing rates during running, and show drastically increased spiking activity during sharp wave-ripples such that the action potentials are not phase-locked to the individual ripple cycles. This GABAergic cell population is comprised of cells located in the CA3 and CA1 subfields and their targets are neurons within the hippocampal formation as well as in remote brain areas. Our findings suggest the existence of a particular subtype of GABAergic cells that preferentially discharge during sharp wave-ripples and broadcast this information within the hippocampal formation and beyond.

Abstract: Episodic memory, consisting of social, contextual and temporal information, is dependent on the integrity of the hippocampus. While these different types of information are thought to preferentially engage distinct subcircuits within the structure, the mechanisms of this specialization remains poorly understood. We found that the anatomically and physiologically

distinct parallel projections from the supramammillary nucleus (SuM) of the hypothalamus to the CA2 and dentate gyrus (DG) hippocampal regions differentially modulate cognition in a task specific manner. Employing immediate-early gene expression labeling, optogenetics and *in vivo* recordings in a newly developed SuM-Cre transgenic mouse line we find that the SuM to DG circuit is preferentially engaged by spatial novelty while the neurons targeting CA2 are activated by social novelty. As a result, photoinhibition of the SuM-DG projections leads to deficits in recognizing contextual change while photostimulation of the SuM-CA2 circuit impairs the expression of social memory. These data demonstrate that the hypothalamus can play a task-specific role in the encoding and expression of hippocampal memory.

Title: Experience-dependent changes in CA1 place cell spatial information and CA1 network activity are disrupted in Fmr1 KO rats

Authors: *A. ASIMINAS[1,3,4], E. A. M. A. ALLISON[2], P. C. KIND[2,3,4,5], E. R. WOOD[2,3,4,5]
[1]Ctr. for Cognitive and Neural Systems, [2]Ctr. for Discovery Brain Sci., The Univ. of Edinburgh, Edinburgh, United Kingdom; [3]Simons Initiative for the Developing Brain, Edinburgh, United Kingdom; [4]The Patrick Wild Ctr., Edinburgh, United Kingdom; [5]Ctr. for Brain Develop. and Repair, Bangalore, India

Abstract: Fragile X syndrome (FXS) is the most common inherited cause of intellectual disability and Autism Spectrum Disorder. It is caused by epigenetic silencing of the fragile X mental retardation gene (*Fmr1*), causing a loss of Fragile-X Mental Retardation Protein (FMRP).

Abnormal neuronal function has been reported in many animal models of FXS, but most studies have used an in vitro approach.Using in-vivo electrophysiology in behaving mice, two recent studies reported reduced spatial specificity (Arbab et al. bioRxiv 2017) and discoordinated place cell discharge (Talbot et al. Neuron 2018) of hippocampal place cells in *Fmr1* KO mice. Building upon our previously reported deficits in hippocampal plasticity and episodic memory in a rat model of FXS (Till et al. Hum Mol Genet 2015), we used in-vivo electrophysiology to examine how loss of FMRP affects hippocampal spatial information processing.We recorded from the CA1 in *Fmr1* KO and WT littermates over six 10 min exploration sessions in a novel environment - three sessions per day (ITI 10 min). Our recordings yielded 332 and 276 putative pyramidal cells from 7 WT and 8 *Fmr1* KO rats respectively. Overall, we found no significant differences between WT and *Fmr1* KO pyramidal cells in firing rate, or in the number, size or in-field firing rate of their place fields. Comparison of firing rate maps yielded similar correlations between sessions for both groups, suggesting no reduction in place cell stability in the *Fmr1* KO rats. However, we found that while on Day 1 the spatial information of place cell activity was similar in *Fmr1* KO and WT littermates, on Day 2 *Fmr1* KO rats showed significant less spatial information than WT, suggesting that the place cells of KO rats fail to show normal experience-dependent increase in spatial tuning over 24 hours. We also examined the temporal firing pattern of simultaneously recorded place cells in each session, and the recurrence of patterns between sessions. Our analyses indicate that the recurrence of the network states between sessions within each day was similar between groups. However, *Fmr1* KO rats exhibited significantly higher recurrence between days than WT rats (who showed significantly less recurrence between days than within days). In conclusion, we found that hippocampal place cells from *Fmr1* KO rats show similar spatial firing properties as those from WT rats but do not show the same experience-dependent increase in spatial specificity or the experience-dependent changes in network coordination. The present study furthers our understanding of the cellular and network processes which are affected by the lack of FMRP, which may contribute to the cognitive impairments observed in FXS.

Title: The effects of the inducible transcription factor, Npas4, on place cell characteristics in CA1 of freely behaving mice

Authors: *A. PAYNE, A. HARTZELL BRIGIDI, C. QUIRK, S. LEUTGEB, B. BLOODGOOD
UCSD, La Jolla, CA

Abstract: In order to form a memory, an animal must be capable of transforming a transient experience into long-lasting changes in cell function. One potential method for capturing such transitory moments is through the action of inducible transcription factors such as Npas4. In hippocampal CA1 pyramidal neurons (PNs), Npas4 is expressed rapidly and transiently following neuronal depolarization and results in a long-lasting and sophisticated reorganization of inhibition along the somato-dendritic axis - simultaneously recruiting inhibitory synapses to the soma while destabilizing those in the apical dendrites. Moreover, we have recently discovered that Npas4 selectively increases the number of somatic inhibitory synapses made by CCK basket cells (CCKBCs). Synapses made by these inhibitory interneurons undergo a unique form of short-term presynaptic plasticity termed depolarization-induced suppression of inhibition (DSI). During DSI, depolarization of the postsynaptic PN results in the production and release of endocannabinoids. These endocannabinoids bind to CB1 receptors on the presynaptic CCKBC and initiate a downstream cascade resulting in the suppression of GABA release. This mechanism allows PNs with increased inhibition from CCKBCs to enter a temporary state of increased activity reminiscent of place cell activity as an animal traverses the receptive field. Since PNs in CA1 are known to be involved in spatial encoding and novelty detection, we propose two potential outcomes following Npas4 expression: First, recruitment of inhibitory synapses to the soma of the PN will alter firing characteristics of these place cells, thus changing their receptive fields. Second, the loss of inhibitory synapses at the dendrites will create an environment that is more conducive to plasticity, allowing these cells to readily encode new environments. Here we compare the spike timing characteristics, receptive field properties, and network dynamics between wild-type and Npas4 knockout neurons to better elucidate how transient expression of Npas4 might contribute to long-lasting changes in place cell characteristics.

Title: Altered hippocampal replay is associated with memory impairment in mice heterozygous for the SCN2A gene

Authors: *S. J. MIDDLETON[1], E. M. KNELLER[2], S. CHEN[2], I. OGIWARA[2], M. MONTAL[4], K. YAMAKAWA[5], T. J. MCHUGH[3]

Abstract: Experimental evidence has implicated hippocampal replay occurring within sharp wave ripples (SPW-Rs) as crucial for learning and memory in healthy subjects. This raises speculation that neurological disorders impairing memory disrupt either SPW-Rs or their underlying neuronal activity. Here, we demonstrate that mice heterozygous for the gene *SCN2A*, a site of frequent de novo mutations in patients with intellectual disability, displayed impaired spatial memory. While no changes were observed during encoding, to either single place cells or cell assemblies, we identified abnormalities restricted to SPW-R episodes which manifest as decreased cell assembly reactivation strengths and truncated hippocampal replay sequences.

Title: Differential effects of rottlerin and MK-801 on aversive memory: Involvement of different signaling molecules in the hippocampus

Authors: *S.-J. HU[1], M.-H. HSIUNG[2]
[1]Dept of Psychology, Natl. Cheng Kung Univ., Tainan, Taiwan; [2]Psychology, Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Rottlerin is a multifunctional drug that has been used to treat cancer cells in the preclinical trials. It inhibits eukaryotic elongation factor 2 kinase (eEF2K), which increases the brain-derived neurotrophic factor (BDNF) protein levels in the hippocampus. The eEF2K, which phosphorylates eukaryotic elongation factor 2 (eEF2), is one of the downstream signaling molecules of the *N*-methyl-D-aspartic acid receptor (NMDAR). Moreover, rottlerin is a mitochondrial uncoupler that affects many protein kinases, such as PKC, Akt/PKB, and extracellular-signal-related kinases 1/2 (ERK1/2). Likewise, MK-801, a non-competitive antagonist of NMDAR, exerts a fast-acting antidepressant-like effect through the eEF2K inhibition-mediated increase of BDNF protein in the hippocampus. Both the NMDA receptor and PKC have long been implicated in the normal function of learning and memory. Blockade of NMDA receptor prevents long-term potentiation (LTP), a cellular mechanism underlying learning and memory. Furthermore, the NMDA receptors in the dorsal hippocampus are involved in the establishment of long-term memory of inhibitory avoidance (IA) task.
IA is widely used in the preclinical research to measure avoidance or aversive behavior, which is one of the symptom clusters in the posttraumatic stress disorder (PTSD). We sought to examine the effect of two putative antidepressants, rottlerin and MK801, on memory acquisition, consolidation, reconsolidation, and retrieval of the IA task. Since both rottlerin and MK-801 increase BDNF protein in the hippocampus, which plays an essential role in enhancing long-term memory, we next examined whether the effects of rottlerin and MK-801 on IA is *via* changes in BDNF and other signaling molecules in the hippocampus.
Our results indicate that systemic rottlerin impaired memory acquisition and consolidation of IA, but had no effect on memory retrieval. Systemic MK-801 impaired acquisition of the same aversive memory, which may be confounded by drug-induced change of shock sensitivity. Intriguingly, MK-801 facilitated memory consolidation and retrieval of IA. We also found that the intra-hippocampal infusion of rottlerin significantly impaired memory acquisition and consolidation of IA, indicating the effects of rottlerin are *via* the hippocampus. However, the intra-hippocampal infusion of MK-801 significantly facilitated memory consolidation and retrieval of IA, indicating the effects of MK-801 are also *via* the hippocampus. Finally, the signaling molecules in the hippocampus underlying the opposite modulatory effects of rottlerin and MK-801 on IA memory are currently under intense investigation.

Title: Vortioxetine reverses the cognitive impairments associated with hippocampal-dependent visuospatial memory induced in a rodent model of androgen deprivation therapy for prostate cancer

Authors: *A. SHARP[1,2], S. LERTPHINYOWONG[1,2], J. GELFOND[3], T. JOHNSON-PAIS[3], R. LEACH[3], M. LISS[3], A. SULLIVAN[2,3], I. THOMPSON[3], D. A. MORILAK[1,2,3]
[1]Pharmacol., [2]Ctr. for Biomed. Neurosci., [3]Mays Cancer Ctr., UT Hlth. San Antonio, San Antonio, TX

Abstract: Androgen deprivation therapy (ADT) is the primary treatment for prostate cancer. However, it is also associated with several serious side effects, including profound cognitive impairment that is observed in more than half of patients treated with ADT. This significantly reduces quality of life for cancer survivors and their families. Typically, the deficits occur in visuospatial cognition and executive function, cognitive domains associated with function of the hippocampus (Hipp) and medial prefrontal cortex (mPFC), respectively. Further, cognitive impairment has been found to increase in severity with duration of ADT treatment, suggesting that it may be possible to slow or reverse the impairment. Vortioxetine (VTX) is a novel multi-modal antidepressant that has been shown to improve cognitive impairment in depressed patients, Thus, we hypothesized that vortioxetine may also reverse the cognitive impairment induced by ADT. Our lab has established a rodent model of ADT by surgically castrating male Sprague-Dawley rats. Castrated animals display deficits in cognitive flexibility on the Attentional Set-Shifting Test (AST), a measure of prefrontal executive function ($p<0.001$, n=6-12), as well as reduced afferent-evoked field potential response recorded in the mPFC after stimulation of the ventral Hipp ($p<0.01$, n=8-9). Chronic dietary VTX (28mg/kg/day) was able to reverse the deficits on AST ($p<0.001$) and normalized response in the ventral Hipp to mPFC pathway ($p<0.05$). These results suggested possible mechanisms for the deficits of executive function after ADT, mediated by changes in mPFC function. The purpose of the present study was to investigate potential changes in behavior measuring visuospatial cognition, and in electrophysiogical afferent response of the dorsal Hipp, which is involved in visuospatial memory, after ADT, and whether VTX was also able to reverse these deficits. Preliminary data (n=8-9) suggest that surgical castration induced a deficit on the Novel Object Location task, and chronic dietary VTX reversed this impairment (both $p<0.05$, n=10-12). Experiments are currently underway to examine changes in local field potentials evoked in the dorsal Hipp. Future experiments will assess changes in dendritic morphology in the Hipp after ADT and VTX. These results suggest that ADT induces cognitive impairment in visuospatial cognition mediated in the Hipp and chronic treatment with the novel antidepressant drug, VTX, may be effective in reversing these deficits.

Title: Avian sharp wave-ripples reveal link to ancestral sleep circuits

Authors: *J. M. ONDRACEK
Zoology, Tech. Univ. Munich, Freising, Germany

Abstract: Sleep in birds and mammals involves two alternating phases of brain activity. While rapid eye movement (REM) sleep resembles activity in the awake brain (desynchronized, high frequency oscillations of low voltage), slow wave sleep (SWS) consists of synchronized and slow high-voltage activity.
Embedded within SWS and REM sleep are local field potential (LFP) events that occur within distinct areas of the mammalian brain. In the hippocampus, sharp wave-ripples (ShWRs), characterized by large amplitude negative deflections that are associated with a fast oscillation, or “ripple”, occur preferentially during phases of SWS [1].
ShWRs are important largely due to their functional role in memory consolidation [2], and the network activity underlying mammalian ShWRs is well understood. However, the recent finding of ShWRs during SWS in a reptile [3] gives rise to the question of whether ShWRs (and their corresponding memory functions) might also arise from other neuroarchitectures.
In this regard, birds represent an important link. Birds, like reptiles, belong to the class of sauropsids and share a (now extinct) stem amniote ancestor with mammals [4]. We chose to investigate ShWRs in the brain structure associated with reptilian ShWRs - the dorsal ventricular ridge (DVR). Although avian and reptilian brains are different with regard to cellular lamination, the DVR in both reptiles and birds is largely similar with regard to its pallial origin.
Here I show the first evidence of ShWR events in the avian DVR. To investigate sleep-related electrical activity in the avian brain, I recorded LFP from the anesthetized DVR of two avian species (Gallus gallus and Taeniopygia guttata). LFP data show clear evidence of ShWR events that are highly similar to those observed in reptiles: repeated occurrence of large negative deflections of LFP (100-300 ms duration). High-pass (HP) filtering of these sharp waves revealed that they contained short bursts of >70-Hz ripple activity locked to the deflection’s descending phase.
These results suggest that although mammalian, reptilian, and avian brains are organized differently, brain activity patterns - and specifically ShWR events - are remarkably similar during sleep. Functional similarities between sauropsid DVR and mammalian hippocampus

suggest that the memory functions of sleep may be invariant to the overall neuroanatomical organization of the brain, and highlight the potential that these ancestral circuits developed over 300 million years ago in a common amniote ancestor.

Title: HippoBellum: Cerebellar modulation of hippocampal functioning

Authors: *Z. ZEIDLER[1], M. BRANDT-FONTAINE[2], Z. MONTES[2], E. I. KROOK-MAGNUSON[3]
[1]Grad. Program in Neurosci., [2]Univ. of Minnesota, Minneapolis, MN; [3]Univ. of Minnesota Syst., Minneapolis, MN

Abstract: The cerebellum is being increasingly recognized for its roles and relationships to non-motor functions and structures. In particular, the cerebellum has been shown to influence hippocampal functioning in both healthy and disease states. Yet important questions about the cerebello-hippocampal relationship remain answered, such as how the local hippocampal network responds to cerebellar stimulation, which populations of hippocampal neurons are sensitive to cerebellar activation, and whether acute modulation of the cerebellum interferes with hippocampal-dependent behavior. Using transgenic mice to optogenetically modulate the cerebellar cortex, we provide evidence that specific populations of hippocampal neurons are active following cerebellar stimulation. Furthermore, we show that cerebellar stimulation can modulate hippocampal population response in vivo. Additionally, acute open-loop optogenetic activation of the cerebellum during memory tasks produced a selective impairment on a hippocampal-dependent spatial memory task. These data point to important components of the

hippocampus' response to cerebellar activation and emphasize the power and specificity of the hippocampo-cerebellar relationship.

Title: Functional left/right asymmetry of rat hippocampus depending on short/long-term memory

Authors: *Y. SAKAGUCHI, Y. SAKURAI
Grad. Sch. of Brain Sci., Doshisha Univ., Kyotanabe-Shi, Japan

Abstract: Functional asymmetry in the left/right hemisphere is a well-known feature in human, e.g., the left-sided function of the language area and the right-sided spacial cognitive function. Especially in the human hippocampus, the right hippocampal volume of the taxi driver is larger than the left one. However, such asymmetrical function is not specific in human but also in the various animals. For example, the hippocampus of rodents have a difference in volume between the left and right hemisphere, and the left hippocampus is more important than the right for forming long-term memory. These evidences suggest the functional asymmetry of the hippocampus, but its details are now not well known. Therefore, we investigated the hippocampal lateralization focusing on the long-term memory (LTM) and the short-term memory (STM). Before starting the behavioral tests, the rats underwent the surgery and one of the left or right hippocampus was electrically destroyed. We used these three tests as the behavioral experiment models; Spontaneous alternation test (SAT) for STM, Spatial preference test (SPT) for STM and Plus maze test (PMT) for LTM. As a result, SAT and SPT showed significantly lower performance in the right lesion group compared with the sham operation and the left lesion group, whereas PMT showed significantly higher performance in the right lesion group compared with the two groups. Therefore, 1. STM is responsible only for the right hippocampus, 2. Both the left and right hippocampus contribute to LTM, and either hippocampus is sufficient for LTM formation, but the right hippocampus might inhibit the left one. We concluded that the rodent hippocampus may be performing complementarily or competitively through interhemispheric interactions for the learning and memory.

Title: Learning and memory in split-brain mice

Authors: *J. JORDAN[1], Y. TONG[2], C. L. PYTTE[3]
[1]Biol., Grad. Center, The City Univ. of New York, New York, NY; [2]Psychology, [3]Queens Col., Flushing, NY

Abstract: Lateralization is an organizing principle of nervous systems across taxa. The hippocampus is essential for the formation of new declarative memories and spatial navigation and is known to be lateralized in many forms of anatomy, physiology, and cognitive function. In the rodent brain, the left and right hippocampi are strongly interconnected via the hippocampal commissure (HC). Despite a number of recent studies examining the role of the left or right hippocampus in memory, very little attention has been paid to the role of interhippocampal communication in memory. Here, we adapted a protocol for rodent split-brain surgery to sever either the corpus callosum (CC) or the CC and HC to test contributions of these interhemispheric pathways to hippocampus-dependent memory. Three groups of mice were operated on: 1) transection of both the HC and CC (HC+CC); 2) transection of just the CC (CC); 3) transection of cortical areas lying above the CC (SHAM). We then tested these mice on a short-term spatial memory version of the Y-Maze in which mice were allowed to explore a start arm and a familiar arm with the third arm blocked off. On a retrieval trial one minute later, all arms were open and preference for the novel arm was measured. We found that both CC and Sham mice exhibited a preference for spatial novelty, whereas the HC+CC mice did not. These results indicate impaired short-term spatial memory in the absence of a functional HC pathway and may contribute to our understanding of the role of interhippocampal communication and learning and memory.

Title: The effects of continuous versus intermittent access to a western style diet on short-term object and place recognition memory in rats

Authors: *M. D. KENDIG[1], R. F. WESTBROOK[2], M. J. MORRIS[1]
[1]Pharmacol., [2]Psychology, Univ. of New South Wales, Sydney, Australia

Abstract: The so-called western diet is rich in saturated fat and refined carbohydrates. Excessive intake of this diet promotes weight gain and may result in deficits in hippocampal-dependent forms of learning and memory. Many people do not eat such diets continuously but instead alternate between periods of healthy and unhealthy eating as part of efforts to maintain healthy body weight. Animal models can systematically vary access to these diets (days per week) and study cognitive and molecular outcomes over time. The present study compared the effects of continuous versus intermittent exposure to a western diet on object and place recognition memory in an established rat model. Adult male Sprague-Dawley rats received 25 days of access to a western-style, cafeteria diet (CAF) for either 7 days per week (continuous group); 5 consecutive days followed by 2 days of chow each week (5:2 group); 3 consecutive days followed by 4 days of chow each week (3:4 group), while a fourth group received chow (control). In an initial test conducted after 16-18 days of CAF, place recognition memory was impaired only in the continuous group relative to controls ($p < 0.05$), but fat mass (assessed via EchoMRI) was elevated in the three CAF-fed groups. In a second test conducted after 23-25 days of CAF, place recognition was impaired in both the 5:2 and continuous CAF groups. Consistent with previous research, there were no between-group differences in object recognition on either test. Groups exposed to CAF did not differ in their daily energy intake of CAF nor in self-selected macronutrient distribution. These results demonstrate that, when matched for total cumulative exposure to the western style diet, the pattern of access to CAF diet determines cognitive and metabolic effects in a graded fashion. Thus, the same total duration of exposure to an unhealthy diet impaired spatial recognition memory when the diet was available 7 or 5 days, but not 3 days per week. Current work is aimed at isolating whether the partial protection in the 3:4 group relates to the length of the CAF or the chow portion of the cycle.

Title: Effects of paternal obesity on behavior and hippocampus CB1-R in offspring

Authors: *G. SINDI[1], Y. SLYVKA[2], Y. ZHANG[2], F. V. NOWAK[2]
[1]Biol. Sci., [2]Biomed. Sci., Ohio Univ., Athens, OH

Abstract: Paternal and maternal diet-induced obesity strongly impact subsequent generations. While the center of the mammalian reward circuit is the dopaminergic neurons of the ventral striatum and substantia nigra, the endocannabinoid system (ECS) modulates reward processing, including food intake and physical activity. Cannabinoid receptor type-1 (CB1-R) is the major ECS receptor in the CNS and is highly expressed in the hippocampus and hypothalamus. Previous studies have focused on the direct effect of CB1-R in mice eating high fat diet (HFD), but not their offspring. In HFD-fed mice, CB1-R expression is increased in hippocampus due to overeating. Our team hypothesized that HFD-induced paternal obesity would also affect offspring appetite and activity. Measures done at 1.5, 6, and 12 months of age demonstrated that voluntary physical activity occurred more in male offspring of HFD-fed fathers (Gr2) at 1.5 months of age than offspring of low fat diet (LFD)-fed fathers (Gr1). Female offspring ran more than males in three groups: HFD-fed father offspring at 6 and 12 months, and LFD-fed father offspring at 1.5 months. Offspring from Gr2 showed higher food consumption at 1.5 months than Gr1 offspring. We hypothesized that alterations within the CNS reward circuitry are related to different levels of physical activity and food preference in offspring of obese HFD-fed fathers versus non-obese LFD-fed fathers. Brain slices from offspring at 1.5, 6, and 12 months of age were used for immunohistochemistry. Sections were incubated in primary polyclonal rabbit anti-CB1-R antibody against the C-terminus of the receptor, and Horseradish Peroxidase (HRP)-conjugated goat anti-rabbit secondary antibody. CB1-R were detected using DAB substrate, which generates a brown to black product when cleaved by HRP, and quantified using ImagePro. All results are reported as mean ± S.E.M. and differences accepted as significant at $p \leq 0.05$. Our results demonstrate that at 12 months of age, CNS reward circuitry is altered with an increase in CB1-R in the CA3 region of the hippocampus in offspring of sires fed a HFD compared to offspring of fathers fed a LFD. At 6 months of age, CB1-R is higher in the CA1 and CA2 regions of Gr2 females than Gr2 males. Currently, we are investigating CB1-R quantification in hypothalamus, a major target region of ECS. This study further clarifies the relationship between paternal obesity, voluntary exercise, and CB1-R expression alterations in the brain which may lead to new strategies for prevention of obesity in offspring of obese parents.

Title: Modulation of low-frequency pulsed magnetic field on hippocampal neural oscillation in depression rats

Authors: *J. YANG, L. WANG, D. MING
Acad. of Med. Engin. and Translational Med., Tianjin Univ., Tianjin City, China

Abstract: Transcranial magnetic stimulation (TMS), as a non-invasive brain stimulation technique, has been approved for some medication-resistant depression by the United States Food and Drug Administration. However, the majority of these studies have focused on the effects of high-frequency TMS, and little is known about low-frequency TMS in depression treatment. Unlike high frequency TMS inducing evoked potentials, low-frequency (<1Hz) magnetic field could modulate the neuronal spike times and spiking frequency, which is considered to constitute the neural oscillations. Accordingly, in the present study we aimed to examine whether LFPMF (1Hz) can modulate hippocampal neural oscillations in a model of depression induced by chronic unpredictable stress (CUS), which can mimic the development and progress of clinical depression. To address this, a depression rat model was established by chronic unpredictable stress (CUS). Rats were exposed to low-frequency pulsed magnetic field (LFPMF) (1Hz, 20mT) for 14 days, one hour per day, then sucrose preference test (SPT) and plus-maze test were assessed to evaluate depression-relevant behaviors. Local field potentials (LFPs) from the hippocampal Schaffer collaterals (CA3) and CA1 region were recorded respectively to explore the neurodynamic alternations, including the degree of synchronization in an identical-frequency rhythm and the strength of coupling between theta-gamma cross bands. In order to analyze LFPs, sample entropy was calculated to make complexity analysis, while phase locked value and phase-amplitude coupling modulation index were used to figure out the correlation of oscillations. Our data showed that LFPMF significantly relieved CUS-induced depression-behaviors and improved the undesirable changes of the identical-frequency synchronization and theta-gamma phase-amplitude coupling in CUS rats. Our study elucidated that LFPMF stimulation (1Hz) can ameliorate the depressive behaviors on the rat model of CUS, suggesting that LFPMF may serve as a potential treatment in depression. Meanwhile the potential electroneurophysiology mechanisms may be the improvement of neural

synchronization and cross- coupling in hippocampal CA3 and CA1 regions.

Abstract: The hippocampus integrates subcortical reward signals into representations of space and memory. Among candidate sources, serotonergic fibers from the raphe nucleus are known to exert tight control over hippocampal physiology. However, the input architecture and behavioral functions of serotonin in the hippocampus remain unknown. Here we report transmission of reward and locomotion information from the raphe to hippocampal CA1. Using 2-photon calcium imaging during exploration in a virtual reality task, we recorded 5HT fibers in CA1 and identified stereotypical patterns of activity. Consistent with the reward related activity, optogenetic activation of CA1 5HT fibers increased reward acquisition in the VR task. These results suggest that serotonergic long range subcortical inputs from the raphe define a subcortical pathway for the representation of rewarded events to the hippocampal network.

Title: Functional segregation along the proximo-distal axis of CA1

Authors: *Y. OTA[1,2], B. J. WILTGEN[1,2,3]
[2]Psychology, [3]Ctr. for Neurosci., [1]Univ. of California, Davis, Davis, CA

Abstract: Recent evidence suggests that some functions of the hippocampus (HPC) may be segregated along its transverse axis. For instance, the HPC receives spatial input from the medial entorhinal cortex (MEC) and postrhinal cortex while it receives odor/object-related information from the lateral entorhinal cortex (LEC) and perirhinal cortex. Although these inputs are mixed in dentate gyrus and CA3, they remain segregated in the entorhinal cortex projections to CA1. The proximal (next to CA2) and distal (next to subiculum) segments of CA1 receive direct projections from MEC and LEC, respectively. This suggests that information processing may be functionally distinct along the proximo-distal axis of CA1. To test this idea, we quantified c-fos expression in proximal and distal CA1 of mice that were either exposed to a novel context, novel objects in a familiar context, or a familiar context without objects. Consistent with previous reports, we found that novel context exposure increased c-fos activity in proximal CA1 while exposure to novel objects resulted in higher c-fos levels in distal CA1 compared to control mice. Using targeted infusions of halorhodopsin, we are currently in the process of silencing distinct regions during testing of spatial and object recognition tasks. We predict that silencing proximal CA1 will impair contextual memory retrieval of a familiar environment. In contrast, we predict that silencing distal CA1 will impair performance on object recognition tasks. Our experiments will further improve the current framework of how the hippocampus forms and retrieves different types of memories.

Title: Altered immediate early gene expression in fos-tTA transgenic mice

Authors: *J. H. WILMOT[1,2], J. A. GRAHAM[2], M. M. LAFRENIERE[2], K. PUHGER[1,2], B. J. WILTGEN[1,2]
[1]Psychology, [2]Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: Memory retrieval is thought to occur when neurons that were engaged during learning are later reactivated. Until recently, testing this prediction has been difficult due to technical limitations. However, newly developed molecular and genetic techniques now allow researchers to test this idea by selectively tagging and manipulating cells that were active during learning. One popular approach to labeling these cells is to use the *fos-tTA* transgenic mouse. In these mice, active (*c-fos*+) neurons express the tetracycline transactivator (tTA), which can be used to drive the expression of other proteins under the *tetO* promoter in order to identify (fluorescent proteins) and/or control (opsins, DREADDS) these cells. Importantly, tagging is restricted to periods when there is no doxycycline present in the animals' diet, allowing temporal control over the tagging window for selective tagging of neurons activated during a specific experience. In addition to tagging cells active during learning, it is common to examine the reactivation of these cells using the immediate early gene *c-fos* as an index of neural activity. However, *c-fos* expression has never been thoroughly characterized in these mice. Here, we demonstrate that *fos-tTA* mice express increased levels of *c-fos* in the hippocampus compared to wild type animals. This difference is observed in mice that undergo different types of behavioral training and can also be seen in home cage control mice. Interestingly, this effect appears to be strain specific, as *fos-tTA* mice maintained on a C57BL/6J background show heightened *c-fos* expression, while F1 hybrids generated by breeding *fos-tTA* mice with wild type 129S6 mice do not. Ongoing experiments are examining the regulation of *tetO-H2B-GFP* in these animals and the use of an AAV to drive *tTA* expression. These results illustrate some of the limitations inherent in the use of *fos-tTA* transgenic mice and provide potential solutions to these issues.

Title: Increases in hippocampal activity are more detrimental to memory retrieval than decreases

Authors: *J. N. KRUEGER[1], J. H. WILMOT[2], K. R. PUHGER[2], S. E. NEMES[3], B. J. WILTGEN[1,2]
[1]Ctr. for Neurosci., Univ. of California Davis, Davis, CA; [2]Dept. of Psychology, [3]Neurobiology, Physiol. and Behavior, Univ. of California, Davis, Davis, CA

Abstract: The hippocampus (HPC) is important for spatial and contextual memory retrieval. This was initially demonstrated using lesions or pharmacological inactivation prior to memory testing. Modern tools like optogenetics and designer receptors exclusively activated by designer drugs (DREADDs) are now being used to manipulate HPC activity in a more targeted manner. The goal of the current experiments was to examine the effects of several of these manipulations on neural activity and memory retrieval. To do so, we used contextual fear conditioning and examined c-Fos expression following testing as a measure of neuronal activity. To decrease activity we used CaMKII-hM4di, ArchT and Halo. To increase activity we used CaMKII-ChR2, CaMKII-hM3Dq and Syn1-hM4Di. Syn1-hM4Di was recently shown to silence inhibitory neurons and increase overall activity. Preliminary results indicate that manipulations that reduce activity (eg CaMKII-hM4Di) have minor effects on retrieval, while manipulations that increase activity (eg CaMKII-ChR2) severely impair retrieval. Interestingly, manipulations that decrease activity in some neurons while increasing activity in many others, also robustly impair memory. Taken together, the data thus far indicate that decreases in HPC activity are often less effective at producing behavioral impairments than increases in HPC activity. The results are discussed in terms of the magnitude of change (net excitation vs. inhibition) vs. the direction of change (increase vs. decrease in activity).

Title: Mechanisms of memory impairment following optogenetic disruption of the ventral hippocampus

Authors: *J. A. GRAHAM[1], N. VISHWAKARMA[1], B. J. WILTGEN[2]
[1]Neurosci., [2]Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: The hippocampus(HPC) is known to be important for spatial and contextual memories. It is also necessary for acquisition and retrieval of memories wherein a previously neutral context or location becomes associated with fear. The ventral portion of the hippocampus(VHC) contains projections to many areas of the brain that are associated with fear memories including the Basal Amygdala(BA), where it is thought that the association between contextual information provided by the hippocampus and information about the fear inducing stimulus from nuclei of the brainstem are stored. Consistent with previous reports(Jimenez et al., 2018), we find that disrupting activity in the VHC via fast acting channel rhodopsin variant ChETA impairs fear memory. This was true regardless of whether we non-selectively stimulated excitatory pyramidal neurons or only VHC-BA projection neurons. Surprisingly, we found optogenetic stimulation did not significantly increase expression of the immediate early gene c-fos beneath the optic fiber tip. This contrasts with what we find in dorsal HPC where large increases in fos expression are visible after stimulation(Krueger et al/Pugher et al, SfN 2018). It is possible that the VHC requires stronger stimulation protocols to initiate c-fos expression due to differential activation of NMDAR receptors in the VHC(Babiec, Jami, Guglietta, Chen, & O'Dell, 2017). We plan to record from neurons expressing ChETA in the VHC slices in order to verify that our stimulation protocol produces robust activity. Finally, we plan to examine the nature of the memory impairment we saw during optogenetic stimulation. Memory retrieval typically requires reactivation of the neural ensemble active during learning. We hypothesize that memory is impaired during optogenetic stimulation because brain activity during stimulation does not match that occurring during acquisition. To test this idea, we plan to artificially match training and testing activation in the VHC with optogenetic stimulation.

Title: Neural circuits underlying trace fear conditioning

Authors: *K. PUHGER[1,2], J. WILMOT[1,2], B. WILTGEN[1,2]
[1]Psychology, [2]Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: In Pavlovian trace fear conditioning, a temporal delay (the trace interval) is inserted between the CS and US presentation. Pavlov theorized that a 'memory trace' or representation of the CS must be maintained during this interval in order for the association to be formed. Recent neurobiological studies indicate that certain brain regions such as the hippocampus (HPC) and medial prefrontal cortex (mPFC) play a distinct role in this task. Lesions and pharmacological inactivation of both the hippocampus or mPFC impair trace fear conditioning. Multi-unit recordings from the HPC show learning-related activity changes, and CA1 single-unit activity increases in response to the CS and exhibit population-level encoding of the trace interval. Recording studies have also found that the mPFC exhibits learning-related increases in activity to the CS and US. Interestingly, a subpopulation of cells in the mPFC showed sustained firing during the trace interval. Recent optogenetic studies have shown that inactivating CA1 or the mPFC selectively during the trace interval impairs learning in trace fear conditioning, suggesting that CA1 and mPFC process information during the trace interval necessary for learning this association. However, there are no strong, direct projections between the mPFC and dorsal hippocampus. They are bidirectionally connected via the midline thalamic nucleus reuniens (NR) which receives dense inputs from both the mPFC and HPC, and projects back to these areas. The NR is important for facilitating communication between the hippocampus and mPFC, and is also critical for spatial working memory and contextual fear memory. In the current study, we utilized ChR2 and eNpHR3.0 for optogenetic stimulation and inhibition to disrupt activity in CA1 and impair trace fear conditioning. Present and future experiments will characterize the neural circuits underlying trace fear conditioning by examining the role of the NR. Next, we will use projection-specific optogenetics to target projections between CA1 and the reuniens. We predict that selective disruption during the trace interval will impair the formation of trace fear memories. To test this idea we will compare manipulations during the trace interval to manipulations during the CS or intertrial interval periods.

Title: The use of EEG evoked responses for the identification of cognitive enhancers in rodents

Authors: *V. DUVEAU, A. WOźNIAK-KWAśNIEWSKA, A. EVRARD, C. RUGGIERO, C. ROUCARD, Y. ROCHE
Synapcell SAS, St Ismier, France

Abstract: Electroencephalography (EEG) and related methodologies have emerged as powerful tools in both, clinical and preclinical research programs, for the identification of physiological and pathological biomarkers. Nowadays, EEG endpoints are commonly used in the clinic to identify and evaluate a pathological state and/or as surrogate biomarkers for clinical trials (Alzheimer's disease, schizophrenia, autism, epilepsy, etc.). EEG biomarkers are easily translatable from humans to rodents, thus offering a unique opportunity to develop more efficient drug discovery programs. In rodents, EEG responses evoked by auditory stimulation can be recorded in various brain areas. They underlie the integration and processing of sensory information, which are altered in many neurological and psychiatric disorders. We distinguish two main types of auditory evoked responses: auditory evoked related potentials (AERP) and auditory steady state response (ASSR). AERPs are composed of successive positive and negative deflections, which differ from their latencies and amplitudes and are well conserved throughout the evolution. ASSRs consist in cortical electrophysiological oscillations entrained to the frequency of a periodic auditory stimulus presented at a gamma rhythm range (that is, 30-80Hz). In this study we investigated the effect of a cognitive enhancer, donepezil, on AERP and 40Hz-ASSR in mice. Our AERP protocol consisted in 250 pairs of white noise clicks at 85dB with an interval of 0.5 sec between paired clicks. The 40Hz-ASSR protocol was composed of 360 trains of stimulation at 85dB. First, we evaluated the effect of donepezil on the total power elicited by the auditory stimulation at 40Hz in mice. Donepezil dose-dependently increased the 40Hz total power with a significant effect observed at the dose of 1 or 1.5 mg/kg, depending on the recorded structure. When tested on AERP alone, donepezil did not modify the amplitudes and latencies of different AERPs' deflections. Then, we tested the effect of donepezil against the modifications induced by scopolamine, a molecule known to provoke cognitive impairments. Scopolamine alone dose-dependently reduced the N1 gating in our AERP paradigm. The administration of

donepezil before scopolamine dose-dependently reversed the modifications induced by scopolamine. This effect was significant at the dose of 1 mg/kg of donepezil. We identified functional biomarkers in mice using EEG and related methodologies. These specific biomarkers could represent a crucial tool for the identification, selection and validation of new innovative therapeutics and more specifically, for the identification of new cognitive enhancers.

Title: Control of fear and extinction memory retrieval via manipulation of BLA-PFC oscillatory network state

Authors: *M. OZAWA[1], P. DAVIS[2], T. PAPOUIN[1], J. MAGUIRE[1], L. REIJMERS[2]
[1]Neurosci., [2]Tufts Univ., Boston, MA

Abstract: The formation and retrieval of a memory is mediated by experience-dependent changes in the brain. Yet, the exact nature of these changes is not fully understood. Contextual fear conditioning (FC) combined with subsequent extinction is a learning paradigm that allows investigation of memory retrieval mechanisms. It leads to the formation of two distinct memories, a fear and extinction memory, both associated with the same context. The basolateral amygdala (BLA) is critical for forming both types of memories. We previously showed that PV-interneurons in the BLA regulate the expression of a conditioned fear response after extinction. We found that after extinction, PV interneurons also control the relationship between a 3-6Hz and 6-12Hz oscillation, the relative balance of which correlated with behavioral expression of conditioned fear. To test whether the two oscillations are causally involved in the retrieval of fear and extinction memories, we used an optogenetic approach to exogenously induce the two oscillatory states in the BLA and tested the effect on memory retrieval. We found that mimicking the two oscillations has opposite effects on fear and extinction memory retrieval. We propose

that the effect of stimulation on behavior is mediated by changes in phase coherence between BLA and prefrontal cortex (PFC).

Title: Amygdala central nucleus inactivation impairs learning-related spike activity and local field potentials in the basilar pontine nucleus

Authors: *J. KIM[1,2], S. J. FARLEY[1,2], J. H. FREEMAN[1,2]
[1]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA; [2]Iowa Neurosci. Inst., Iowa City, IA

Abstract: Accumulating evidence shows that amygdala central nucleus (CeA) output to the basilar pontine nucleus (BPN) may function as a modulator of sensory information to the cerebellum (Farley 2016, 2018; Pochiro 2015; Siegel 2015; Taub 2010). Additionally, pharmacological inactivation of the CeA during eyeblink conditioning reveals that conditioned responses (CRs) are strongly attenuated and only modest levels of acquisition occur without CeA input (Farley 2018). In this study, we recorded single unit and local field potential (LFP) activity in the BPN of adult rats as they were trained in the cerebellum-dependent task, delay eyeblink conditioning. In this task, a neutral conditioned stimulus (CS; 2 kHz tone, 400ms duration) is paired with an unconditioned stimulus (US; 2.5 mA periorbital stimulus). We first analyzed pontine baseline LFP activity with and without bilateral CeA inactivation using the $GABA_A$ agonist, muscimol (2mM). A stable recording was acquired, muscimol infused, and then recording continued following a brief diffusion period. After 48 hours, rats were subsequently exposed to a counter-balanced order of saline or muscimol CS-alone sessions (50-trials) while recording BPN spike and LPF activity. Following CS alone sessions, rats were then randomly divided into muscimol or saline groups for training in delay eyeblink conditioning. Bilateral infusions to the CeA occurred before each of the first 5 eyeblink sessions (100-trials/session). Training continued without infusions from session 6 until reaching an 80% CR criterion. After criterion, rats completed counter-balanced muscimol or saline retention sessions. CeA inactivation modulated behavioral CRs and neural activity in the BPN. Accompanying the impairment in CRs, BPN spike activity, which was CS-responsive under the vehicle control sessions, was significantly decreased when CeA was inactivated by muscimol. BPN LFP signals

also showed the notable modulation by CeA activation/inactivation. Specifically, CeA inactivation resulted in the most significant decreases in the alpha (12 - 18 Hz) and beta (20 - 30 Hz) bands. To a lesser extent, LFP power also decreased in the theta (4-8 Hz) band. The results suggest that the CeA modulation of learning and neural activity in BPN might occur via higher frequency bands.

Title: Interplay of resonant and synchronizing generators in a hippocampal theta model

Authors: *V. GUNTU[1], A. M. HUMMOS[2], S. S. NAIR, 65211[3]
[1]Columbia, MO; [2]Univ. of Missouri, Columbia, MO; [3]Univ. of Missouri, COLUMBIA, MO

Abstract: Rhythmic activity characterizes neuronal processing in multiple brain areas. Study of rhythms indicate the involvement of a multitude of rhythm generators, likely through a variety of mechanisms. Considering the multitude of involved mechanisms in rhythm generation, inactivation of circuit components can produce complex and unpredictable results.
We use computational modeling to examine interaction between circuit components that participate in rhythm generation. We distinguish between resonant components and synchronizing components and demonstrate that this categorization permits predicting the rules of which components can interfere with one another and which can substitute for one another. Resonant mechanisms inherently produce rhythmic signals as a product of their dynamics and include spike-frequency adaptation, slow inhibition, rhythmic external input, and slow neuronal currents. Synchronizing mechanisms promote coordinated activity and include inhibitory feedback, non-rhythmic external input, and recurrent excitatory connections. Some circuit components can provide both resonance and synchronization.
We found the most robust rhythm generation to require at least one resonant component and one synchronizing component. We found that pyramidal cells adaptation can interfere with theta produced by slow inhibition, and fast inhibition can either substitute for or interfere with rhythm generation by slow inhibition, depending on the cholinergic state. These results begin to shed light on the conflicting evidence produced by studies inactivating circuit components, and also predicts circuit states where inactivating a component known to participate in rhythm generation might paradoxically enhance rhythmic activity. We conclude that effects of component inactivation can only be predicted in the context of what other components are present and on the neuromodulatory state of the circuit.

Title: Do ethological differences between species shape neural mechanisms in the hippocampus?

Authors: *S. L. DUNN[1], S. M. TOWN[1], J. K. BIZLEY[1], D. BENDOR[2]
[1]Ear Inst., [2]Inst. of Behavioural Neurosci., UCL, London, United Kingdom

Abstract: The hippocampus is a brain region with important roles in memory and spatial navigation, which is positioned at the confluence of many streams of multimodal sensory processing. In rodents, this information is used to create a representation of the current environment. The hippocampal local field potential (LFP) gives insight into how the hippocampus processes information to create this representation. For example, theta oscillations (5-12Hz in the rat), represent a well-defined network state during which sensory information is thought to enter the hippocampus. Oscillations such as theta play a critical role in many hippocampal models of memory and spatial navigation. However, these models are based almost exclusively on rodent studies, and it remains an open question whether the specific ethological constraints of the rodent shape these neural mechanisms. Rodents primarily rely on the proximal sensing strategies of sniffing and whisking, so their sensory world is closely tied to their current location. In species where distal sensing is more dominant, activity in the hippocampus is not always consistent with the rodent data. We have recorded hippocampal LFP in the rat and the ferret (*Mustela putorius*), a predatory carnivore that relies predominantly on distal senses, to investigate the impact of ethological differences on hippocampal processing. We have identified theta oscillations in the ferret hippocampus which occur at a 3.5-7.5 Hz, a lower frequency band than commonly observed in the rat. Ferret hippocampal theta showed a positive correlation with the animals' speed, however the gradient of this relationship was roughly half that found in the rat over the same speed range. Rats and ferrets were trained on comparable auditory/visual localisation tasks designed to manipulate sensory attention. While theta activity was greatly diminished in rodents during immobility, we observed robust theta activity in ferrets during the entire behavioural task, including periods of immobility.

Title: Discrete structure of the brain rhythms

Authors: *Y. A. DABAGHIAN[1], L. PEROTTI[2]
[1]Neurol., Univ. of Texas at Houston, McGovern Med. S, Houston, TX; [2]Physics, Texas Southern Univ., Houston, TX

Abstract: Neurons in the brain are submerged into oscillating extracellular potential—Local Field Potential (LFP), which is one of the principal determinants of the brain activity and a key component of many neurophysiological mechanisms. Our understanding of the LFP's structure and of its physiological functions depend on the mathematical approaches used for its analysis. Most current signal decomposition methods are based on formal decompositions (sinusoids, wavelets, etc.), and the goal of the subsequent analysis reduces to identifying the combination that reproduces the original signal as closely as possible. Since all decompositions are mathematically complete and useful in their own way, it may appear that the question about the "actual" structure of the signal is of little importance if not at all meaningless. However, this is not the case: for as long as the physiological mechanisms of the LFP oscillations remain unknown, the search of a physically adequate description of their structure remains a matter of fundamental importance.
We propose a novel approach to analyzing biological signals, in which the signal's prime components are not *a priori* presumed, but discovered empirically. By applying this method to the analysis of the hippocampal "brain waves" we demonstrate that these signals decompose into a superposition of a few phase modulated oscillatory processes, which we call the oscillons. Since oscillons emerged as a result of *empirical* data analysis, we hypothesize that they represent the actual, physical structure of synchronized neuronal oscillations, whereas Fourier-defined brain waves are nothing but poorly resolved oscillons. In particular, there is a single discrete θ-oscillon that corresponds to the standard θ-rhythm and a couple of γ-oscillons that correspond to slow and fast γ-rhythms, and so forth. Proving this hypothesis will advance our principal

understanding of the biological oscillations and help to connect the experimental data with computational models of the neuronal synchronization.

Title: Cortico-hippocampal gene expression following rTMS in rats is dependent on age and cognitive status

Authors: M. WEILER[1], K. C. STIEGER[2], *J. M. LONG[2], E. LEHRMANN[2], Y. ZHANG[2], K. G. BECKER[2], P. R. RAPP[2]
[1]Natl. Inst. on Aging, NIH, baltimore, MD; [2]Natl. Inst. on Aging, NIH, Baltimore, MD

Abstract: Repetitive transcranial magnetic stimulation (rTMS) is FDA-approved for the treatment of pharmacologically refractory depression, and there is increasing interest in potential application for neurodegenerative disease, substance abuse, and other conditions. Although the molecular basis is largely unknown, considerable evidence indicates that the effects of TMS are 'state-dependent', raising the possibility that age and cognitive status might differentially affect the neurobiological response to rTMS. Using genome-wide microarray, we investigated the effects of rTMS on hippocampal and neocortical gene expression in young and behaviorally characterized aged Long-Evans rats. Spatial memory was assessed in a standardized Morris water maze protocol and aged rats were classified as Aged-Impaired (AI) or Aged-Unimpaired (AU). A total of 24 animals were examined: 4 Young/stimulated, 4 Young/sham, 5 AU/stimulated, 4 AU/sham, 3 AI/stimulated and 4 AI/sham. rTMS was implemented using a "MagStim rapid" stimulator and a 70mm figure-of-eight coil (MagStim Company Ltd.). Rats were anesthetized (dexmedetomidine, 0.03 and 0.035 $mg.kg^{-1}$ aged and young animals, respectively) and received intermittent theta burst stimulation (iTBS; 600 pulses applied as bursts of 3 pulses, 50Hz, repeated at 5Hz as 20 trains of 2s repeated at intervals of 10s). This pattern was repeated 5 times at 15 min intervals. Stimulus intensity was individually adjusted, just below the threshold for evoking visible neck muscle activity (11-20% machine power). Forty-eight hours after rTMS or sham treatment, cortical and hippocampal samples were microdissected and subsequently analyzed using Agilent rat whole genome microarrays. iTBS significantly altered cortico-hippocampal gene expression, with almost no overlap in the profile of specific genes affected in Y, AU and AI brains. In addition, the number of genes affected was far greater in the

Y group (cortex: 56 genes upregulated and 58 downregulated; hippocampus: 72 genes upregulated and 28 downregulated), followed by the AU (cortex: 6 genes upregulated and 22 downregulated; hippocampus: 1 gene upregulated) and AI (cortex: 1 gene upregulated and 6 downregulated; hippocampus: 6 genes upregulated and 6 downregulated). Our results highlight not only the divergent effects of TMS as a function of chronological age, but also that age-related cognitive impairment represents a distinct condition differentially affected by TMS. The neurobiological mechanisms responsible for the therapeutic effects reported in the growing clinical application of rTMS, including Alzheimer's disease, merit careful investigation.

Title: D-cycloserine enhances location specificity of CA1 place cells by enhancing signal-to-noise ratios and transiently increasing theta cell activity

Authors: *P. J. NGUYEN-LEE[1], C. HACKER[2], L. T. THOMPSON[2]
[2]Neuroscience, Behavioral & Brain Sci., [1]Univ. of Texas At Dallas, Richardson, TX

Abstract: Place cells exhibit stable location-specific firing in discrete locations in an environment, and fire at lower (often zero) rates in other locations and environments, forming a cognitive map linking locations and events in space. Hippocampal theta cells provide feedback and feedforward inhibition to CA1 place cells, helping regulate their excitability. Previous studies from our lab have demonstrated that D-cycloserine (DCS), an NR1 partial agonist, has nootropic effects, facilitating both spatial maze learning and rabbit trace eyeblink conditioning at a dose of 6 mg/kg in young animals. Our objectives here were to 1) investigate the effects of DCS on in-field and out-field firing rates of hippocampal place cells, and 2) investigate the effects of DCS on theta cell firing in rats actively exploring a radial-arm maze.
Young male and female FBN hybrid rats were trained to sample all maze arms within 5 min sessions using droplets of chocolate milk as incentives. Trained rats were stereotaxically implanted with chronic implants consisting of 4 microdrivable tetrode bundles over dorsal CA1. Baseline recordings were used to evaluate stability of place cell and theta cell waveforms and firing. In a blind fashion, rats were given either DCS (6 mg/kg) or equivolume PBS. Immediately

post-injection, recording sessions on the maze assessed unit activity every 15 min for the first 2 h, every 30 min up to 4th h, and then at the 6th, 12th, and 24th h post-injection. To classify place and theta cells, activity was sampled using a Plexon MAP system, and clustered with an agglomerative sorting algorithm verified by visual inspection. Spatial location histograms for aggregate spike counts and firing rates were then computed to quantify in- and out-of-place-field firing and theta cell firing over time.
Our results show that DCS decreased place cell firing, with out-of-field firing rates decreased more than in-field, and theta cells showed increased firing rates. DCS effects on unit activity persisted less than 4 h in behaving rats. The net effect was a sharpening of place fields, with enhanced signal-to-noise ratios, the converse of the impact of advanced age on place cell firing characterized by broader poorly tuned place fields. The net effect of DCS is consistent with nootropic effects in spatial memory tasks.

Title: Hippocampal slow and fast gamma rhythms correlate differentially with successful memory performance in a goal-directed spatial memory task

Authors: *C. ZHENG[1,2,3,4], L. L. COLGIN[3,4,5]
[1]Acad. of Med. Engin. and Translational Med., [2]Dept. of Biomed. Engin., Tianjin Univ., Tianjin, China; [3]Ctr. for Learning and Memory, [4]Dept. of Neurosci., [5]Inst. for Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: Hippocampal gamma rhythms are thought to play a role in memory processing by coordinating the activity of distributed neurons that code related information. Increasing evidence in behaving rats suggests that slow (~25-55 Hz) and fast (~60-100 Hz) gamma rhythms reflect functionally distinct states of the hippocampal network. We have previously shown that place cell ensembles code spatial information differently during slow and fast gamma, with relatively long paths represented in a temporally compressed manner during slow gamma and ongoing trajectories accurately followed in real-time during fast gamma. However, the relevance of these different firing modes to memory performance remains unclear. In this study, we used a delayed match-to-sample circular track task to test whether different place cell representations

during slow and fast gamma are related to goal-directed spatial memory. Place cell ensemble activity and local field potentials were recorded in hippocampal subfield CA1 in 4 rats. Behavioral trials consisted of a sample phase in which a reward location was indicated by cues and a test phase in which rats were required to recall the reward location from memory. A Bayesian decoding approach was used to continuously decode place cell ensemble activity in each trial and showed that predictive firing representing paths toward the reward location by place cell ensembles developed with learning. Also, in later trials, place cell ensemble activity predicted locations where rats stopped for both correct and error trials. Furthermore, across correct trials, fast gamma power was significantly increased during the sample phase, and slow gamma power was significantly enhanced during the test phase. On the other hand, slow gamma power in the sample phase of error trials was significantly higher than slow gamma power in the sample phase of correct trials. These results suggest that slow and fast gamma support memory retrieval and memory encoding, respectively, and raise the possibility that slow gamma interference with fast gamma-associated memory encoding relates to errors in memory performance.

Title: Preferential reactivation of CA3 place cells representing a novel experience during post-learning sleep

Authors: *E. HWAUN, L. L. COLGIN
UT Austin, Austin, TX

Abstract: A popular model of memory consolidation posits that recent memories stored in the hippocampus are reactivated during sleep and thereby transferred to neocortex for long-term storage. This process is thought to take place specifically during sharp wave-ripples (SWRs) in non-rapid eye movement (NREM) sleep. To reduce redundancy in memory storage, one would expect that recent memories containing novel information are preferentially reactivated and consolidated. Indeed, a previous study has shown enhanced reactivation of neurons in hippocampal subregion CA1 during awake SWRs in novel environments (Cheng and Frank 2008). But whether this enhanced reactivation persists into subsequent sleep and manifests as

replay of novel experiences remains unknown. In addition, hippocampal memories are thought to be stored in the recurrent collateral system of CA3, yet it remains unclear whether novelty-selective reactivation occurs in CA3. To address these questions, we recorded place cells in CA3 as rats were exposed to a familiar and a novel environment and during the subsequent night's sleep. At the individual cell level, our data suggest that CA3 firing rates during SWRs in NREM sleep increased in a novelty-dependent manner. Moreover, we observed novelty-dependent decreases in CA3 place cell firing rates during REM sleep, potentially supporting a homeostatic role for REM sleep. At the population level, ensembles of CA3 place cells during NREM sleep replayed trajectories from the novel environment with higher fidelity than trajectories from the familiar environment. Together, these results support the hypothesis that CA3 representations of novel experiences are selectively reactivated during post-learning sleep.

Title: CA2 place cells remap in response to social olfactory stimuli

Authors: *A. J. MABLY[1], L. T. HEWITT[2], L. L. COLGIN[3,1,2]
[1]Ctr. for Learning and Memory, [2]Inst. for Neurosci., [3]Dept. of Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: Several reports have implicated hippocampal subfield CA2 in social memory. A recent study showed that place cells in CA2, but not CA1, change their spatial firing patterns ("remap") during social interactions (Alexander et al., 2016). However, it was unclear whether these effects were specifically caused by social interactions or by associated sensory stimuli such as social olfactory stimuli. Here we show that CA2 place cells remap in rats interacting with a familiar rat's empty homecage. Such remapping did not occur in response to interactions with an identical cage containing clean bedding and no rat-associated odors. Our results suggest that CA2 place cells respond to the olfactory content of social experiences. Control experiments testing responses to odors unrelated to social stimuli will also be discussed.

Title: Persistent co-activity patterns of neurons in the medial entorhinal cortex across waking and sleep states are not explained by similar patterns of place cell co-activity

Authors: *J. B. TRIMPER[1], S. G. TRETTEL[2], E. HWAUN[3], I. R. FIETE[4], L. L. COLGIN[5]
[1]Neuroscience, Ctr. for Learning & Memory, The Univ. of Texas At Austin, Austin, TX; [2]Univ. of Texas at Austin, Austin, TX; [4]Ctr. for Learning and Memory, [3]UT Austin, Austin, TX; [5]Ctr. for Learning and Memory, Univ. of Texas At Austin, Austin, TX

Abstract: Multiple spatially selective subtypes of neurons, including head direction cells and grid cells, are found within the medial entorhinal cortex of rats and other species. The question of which mechanisms drive these neurons' activity patterns remains an area of active study. Continuous attractor network models posit that recurrent connectivity between grid cells controls their patterns of co-activation, whereas alternative models point to correlated inputs from sensory cortex or hippocampus. To clarify this issue, we recorded single units from the superficial layers (II/III) of the medial entorhinal cortex in six rats performing active exploratory behaviors and throughout subsequent overnight sleep. We found that the degree of spatial overlap between neurons' firing patterns observed during active waking behaviors predicted neuronal co-activity patterns during REM and non-REM sleep, when sensory inputs are absent. This relationship was observed for grid cell pairs from the same module, but not for grid cell pairs from different modules, further supporting recurrent connectivity as the mechanism for grid field formation. Through analyses of place cell recordings, along with modeling and simulations, we also found that medial entorhinal cell co-activity patterns were not explained by similar place cell activity patterns. These results suggest that, barring grid-like structured input from other cortical areas, local recurrent connectivity drives the co-activity of spatially selective cells in the superficial layers of medial entorhinal cortex across behavioral states.

Title: Maturation of hippocampal oscillatory activities during Barnes maze navigation in the juvenile rat

Authors: *D. G. MCHAIL[1], R. H. OGOE[2], C. KIMBALL[1], T. C. DUMAS[2]
[2]Psychology, [1]George Mason Univ., Fairfax, VA

Abstract: Spatial navigation is a critical cognitive ability, yet the supporting neural mechanisms are not well understood. The hippocampus is a forebrain structure in mammals that is necessary for spatial cognition. One emerging approach to better understand how the hippocampus subserves spatial navigation is neurodevelopmental, relating changes in neuron function to changes in spatial behavior. In rodents, spatial navigation ability first emerges around three weeks of age. Also around three weeks of age in rodents, hippocampal excitatory synapses undergo changes in composition and function that facilitate the ability to induce long lasting changes in synaptic strength (Blair et al., J. Neuroscience, 2013; Stoneham et al., Biological Bulletin, 2013). It is not known how these synaptic changes relate to the development of hippocampal circuit processes, such as activity oscillations in the local field potential at the population level (e.g. theta, gamma, sharp-wave ripples) known to define functional states and coordinate activity of spatially tuned cells. Therefore, we used lightweight tetrode hyperdrives to record population neural activity from hippocampal area CA1 of rats younger and older than three weeks during performance in an adapted Barnes maze (McHail et al., Learning and Memory, 2018). Preliminary results suggest that theta, gamma, and SWRs are prominent during maze behaviors in both age groups, but their relationships to maze performance might differ with increasing age and accuracy of navigation to goal. Our findings suggest that alterations in population oscillatory activities mediate the postnatal development of hippocampal networks and maturation of spatial cognition and support this approach as a valuable tool to relate neural network operations to cognitive states.

Title: Thalamic reticular nucleus controls the gain of the head-direction signal

Authors: *A. J. DUSZKIEWICZ[1], E. BROWN[1], M. YAMASAKI[3], M. WATANABE[4], A. PEYRACHE[2]
[1]Montreal Neurolog. Inst. and Hosp., [2]Montreal Neurolog. Inst., McGill Univ., Montreal, QC, Canada; [3]Dept. of Anatomy, Fac. of Med., Hokkaido Univ., Sapporo, Japan; [4]Dept. of Anatomy, Fac. of Med., Hokkaido Univ. Sch. Med., Sapporo, Japan

Abstract: As we navigate the world, it is crucial to maintain a robust sense of where we are. Head-direction (HD) cells serve as the brain's internal 'compass' and each of them is tuned to the specific direction the animal is facing, independently of its location and ongoing behavior. The anterodorsal thalamic nucleus (AD) is a key relay of the HD signal. AD neurons seem to be reciprocally connected with the reticular nucleus (TRN) - an inhibitory thalamic nucleus believed to control the routing of sensory information. Recurrent inhibition is important in shaping attractor network dynamics and it may select subsets of neurons coding for the same direction. Therefore, although the HD signal itself may originate from subthalamic nuclei, the AD-TRN system may play a central role in its processing. Still, connectivity and functional importance of the AD-TRN circuit remain elusive. In order to characterize the functional significance of the AD-TRN circuit, we used a combination of high-density single unit recordings and optogenetic interrogation in freely moving mice, as well as anatomical tract tracing. We observed that TRN sends dense projections to AD and that the vast majority of AD neurons project to back to TRN. Preliminary electrophysiological-optogenetic analysis of this reciprocal connectivity indicates that TRN inhibition leads to global increase in peak firing rates of thalamic HD cells. Further studies will examine whether this gain control mechanism is dependent on the feedback from AD neurons to TRN.

Title: Thalamic nuclei are specifically entrained to hippocampal oscillatory dynamics

Authors: *G. VIEJO[1], G. BUZSAKI[2], A. PEYRACHE[3]
[1]Montreal Neurolog. Inst., Univ. McGill, Montreal, QC, Canada; [2]New York University, Sch. of Med., New York, NY; [3]Montreal Neurolog. Inst., McGill Univ., Montreal, QC, Canada

Abstract: The brain is organized in parallel and interacting loops that coordinate large-scale neuronal assemblies and support cognitive functions. The thalamus, a collection of anatomically separated nuclei, acts as an essential component of large-scale brain circuits, relaying sensory inputs to the cortex and mediating cortico-cortical interactions. Although thalamic nuclei have been intensively characterized at the anatomical and genetical levels, their in-vivo dynamics remain poorly described. Here, we provide an electrophysiological characterization of the anterior thalamus, a critical "hub" of the limbic system playing a central role in memory and spatial navigation. We demonstrate that neurons of different anterior nuclei, including the antero-dorsal (AD), antero-ventral (AV), and antero-medial (AM), are characterized by specific spike train dynamics. In addition, the entrainment of thalamic neurons to the two dominant oscillatory patterns of the hippocampus, sharp-wave ripples (SWRs) and theta oscillations are unique to each thalamic nucleus. Finally, we show how the response to SWRs and theta oscillations are intrinsically related and invariant, indicating that the responses result from specific anatomical pathway rather than different brain-state dynamics. Our results provide an essential description of the dynamical organization of the hippocampo-thalamic network, a critical step towards the understanding of how neuronal populations are coordinated in the limbic system.

Title: Psychophysics of political preferences mediated by information

Authors: *B. LU, J. ZIMMERMANN, P. W. GLIMCHER
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Unlike value-based decision-making, it is not immediately obvious that political decisions are made using some principled evaluation of alternatives that can be operationalized in the lab. Many scholars consider politics to be a privileged class of decision-making, much like religious beliefs, that defy logical thought processes. Since the mid-20th century, political science has tried to make sense of this behavior, first using normative economic and later decision theoretic models that have been of great use in neuroscience. One school of thought holds political awareness and exposure to new information as the key mediators to political preference change, whereas others emphasize the role of partisanship. Here, we developed a novel psychophysics task that orthogonalizes partisanship and information flow to evaluate the optimal conditions for preference change—one which renders political decision-making tractable to neuroeconomic-style analysis. Over 500 Amazon Mechanical Turk subjects and 100 traditional lab participants engaged in this task, which consists of making preference ratings on real proposed laws that have appeared before US Congress. Subjects first reported their preferences based solely on a synopsis of the proposal—subsequently they must reevaluate those preferences after learning about the true percent of Congressmen of each party that voted in favor of the proposed law. Proposals uniformly tiled the space of Democratic and Republican support and were controlled for their intrinsic perceived partisanship, i.e., the true levels of support for each bill were completely uncorrelated with participants' estimates of that support. Behavioral results among both study populations dichotomized the pool: roughly 50% of subjects exhibited robust preference changes (to one or both partisan signals) while the remainder did not. Neither trait-level political awareness nor partisanship alone account for this divide, which casts doubt on the established awareness model for political preference shifts. This result, persistent across repetitions, is key to ongoing functional imaging work that examines political preference representation in the brain. Previous studies report a common currency among neural correlates of economic value and this work will assess whether political preferences lie in this same axis.

Title: Psychosocial stressors promote opioid use by sharpening the neural representation of subjective value

Authors: *A. B. KONOVA[1], S. LOPEZ-GUZMAN[2,3], C. IFRAH[4], N. BANAVAR[2], K. LOUIE[2], J. ROTROSEN[5], P. W. GLIMCHER[2]
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY; [3]Sch. of Med. and Hlth. Sci., Univ. del Rosario, Bogotá, Colombia; [4]Univ. of Pennsylvania, Philadelphia, PA; [5]Psychiatry, New York Univ. Sch. of Med., New York, NY

Abstract: Stress is a major impediment to recovery in mental illness. Treatment-seeking opioid users, for example, experience frequent and intense psychosocial stress that limits their capacity to abstain from drug use, leading to relapse, treatment dropout, and even death. However, how psychosocial stressors bias behavior toward rewarding but overall less adaptive alternatives (e.g., opioid use) and away from an individual's health goals is poorly understood. Here we test the hypothesis that underlying this bias is a stressor- and anxiety-related adaptation of the brain's subjective valuation (SV) system. Method: We studied 87 chronic opioid users seeking medication-assisted treatment. Patients completed up to 15 sessions (762 in total). At each, we probed recent notable life events via interview, state anxiety, and opioid use (by self-report and urine drug screens). Text analysis of all interview reports was used to determine the relevant psychosocial domains in which our sample reported life events, and the presence/absence of recent positive/negative events in each domain was coded for each session. A subset of 17 patients (7 scanned 2x) additionally completed 1 h fMRI scans during which they made financial decisions in two economic tasks. We modeled choice behavior on the tasks to extract estimates of trial-by-trial SV for each patient. To quantify how recent psychosocial stressors and state anxiety affect the neural representation of SV, we examined their effect on SV coding in striatum, VMPFC, and amygdala, defined based on meta-analytic data on value and stress. Results & Conclusions: Patients reported having experienced a recent negative event in the psychosocial domains of housing/financial or social/interpersonal in 26% of sessions and a positive event in 19% of sessions. The two event types, positive vs. negative, occurred independently of each other (P=0.77) and had differential effects on prospective opioid use, conferring either risk or resilience (adj. R^2=0.43, DF=744; negative events β=0.32, positive events β=-0.30). An increase/decrease in state anxiety mediated these effects (adj. R^2=0.67, DF=734; negative events β=2.52, positive events β=-1.67). Initial fMRI analyses showed that the higher state anxiety following recent negative events correlated with stronger SV coding in the amygdala (P=0.015) and VMPFC (P=0.12), revealing a potential mechanism through which psychosocial stressors can bias behavior toward rewards and consistent with the known effect of stress/arousal on neuromodulator systems. Current efforts focus on increasing our MRI sample size and testing how SV representations adapt over the hour long scans.

Title: Stress causes distinct time-dependent increases in reward valuation in the presence versus absence of explicit temptation

Authors: *C. M. RAIO, A. B. KONOVA, N. V. BANAVAR, P. W. GLIMCHER
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: States of stress and craving are both thought to play a critical role in driving reward pursuit in ways that are important in addiction. However, it is unclear whether these constructs influence reward valuation in similar ways (e.g., by both increasing the subjective value of rewards), or a distinct manner (e.g., by stress rendering individuals more susceptible to cues that induce craving without affecting reward valuation via a second mechanism). The goal of this study was to identify the specificity and independence of stress and craving effects on the valuation of primary rewards, and to characterize how these effects evolve over time. Healthy, hungry non-dieters were randomly assigned to a Control (n=30), Stress (n=30), or Stress+Craving (n=37) group. All participants completed an economic decision-making task in which they reported their willingness to pay ($0-$10) for the opportunity to purchase food items. These 'bids' were placed continuously for different quantities of each snack, allowing us to capture dynamic changes in participants' subjective value of food rewards over time. Bids were realized using a standard economic (Becker-Degroot-Marschak) auction procedure at a fixed low hazard rate. After baseline bids were acquired, participants either underwent a physiological stressor (Stress and Stress+Craving group) or a control task (Control group), before completing the bidding task. After the stress task, the Stress+Craving group additionally completed a cue-induced craving manipulation with one of the foods based on previous work (Konova et al., 2018). Saliva samples were collected to assess neuroendocrine markers of stress. Perceived stress and salivary cortisol were greater in both stress groups compared to controls. Bids did not differ between groups at baseline, however, after their respective manipulations, the stress groups demonstrated a marked increase in bids relative to controls. Interestingly, these effects unfolded

differently over time: whereas the Stress+Craving group showed an immediate increase in bids, the Stress group showed an increase in bids progressively over time, peaking only toward the end of the task. In contrast, bids in the Control group consistently decreased over time. Our results suggest that both acute stress exposure and cue-induced craving enhance the subjective value of food rewards, but that these effects emerge with distinct temporal profiles. These findings provide important insight into maladaptive choice behavior spanning addiction, anxiety and health behavior more generally.

Title: Collaboration and optimization in the personality game

Authors: *K. MOGI
Sony Comp Sci. Lab., Shinagawa-Ku, Japan

Abstract: Personality (Digman 1990, Shrout and Fiske 1995) is an important aspect of the robustness of human cognition, as it represents traits not optimized by simple evaluation function. In assessing human intelligence, the g-factor (Spearman 1904) provides the founding model, where it represents qualities and quantities of resources generically used in various different cognitive functions. Personality, on the other hand, cannot be accounted for as a single scheme of generic resource management. Personality is rather a complex scheme of context-dependent resource allocation in such diverse areas as academic performance (Poropat 2009), work achievements (Mount and Barrick 1998), and the tendency to innovate (Fairweather 2012), subserved by brain circuits correlated with the “big five” factors of personality (Kennis et al. 2013, Wei-Yin et al. 2013). Personality is a social construct formed through interaction among agents, where the self-evaluation of personality often contradicts with the perception of others. A personality game can be formulated, where there is a trade-off between adherence to one’s own assessments of personality and those by others, with the emergence of the Nash equilibrium (Nash 1950). Here I describe a game theoretic analysis of collaboration and optimization in the personality game. An interactive game of personality evaluation is introduced, within a group where there is a connected graph of acquaintances. Analysis of the data suggests that subjects are able to significantly predict how others would evaluate the personality of themselves, as distinct from their own perception of their personality ($p<0.001$). Subjects feel anxiety when there is a significant dissociation between own perception and evaluation by others in agreeableness

($p<0.01$). There are behavioral changes induced by the cognitive dissonance (Festinger 1957), where subjects tend to behave according to others' expectations on openness ($p<0.001$), conscientiousness ($p<0.05$), and neuroticism ($0<0.01$). These data suggest that personality is a social construct formed through collaboration and optimization in interpersonal contexts, leading to a Nash equilibrium.

Abstract: In social setting, social signals such as reward to others often modulate one's own reward valuation and decisions. However, the core computations of this process is still poorly understood: how social signal is converted into the self-oriented decision value. Here, we demonstrate the social value conversion process, using behavioral analysis, modeling and human fMRI. Our behavioral task involves three types of trials. Standard trials assess a basic decision process, in which the subject chooses between two options, each of which is associated with one's own probabilistic outcome (standard reward). Other-bonus trials examine social value conversion, in which a number in an option additional to standard reward indicates a bonus reward to others, while self-bonus trial is a control in which an additional number indicates a bonus to the self. Using logistic regression in the choice behavior, we quantified self- and others-bonus value and final decision value difference. These quantifications enabled us to analyze neural correlates of these bonus and decision values. Here, we show three-stage processing of

social value conversion from the offer to the effective value and then to the final decision value. First, a value of others' bonus on offer, called offered value, was encoded uniquely in the right temporoparietal junction (rTPJ), and also in the left dorsolateral prefrontal cortex (ldlPFC), commonly activated by offered self-bonus value. The effective value, an intermediate value representing the effective influence of the offer on the decision, was reprsented in right anterior insula (rAI), and the final decision value was encoded in ventromedial prefrontal cortex (vmPFC). Second, using psychophysiological interaction (PPI) and dynamic causal modeling (DCM) analyses, we demonstrated the three-staged feedforward processing; from the rTPJ and ldPFC to the rAI, and the rAI to the vmPFC. Further, we showed that these characteristics of social conversion underlie distinct socio-behavioral phenotypes. We demonstrate that the variability in the conversion underlie difference between prosocial and selfish subjects, differential emphasis of the rAI and ldlPFC coupling to the vmPFC responses, respectively. Together, these findings identified fundamental neural computation processes for social value conversion, which underlies more complex social decision-making behaviors.

Title: A model of reaching movements as a reflection of ongoing decision making

Authors: *N. J. WISPINSKI[1], C. S. CHAPMAN[2]
[1]Psychology, [2]Kinesiology, Sport, and Recreation, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Decision making is often conceptualized as a discrete stage in a serial process, occurring after perception but before movement planning. In contrast with this view, studies have shown that decision making can continue into movement to influence how we move in physical space. Perhaps the most notable example of the interaction between decision making and movement are "changes of mind", where participants initially begin moving toward one option before switching their movement in-flight toward an alternative option in light of new information. Previous models explain changes of mind as a discrete switching between straight

reaches toward each available option. However, these models cannot account for results such as intermediate reach trajectories when participants are indecisive. Here, we propose a new computational model and argue that decision making is better conceptualized as an ongoing and graded competition between parallel movement plans, gated by a decision about when to begin moving. This model builds on a conventional evidence accumulation process, adding a second set of mutually inhibited “motor” accumulators. These “motor” accumulators weight competing direction vectors (or reach angles) toward or away from each available option, and result in a single, prepared reach angle at every time step. When the conventional accumulation process crosses a decision threshold, a movement is initiated and prepared reach angles, which have been continuously updating, now guide actual movement. This model is able to explain reaction times, choices, changes of mind, and individual reach trajectories in a simple value-based decision making task. Further, as a result of its core mechanism—approach or avoid movement directions proportional to their current desirability—this model can generalize to account for many movement trajectories in go-before-you-know and obstacle avoidance tasks. These findings provide a simple formalization for the powerful idea that decisions are the result of ongoing, graded competition between multiple motor plans from stimuli onset to movement completion.

Title: Estimating the costs of cognitive control: Theoretical validation and potential pitfalls

Authors: *S. MUSSLICK[1], J. D. COHEN[1], A. SHENHAV[2]
[1]Princeton Univ., Princeton, NJ; [2]Brown Univ., Providence, RI

Abstract: Cognitive control is critical for accomplishing daily tasks and yet we experience it as costly/effortful. Researchers have been increasingly interested in estimating just how costly cognitive control is for a given individual, in order to better understand underlying mechanisms and predict motivational impairments outside the lab. Here we leverage an economic model of control allocation to (a) demonstrate how an individual's control cost function can be estimated from task performance and (b) highlight the conditions under which such costs will be confounded with other motivational variables (e.g. sensitivity to reward). We show that poorly calibrated estimates of these other variables can lead to cost estimates that are quantitatively or even qualitatively different than their true values.

We simulated agents performing cognitive control tasks while trying to maximize expected returns and minimize control costs (Musslick, Shenhav, Botvinick & Cohen, 2015, RLDM). We then tested our ability to recover the agent's (known) control cost function based on observed task behavior, as we varied other internal variables describing how the agent processes their environment: task automaticity (quality of task performance in the absence of cognitive control), control efficacy (degree to which increased control increases the likelihood of reaching one's goal), reward sensitivity (utility of monetary rewards), and accuracy bias (intrinsic reward for performing accurately). We then tested our ability to accurately recover an agent's true control costs as our assumptions about these other parameters deviated from their actual values.
When assuming perfect knowledge of the other internal variables (task automaticity, etc.), our estimation procedure successfully recovered the control cost function for the agents. However, if we assumed imperfect knowledge of these variables, the inferred control cost estimates rapidly deviated from their true values. Critically, they could even produce a cost profile for the individual opposite to the ground truth. For instance, an agent with a high cost of control appeared to instead have a low cost of control if the agent was high in task automaticity.
Our findings show that individual differences in the costs of control can be inferred from an individual's behavior, but the validity of those estimates depends heavily on an experimenter's ability to estimate other cognitive/motivational variables. More generally, they provide a method for quantifying limits on the validity of a given measure of task performance (e.g., Stroop interference) as an individual difference measure for a given cognitive variable.

Title: Smooth pursuit eye movements as dynamic readout of reward-based target selection in healthy and Parkinson’s disease participants

Authors: *A. MONTAGNINI[1], J.-B. DAMASSE[2], G. K. MANN[3], C. B. JONES[4], M. J. MCKEOWN[4], M. SPERING[3]
[1]Inst. de Neurosciences De La Timone, CNRS & Aix-Marseille Univ., Marseille, France; [2]Inst. de Neurosciences De La Timone, CNRS and Aix-Marseille Univ., Marseille, France;

[3]Ophthalmology & Visual Sci., [4]Dept. of Medicine, Div. of Neurol. and Ctr. for Brain Hlth., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The efficient selection of one out of several options relies on the estimate of the consequences of this selection, such as a reward or a punishment. The Iowa Gambling Task (IGT, Bechara et al., 1994) has been widely used to test reward-based decision-making performance, when the selection of each particular target was associated to a stochastic reward schedule with varying global payoffs. The IGT has allowed unveiling specific deficits in Parkinson's Disease (PD) patients. Voluntary eye movements efficiently adapt to the contextual requirements in humans, including reward contingencies, under several experimental conditions. Work from our group and others demonstrates that when tracking a visual moving target, smooth pursuit eye movements are dynamically modulated by reward in the very early phases, including prediction-driven anticipation (Damasse et al., 2018). Here we designed a novel smooth pursuit task inspired by the IGT where participants had to track one of two moving targets associated with different schedules of monetary gains or losses. In the main experiment, each target's direction was associated either with a globally advantageous (yielding an overall gain across trials), or disadvantageous (yielding an overall loss) schedule. In the baseline condition, the target to be tracked was explicitly instructed (e.g. "Follow the black target") and the overall monetary gain did not depend on the oculomotor performance. Participants were patients diagnosed with Parkinson's disease (PD), tested both ON and OFF Dopamine medication. We also tested age-matched and young healthy controls. We analyzed reward-based pursuit behavior during different epochs, namely the anticipation phase preceding target motion onset, the visually-guided initiation (which typically follows the vector-average of the two motion signals - Joshua and Lisberger, 2011), and the steady-state tracking phase. In young controls, but not in the other groups, smooth eye movements were dramatically biased, in the main experiment, toward the selected direction, both during the anticipatory epoch and the vector-averaging initiation. PD patients' and age-matched controls' eye movements did not express target selection until after the vector-average phase, about 300ms after target motion onset. Finally, during the late pursuit epoch, PD patients showed larger instability and more frequent *changes of mind* about which target to be tracked. Overall our results point to significant differences across experimental groups in target selection during different time epoch of a reward-based choice-pursuit task.

Title: learning from reward feedback in high-dimensional environments

Authors: *S. FARASHAHI, V. NOMOF, Z. ASLAMI, A. SOLTANI
Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Learning from reward feedback can become extremely challenging in high-dimensional environments with myriad choice options each with many features (curse of dimensionality), as it is the case in the real world. One solution for the curse of dimensionality is to learn reward values of individual features and combine these values to estimate reward values for each option (feature-based learning) instead of learning the value of individual options directly (object-based learning). We have hypothesized that this feature-based learning occurs not just because it can reduce dimensionality, but more importantly because it is faster and therefore more adaptable. Based on this hypothesis, we have recently proposed a framework for learning in high-dimensional environments for which we provided some experimental evidence (Farashahi et al., 2017). This framework also predicts that if the environment is stable (reward values associated with different options do not change very often), the decision maker may gradually learn the reward values of conjunctions of features as a compromise between fast but less accurate feature-based learning and slow but more accurate object-based learning. Here, we tested this prediction in an experiment in which human subjects selected between pairs of visual targets (27 objects defined by three visual features: color, pattern, and shape) and received binary reward feedback on every trial. The reward probability on a given option was determined by the combination of all features whereas one "informative" feature and the conjunctions of the other two "uninformative" features could predict reward probabilities to some extent. We found that majority of subjects learned the informative feature first before learning about the conjunctions of the uninformative features. This was reflected in choice behavior (as revealed by fitting of subject's choices) as well as estimates of reward probabilities. Interestingly, we also found that subjects who only learned individual feature values attributed reward outcomes to the informative feature at the expense of non-informative features. Specifically, these subjects increased (decreased) their tendency to choose objects that shared the same informative features as the rewarded (unrewarded) objects on the previous trial but did the opposite for the non-informative features. Overall, these results suggest that learning about conjunctions of features and competitive associations of reward to individual features (e.g. via attentional selection) can provide plausible mechanisms for adaptive learning in high-dimensional environments.

Title: Towards a neurometric-based construct validity of trust

Authors: *P.-H. A. CHEN[1], D. S. FARERI[3], B. GÜROğLU[4], M. R. DELGADO[5], L. J. CHANG[2]
[1]Psychological and Brain Sci., [2]Dartmouth Col., Hanover, NH; [3]Psychology, Adelphi Univ., Garden City, NY; [4]3Leiden Univ., Leiden, Netherlands; [5]Dept Psychol, Rutgers Univ. Newark, Newark, NJ

Abstract: Trust is a nebulous construct central to successful cooperative exchanges and interpersonal relationships. In this study, we introduce a new approach to establishing construct validity of trust using "neurometrics". In study 1, we combine data from two studies (n=40) to develop a whole-brain multivariate pattern that can classify whether new participants will trust a relationship partner using a linear support vector machine combined with leave-one-subject-out cross-validation. Our trust signature was able to successfully discriminate decisions to invest compared to keep money with 74% accuracy ($p < 0.001$). In study 2, we find that the pattern can accurately discriminate trust decisions with an accuracy of 68% ($p < 0.001$) in participants collected in a separate country (n=17) demonstrating generalizability of the pattern. In study 3, we establish construct validity by testing the pattern on ten separate datasets measuring distinct psychological processes. We find that our trust signature can successfully discriminate safe compared to risky decisions (accuracy = 93%, $p < 0.001$) and viewing neutral images from those depicting negative arousing scenes (accuracy = 65%, $p < 0.001$). This is consistent with the notion that trust involves an expectation of reciprocation by a relationship partner to avoid negative betrayal experiences. Moreover, we find that the signature does not generalize to reward, social closeness, facial familiarity, cognitive control, self-referential processing, and language processing indicating that the pattern is highly specific. These results provide strong support for the use of "neurometrics" in identifying the psychological processes associated with a brain-based multivariate representation.

Title: Behavioral and neural evidence for quantum reinforcement learning during decision making

Authors: J.-A. LI, Z. WEI, *X. ZHANG
Univ. of Sci. & Technol. of China, Hefei, China

Abstract: Our daily decision making and judgement might obey quantum-like mechanisms. However, little is known about quantum characteristics of value-based decision (VBD) making. In the present study, we applied quantum reinforcement learning (QRL) to determine whether VBDs can be properly explained by quantum framework and how this framework is implemented in the brain. We compared several QRL models (Quantum-Superposition-state-Learning , QSL; Quantum-Superposition-state-Plus- Perseverance, QSPP) and classical reinforcement learning (CRL) models (Value-Plus-Perseverance with decay learning rule, VPPDecay; VPPDelta; etc.) based on behavioral and functional magnetic resonance imaging data from healthy and smoking subjects performing the Iowa Gambling Task (Fig. 1a). We executed the model comparisons based on Akaike and Bayesian information criterion (AIC and BIC) and simulation method and analyzed the entropy and the interaction of entropy and loss predicted by VPPDelta and QSPP based on the blood oxygen level dependent data in both groups. In the behavioral analysis, QRL models provided post hoc fits (Fig. 1b) and simulation better than or comparable to CRL models in both groups. In the fMRI analysis, for the interaction of entropy and loss, we found that the left medial frontal gyrus (MFG) was activated in QSPP but not in VPPDelta in both groups (Fig. 1c), and a set of regions, notably the left anterior cingulate cortex (ACC) and the left orbital frontal cortex (OFC) (Fig. 1d), were activated in QSPP in control group but not in VPPDelta or in smoking group. The behavioral results indicate the QRL method is a powerful quantum framework to describe behavior sequences. These regions which related to the interaction of entropy and loss, including the MFG, the ACC and the OFC, might work as a network in a quantum-like manner, integrating outcomes and learning from experience. In addition, these results provided the first fMRI evidence for quantum

cognition. We anticipate this study will lend support to the fields of quantum cognition and open up a new direction termed as quantum neuroeconomics.

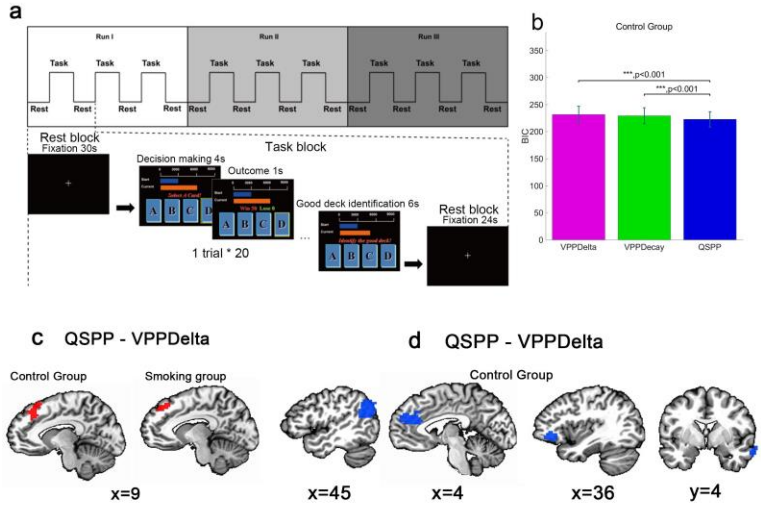

Figure 1: a, a diagram of the IGT and fMRI scan processes. There were three fMRI scan runs of 7 min. Between every two scans, an interval occurred about 1 min. Each scan consisted of one 30s rest block and three 106s-task-and-24s-rest cycles. The last 6s part of task block was designed for good deck identification, which was not analyzed in current paper. The former 100s part contains 20 trials and each trial was divided into two events: (1) during the decision making phase, 4s were provided for card selection and the program would make a random selection if no decision was made during the period, (2) during the outcome phase, the gain and loss were presented on the screen for 1s. There was no inter-trial intervals(ITIs). The blue bar above the decks showed the initial 3000 points throughout the task, and the orange one showed the current accumulated points. b, model BIC results of VPPDelta, VPPDecay and QSPP in control group. QSPP had better fits than other models. All error bars indicate the SEM. c-d, fMRI results of the entropy × loss interaction. c, the interaction positively related to the left medial frontal gyrus (MFG)/superior frontal gyrus in both control group (control QSPP - control VPPDelta) and smoking group (smoking QSPP - smoking VPPDelta). d, the interaction positively related to the left middle temporal gyrus/superior temporal gyrus/angular gyrus, the left anterior cingulate cortex (ACC), the left orbital frontal cortex (OFC) and the right middle temporal gyrus/superior temporal gyrus only in control group (control QSPP - control VPPDelta). All coordinates are plotted in RAI (DICOM) order (-right +left, -anterior +posterior, -inferior +superior).

Title: Dynamic modulation of brain network integration and arousal during exploration and exploitation

Authors: *N. TARDIFF, S. L. THOMPSON-SCHILL
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Successful learning and decision-making require a balance between the stability necessary to support ongoing behavior and the flexibility necessary to adapt to new exigencies. Theories of norepinephrine (NE) function have ascribed it a key role in adjusting this balance. In particular, NE has been proposed to mediate the tradeoff between exploration and exploitation (Aston-Jones & Cohen, 2005). Alterations of cognitive state, in turn, appear to be supported by large-scale, dynamic changes in functional brain connectivity. For example, a number of studies have demonstrated that demanding tasks requiring stability are associated with increased integration among functional brain networks. Notably, recent neuroimaging studies provide evidence that NE influences the level of integration between functional brain networks, suggesting one route by which NE may alter the balance between stability and flexibility.
Here we utilized an exploration/exploitation task to probe the relationships between flexibility, NE-linked arousal—as measured indirectly via pupil diameter—and network dynamics. We predicted that network integration and pupil diameter would show opposing profiles around exploration, with pupil diameter increasing with exploratory choice and network integration decreasing. Subjects ($N = 19$, $M_{age} = 23$, 9 female) underwent concurrent fMRI and pupillometry while completing a bandit task, a type of task known to induce changes in NE activity as measured by pupil diameter. We parcellated the brain into 234 regions, estimated functional connectivity via wavelet coherence, and used a dynamic community detection algorithm to track changes in network architecture over time. At each time point, we calculated a measure of network integration, indexing the extent to which nodes from different resting-state networks were placed into the same community.
Supporting our predictions, we found that pupil dilation was larger following trials on which subjects explored, and this rise in pupil diameter was accompanied by a decrease in global brain network integration. Follow-up analyses of between-system integration revealed that frontoparietal-somatomotor, dorsal attention-somatomotor, and ventral attention-default integration showed the most reliable decreases. These data provide preliminary evidence that while task-focused states are facilitated by increased integration, exploratory states may be facilitated by less integration between functional networks.

Title: Expectations about the source of surprise dictate the relationship between feedback-related eeg signals and learning

Authors: *M. R. NASSAR[1], R. BRUCKNER[2], M. J. FRANK[3]
[1]Metcalf Hall, Brown Univ., Providence, RI; [2]Freie Univ. Berlin, Berlin, Germany; [3]Brown Univ., Brown Inst. for Brain Sci., Providence, RI

Abstract: Successful decision-making requires learning expectations based on experience. This learning should be calibrated according to the surprise associated with each outcome, but also to the most likely source of surprise. For example, when occasional change points are expected, surprising outcomes render past information irrelevant and demand increased learning. In contrast, when signal corruption is expected to occur occasionally, surprising outcomes can suggest a corrupt signal that should be ignored by learning systems. To explore whether and how the brain contextualizes surprise signals to optimize learning, we collected EEG and behavioral data in a task that required subjects to make inferences based on noisy observations of a process that included either change points or signal corruption. In change point blocks participants increased learning from surprising outcomes, whereas in the signal corruption blocks participants decreased learning from surprising outcomes. Thus the effects of surprise on learning depended on subjective expectations about the source of the surprise. Despite this behavioral interaction, feedback-related EEG signals related to surprise were agnostic to its source. A large positive medial prefrontal deflection peaking ~400 ms after outcome presentation was enhanced for surprising outcomes in both conditions equally. Computational fits to behavior showed that the impact of this signal on learning differed across conditions: larger EEG deflections predicted more learning in change point blocks but less learning in signal corruption blocks. Taken together these findings suggest that medial prefrontal surprise signals do not naively reflect increased behavioral updating, but may be used adaptively to modulate learning in either direction.

Title: A visual bandit task in mice reveals a female-specific strategy associated with enhanced acquisition of the optimal choice

Authors: *S. CHEN[1], B. EBITZ[2], J. JEONG[3], M. CHU[3], Z. MAHAMED[2], S. BINDAS[4], B. HAYDEN[2], N. GRISSOM[3]

Abstract: Neurodevelopmental disorders, such as autism spectrum disorders (ASD), have a strong male bias in diagnosis, and are associated with challenges in learning to predict positive outcomes of behavior. Do sex-specific mechanisms of goal-directed learning contribute to the male-specific vulnerability to ASD? One commonly used task, the multi-armed bandit, examines the dynamics of reinforcement learning and decision making, requiring a person or animal to choose each trial between exploitation of a previously experienced option, versus exploration of other options with unknown, but potentially more rewarding, outcomes. Visually cued bandit tasks have been widely employed in humans and nonhuman primates, but are largely unused in rodents. This has limited the ability to understand the neural mechanisms of complex reward environments in rodent models. We used a two-arm bandit task in thirty-two 129/B6 F1 mice (16 male and 16 female) to examine whether there are baseline sex differences in the ability to learning the reward probabilities associated with two visual cues presented on a touchscreen (80% chance of payoff versus 20%). Female mice learned to choose the cue associated with the higher probability of reward faster. A multiple linear regression analysis revealed that female mice relied more on spatial repetition in decision making at the early stage of learning, but switched from this strategy to using information of reward outcome of cues more rapidly than did male mice. We wished to examine neural mechanisms that might support these sex differences in strategy selection. Animals were sacrificed immediately following behavior on their final test day, and c-fos gene expression was used as a proxy for neural activity. In the nucleus accumbens, fos expression was more lateralized in females, while in males, fos expression was equal between left and right accumbens. This suggests that more lateralized activation of the brain in females may drive female-specific decision-making strategies that result in faster learning, and shed light on sex-specific mechanisms in neurodevelopmental disorders.

Title: Leaky-integrating dynamics, approximating Bayesian assumption of environmental non-stationarity (change points), outperform Q-learning (delta rule) in accounting for human prediction and choice behavior

Authors: *C. K. RYALI[1], A. J. YU[2]
[1]Computer Sci. and Engin., [2]Cognitive Sci., UC San Diego, San Diego, CA

Abstract: Understanding how humans and animals learn about statistical regularities in stable and volatile environments and utilize these regularities to make predictions and decisions is an important problem in neuroscience and psychology. Using a Bayesian modeling framework, specifically the Dynamic Belief Model (DBM), we previously showed that in many task contexts, human prediction and choice behavior reflects a default tendency to assume the environmental statistics to undergo abrupt, unsignaled changes from time to time, known as change points, even when the environmental statistics are actually stable. Here, we show that near-Bayes-optimal learning and prediction in the DBM setting can be implemented in a computationally inexpensive and neurally plausible manner by a special case of leaky integration dynamics, also known as exponential filtering (Exp). We show that Exp can predict human choice and prediction behavior in a 2-alternative choice task and a visual search task as well as DBM, and significantly better than either Q-learning (equivalent to the Rescorla-Wagner learning rule), or an alternative Bayesian model, the Fixed Belief Model (FBM), which assumes environmental statistics to be stable over time. Using the theoretical relationship we derive between DBM and Exp, we show that the advantage Exp enjoys over Q-learning and FBM is due to the "persistent" influence of the prior assumed by DBM/Exp, which is absent in Q-learning and FBM. Furthermore, we show that the theoretical equivalence between DBM and Exp breaks down when change points are rare, but this seems to be irrelevant in most behavioral tasks where observations are quite noisy since humans appear to assume frequent change points by default even when they are rare or even non-existent.

Title: Effective learning is accompanied by high dimensional and efficient representations of neural activity

Authors: *E. TANG[1], M. G. MATTAR[3], C. GIUSTI[4], S. L. THOMPSON-SCHILL[2], D. S. BASSETT[1]

Abstract: A fundamental cognitive process is the ability to map objects into meaningful categories depending on the task at hand. Exactly how such mental constructs emerge and what kind of space best embeds this mapping remains incompletely understood. Here we develop tools to quantify the space and organization of such a mapping, thereby providing a framework for studying the geometric representations of neural responses as reflected in functional MRI. Considering how human subjects learn the values of novel objects, we show that quick learners have a higher dimensional geometric representation than slow learners, and hence more easily distinguishable whole-brain responses to objects of different value. Furthermore, we find that quick learners display a more compact embedding of the task-relevant information, where the ratio of task-relevant dimension to embedding dimension is consistent with a greater efficiency of cognitive coding. Lastly, we investigate the neurophysiological drivers of high dimensional patterns at both regional and voxel levels, and complete our study with a complementary test of the distinguishability of associated whole-brain responses. Our results demonstrate a spatial organization of neural responses characteristic of learning, and offer a suite of geometric measures applicable to the study of efficient coding in higher-order cognitive processes more broadly.

Title: Reaction time in speeded decision processing: How stimulus predictability affects the emergence of 1/f noise

Authors: *P. ALEFANTIS[1], C. SIETTOS[2], N. P. SMYRNIS[3]
[1]Univ. Mental Hlth. Res. Inst., Athens, Greece; [2]Sch. of Applied Mathematics and Physical Sciences, Natl. Tech. Univ. of Athens, Athens, Greece; [3]Psychiatry Dept., Natl. and Kapodistrian Univesrity of Athens Med., Athens, Greece

Abstract: Measurement of Reaction Time (RT) in speeded decision processing tasks has shown a large intra-subject variability of RT (ISV-RT). Decomposing the frequency spectrum of the underlying time series of the RT have shown that ISV-RT may be rooted at a long memory process called 1/f noise. 1/f noise is theorized to be a characteristic signature for system complexity and has been associated with the most elementary aspect of cognitive process, the formation of representations. In this study we investigate how the 1/f noise measured using an 1-Back working memory task is affected by stimulus predictability. We used 6 different task conditions in which the inter-trial interval (ITI) was either fixed at 1s, or varied in a uniform distribution of ITI with a mean of 1s and range of .5, 1, 1.2 , 1.5, 2s respectively. The spectrum density of RT confirmed the presence of 1/f noise measured as a decreasing linear trend a in the log-log scale indicating higher power at long frequencies that was reduced in higher frequencies. More importantly this 1/f noise pattern (Alpha parameter) decreased significantly with increasing variability of ITI (see figure 1). These results suggest that the cognitive process of formation of stable representations over time during task performance implied by the presence of 1/f noise in RT is sensitive to stimulus predictability and is drastically reduced when the time of stimulus presentation becomes highly unpredictable. Alternatively the formation of stable cognitive representations seems to be facilitated by the rhythmic presentation of stimuli.

Title: Data-driven mapping of over 100 naturalistic tasks in the human brain

Authors: *T. NAKAI[1,2], S. NISHIMOTO[1,2,3]
[1]Ctr. for Information and Neural Networks (cinet), NICT, Osaka, Japan; [2]Grad. Sch. of Frontier Biosciences, Osaka Univ., Osaka, Japan; [3]Grad. Sch. of Medicine, Osaka Univ., Osaka, Japan

Abstract: The central issue in neuroimaging is to reveal how our daily cognitive processes are represented in the brain. The tasks generally used in standard neuroimaging studies have been far

from our daily activity, and may have not efficiently evoked cognitive processes in the naturalistic situation. It has also been unknown how cognitive processes underlying various daily activities are mutually related. To tackle these issues, we performed fMRI experiments for each subject with over 100 naturalistic tasks. By combining a data-driven mapping and interpretation based on the meta-data, we examined cortical organization of multiple naturalistic tasks.We prepared 103 naturalistic tasks, which can be performed without any pre-experimental training. Six participants (ages 22-33, 2 female) performed tasks while we recorded the evoked brain activity using a 3T MRI scanner (Siemens Trio TIM; TR = 2000 ms, voxel size = 2 mm isotropic, multiband factor = 3). The experiment was composed of 18 runs. Each run contained 77-83 tasks with duration of 6-12 s. We built a voxel-wise encoding model (R=FW), where R was brain activity, F represented 103-dimensional task-feature vectors (1/0 for each time point), and the weight matrix W was estimated using an L2-regularized linear regression. Model accuracy was calculated using Pearson's correlation coefficient between predicted and measured activity in the hold-out test dataset. To examine the dominant cognitive factors that underlie the activity patterns, we performed principal-component analysis (PCA) with the estimated weight matrix. The top PCs contrasted the tasks regarding their sensory factors such as auditory features (e.g., Music category judgment), and cognitive factor such as language features (e.g., Metaphor comprehension). Projections of the PC coefficients into the cortical space revealed that the auditory PC showed large weight in the bilateral temporal regions, while the language PC showed large weight in the bilateral fronto-temporal regions.To assess cognitive factors related to each PC, we calculated Pearson’s correlation coefficients between each PC map and the reference terms in Neurosynth (Yarkoni et al., 2011). The language PC map had higher correlation with the term ‘semantic’, and ‘sentence’, while the auditory PC map had higher correlation with the term ‘listening’, and ’sounds’.Using t-distributed stochastic neighbor embedding, we further found a distinct task distribution in the cognitive map, such that Shopping task was closely positioned to Money counting task. Our data-driven method provides a new insight into the cortical implementation of the cognitive map in the naturalistic situation.

Abstract: In social environments, expectation of reward for ourselves and associated decision-making often depend on others' behavior. Thus, our decision processes should include consideration about others' decisions. However, a fundamental of the computational process is still poorly understood: how humans integrate the prediction of others' behavior into self-oriented decisions. To address this issue, we devised a novel behavioral task in human fMRI, combined with computational modeling. In our task, there is a main trial together with two types of control trial, self and other trials. Main trial required the subject to choose an option, using the prediction of others' choice, because a set of options to choose depended upon the others' choice. Self and other trials examined each component in the main trial, which is making probabilistic self-value-based decisions and predicting others' decisions, respectively. Probing the behavior, we first confirmed that the subject's behavior followed self-value difference and predicted-others' value difference in the self and other trials, respectively. In the main trials, the subject's decision followed the self-value difference generated by predictions of others' choices. That is, the subject's choice was governed by a balance of the two possible self-value differences that corresponded to two different predictions of others' choices. The relative contribution of the two self-value differences varied along with the uncertainty in predicting others' choices. We then examined the BOLD signals, using model-based analysis. First, we found that activations in right temporoparietal junction (rTPJ) and medial prefrontal cortex (mPFC) were significantly correlated to prediction uncertainty of others' decision, so that at the group level, the individuals' higher activations in these regions are related to efficiency in using the prediction of others to guide their decisions. The activations in these regions are also significantly correlated to the predictions in both main and other trials. Second, we found that the mPFC responses are significantly activated by self-decisions in both self and main trials. Third, using psychophysiological interaction analysis, we found that the rTPJ activations had impact on the mPFC responses, only mediated through the responses in right inferior frontal gyrus. Taken together, these findings suggest that predicting about others' behavior recruits additional neuro-computational process for using the uncertainty in the prediction to integrate the prediction to generating self-oriented decisions.

Title: Dissociating conflict and uncertainty- An evidence accumulation model

Authors: *A. MANDALI, V. VOON
Dept. of Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Introduction: The likelihood of obtaining a reward (*uncertainty*) and the similarity between choices (*conflict*) critically influence decision making. Conflict and uncertainty are commonly confounded but can be dissociated. Here we study their interaction using a sequential learning task in healthy volunteers (HV) and patients (obsessive-compulsive disorder: OCD, alcohol dependent-AD), by posing it as an evidence accumulation problem.
Method: We defined 2 variables i.e., *Conflict*- high or low (difference between reward probabilities of the stimuli) and *Uncertainty*- low, medium or high (inverse U-shaped probability-uncertainty function). The above variables were used as inputs along with the behavioural data in a hierarchical drift diffusion model to extract threshold ('*a*'- amount of evidence accumulated before making a decision) and drift rate ('*v*'- information processing speed) parameters.
Results: Using the conflict information alone, we show that HVs distinguish low and high conflict by accumulating more evidence (*a*) during high conflict, which was absent in both OCD and AD patients. We then included both uncertainty and conflict in the model and showed a critical interaction between them. HV accumulated more evidence when stimuli were high conflict-certain compared to low conflict-certain. But when the choices were high conflict with no certainty in reward, they unexpectedly did the opposite i.e., accumulated significantly less evidence. In contrast, OCD patients accumulated more evidence in the high conflict-uncertain condition yet performed sub-optimally. ADs showed deficits in processing conflict with similar threshold and drift rates for both high and low conflict conditions.
Discussion: We show that the interaction between conflict and uncertainty critically influences the choice selection mechanisms through evidence accumulation. We also show that OCD patients perform sub-optimally in the presence of high uncertainty especially during difficult decisions with increased thresholds reflecting their indecisiveness and 'checking' symptomology.

Title: A divisive model of evidence accumulation explains unequal weighting of evidence over time in an auditory perceptual decision making task

Authors: *W. KEUNG, T. A. HAGEN, R. C. WILSON
Univ. of Arizona, Tucson, AZ

Abstract: Effective decision making often requires us to integrate noisy evidence over time. For example, when listening to a talk, ideally we would integrate evidence equally from all parts of the presentation - the beginning, middle and end - to assess the quality of the science. However,

in practice we often weigh information differently over time leading us to make suboptimal decisions. Here we refer to this suboptimal weighting of information over time as the "kernel" of integration. For example, overweighing the beginning of the talk indicates a primacy kernel, while overweighting the end indicates a recency kernel. Several studies have shown that integration kernels on the order of 1 second vary considerably between species and task design with evidence for primacy, recency and flat integration kernels all existing in the literature. In addition we have recently found evidence in humans for a "bump" integration kernel in which in which evidence from the middle of the stimulus is weighed most strongly (Keung et al 2018 bioRxiv). In the present work we show how all four of these integration kernels can be accounted for by a single neural network with divisive normalization. In particular, we adapted the dynamic divisive normalization model of Louie et al (2014) that has previously been used to describe choices and neural firing in value-based decisions (that do not involve temporal integration of evidence over time). In this network, evidence for competing choices is accumulated in pools of neurons that self excite and compete via divisive inhibition. We show theoretically how this network acts as an integrator, and provide a formal expression for the integration kernel over time. This expression shows how the model can generate all all four types of integration kernel observed in the literature (primacy, recent, flat and bump) providing a qualitative account for previous results. In addition the model provides a close quantitative fit to human behavioral data. Overall our model provides a unifying account of evidence integration across species and makes testable predictions at the neural and behavioral levels.

Title: A Bayesian model explains how individual and mutual properties of action and outcome affect sense of agency

Authors: *R. LEGASPI, T. TOYOIZUMI
RIKEN Ctr. for Brain Sci., Saitama Prefecture, Japan

Abstract: *Sense of agency* is fundamental to the experience of volition, self-consciousness and responsibility for one's own actions, and the degradation of this experience characterizes certain psychiatric disorders. We have introduced a theoretical model of sense of agency (Legaspi &

Toyoizumi, SfN 2017), which adapted the Bayesian inference model of Sato, Toyoizumi & Aihara (Neural Comp 2007) originally used to explain the *ventriloquism effect* as an effort to estimate a common cause behind the audio-visual stimuli. However, we have yet to explain through our model how action and consequent outcome signals, when each happens in isolation or interact with each other, affect the experience of agency.
Our Bayesian model exhibits the following requirements to experience a high sense of agency: (A) the perceived action-outcome pairing must be *consistent* with the causal role of one's action in producing the immediate outcome, and (B) the perceived action or outcome signals must be *reliable* when they happen in isolation, i.e., the amplitudes of sensory jitters must be small enough not to increase sensory uncertainty. Both (A) and (B) increase the confidence of the Bayesian estimate modeled as sense of agency.
The above predictions of our Bayesian model accounted for the *intentional binding effect*, hailed as the implicit measure of agency, in two pertinent studies. The first is the seminal experiment reported by Haggard, Clark & Kalogeras (Nature 2002) that showed voluntary actions produced intentional binding but involuntary actions produced the prolonged opposite perception of the action-outcome interval, which was accounted for by (A). The second study is by Wolpe, Haggard, Siebner & Rowe (Exp Brain Res 2013) that showed the contribution of sensory uncertainty to intentional binding by manipulating the intensity of outcome tones, which was accounted for by (B).
Moreover, we now observe our Bayesian model also predicts that a prior belief of the action causing the outcome can modulate sense of agency, hence, also influences intentional binding. The strength of this prior moves the perception of the action and outcome towards each other, and weakening it consequently diminishes the action-outcome effect similar to when their signals are perceived as unrelated. This accounted for both the repulsion effect from involuntary actions reported by Haggard et al. and the diminished action binding reported by Wolpe et al.

Title: Decomposing Simon task BOLD activation using a drift-diffusion model framework

Authors: *J. R. MCINTOSH, P. SAJDA
Dept. of Biomed. Engin., Columbia Univ., New York, NY

Abstract: The Simon effect is observed in spatial conflict tasks where the response time of subjects is increased if stimuli are presented in a lateralized manner so that they are incongruous with the response information that they represent symbolically. A limited number of studies have used fMRI to investigate this phenomenon, and while some have been driven by considerations of an underlying model, none have attempted to directly tie model and BOLD response together. It is likely that this is due to Simon models having been predominantly descriptive of the phenomenon rather than capturing the full spectrum of behavior at the level of individual subjects. Drift-diffusion models (DDM) which capture full response distributions for correct and incorrect responses have recently been extended to capture conflict tasks. In this study we fit a Simon-Effect DDM which includes specific estimates of automatic response bias and conflict monitoring based deployment of attention to individual subject behavioral data. Both of these parameters are needed because while a bias term captures the increased mean response time in incongruent trials, the attention term is needed to capture a compensatory decrease in the standard deviation.The expected decision-variable, across-trial model parameter modulations and overall parameter fits are used to interpret the BOLD response at multiple time scales. We find evidence of lateralized regions in visual cortex correlated with the decision-variable, with precuneus cortex being modulated by the expected decision-variable in conflict trials - a potential marker for conflict. We find neighboring regions of the precuneus are also correlated with across-trial fluctuations of drift or attention, and an across subject measure of bias. Taken together a potential interpretation is that precuneus is acting to locally monitor conflict which is then used by anterior cingulate cortex (ACC) in the deployment of attention to reduce the impact of lateralized stimuli on the representation of the decision-variable.
The model based analysis allows us to paint a rich picture of brain activity during spatial conflict tasks, with which we can in turn tease apart different patterns of activity which would be collapsed together with more standard analyses.

Title: Model-based quantitative analysis of two ‘guilt aversion’s

Authors: *S. NUMANO[1], M. HARUNO[2]
[1]Grad. Sch. of Frontier Biosciences, Osaka Uni, Suita-Shi, Japan; [2]Natl. Inst. of Information and Communication Technol., Osaka, Japan

Abstract: It has long been proposed that ‘guilt’ has strong impacts on our behavior and mental states. However, there are at least two definitions of ‘guilt aversion’. One definition of ‘guilt aversion’ is the propensity to avoid imbalance between self and other’s outcomes (inequity guilt-aversion), and the other is the propensity to minimize the difference between other’s expectation and his actual outcome (intention guilt-aversion). A previous study tried to distinguish inequity and guilt aversions, and showed that these two aversions are computed in different cortical areas (Nihonsugi et al., 2015). However, no study have attempted to dissociate the two guilt aversions. In this study, we approached this issue based on the large amount of behavioral and personality traits’ questionnaire data collected online.More than 7000 volunteers participated in the online experiments. First, participants answered 24 psychological personality questionnaires, such as Big Five personality trait and Beck Depression Inventory II (BDI). Then, they performed a trust game (Nihonsugi et al., 2015) which can measure both inequity and intentional guilt aversions as regression coefficients. We analyzed the data, based on the logistic model which consisted of three separate components: reward, guilt, and inequity. We examined correlations between the regression coefficients and the personality traits scores. We found significant correlation between intentional guilt and BDI (r=0.225 and P=0.003, linear regression), as well as the sex differences in both intention and inequity guilt-aversions (P=0.0114 and P=0.0028, respectively, Welch’s t-test) .

Title: Graph theory measures of functional connectivity in divergent and convergent thinking in "Big-C" creativity

Authors: *K. JAPARDI, A. ANDERSON, K. KNUDSEN, S. BOOKHEIMER, R. BILDER
Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA

Abstract: Objectives: Divergent thinking (DT) and convergent thinking (CT) are considered critical for creative thinking but the patterns of functional connectivity underlying these abilities remain unknown. The Big-C Study examined whether a “Big-C” (exceptionally creative) group and a smart comparison group: (1) display task-dependent group differences in functional connectivity across global and local graph theory metrics and (2) display significant group-by-network interactions across functional tasks. We hypothesized that Big-C individuals would

differ from the comparison group across graph theory metrics, showing greater network efficiency and highly clustered networks. Methods: We analyzed 66 participants including 21 Big-C visual artists (VIS), 21 Big-C scientists (SCI), and 24 smart comparison group individuals (SCG), matched on age, sex, and intelligence. Participants had fMRI scans during an Alternate Uses Task (AUT) and Remote Associates Task (RAT), to measure DT and CT respectively, and completed a six-minute resting state scan (REST). Analyses followed using a 333 ROI atlas using similar methods detailed in Power et al 2014 and Cole et al 2014. Graph theory metrics included modularity (Q), small worldness (SW), characteristic path length (CPL), local efficiency (EL), and clustering coefficient (CC). Local metrics were compared across six networks: default mode, dorsal attention, frontoparietal, salience, ventral attention, and visual. Results: Big-C visual artists and scientists, relative to SCG participants, displayed higher EL and CC in the visual network across multiple conditions, but Big-C visual artists showed lower EL and CC of the frontoparietal network at rest (See Table 1). Conclusions: Our findings are partially congruent with our initial hypothesis, suggesting that Big-C individuals differ from comparison individuals along network efficiency and clustering, but display similar global patterns of functional connectivity. These findings are also compatible with our hypothesis that Big-C creativity may rely on efficient visuospatial processing and disengagement of cognitive control.

Table 1: Group results for local efficiency and clustering coefficient. (df = 11,166; p < 0.001)

Metric	**Contrast**	**Task**	**Network**	***t-stat***
EL	VIS < SCG	REST	Frontoparietal	-3.77
EL	VIS > SCG	REST	Visual	4.5
EL	SCI > SCG	AUT Unusual Uses	Visual	4.26
EL	VIS > SCG	AUT Typical Qualities	Visual	3.65
EL	SCI > SCG	AUT Typical Qualities	Visual	3.76
CC	VIS < SCG	REST	Frontoparietal	-3.97
CC	SCI > SCG	AUT Unusual Uses	Visual	4.77

Title: Does seeing the world from the perspective of an autonomous vehicle alter the view of autonomous vehicles?

Authors: *J. PAK[1], C. WILLEY[2], N. AKRAM[2], U. MAOZ[3]
[1]Brain Inst., Irvine, CA; [2]UCLA, Los Angeles, CA; [3]Psychology & Brain Inst., UCLA, Orange, CA

Abstract: Numerous vehicles with some self-driving abilities now occupy the roads, and the number and level of autonomy of these vehicles are growing. Such autonomous vehicles (AV) are at the spotlight of both academia and industry. While many studies focus on algorithmic perfection and optimization of the operating artificial intelligence, less in known about how humans view such AVs. In the current study, we examined how participants viewed driving quality, safety, and other measures for a series of video clips depicting a car driving through city streets and interacting with other cars and pedestrians. Our video is a three-dimensional, internal reconstruction of actual footage of an AV driving in a city, occasionally with human intervention. The video clips were presented in random order, and participants answered questionnaires about the quality of driving in each video. Questionnaires were presented before, in-between, and after a series of video clips to detect any change in participants' opinion about AVs following the clips. Preliminary results suggest that subjects' opinion about quality of driving was lower when they believed an AV was driving than when they believed a human was driving.

Title: Belief updating and demand for instrumental information

Authors: *N. M. SINGLETARY[1], G. HORGA[2], J. GOTTLIEB[1]
[1]Mortimer B. Zuckerman Mind Brain Behavior Inst., [2]Dept. of Psychiatry, Columbia Univ., New York, NY

Abstract: Real-world decisions typically start by determining which sources of information to sample before committing to a particular option. However, the vast majority of laboratory tasks

have eschewed this sampling process and provide DMs with preselected cues, leaving the mechanisms of information demand poorly understood. We developed a new task to test human information sampling behavior, its relation to belief updating, and its neural substrates. Bayesian theory predicts that the leverage an informative cue should have on a DM's current beliefs and the DM's willingness to pay for the cue is a function of the prior decision uncertainty and the anticipated information quality. Moreover, cue information gain should interact with the incentive structure, such that the willingness to pay (WTP) for a cue multiplicatively increases with the gain (loss) for a correct (incorrect) answer. To examine these predictions, we tested participants (n = 10, 3 female) on a 2-alternative forced choice (2-AFC) task where they declared their WTP for obtaining an additional cue (Exp. 1, WTP) or estimated the probability of one alternative being true with or without the benefit of an additional cue (Exp. 2, belief updating). In each trial block, participants saw a series of trials in which they were told the prior probability that they were in a portrait or a landscape gallery (i.e., a gallery where the majority of pictures are portraits or landscapes, respectively). In addition, participants were told the majority ratio of the pictures in the gallery, which established the likelihood that the cue came from its respective gallery (information quality). Finally, participants were told the penalty for making an error. At the end of each block, participants declared their decision on a randomly selected trial. Their payout for the block was the initial endowment minus the error penalty (if any) and minus the bid if it was high enough to purchase a cue on this trial. While the participants broadly conformed to Bayesian predictions, they also showed two noteworthy deviations. In the belief-updating task, beta coefficient for the log-odds of the likelihood (information quality) was greater than that of the prior. In the WTP task the participants showed sensitivity to error costs and information gain but not the predicted interaction between the two factors. These results are pilot results that will be expanded upon in a larger sample. The findings set the stage for understanding the neural substrates of specific cognitive processes underlying belief updating and information demand during decision making.

Title: Application of entropy, information gain, and decision trees for intelligent decision making and data fusion

Authors: *H. C. YUAN[1], M. CHAO[2]
[1]Independent Lab., San Marino, CA; [2]Independent Lab., Rancho Palos Verdes, CA

Abstract: Intelligent decision makers need to be able to evaluate the consequences of their actions or the sequence of choices they have. In many problems involving intelligent decisions, the number of possible sequences can be quite large. This poster investigates how intelligent decisions can be made through construction of a decision tree and applying concepts from information theory such as information gain, entropy, and supervised datasets. A decision tree builds classification or regression models in the form of a tree structure. It breaks down a dataset into smaller and smaller subsets while at the same time an associated decision tree is incrementally developed. The final result is a tree with decision nodes and leaf nodes. A decision node has two or more branches. A leaf node represents a classification or decision. The root node is the topmost decision node in a tree. Decision trees can handle both categorical and numerical data. A decision tree is built top-down from a root node and partitions the data into subsets with similar or homogeneous values. Entropy is used to calculate the homogeneity of a dataset. If the dataset is completely homogeneous the entropy is zero, and if the dataset is uniformly divided, it has entropy of one. The information gain is based on the decrease in entropy after a dataset is split on an attribute. Constructing a decision tree is finding the attribute that returns the highest information gain or the most homogeneous branches. A decision tree is transformed to a set of rules by mapping from the root node to the leaf nodes. The rules can be applied to a new or unclassified dataset to predict which inputs will have a given outcome. This poster also examines the use of an algorithm for building decision trees called ID3 (Iterative Dichotomiser 3) by J. R. Quinlan employing a top-down, greedy search using entropy and information gain through the space of possible branches in the dataset with no backtracking. As an application, this poster examines how decision trees can be applied to fuse avionics data (aircraft range, velocity) in decision making for classification, surveillance, and early warning decisions. An application to airborne avionics for air vehicle classification for reconnaissance strategies is also given.

Title: Increased curiosity enhances memory in older adults

Authors: *E. TEDESCHI, C. MARVIN, E. LANG, D. VARATHAN, D. SHOHAMY
Columbia Univ., New York, NY

Abstract: Curiosity is a fundamental aspect of intrinsically motivated learning, but there are many open questions regarding the cognitive and neural mechanisms by which curiosity drives learning. Previous research has suggested that curiosity may leverage basic reward mechanisms, where desired information is the reward, and curiosity can be viewed as the drive to obtain it. This framework makes predictions regarding how curiosity might change across the lifespan. Reward sensitivity is thought to decrease with healthy aging as a function of decreased dopaminergic activity. This suggests that, to the extent that curiosity is related to these same mechanisms, curiosity should also decrease with age. This prediction is consistent with the conventional wisdom that curiosity declines with age. However, few empirical studies have tested this prediction about aging, and those that do exist have provided inconsistent results. A better understanding of the relationship between curiosity and age could help test the reward hypothesis and potentially shed light on other potential mechanisms of curiosity.
We conducted two studies designed to examine age related changes in curiosity. In both studies, groups of older and younger adults were shown a series of trivia questions. For each question, participants chose whether to wait up to 30 seconds to see the answer, or to immediately skip to the next question. Choosing to wait was interpreted as a measure of curiosity. After the task, participants were given a surprise memory test for the answers to questions that they waited for. In Study 1, behavioral results showed that older adults were more likely to wait for answers than younger adults. Moreover, older adults were more likely to correctly recall the answers on the memory test. Study 2 sought to replicate and further investigate these findings, repeating the behavioral assessment while participants were scanned with fMRI with two new groups of older and younger adults. Behaviorally, the results of Study 2 replicated those of Study 1: older participants were more willing to wait for answers and also had better recall memory for the answers. fMRI results show that the decision to wait for information is related to increased BOLD activity in the striatum, DLPFC, and VMPFC in young participants, consistent with the "information as reward" hypothesis. Together, these results raise the possibility that while reward mechanisms may contribute to curiosity-driven learning in young adults, there may be other additional mechanisms contributing to curiosity in older adults, which may instead be related more to semantic knowledge.

Title: Multimodal ERP analysis of mental arithmetic processing performance and its relationship to selective attention, and fatigue

Authors: M. N. BAKER, C. SHEN, S. J. PANZENHAGEN, B. CLARK, D. H. HUGHES, *A. W. CHIU
Biololgy and Biomed. Engin., Rose-Hulman Inst. of Technol., Terre Haute, IN

Abstract: In this study, we investigated a person's evoked-response potentials (ERPs) to errors during mental arithmetic processing (MAP). The purpose of this project was to evaluate how ERPs were affected by the mode of stimulus delivery, the subject's language ability, self-identified learning style, selective attention, and fatigue. Gender non-specific, ethnicity non-specific human subjects between the ages of 18-55, capable of performing simple mental mathematical problems, were recruited. Each subject were given 360 simple math problems, along with the corresponding answers (80% correct; 20% incorrect). These questions were presented in batches of three alternating forms, visual only (shown on a computer screen), auditory only (presented via headphones), and mixed mode (a combination of visual and auditory). Subjects were instructed to solve the math problems mentally, and keep track of the correct solutions. When presented with errors in mathematical solutions, the averaged ERPs showed an increased latency. The longer latency suggested the possibility of a longer processing time when subjects realized that the answers were not what they had in mind. Not unexpectedly, there was also a significant increase in the averaged ERP peak amplitudes when presented with incorrect solutions, over four times as large as those derived from the correct solutions ($p<<0.01$). There was a weak correlation of theta rhythms ($R^2=0.68$) and alpha rhythms ($R^2=0.40$) at Fz with the visual ERP latency, and an even weaker correlation with auditory ERP latency ($R^2<0.30$). Consistent with recent publications in psychology and education journals, there was little or no evidence of any dependence between the ERP latency and amplitude to the reported visual/verbal dimensions in the Index of Learning Styles. On average, subjects missed an average of 34% of the problems when they are presented in the auditory mode, versus 24% in the visual mode. Follow-up research may involve tasks that are more conducive to other various mode of delivery, and may offer alternative ways to evaluate cognitive function and attention in a quantitative manner.

Title: The modified law of effect and the partial reinforcement extinction effect

Authors: *A. P. BLAISDELL, B. M. SEITZ, C. INDUDHARA
Psychology, UCLA, Los Angeles, CA

Abstract: We present our recent modification to Thorndike's original Law of Effect (1911) that expands its explanatory power (Blaisdell, Stolyarova, & Stahlman, 2016). In addition to providing an account for the inverse relationship between reward probability and response variation, the Modified Law of Effect (MLOE) also provides an account for the partial reinforcement extinction effect (PREE). The PREE is the finding of more rapid extinction to an instrumental or Pavlovian response that had previously been reinforced continuously (CRF) compared to a response that had only been partially reinforced (PRF). According to the MLOE, a CRF cue acquires a strong excitatory S-R but very weak or no inhibitory S-R; while a PRF cue acquires strong excitatory and inhibitory S-R associations. During extinction, the inhibitory S-R association will increase rapidly for the CRF cue but much more slowly for the PRF cue (because learning is negatively accelerating). We tested the MLOE account of the PREE using a within-subject operant procedure in pigeons and humans in which we manipulate whether or not an inhibitory S-R association develops to the PRF cue. Results support predictions of the MLOE that inhibitory S-R associations play a role in the PREE.

Higher Sch. of, Moskva, Russian Federation

Abstract: Bidding is a pivotal socioeconomic process underlying consumer behavior dynamics. Yet how humans learn to bid efficiently in complex markets remains an open question. We used model-based neuroimaging to investigate the neural mechanisms of bidding behavior. Twenty-seven subjects (nine male) played a prototypical bidding game: a double action, with three market types, which differed in levels of supply and demand. We compared different computational learning models of bidding: directional learning models (DL), where the model bid is "nudged" depending on whether it was accepted or rejected, along with standard reinforcement learning models (RL). We found that DL fit the behavior best and resulted in higher payoffs. We found the binary learning signal associated with DL to be represented by neural activity in the striatum distinctly posterior to a weaker reward prediction error signal. We posited that DL is an efficient heuristic for valuation when the action (bid) space is continuous. Indeed, we found that the posterior parietal cortex represents the continuous action-space of the task, and the frontopolar prefrontal cortex distinguishes among conditions of social competition. These findings provide a conceptual model that accounts for a sequence of processes that are required to perform successful and flexible bidding: (a) market competition type recognition, (b) bid choice informed by the game structure, and (c) feedback-driven learning by means of a DL algorithm. Our results suggest that an efficient DL heuristic underlies price adjustments during repeated bidding.

Title: Option transfer in humans enables faster exploration

Authors: *L. XIA[1], A. G. COLLINS[2]
[1]Mathematics Dept., Univ. of California Berkeley, Berkeley, CA; [2]UC Berkeley, Psychology Dept., Univ. of California, Berkeley, Berkeley, CA

Abstract: Humans' ability to flexibly transfer previously learned skills to novel contexts is one of the fundamental gaps that sets humans apart from current state-of-the-art artificial intelligence (AI) algorithms. However, how humans transfer skills is not well understood. Studying how humans generalize learned skills will not only provide insights to how humans learn and adapt, but also help develop the next generation AI algorithms with more human-like learning efficiency and flexibility. Recent work showed that humans can transfer one-step policies to

novel contexts. However, flexible real world behavior often requires multiple steps. The options framework from hierarchical reinforcement learning (HRL) provides a potential solution to counter this complexity by introducing behavioral modules called “options”. Options are abstract multi-step policies, assembled from primitive actions or simpler options, that can represent meaningful reusable skills. Options induce hierarchical structure in the action space, coinciding with the hierarchical structure in natural human behavior. Therefore, the options framework is considered a promising upgrade from traditional flat reinforcement learning (RL) models. In this pilot study, we aim to test if humans can indeed learn and reuse options. We designed a novel sequential decision making protocol that provides behavioral markers of reusing learned options. Participants (N=29, age 18-24, 19 females) learned to choose the correct action at each step in order to receive reward. Results showed significant transfer effects that cannot be explained by traditional flat RL models. Furthermore, transfer was visible both in simple options including only primitive actions, and complex options that themselves recruited simpler options. This not only provides evidence for option learning and reuse, but also points to the possibility that option transfer happens at multiple levels of hierarchy. In conclusion, while previous theoretical work showed that reusing options promotes fast exploration of new environments, our results provide evidence that humans do transfer learned options and benefit from it by learning faster.

Title: Credit assignment in reinforcement learning is impaired in individuals with obsessive-compulsive and schizotypal traits

Authors: *S. SUZUKI[1], K. KATAHIRA[2], Y. YAMASHITA[3]
[1]Frontier Res. Inst. for Interdisciplinary Sci., Tohoku Univ., Sendai, Japan; [2]Dept. of Psychology, Grad. Sch. of Informatics, Nagoya Univ., Nagoya, Japan; [3]Dept. of Functional Brain Research, Natl. Inst. of Neurosci., Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan

Abstract: Learning from experience is indispensable for appropriate decision-making. The reinforcement learning framework posits that a trial-and-error learning enables the agent to make optimal decisions if the correct “credit assignment” is attained: that is, choices that lead to

reward delivery were reinforced. In other words, the optimal learning requires the agent to associate an outcome with the choice that leads to its delivery. Yet, little is known about how the credit assignment is modulated by psychiatric symptoms such as schizotypal personality, obsessive compulsivity, depression and anxiety. To address this issue, we conducted a large-scale online experiment (N = 876) consisting of a reinforcement-learning task and questionnaires about psychiatric symptoms. In the online experiment, participants were first engaged in a conventional three-armed bandit task (i.e., reinforcement-learning task), and then asked to complete questionnaires about schizotypal personality, obsessive compulsivity, depression, state anxiety, trait anxiety, impulsivity and socioeconomic status. Applying a factor analysis to the questionnaire data, we found evidence for two dissociable dimensions underlying the psychiatric symptoms: the first one was associated with anxious and depressive traits, while the second one was associated with obsessive-compulsive and schizotypal traits. Furthermore, a generalized linear mixed model analysis revealed that the correct credit assignment in reinforcement learning task was impaired selectively in participants with high obsessive-compulsive/schizotypal traits, but not with high anxious/depressive traits. These results obtained from the large-scale online experiment highlight a new link between credit assignment in reinforcement learning and self-reported psychiatric symptoms, and may potentially contribute to deeper understanding of obsessive-compulsive disorder and schizophrenia.

Abstract: Introduction: The left prefrontal cortex is known to play a key role in trial-and-error learning process that selects between competing rewards and costs. This study investigated a shift in the performance of trial-and-error behavioral tasks by transcranial direct current stimulation (tDCS) of the left prefrontal cortex.
Methods: Before the behavioral tasks, 13 healthy right-handed subjects (7 male, 6 female, aged 25.6±7.0 years) were stimulated with tDCS (2 mA) for 20 min. The tDCS was conducted with anode or cathode electrode placed over F3 (International 10-20 system) and the other electrode placed over the right supraorbital area. In sham experiments, tDCS was turned off after 60 s.
In each of 30 behavioral trials, one of three colored circles showing 10%, 50% or 90% reward probability was randomly presented for 2 s as a cue, and the subject was required to decide as quickly as possible whether to perform first finger abduction in response to the circle's color. If the picture of a coin (100 Japanese yen) appeared as a reward stimulus after finger abduction, the subject received the actual coin after the experiment. However, if a mauve circle appeared as a cost stimulus after finger abduction, the coin was deducted from the total reward per occurrence. The total reward amount and number of correct behaviors and commission errors as the behavioral data were counted. The differences in behavioral data and the total reward after each tDCS were statistically analyzed by repeated measures ANOVA. This study was approved by our institution's ethical committee.
Results: The number of correct behaviors was significantly greatest in cathode tDCS, and that of commission errors was significantly lowest in cathode versus anode tDCS. The total reward of the subjects was also significantly highest in cathode tDCS.
Discussion: Cathode tDCS of the left prefrontal cortex induced an increase in sensitivity for reward/cost selection and a shift in the performance of correct behavior. These results imply that trial-and-error behavioral learning including the reward-related circuit might be altered by tDCS.

Title: Cortical thickness and volume of the right posterior parietal cortex predict individual learning rate in healthy adults

Authors: *M. CHAWLA[1,2], P. HOMAN[5], C. GORDON[3], E. FELTHAM[2], I. HARPAZ-ROTEM[3], D. SCHILLER[6], I. LEVY[4]

At Mount Sinai, New York, NY; [6]Psychiatry and Neurosci. Departments, and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Introduction: Gray-matter volume (GMV) of a region in the right posterior parietal cortex (rPPC) has been shown to predict individual risk attitudes over and above the effects of age, such that individuals with higher GMV in this region have higher risk tolerance in financial decision-making (Gilaie-Dotan *et al.*, 2014; Grubb *et al.*, 2016). We hypothesized that decreased GMV and cortical thickness in this region is associated with reduced computational capacity, which in turn gives rise to reduced risk tolerance. Here we tested whether structure of the same region also accounts for individual differences in another type of computational capacity - the ability to learn flexible associations between cues and outcomes.
Methods: A reversal-learning task (Schiller *et al.*, 2008) was administered to 61 healthy adults (mean age = 28.10 [18 - 46], 14 Females, 47 Males) while in the scanner. In this task, participants were presented with two stimuli. In the first part of the task, one stimulus (CS+) was sometimes co-terminated with a mild electric shock, while the other stimulus was never co-terminated with a shock. An unsignaled switch between the CS+ and the CS- occurred halfway through the task, without the participants' foreknowledge, and outcome contingencies were reversed. Skin conductance responses (SCR) were used to indicate learning of conditioned associations. Hierarchical Bayesian analysis was used to fit the SCR with a Rescorla Wagner model, and calculate the learning rate for each participant. The Freesurfer pipeline was used to extract neural structural measures of GMV and cortical thickness using a mask for the rPPC region-of-interest.

Results: Multiple regression models were calculated to predict learning rate based on either the rPPC cortical thickness or its GMV. Mean thickness/volume, movement parameters, age and gender were also included in the models. Cortical thickness of the rPPC significantly predicted the learning rate (B= -.025, p = .017). In a separate regression, GMV of the rPPC showed a trend towards significance (B = -.012, p = .077). Age was a significant predictor in both regressions (p < .001).
Conclusion: Our results suggest a general role for the structure of rPPC in shaping individual differences in learning and decision making under uncertainty, with both appetitive and aversive outcomes.

Title: A randomized controlled trial of neurofeedback-augmented meditation training

Authors: *R. VAN LUTTERVELD, A. ROY, P. PAL, J. BREWER
Preventive Med., Univ. of Massachusetts, Worcester, MA

Abstract: Introduction: Meditation has shown a number of beneficial effects, including lowering stress and improving attention. However, learning to meditate is not straightforward as there are no easily discernible outward signs of performance and thus direct feedback is currently not possible. Real-time neurofeedback based on brain activity patterns that are associated with effective meditation practice may provide a solution to this issue. Previous neuroimaging studies showed that brain activity in the posterior cingulate cortex (PCC) is related to the subjective experience of effortless awareness (which is a major component of meditation). In the present study, we tested the efficacy of EEG neurofeedback from the PCC during meditation practice as an add-on treatment to a Mindfulness-Based Stress Reduction (MBSR) course. We hypothesized that 1) The neurofeedback group would show a larger change in PCC activity during meditation vs a resting-state baseline from pre- to post-MBSR compared to an active control group as assessed using fMRI and 2) These changes in PCC activity from pre to post were associated with changes in selective attention and perceived stress.
Methods: Sixty-three novice meditators participated in this randomized controlled trial. All

participants participated in an MBSR course and in addition performed 5 EEG sessions during which participants meditated (breath awareness meditation). Participants were randomized to receive neurofeedback or no neurofeedback during the EEG sessions. At pre- and at post-intervention, participants performed 3 meditation runs that included a resting-state baseline in an fMRI scanner. Perceived stress was measured using the Perceived Stress Scale and sustained attention was measured using a Rapid Visual Information Processing task at the same time-points. fMRI data were analyzed using SnPM and MarsBar in a region-of-interest approach. Correlations between changes in PCC activity and changes in behavioral outcomes were assessed using Spearman's rank-order correlation.
Results: No significant interaction effect between groups and time was observed for PCC activity. Also, no main effect of time was observed. No significant associations were observed between changes in PCC activity from pre to post and changes in behavioral outcomes.
Discussion: These negative findings highlight a number of issues that arose during the study that apply to neurofeedback protocols in general, including type of feedback and dosage of neurofeedback.

Abstract: The ability to accurately recognize and produce mental durations is fundamentally important in everyday life, and a self-setting of durations without cue is affected by various factors. Parkinson's disease (PD) is associated with various cognitive impairments, however, a cognitive modification for production remains to be elucidated in patients with PD. Here, we examined whether patients with PD can correct and maintain a subjective duration/distance production. After training sessions in which participants repeatedly memorized a duration or distance, we compared a learning performance of duration with distance productions in 20 PD patients and 20 healthy controls. Results were further analyzed in relation to deficiency of presynaptic dopamine transporter (DaT) in the striatum. We observed that learned durations immediately returned to baseline values in pre-training within a few minutes, but that the patients were able to continue the learned distance production. In contrast, healthy controls were able to maintain the learned duration and distance productions. Time compression in PD's internal clock may become entrained to their altered duration production even after learning of accurate duration. We also observed that striatal DaT deficits positively correlated with duration underproduction in patients with PD. These deficits may be associated with severe time compression and entrainment, thus disturbing cognitive modification for duration production.

Abstract: Neurofeedback training (NFT) is a non-invasive technique for real-time self-regulation of brain activity, with benefits on human cognition, health, and task performance optimization. However, in current protocols, the benefits differ between subjects, leading to frustration of potential users, economic costs, and discredit in NFT and its professionals. Self-regulation is an important adaptation process to environmental and social challenges. In fact, self-regulation deficits are associated with diverse behavioral problems and mental disorders such as depression, rumination, distraction, anxiety, stress, and attention control. Therefore, understanding how to influence individual self-regulation learning ability through training methods could be the key to unlock predictors and optimize the success of NFT, and vice-versa.
In literature, it has been hypothesized that the "optimal" state of NFT learning is reached when irrelevant associations between internal states and external reward are avoided, and when the learner stays engaged, focused and undistracted. If these conditions hold, the learner should be skillful in gating incoming information provided by the NFT system and avoiding task-irrelevant thoughts. Also, current literature speculates that these states relate with up-regulation of sensory motor rhythm (SMR) and/or upper alpha rhythm (UA), and can be potentially provoked by relaxation/attentional stimulus tasks, like mindfulness meditation techniques.
In this way, during our intervention, healthy adult participants (18-65 years old) receive sequentially implicit (pre-)training of self-regulation (PRET) then NFT. PRET consists of one run per randomized stimulus task, to potential induce the "optimal" state (audio and/or visual relaxation/attentional stimulus tasks), in a within-subject ABA design (A condition: target condition - stimulus tasks; B condition: reverse target condition - active baseline), to facilitate the analysis of stimulus dependent oscillations. NFT of SMR or UA, follows a pre-post training design to investigate changes in the learning outcome (self-regulation performance) and behavioral outcome (mindfulness trait changes) possibly induced by PRET.
In conclusion, our framework is trying to uncover some of the aspects of the "optimal" mental state to self-regulate brain activity with neurofeedback. Namely, how can we stimulate subjects to get in this personalized "optimal" state? Also, if the stimulated "optimal" state affects Neurofeedback self-regulation performance?

Title: Elucidating cross-modal integration in the superior temporal sulcus via representational similarity analysis

Authors: *C. W. KORN[1], J. P. GLAESCHER[2]
[1]Inst. for Systems Neurosci., [2]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: The superior temporal sulcus (STS) has been shown to integrate information across stimuli from different sensory modalities such as vision and audition. However, it is unclear to which extent neural representations in the STS relate to representations in unisensory brain areas such as visual and auditory cortices. Here, we harnessed representational similarity analysis (RSA) to address this question. Our study also addressed how reward learning may influence crossmodal representations in the STS. Our fMRI task employed a block design in which human participants (n=43) were repeatedly presented with semantically congruent pictures and sounds (e.g., a picture of a guitar and a 400 ms sound of guitar strings). Visual and auditory stimuli were presented simultaneously or in isolation. In the middle of the experiment, participants learned in a separate fMRI session that for some stimulus combinations either the visual or the auditory stimulus were rewarded. Reward learning behavior was analyzed using hierarchical Bayesian modelling. To define functional regions of interest, we administered a localizer task with an independent set of stimuli. Crossmodal integration in the STS was evident in the pattern of representational similarities between the unimodal and crossmodal stimuli. Crucially, multivariate analyses showed that activations in unisensory brain areas predicted activations in the STS. Reward learning behavior could be well described by a simple variant of reinforcement learning and reward information altered the representation of auditory stimuli in the STS. Taken together, our results provide a refined framework for interpreting the role of the STS in crossmodal integration.

Title: The signal for good news and value of information in human choice behavior

Authors: *J. SAWALHA[1], M. L. SPETCH[2], C. S. CHAPMAN[3]
[2]Psychology, [3]Physical Educ. and Recreation, [1]Univ. of Alberta, Edmonton, AB, Canada

Abstract: Surprisingly, pigeons have been shown to sacrifice food rewards to get information about the upcoming outcome when making choices in a delay decision task. For instance, when choosing between an option which offers a reward 100% of the time after a delay (e.g. 10 s), versus an option that gives rewards only 50% of the time after the same delay but gives information about the reward (pecking it leads to a color that signals reward / no reward), pigeons sometimes prefer the 50% option. However, when the information is not immediate (e.g. it takes a few seconds after the peck for the color change to occur) pigeons almost exclusively choose the 100% option. Here, we tested if this same preference for immediate information would be evident in human choice behavior. In four experiments we adapted the pigeon task to a human reaching choice task to test two questions: 1) Do humans prefer information over no information, especially when it is received immediately? 2) Do humans show an asymmetry for information biased by valence, preferring good news and avoiding bad news? In Experiments 1 (n = 30) and 2 (n = 30) participants reached to choose between shapes on a touchscreen that either revealed the outcome (turned green for good or red for bad) or not (stayed the same color) and did so either immediately or after a delay (2s). Unlike pigeons, the results show that humans do not have a preference for information (immediate or delayed), instead choosing almost exclusively based on the probability of payoff. In Experiments 3 (n =20) and 4 (n=25), participants again reached to choose between shapes, a “good news” shape that sometimes changed color when the outcome was good, a “bad news” shape that sometimes changed color when the outcome was bad, and a neutral shape which never changed color. Here we see a significant preference to choose “good news” shapes and avoid “bad news” shapes. These results support the Signal for Good News (SiGN) hypothesis which argues that receiving a signal of good news in a 50/50 gamble task is more rewarding because it causes a large positive reward prediction error. However, our results also show that, unlike pigeons, humans avoid bad news, suggesting loss aversion may spill into the information domain.

Title: Learning to learn: Lateral frontal and cingulo-opercular cortex support the learning and transfer of hierarchical task structure

Authors: *A. EICHENBAUM, J. SCIMECA, M. D'ESPOSITO
Helen Wills Neurosci. Inst., Univ. of California, Berkeley, CA

Abstract: Lateral frontal cortex supports the learning and execution of hierarchical rules, and increasingly abstract hierarchical rules recruit increasingly rostral areas of frontal cortex. Rule learning can be bolstered by applying knowledge of previously learned rules to novel environments that share a common hierarchical structure. Here we used fMRI to characterize the contributions of frontal cortex to the transfer of abstract hierarchical rule structure. Human subjects (N = 19, 13 females, mean age = 19.3 years) performed 5 blocks of a reinforcement-learning task in which a hierarchical rule structure could be learned from deterministic binary feedback. The first block contained no hierarchical structure ("Flat") and required learning to occur independently for each stimulus. All subsequent blocks ("Hier") contained structure that allowed more efficient learning to occur. Stimuli were composed of features from several dimensions (shapes, colors, and textures). Each block used novel features for each dimension, however the Hier blocks all shared a 2^{nd}-order hierarchical rule structure: shapes cued 1^{st}-order rules based on either color or texture.
Subjects learned stimulus-response pairings more efficiently and to a greater extent in the Hier blocks compared to the Flat block, an index of hierarchical learning. Moreover, we observed markedly greater learning efficiency in the final two Hier blocks compared to the first two, providing evidence that subjects discovered and generalized the global hierarchical rule structure. In the brain, we observed elevated activity in lateral frontal cortex (left dorsal premotor cortex (PMd), left anterior dorsal premotor cortex (prePMd), left mid inferior frontal sulcus (Mid-IFS)) across all blocks. Activity in these regions peaked in the 2^{nd} Hier block, when participants could first search for and discover the global hierarchical structure. Of these lateral frontal regions, only PMd activity in the final two Hier blocks predicted behavioral transfer (behavioral improvement from the 1^{st} to 4^{th} Hier block). To identify other regions that correlated with behavioral transfer, we performed a whole-brain analysis, revealing regions in bilateral anterior insula (AI) and anterior cingulate cortex (ACC). These regions constitute the core nodes

of a “cingulo-opercular network” (CON), and activity across the CON (bilateral AI, anterior prefrontal cortex, thalamus, and ACC) strongly correlated with behavioral transfer. These results extend existing models of hierarchical gradients in the frontal cortex and provide novel evidence that regions in the CON support generalization of structured knowledge.

Title: Hippocampal GABA differences based on video game genre preferences

Authors: *K. PRENA, H. CHENG, S. D. NEWMAN
Indiana Univ., Bloomington, IN

Abstract: We have previously demonstrated that time spent gaming weekly is positively related to declarative memory performance. One possible explanation for this is that video games trigger the reward cascade, which increases dopamine and decreases gamma aminobutyric acid (GABA) in the hippocampus (both of which improve declarative memory formation). Recent video game research has demonstrated that changes to game structure can cause differences in cognitive performance. Our previous work showed that differences in game reward conditions caused variations in declarative memory performance. In this preliminary study differences in game genre preferences was related to hippocampal GABA. GABA was measured from 19 males between the ages of 18 and 25 (20.58, *SD* = 1.92) using magnetic resonance spectroscopy. Participants were asked to list their favorite games, how frequently they have played that game in the recent month, and the categories that best describe each game (education, sports, fighting, action, puzzle, skill, racing, exergame). Each genre was dummy coded to identify two groups of participants for each category: those who recently played those categories and those who did not. Participants started playing video games at the age of 8.95 (*SD* = 2.99). There was a significant difference in GABA between those who play fantasy games (*n* = 6, *M*=111.33, *SD*=37.82) and those who do not (*n* = 13, *M* = 162.54, *SD*=38.69); *t*(17) = 1.90, *p* = .015. There was a no significant difference in GABA between those who play action games (*n* = 6, *M*=119.67, *SD*=37.31) and those who do not (*n* = 13, *M* = 158.69, *SD* = 43.46); *t*(17) = 1.90, *p* = .075, between those who play skill games (*n* = 7, *M*=159.67, *SD*=48.54) and those who do not (*n* = 12, *M* = 123.57, *SD* = 26.46); *t*(17) = 1.80, *p* = .089, and between those who play fighting games (*n* = 7, *M* = 123.43, *SD* = 36.94) and those who do not (*n* = 12, *M* = 159.75, *SD* = 44.57); *t*(17) = 1.82, *p* = .087. These results indicate the importance of understanding video game reward

structure to explain differences in hippocampal behavior, and suggest that fantasy games may lead to differences in GABA.

Title: Computations of volatility in complex, uncertain environments

Authors: *M. RAKHSHAN[1], B. Y. HAYDEN[2], A. IZQUIERDO[3], A. SOLTANI[1]
[1]Psychological & Brain Sci., Dartmouth Col., Hanover, NH; [2]Univ. of Minnesota, Saint Paul, MN; [3]Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: The world is both uncertain and variable. When an unpredicted outcome occurs, a decision-maker must be able to distinguish randomness that reflects the stochastic nature of events from randomness that reflects changes in the underlying outcome probabilities. For learning to be successful, the decision-maker must distinguish variability (or *expected uncertainty*), which should not lead to behavioral adjustments, from *volatility* (or unexpected uncertainty). Although expected uncertainty can be specific to a stimulus or an action, it is unclear how expected uncertainty of an individual option interacts with environmental volatility, or how rapidly reward contingencies change. Here, we developed a novel concurrent probabilistic reversal learning task to study how volatility and its influence on learning may depend on the relationship between actions in more complex environments. Human subjects learned about the associations between three stimuli (two main stimuli, S_1 or S_2, and one modulating stimulus, S_m, each with different levels of volatility) and two sets of actions. Stimuli S_1 and S_2 were associated with two different sets of actions (left /right and up/down) that were rewarded with complementary probabilities and these probabilities reversed every L_1 and L_2 trials ($L_1 << L_2$), respectively. Reward probabilities for actions associated with stimulus S_m reversed every L_m trials. Using this task, we examined how the influence of S_m volatility depends on whether its actions match those of either S_1 or S_2, or by similarity of L_m to L_1 or L_2. First, we found that for the volatile stimulus (S_1), learning was slower when its actions matched those of the stable S_m ($L_m \sim L_2$). In contrast, learning of the stable stimulus (S_2) was enhanced when its actions matched those of the stable S_m. Overall performance was attenuated for stimuli with actions matching those of S_m, perhaps due to interference. Second, subjects showed a stronger difference between WinStay and LoseSwitch strategies, as a measure of differential response to reward vs. nonreward, for the volatile compared to stable stimulus. At the same time, matching

S_m enhanced this differential response for the volatile stimulus but decreased it for the stable stimulus. Third, the difference between WinStay and LoseStay strategies, as a measure of overall response to reward, was weaker for the volatile relative to stable stimulus. This measure was reduced most by the stable than volatile matching S_m. Overall, these results reveal multiple forms of interactions between volatility associated with individual stimuli/actions and how these interactions influence learning in complex environments.

Title: Separable attention processes constrain multidimensional reinforcement learning

Authors: *A. RADULESCU[1], Y. NIV[2]
[1]Dept. of Psychology, [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Two prominent theories suggest different targets for selective attention in reward learning: Mackintosh (1975) suggests that attention should be directed towards stimulus features that are most predictive of reward; Pearce and Hall (1980) suggest instead that attention should be directed to features that we are most uncertain about. Both theories have received empirical support, leading Dayan et al. (2000) to suggest that both should exist concurrently - when making choices, one should attend to the most predictive features, whereas when learning from prediction errors one should attend to (and learn about) the most uncertain features.
Here we combine eye tracking with a multidimensional reinforcement learning task in order to simultaneously measure the dynamics of attention for valuation and attention for learning and test for this dual-attention theory. In each trial of the 'Dimensions Task' (Leong et al. 2017), human participants chose between 3 multidimensional stimuli that differed along 3 spatially distinct dimensions: faces, houses and tools. In each block of trials there was one relevant dimension. Within that dimension, the stimulus containing a "target" feature yielded 1 point 75% of the time. The two other stimuli yielded 1 point only 25% of the time. To maximize reward, participants had to learn which dimension determines reward and, within this dimension, what is the target feature. To measure participants' focus of attention, we continuously monitored eye movements during the choice and learning phases of each trial.

We found that while attention for valuation and attention for learning became similar over the course of a block, they reflected separate computations. Trial-by-trial computational modeling in combination with an empirically derived index of attention, showed that this dissociation is behaviorally relevant: the best predictor of choices was a reinforcement learning model that used attention measured during the choice and learning phases of the task to separately bias valuation and learning. Our results establish that attention for choice and attention for learning are separable cognitive processes, and provide a framework for building computational models that predict how their dynamics shift as a function of learning.

Abstract: Neural activity patterns associated with individual finger movements can be decoded from fMRI data. Here we demonstrate the feasibility of using real-time fMRI neurofeedback to modify patterns of activity related to finger individuation, with implications for sensorimotor rehabilitation. First we investigate whether we can reliably decode patterns associated with individual finger movements, in real-time, from short (6 sec) time windows. We designed an fMRI experiment to localize the brain activity patterns elicited by pressing each of the four fingers of the right hand. This experiment had the same timings and stimuli as a subsequent neurofeedback experiment in which an initial baseline period was followed by blocks of finger pressing with intermittent feedback provided every 16 sec. Subjects participated in two finger localizer sessions, identical except for the order of finger presses. Decodability of finger presses within each session was excellent within primary somatosensory (S1, 90%) and motor (M1, 75%) cortices compared to chance (25%). When real-time processing limitations were imposed on within-session decoding, the decodability suffered (S1: 80%; M1: 65%), and further worsened between sessions (S1: 75%; M1: 60%), yet was still reliably above chance. Next, we investigated whether these brain patterns could be identified in real-time and recognized by human

participants using explicit search strategies (in this case, finger presses). We designed a neurofeedback experiment where participants had to determine which of the four fingers was being presented by the visual feedback of the real-time decoder output. After each trial of finger presses, if the decoder output for a target finger exceeded a threshold (50% probability), the target was considered found, and a new random finger target was selected. If the decoder output was perfectly accurate, it should take on average 2.5 trials for participants to discover the target. In a simulated experiment (10,000 targets), we found it took a simulated participant 3.5 trials to discover targets from S1, and 4.3 trials to discover targets from M1. Because success was based on decoder output and not the pressed finger, we also checked how often success corresponded to pressing the correct finger (S1: 82%; M1: 55%). Overall, our results show that decodability of individual finger presses is impaired by ~15% due to real-time limitations. While neurofeedback targets can be found using activity spread across sensorimotor cortex, targets are found quicker and more accurately within S1 than M1. This work provides a framework to investigate the limitations associated with ROI selection and real-time neurofeedback.

Title: Confidence modulates feedback processing during human probabilistic learning

Authors: *M. BEN YEHUDA, R. A. MURPHY, N. YEUNG
Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom

Abstract: Background & Aims: Learning stimulus-response contingencies with noisy feedback comes with an inherent degree of uncertainty. The aim of this project was to investigate how people's subjective sense of confidence about their knowledge affects how they learn and process incoming feedback, as
well as how confidence guides decisions about further information seeking.
Method: Three experiments (n = 25 in each) used a combination of behavioral and scalp electrophysiological (EEG) measures. Participants were required to learn associations between two stimuli and two responses.
Following probabilistic feedback (75% reliable), participants rated their confidence in having responded correctly. This allowed us to track changes in confidence during learning, and to relate

these to changes in feedback processing as indexed by EEG event-related potentials (ERP) in Experiment 2 and by participants' choices to pay for vs. decline feedback in Experiment 3.
Results: Participants' response accuracy followed a traditional learning curve that reached asymptote relatively quickly, but their explicitly reported confidence lagged accuracy and continued increasing, reaching asymptote significantly later than accuracy did ($p < .001$ for all experiments). Analysis of the period following accuracy asymptote indicated that, while their behavioural policy remained stable, the extent to which surprising negative feedback impacted confidence decreased as subjects progressed through a learning block, despite the increasing reward prediction errors (RPE) as learning continued ($p < .05$ in Experiment 1 and $p < .01$ in Experiment 2).
This behavioural effect was mirrored in ERPs time-locked to feedback delivery on trials following the accuracy asymptote. Specifically, confidence at trial t-1 negatively predicted the size of the P3 at trial t ($\beta = -0.09$; $p < .001$), indicating decreased processing of feedback as confidence increased. Consistent with this account, confidence also significantly predicted the trial in which people stopped paying for feedback in Experiment 3 ($\beta = 0.52$; $p = .01$), whereas accuracy did not ($\beta = 0.02$; $p = .93$).
Conclusions: The results suggest that subjective confidence adjusts how feedback is processed and incorporated in one's model of stimulus-response contingencies, regulating the weighting of the impact of RPE: higher confidence leads to a higher RPE upon receiving negative feedback, but decreased feedback processing. Consistent with this confidence-modulated change in feedback processing, participants' confidence ratings also predicted when they would stop paying for further feedback.

Title: Mesolimbic connectivity during neurofeedback training predicts learning to volitionally activate the ventral tegmental area

Authors: J. N. THORP[1], *S. HAKIMI[1], K. C. DICKERSON[1], J. J. MACINNES[2], R. A. ADCOCK[1]

[1]Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC; [2]Inst. for Learning & Brain Sci., Univ. of Washington, Seattle, WA

Abstract: Activation of the ventral tegmental area (VTA) and mesolimbic networks is essential to motivation and learning, however current interventions to target these regions can come with unmanageable financial and physical costs. Neurofeedback has been shown to be an effective, non-invasive therapy in a variety of contexts, however the ability to learn from and properly use neurofeedback is highly variable across subjects. In a recent study, MacInnes & Dickerson et al. (2016) showed that participants could learn to volitionally sustain their VTA activation through fMRI neurofeedback training, and that this feedback was accompanied by increased functional connectivity between the VTA and other mesolimbic areas, namely the hippocampus (HPC). However, the mechanism through which this training impacts learning is not yet known. Here, we test a mechanistic model of how mesolimbic functional connectivity drives learning from neurofeedback to self-activate the VTA. The activation task itself was divided into 5 runs: a pre-test without neurofeedback, three training runs with neurofeedback, and a post-test without neurofeedback. Connectivity was calculated for each run from the VTA to the HPC, due to the HPC's overall role in learning as well as mental imagery - a common strategy for VTA activation. A repeated measures ANOVA was then run with connectivity during each of the three runs as within-subject measures, sex as a between-subjects factor, and overall change in VTA activation from pre-test to post-test as well as age as covariates. Results show a trend-level relationship between connectivity and VTA change ($F = 3.272$, $p = 0.052$), in which higher VTA-HPC functional connectivity over the course of the training period predicts greater VTA activation change from pre-test to post-test, an initial demonstration that prompts further interrogation; there was no effect of age or sex. This approach provides new insight into the mechanisms of learning from neurofeedback, and therefore can inform the propagation of volitional brain activation for basic science and development of new interventions.

Title: Reinforcer inflation in humans using inter-trial interval alterations as reinforcers

Authors: *C. LONG, C. L. PICKENS
Kansas State Univ., Manhattan, KS

Abstract: Reinforcer revaluation experiments are multi-stage experiments in which a subject learns that a cue predicts, or a response earns some outcome in the first phase. In a subsequent phase, the value of the outcome is altered and the subject needs to spontaneously adjust their behavior. These experiments are common in non-human animals, but less common in humans. One possible reason why revaluation experiments are rare in humans is that these experiments tend to use consumable items (ex: foods) or physically aversive stimuli (ex: shocks) as the outcomes, and it is more difficult to use these outcomes with human participants. The purpose of this study was to examine whether reinforcer inflation, in which the value of an outcome is increased, can be performed in humans using a more innocuous outcome. For this, we used changes in the inter-trial interval (ITI) in a discrimination task as our outcome, as humans are often very eager to complete an experiment as quickly as possible. Undergraduate students were given cue exposure phases alternating with response phases. In the cue exposure phases, the participants were exposed to colored squares (red, green, yellow, blue) associated with delays that were longer (13-second) or shorter (0.5-second) than the standard delay of 4 seconds (associated with a black square stimulus). In the response phases, the participants were presented with different shapes (clubs, hearts, spades, diamonds). Responses during the shape presentations would earn a colored square (ex: responses during the club earned the red square and a 0.5-second ITI, responses during the heart earned the green square and a 13-second ITI). Withholding responses during the shapes always earned the black square and a 4-second ITI. In the final cue exposure phase, the value of one of the colored squares that previously predicted a long delay was increased/inflated by now having it predict a shorter delay (ex: the green square went from predicting a 13-second delay to predicting a 0.5-second delay). In the subsequent response phase (which functioned as an extinction test, as responses always led to the black square and 4-second delay), responses to the shape that predicted the inflated colored square stimulus increased compared to responses to another shape that continued to predict a colored square associated with a 13-second delay. This suggests that ITI changes can act as reinforcers to support responding, and that these reinforcers are sensitive to inflation.

Title: The effects of tyrosine supplementation on classical conditioning

Authors: T. N. OCHOA[1], A. BICCUM[1], *E. BARKLEY-LEVENSON[2]
[2]Psychology, [1]Hofstra Univ., Hempstead, NY

Abstract: The role of dopamine in classical conditioning has not been extensively studied. Prior studies demonstrate the amino acid tyrosine to be an effective method of increasing cerebral dopamine levels. This study studied the effects of dopamine, through the supplementation of tyrosine, on associative learning task performance in 37 (females = 22) healthy, human participants. Participants were randomly assigned to either the tyrosine supplemented group (n=19) or to a placebo group (n=18) who received a microcrystalline cellulose powder. A complex, real world scene containing four embedded items was presented to participants both prior to and after supplementation to measure its effects on learning. One item embedded in the scene served as the conditioned stimulus (CS). One version of that item (e.g. a black spoon) was paired with a loud, aversive tone (CS+) while a second version of the item (e.g. a brown spoon) was not paired the aversive stimulus (CS-). The remaining items were never paired with the stimulus and served as distractor variables. Participants rated their expectation of hearing the loud tone during each trial; these expectancy ratings were used to determine when each participant became aware of the contingency. A pre-test was conducted to determine baseline learning scores while the post-test was conducted to determine if tyrosine supplementation enhanced learning as demonstrated through: (1) fewer trials to learn the contingency, (2) decreased reaction time, (3) increased total number of correct predictions. The experimental group displayed a significant increase in total number of correct responses, relative to the control group ($F(35)=8.43$, $p=0.006$). The experimental group also displayed a significant decrease in average reaction time, relative to the control group in the post-test ($F(35)=5.17$, $p=0.029$). No sex differences were found ($F(35)=3.294$, $p=0.078$). These results demonstrate a significant main effect of tyrosine supplementation on associative learning task performance. Furthermore, the results help establish dopamine as a neurochemical component involved in associative learning.

Title: Working memory contributions to probabilistic reinforcement learning

Authors: *W. RYAN[1], A. G. E. COLLINS[2]
[1]Dept. of Psychology, [2]Dept. of Psychology & Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: Two major brain networks contribute to learning: a cortico-striatal network thought to implement instrumental, value-based reinforcement learning (RL), and a prefrontal cortex centered executive function network thought to be crucial for flexible, goal-directed learning, an important part of which is working memory (WM). WM is commonly believed to be critical for learning in deterministic settings, where feedback is always accurate and fast learning is key, such that holding a past trial's information in WM for future decision is useful. By contrast, RL is crucial in stochastic settings, where feedback is noisy and learning requires new and conflicting information to be integrated over time.
However, WM could also be used in stochastic environments; either holding in memory past trials, thus implementing win-stay lose-shift strategies, or maintaining internally generated hypotheses about the best choices for each stimuli. In this work we aim to show evidence that WM also contributes to learning in stochastic environments. Furthermore, we investigate the nature of the information held in WM in such cases. We hypothesize that participants may maintain both types of information, and that the balance may change as learning progresses.
We used a probabilistic reinforcement learning task. In multiple independent learning blocks, participants used binary probabilistic feedback to learn which of three actions was most likely to lead to reward for each stimulus. There were two key manipulations. First, the number of stimuli being learned during each block (set size) was either low (3) or high (6), changing the cognitive load on WM (Collins & Frank 2012). Second, the feedback reliability also independently varied across blocks from low (65%) to high (92%). We predicted that participants would learn slower in high than low set sizes, reflecting WM limitations. Furthermore, we expected that WM would be used less when feedback was less reliable and RL more useful.
Results with 40 laboratory participants confirmed our predictions, and were replicated with 55 Amazon Mechanical Turk participants. Logistic regression analyses showed that participants learned more slowly in high vs. low set size blocks, and that this effect of set size on learning was weaker in low vs. high reliability blocks, indicating a trade-off between WM and RL contributions. We will use computational modeling to identify the nature of the information held in WM in stochastic environments. Our results highlight the fact that human learning is always a mixture of multiple processes, and further our understanding of working memory contributions to reinforcement learning.

Title: Out-of-the-box decoding of error-related brain signals with deep learning

Authors: *J. BEHNCKE[1], R. SCHIRRMEISTER[1], W. BURGARD[2], T. BALL[1]
[1]Univ. Med. Ctr. Freiburg, Freiburg, Germany; [2]Albert-Ludwigs-University, Freiburg, Germany

Abstract: Assistive devices controlled by human brain signals exhibit a high potential to enhance processes in everyday life or even to endow severely impaired persons with more autonomy. Though, cooperative brain-controlled systems require a proper error management, depending on a highly accurate decoding framework. Deep learning (LeCun et al. 2015) has not only boosted performances in classical fields like computer vision, but recently has also been applied to problems in neurological contexts. Thus, deep learning methods could perfectly serve to decode error-related brain signals. Still, performances have substantial space for improvement and techniques have to be adjusted to specific needs.Here, we present findings from error-related analyses of invasive and non-invasive recordings obtained by several experimental paradigms. For discrimination of erroneous and correct realization of a task, conventional methods like regularized Linear Discriminant Analysis (rLDA) or Filter Bank Common Spatial Patterns (FB-CSP) combined with rLDA were compared to a deep learning implementation (Schirrmeister et al. 2017) based on Deep Convolutional Neural Networks (deep ConvNets), both, when observing or performing the task. Beyond, transfer learning techniques were utilized to generalize across paradigms and to overcome typical problems when only few data are available.We can show a significant improvement of decoding when the classifier relied on deep ConvNets instead of using rLDA or FB-CSP+rLDA. Utilizing data of the same participant but gained in different paradigms, a transferability of learned patterns in error-related brain signals could be proved, emphasizing the beneficing of transfer learning techniques in this context. Especially when only little data is available, the pretraining on a different data set significantly improves the decoding performance, according to examples in conventional computer science classification problems. Astonishingly, the deep ConvNet implementation was always used “out of the box”. That suggests a simple utilization in numerous contexts but also indicates space for improvement by fine-tuning the network.

Title: Improving face recognition in older adults with real-time magnetoencephalography (MEG) neurofeedback

Authors: *M. HAMADA[1], R. FUKUMA[2], M. P. TAKAHASHI[3,4], T. YANAGISAWA[5,6,7]
[2]Dept. of Neurosurg., [3]Dept. of Functional Diagnos. Sci., [4]Dept. of Neurol., [1]Osaka Univ. Grad. Sch. of Med., Suita, Japan; [5]Osaka Univ., Osaka, Japan; [6]Inst. for Advanced Co-creation Studies, Osaka Univ., Suita, Japan; [7]JST PRESTO, Suita, Japan

Abstract: Introduction
The causes for the age-related decline in visual recognition have not been fully explored. Although vision impairments associated with aging are an important factor, age-related alteration in cognitive processing also appears to be a factor. Prior studies have shown that cognitive processing improves with age, peaking during early adulthood and declining thereafter as a result of age-related cognitive slowing. As cognitive processing declines, so too does visual object category response selectivity. The fusiform face area (FFA) is selective for faces and is involved in higher-order visual processing, but it is not clear whether FFA activation improves face recognition. We hypothesized that alteration of FFA activity through neurofeedback training may improve face recognition.
Method
We developed a neurofeedback training system using real-time magnetoencephalography (MEG). FFA cortical activity was estimated online from MEG signals, based on which a decoder was trained to classify images of faces and houses. The performance of 15 healthy older adults (aged 56–76) in recognizing these images was measured by a part-to-whole matching test before and after a 10-minute training to control decoder output.
Results
Accuracy in the part-to-whole matching test significantly improved after neurofeedback training ($p = 0.0000356$, Student's t-test, uncorrected), and FFA activity also increased. We found that increased FFA activation correlated with greater test accuracy.

Conclusion
Neurofeedback training successfully improved face recognition ability based on FFA activation. We suggest that degeneration of FFA activity results in elderly subjects' decreased ability to recognize faces.

Title: Adolescent-specific attenuation of Pavlovian biases on motivated behaviors

Authors: *H. A. RAAB, S. HIRALALL, C. A. HARTLEY
Dept. of Psychology, New York Univ., New York, NY

Abstract: Over the course of development, a repertoire of behaviors is critical to support adaptive function in diverse environments. This behavioral repertoire can be acquired through distinct learning systems. Pavlovian learning yields reflexive approach behaviors to cues predicting reward and behavioral inhibition in the face of anticipated punishment, whereas instrumental learning fosters goal-directed actions that bring about beneficial outcomes. In the present study, we investigated the extent to which these learning systems cooperate or compete in children, adolescents, and adults aged 8-25 (n = 61). To examine the degree to which reflexive Pavlovian responses bias instrumental learning, we used a Go/No Go task that orthogonalizes valence and action. There are four resulting trial types: Go to Win, No Go to Win, Go to Avoid Losing, and No Go to Avoid Losing. Critically, for Go to Win and No Go to Avoid Losing the

Pavlovian expectancies are aligned with the instrumental contingencies, whereas for No Go to Win and Go to Avoid Losing Pavlovian and instrumental responses are in conflict. Children and adults performed more accurately on the trials for which Pavlovian expectancies and instrumental contingencies are aligned as compared to in conflict, indicating a robust Pavlovian bias on instrumental learning. However, this valence-by-action interaction was not evident in adolescents, whose performance was comparable across trial types. Computational models of participants' behavior further corroborated the attenuation of Pavlovian biases on instrumental learning, specifically during adolescence. This developmental shift in Pavlovian and instrumental contributions to motivated behaviors may foster a more flexible behavioral repertoire during the transition from adolescence into adulthood. Across development the neural circuitry implicated in motivated behavior undergoes significant structural and functional changes. In future studies, we aim to examine how these age-related changes in the brain may underlie this nonlinear behavioral trajectory.

Title: Brain network dynamics of arbitrary visuomotor learning

Authors: *A. BROVELLI[1], R. BASANISI[1], B. L. GIORDANO[1], S. PANZERI[2]
[1]CNRS & Aix-Marseille Universtity, Inst. de Neurosciences de la Timone (INT), Marseille Cedex 05, France; [2]Inst. Italiano Di Tecnologia, Rovereto, Italy

Abstract: Acquisition and consolidation of instrumental behaviors are known to engage two distinct decision-making processes. Acquisition relies on flexible goal-directed actions selected according to expected outcomes as well as current goals and motivational state. Consolidation is characterised by the gradual formation of stimulus-driven habitual responses. At the neural level, goal-directed actions are thought to be primarily controlled by the associative fronto-striatal circuit, whereas selection of action during gradual automaticity and consolidation recruits the sensorimotor fronto-striatal territories. Although the functional specificity of different fronto-striatal areas is relatively well understood, little is known about the dynamics of interaction between brain regions, or functional connectivity dynamics, during learning.To address this

issue, we measured brain activity using magnetoencephalography (MEG) while participants learned deterministic relations between stimuli, actions and outcomes by trial-and-error (arbitrary visuomotor learning). Single-trial high-gamma activity (HGA) from 60-120Hz aligned on motor response was estimated at the single-trial level within 96 anatomically-identified brain regions of the MarsAtlas parcellation scheme. To characterise the dynamics of learning-related modulations at the area-level, we computed the mutual information between HGA and learning phases. To quantify whether directional influences between areas encoded learning phases, we used a novel information theoretical metric that is able to track, in a time-resolved manner, the amount and content of information flow between neural signals. Statistical significance was assessed by means of cluster-based permutations tests. Regions in the ventromedial prefrontal and orbitofrontal cortex were found to encode learning phases prior to action selection. Anatomically, these regions are part of the limbic and associative fronto-striatal circuits, and may thus reflect goal-directed processes. In addition, the dorsolateral premotor and motor regions in sensorimotor territories were found to encode learning after action execution. Preliminary results on directional influences between these brain areas will be presented.

Abstract: In order to make adaptive decisions, humans and other animals must flexibly represent the current value of expected outcomes. The ability to infer values “on-the-fly” has been classically examined using the reinforcer devaluation paradigm, in which responses to a conditioned stimulus (CS) are probed before and after selective devaluation of the unconditioned stimulus (US) predicted by the CS. Intact animals respond less to the CS predicting the devalued

US. Rodent and non-human primate studies demonstrate that lesions of the orbitofrontal cortex (OFC) result in continued responding to the CS predicting the devalued US, suggesting that this region is necessary for inferring the current value of the predicted US. Human neuroimaging studies have established a correlational link between OFC activity and updated reward expectations in devaluation tasks, but whether this region plays a causal role in human outcome-guided behavior has not been determined. Here we used a between-subjects design in which we temporarily disrupted OFC activity by applying continuous theta burst stimulation (cTBS) to a dorsolateral prefrontal cortex target that was determined to be maximally functionally connected to the OFC in resting-state fMRI scans. Subjects first underwent conditioning to learn associations between two sets of visual CS's and individually selected, value-matched appetitive sweet and savory food odors (US's). On a subsequent day, hungry subjects made free choices between pairs of CS's to receive the sweet or savory food odor associated with the selected CS. Next, cTBS was applied at either 80% (STIM: N=28) or 5% (SHAM: N=28) of resting motor threshold. After stimulation, subjects were provided with an *ad libitum* meal corresponding to one of the two food odors, after which they performed the free choice task in extinction. Odor pleasantness ratings acquired before and after the meal showed robust and selective devaluation of the odor related to the eaten meal in both STIM and SHAM subjects, demonstrating that cTBS did not disrupt devaluation of the US. However, whereas SHAM subjects significantly reduced choices of CS's predicting the devalued US in the early trials of the choice task, STIM subjects failed to exhibit a significant devaluation effect, and selected the CS associated with the devalued US significantly more often compared to the SHAM group. These results demonstrate that indirect stimulation of the human OFC using connectivity-based cTBS disrupts outcome-guided behavior in humans. They further support mounting evidence across species that the OFC represents the identity of expected outcomes, and uses this information to infer their current value.

Abstract: Pupil responses are known to indicate brain processes involved in perception, attention and decision-making. They can provide an accessible biomarker of human memory performance and cognitive states in general. Here we investigated changes in the pupil size during encoding and recall of word lists, and compared them to electrophysiological changes recorded in epilepsy patients implanted with intracranial electrodes. Consistent patterns in the pupil response were found across and within distinct phases of the free recall task. The pupil was most constricted in the initial fixation phase and was gradually more dilated through the subsequent encoding, distractor and recall phases of the task, as the word items were maintained in memory. Within the final recall phase, retrieving memory for individual words was associated with pupil dilation in absence of visual stimulation. Words that were successfully recalled showed significant differences in pupil response during their encoding compared to those that were forgotten - the pupil was more constricted before and more dilated after the onset of word presentation. This pattern of changes was also observed for intracranially recorded high gamma activity, revealing consistent sequence of latencies during word encoding. A model is proposed for the role of pupil dilation and the correlated high gamma activity in the brain. Our results suggest pupil size as a non-invasive biomarker of brain activities associated with memory processing in the brain, which can be used for modulation and treatment of deficits in memory and cognition.

Title: Hippocampal representations of temporal statistics predict subsequent reasoning

Authors: *A. PUDHIYIDATH[1], A. C. SCHAPIRO[2], R. J. MOLITOR[1], A. R. PRESTON[1]
[1]The Univ. of Texas at Austin, Austin, TX; [2]Psychiatry, Beth Israel Deaconess Med. Ctr. / Harvard Med., Boston, MA

Abstract: Events unfold in a continuous fashion, and yet we segment experience into discrete memories with both a beginning and an end. Recent data indicate that hippocampus and prefrontal cortex play critical roles in representing the temporal structure of experience. Here, our goal is to test how hippocampal and prefrontal representations that code temporal statistics of the environment bias reasoning decisions about relationships among memory elements that occur within the same or different temporal contexts. We used a modified version of the temporal community structure paradigm developed by Schapiro et al. (2013) to generate an iterative sequence of novel, 3D objects that participants viewed while undergoing fMRI scanning. Unbeknownst to the participants, the sequence was structured in such a way that each object belonged to one of three highly structured temporal communities. The presentation order of the objects followed a mutually predictive temporal order, shifting into another temporal community via 'boundary objects' that demarcated the entry and exit points of a temporal cluster. After viewing the temporally mediated sequence, participants completed a series of reasoning tasks outside of the scanner, including inductive generalization. We hypothesized that participants' knowledge of the temporal community structure would bias their choices during inductive reasoning. Behaviorally, we found that participants were more likely to induce that members of the same temporal community shared non-temporal properties (e.g., preferred habitat) than members of different communities. At the neural level, we found that bilateral anterior hippocampus representations were more similar for objects in the same temporal community relative to those in different communities, with the degree of similarity predicting participants' decisions about the objects. Moreover, we found that medial prefrontal cortex representations differentiated boundary items from one another, suggesting that this region may be integral to event segmentation processes that guide temporal knowledge acquisition. Collectively, these findings add to a growing body of literature demonstrating how spatial and temporal codes within the hippocampus influence decision-making beyond the domain of memory.

Title: Subsequent memory and hippocampal activation in borderline personality disorder

Authors: *D. CARCONE, A. C. LEE, A. C. RUOCCO
Univ. of Toronto, Toronto, ON, Canada

Abstract: Background: Individuals with borderline personality disorder (BPD) report everyday problems with forgetfulness and display deficits on standardized measures of memory functioning. The medial temporal lobe, involved in memory encoding and consolidation, is smaller in individuals with BPD and shows an altered pattern of resting metabolism. The neural correlates of memory encoding in BPD have not been studied outside of the context of emotionally-valenced material. The goal of this study was to examine the neural underpinnings of memory encoding in BPD using fMRI and compare how patterns of brain activation associated with subsequent successful memory performance may be different than healthy controls.
Method: The present study assessed 20 individuals with BPD and 21 healthy controls. Participants viewed emotionally-neutral scenes during fMRI scanning and subsequently completed a recognition memory test. The difference in brain activation during presentation of later-remembered versus forgotten scenes was examined using non-parametric statistics. Analyses considered the bilateral hippocampus as an *a priori* region of interest.
Results: Left hippocampal activation was observed when contrasting activation during subsequently remembered versus forgotten trials for healthy controls, while no significant hippocampal activation was observed for the BPD group. Comparing BPD and healthy control groups on these contrasts revealed no significant differences in hippocampal activation. However, the magnitude of left hippocampal response for healthy controls was moderately correlated with memory performance ($r = .45$, $p<.04$), while no correlation was observed for participants with BPD ($r = -.33$, $p=.18$). The strength of this correlation was significantly different between groups ($z=2.3$, $p<.02$).
Conclusions: These results demonstrate that the memory disruptions associated with BPD may not be wholly driven by emotional interference. The results also suggest that hippocampal dysfunction at the time of memory formation may be meaningfully associated with the deficits in memory retrieval exhibited by individuals with BPD. Follow-up analyses will use multi-voxel pattern classification to determine whether a multivariate statistical approach is more sensitive to differences in hippocampal activity between BPD and healthy control groups.

Title: Selectivity in knowledge acquisition effectively confers productivity: Behavioral experiments and neural network simulation

Authors: *H. KURASHIGE[1,2], Y. YAMASHITA[2], T. HANAKAWA[2], M. HONDA[2]
[1]The Univ. of Electro-Communications, Chofu, Tokyo, Japan; [2]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan

Abstract: Knowledge acquisition is not a passive process. Many studies in cognitive neuroscience psychology have shown that we actively select information from the environment and have identified several factors governing the selectivity, such as congruency with prior knowledge, familiarity, curiosity, anticipation to use, and actual use. In addition, the results of functional imaging and neurophysiological measurements have shown several brain regions are involved with these factors and resultant selective knowledge acquisition. On the other hand, functional consequence of the selectivity in knowledge acquisition is unclear even though it is vital determinant for our cognitive development. In this study, we hypothesized that selectivity in knowledge acquisition results in effective augmentation of productivity, especially in creativity-demanding task. To test this, we conducted two human experiments using novel compositional Japanese words. Both experiments consisted of knowledge acquisition through a flash presentation of these compositional words, memory recognition test for these words, and essay composition task based on these words. In experiment 1, we showed that the acquisition strength of these compositional words was positively related to the productivity for the essay composition based on the words. While this result seemed to support our hypothesis, it might also reflect better memory independent of spontaneous selection. Therefore, in experiment 2, we confirmed that spontaneous selectivity in knowledge acquisition, rather than memory strength per se, conferred greater productivity. The results of these experiments suggested that the selective acquisition of knowledge effectively augmented productivity. In addition, we conducted neural network simulation in which Hebbian and homeostatic plasticity rules were incorporated. In this simulation, we found that novel information that was assigned to locations more easily accessible to the entire network was better assimilated and therefore selectively acquired. Because information encoded in such location is probably able to activate vast network regions, this mechanism of selective acquisition may explain the link between selectivity in knowledge acquisition and productivity observed in our experimental observations. Together, the present study showed a rational aspect in knowledge acquisition.

Title: Tracking the development of specific and generalized representations during concept learning

Authors: *C. R. BOWMAN, D. ZEITHAMOVA
Univ. of Oregon, Eugene, OR

Abstract: Healthy memory function allows us to both remember specific past experiences as well as link across experiences to form new knowledge. Recent work has shown that the ventromedial prefrontal cortex (VMPFC) and hippocampus support integration across events in both episodic memory and in concept learning. The detection of generalized representations within a single session contrasts with memory consolidation studies that often show generalized memories in the VMPFC only after a delay, thought to reflect consolidation of representations from the hippocampus to cortex. Using a category-learning task, we sought to better understand how concept representations emerge across learning in a single session, and how they relate to the development of specific representations of individual category exemplars. While undergoing fMRI, subjects completed an observational category-learning task where they learned to classify cartoon animals into two species. Subjects completed runs of study interspersed with generalization tests. In study runs, subjects saw multiple repetitions of 8 training items presented individually along with their species labels. In test runs, subjects saw the training items as well as new items that had never been given a species label. Subjects were asked to classify items into the two species. Behavioral results showed that subjects classified new items at above-chance levels from the first test, suggesting they may be able generalize based on limited experience. Across generalization tests, classification accuracy for the old items steadily improved, whereas accuracy for new items remained relatively constant, leading to a classification advantage for old relative to new items late in learning. Pattern similarity analysis was used to track the development of specific and generalized representations in the VMPFC. Across pairs of study runs, we compared patterns of activation for repeated presentations of the same item to items in the same category (item representations), as well as the similarity of items within the same category to items in different categories (category representations). Mirroring behavioral increases in accuracy for classifying old items, we found that VMPFC representations of individual items grew stronger from the first half of training to the second half. We did not, however, find evidence of category representations in the VMPFC during training, suggesting

that generalized representations in the VMPFC may instead arise during test in response to generalization demands. These results may reconcile the conflicting findings regarding early VMPFC contributions to memory generalization.

Title: Exploring event structure in music perception

Authors: *J. A. WILLIAMS[1], C. BALDASSANO[1], J. CHEN[2], U. HASSON[1], K. NORMAN[1]
[1]Neurosci., Princeton Univ., Princeton, NJ; [2]Psychology, Johns Hopkins Univ., Baltimore, MD

Abstract: While perceiving continuous natural stimuli, humans automatically segment experiences into discrete events (Baldassano et al., 2017). To better understand how these experiences are discretized, recent fMRI studies of event segmentation have employed the use of stimuli like movies and audio narratives. These studies have identified brain regions that transition between long-lasting (on the order of minutes) stable patterns of activity. There is reason to believe that music contains a similar hierarchical structure to movies and audio narratives (Farbood et al., 2015). We hypothesize that brain activity patterns reflect the event structure of songs, and that event boundaries from higher-order cortical regions are inherited (in a hierarchical fashion) by lower-order regions. To test this we used fMRI to record participants' brain activity as they listened to 16 familiar songs (8 jazz and 8 classical). The song durations ranged from 90 seconds to 225 seconds. Next, we collected annotations for these songs by asking a separate group of subjects to mark when "meaningful" changes occurred in a song. Then, for each song, we identified temporal boundaries between stable patterns of brain activity using a Hidden Markov Model, and compared these model boundaries to the human annotations. Compared to a null model with random boundaries, we identified multiple brain regions with significant matches to the observer-identified boundaries, including A1, mPFC, superior parietal cortex, and angular gyrus ($p<0.05$, FDR-corrected). The higher-order regions found in this analysis resemble the network of regions found in previous event segmentation studies, with some differences that may reflect the difference between event segmentation in narratives and music. Furthermore, the overlap between regions in this study and previous studies suggests that a shared network of regions is involved in representing hierarchical structure in complex time-varying stimuli and detecting meaningful changes in these types of stimuli.

Title: Effects of transcranial direct current stimulation (tDCS) on episodic memory: A systematic review and meta-analysis

Authors: *G. GALLI[1], M. VADILLO[2], M. SIROTA[3], M. FEURRA[4], A. MEDVEDEVA[1]

Abstract: In the past decade, several studies have examined the effects of transcranial direct current stimulation (tDCS) on long-term episodic memory formation and retrieval. These studies yielded conflicting results, likely due to differences in stimulation parameters, experimental design and outcome measures. Here, we conducted four meta-analyses to assess the robustness of tDCS effects on episodic memory. We analysed the effects of anodal and cathodal tDCS on episodic memory accuracy and response times. Although all selected studies reported a significant effect of tDCS in at least one condition in the published paper, we found only statistically non-significant close-to-zero effects of anodal and cathodal stimulation on accuracy and reaction times. A moderator analysis suggested that the location, duration, and time of administration of the stimulation moderated the effectiveness of tDCS. To warrant theoretical advancement and practical implications, more rigorous research is needed to fully understand whether tDCS reliably modulates episodic memory, and the specific circumstances under which this modulation does, and does not, occur.

Title: Neural pattern similarity during encoding tracks subsequent memory in young, but not older, adults

Authors: *J. D. KOEN[1], N. HAUCK[2], M. D. RUGG[3]
[1]Univ. of Texas at Dallas, Dallas, TX; [2]Ctr. for Vital Longevity, Univ. of Texas At Dallas, Dallas, TX; [3]Ctr. for Vital Longevity, Univ. of Texas at Dallas Ctr. for Vital Longevity, Dallas, TX

Abstract: We conducted a study to examine the hypothesis that age-related neural dedifferentiation -reduction in the regional specificity and precision of neural representations in older relative to younger adults - during memory encoding results in degraded memory representations that contribute to age differences in episodic memory. This hypothesis was tested using trial-level neural (BOLD) responses elicited in the parahippocampal place area (PPA) and lateral occipital cortex (LOC) while young and older adults studied pictures of objects and scenes for a subsequent memory task. Pattern similarity was computed as the difference in the across-voxel correlation within (e.g., scenes and scenes) versus between (e.g., scenes and objects) categories. In young adults, trials that were subsequently recollected were associated with higher values of within-category pattern similarity compared to trials for which subsequent recollection failed. This effect was limited to the PPA, and was graded such that trials that were subsequently recognized in the absence of recollection also had higher measures of pattern similarity when compared to trials that were subsequently forgotten. These subsequent memory effects were not present in older adults. In addition, although older adults demonstrated higher levels of within- versus between-category pattern similarity in the PPA for scenes than for objects, the difference was smaller than that evident in young participants (there was no analogous age difference in the LOC). The above pattern of results are consistent with our prior findings using a differentiation index - a measure of neural selectivity for a regions preferred stimulus category (e.g., scenes in the PPA) - which showed age differences in differentiation limited to the PPA. This finding might indicate that age is associated with differences in the stability with which individual events are represented in category-selective cortical regions or, at least, in the PPA. Together, the results

are consistent with the hypothesis that neural dedifferentiation is associated with less effective memory encoding.

Title: Split sleep is superior to consolidated nocturnal sleep for the retention of factual knowledge

Authors: *J. N. COUSINS, E. VAN RIJN, K. WONG, T. TEO, M. W. L. CHEE
Cognitive Neurosci. Lab., Duke-Nus Med. Sch., Singapore, Singapore

Abstract: Chronic sleep restriction is widespread, yet we know little about how to apportion the limited amount of sleep people obtain in order to minimize cognitive impairment. Should sleep in humans be obtained in a single bout of nocturnal sleep or split between nocturnal and daytime sleep periods? Daytime naps provide benefits for consolidation of material learned before sleep, and encoding of new information after sleep. However, it remains unclear how pre and post-nap learning are affected under a habitual split sleep schedule. We compared long-term memory in 58 participants who learned across 3 consecutive days with consolidated (6.5-hour nocturnal sleep opportunity) or split sleep (5h nocturnal sleep +1.5h daytime nap opportunities). On each day, participants spent one-hour learning detailed facts about six species of amphibian in the morning (11:00), and one-hour learning six different species of amphibian after the nap period in the afternoon (17:00). Participants were tested the following evening after a nocturnal recovery sleep opportunity (9-hours), via 360 two-alternative forced choice questions. A mixed ANOVA with group (5h+Nap/6.5h) and learning-time (morning/afternoon) showed a significant main effect of group ($p=0.046$) and a group*learning-time interaction ($p=0.021$). The 5h+Nap group remembered significantly more about species learned in the afternoon ($p=0.01$), while groups did not differ for species learned prior to the nap in the morning ($p=0.23$). This suggests that when available nocturnal sleep is curtailed to suboptimal levels, a split sleep schedule enhances learning after a nap opportunity, but critically this schedule does not impair morning learning, where less preceding nocturnal sleep was obtained. A split sleep schedule may therefore optimize the cognitive functions that underpin learning.

Title: Prefrontal - temporal interactions underlie successful long-term memory encoding: A meta-analytic functional co-activation mapping study

Authors: *R. S. BLUMENFELD, S. E. DUARTE, K. K. CHENG
Psychology and Sociology Dept., California State Polytechnic Univ. Pomona, Pomona, CA

Abstract: The ability to successfully encode information into long-term memory (LTM) is fundamentally important for our daily functioning. Results from neuroimaging studies of successful LTM encoding consistently implicate a network of brain regions including areas within the lateral prefrontal cortex, inferotemporal cortex, and within medial temporal lobe. We were interested in investigating the interactions amongst these regions during successful LTM encoding. We hypothesized that during successful encoding, left mid-ventrolateral prefrontal cortex (VLPFC) would act as a global hub playing an essential role in mediating communication between other prefrontal regions and temporal regions. To test this hypothesis, we used meta-analytic functional co-activation mapping to construct a network model (graph) representing patterns of co-activation amongst brain regions associated with LTM encoding success across 80 studies in the LTM encoding neuroimaging literature. In this graph, nodes represent brain regions and edges represent the normalized number of times two regions are co-activated across studies in the successful encoding (subsequent memory effect) literature. Interrogating this network using graph-theoretical metrics, we find, consistent with our hypothesis, that a region of left VLPFC (pars triangularis) has the highest degree centrality in the network. Further results from community detection analyses demonstrate that the encoding network is decomposable into separate prefrontal and temporal sub-networks with left VLPFC, left fusiform gyrus and left inferior temporal cortex forming the network core. Although medial temporal regions are important central nodes in this network, our data indicates that the strongest paths do not flow through them, but rather through inferior temporal regions. Overall in this graph, we find the pattern and the extent of prefrontal-temporal interactions are different than those within a larger-scale control graph constructed from the BrainMap database. Next, we constructed separate graphs associated with successful “item” and “associative” encoding co-activation. We find that these graphs have similar properties but differ in their prefrontal contributions, with “item” having stronger co-activation within VLPFC subregions and “associative” encoding having

stronger connectivity between dorsolateral prefrontal cortex (DLPFC) and VLPFC. In conclusion, our pattern of results is consistent with the idea a unique pattern of prefrontal-temporal interactions underlies successful LTM encoding.

Title: Theta oscillaton is associated with the amount of successful context encoded

Authors: *U. CABALLERO SANCHEZ, T. ROMAN-LOPEZ, C. SANCHEZ-GACUZ, M. MENDEZ-DIAZ, O. PROSPERO-GARCIA, A. RUIZ-CONTRERAS
Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Episodic memory is the ability to remember events in a temporal and spatial context. Subsequent memory effect is defined as the brain responses during encoding when the retrieval of information was successful. Subsequent memory effect has been related with theta oscillation which is higher, particularly at occipital and frontal regions, depending on the context awareness during retrieval, evaluated by a self-reported manner by means of the “remember/know” paradigm; however, it is required a more direct measure for a specific context encoding. Noteworthy, it is not clear if theta activity during encoding is related to the type of context retrieved, i.e., spatial, temporal or both. The aim of this study was to evaluate theta oscillation associated to subsequent memory effect depending on the context recollected during retrieval, at occipital and frontal regions. Participants solved a source memory task, which consisted in six blocks where natural and artificial images were shown. Each block was composed by an encoding, followed by a retrieval phase. During encoding, to manipulate the spatial context, each image was displayed over or under the fixation point for 1000 ms; to manipulate the temporal context, two independent lists of images were presented. Thus, spatial and temporal context were imbedded in each block. Participants had to classify, by a button press, images as natural or artificial. During the retrieval phase, participants had to indicate, by button press, where and when the image was showed up during the encoding phase. A subsequent memory effect was evidenced by higher theta amplitude (detected by the Hilbert transform) at O2 when participants recollected both spatial and temporal contexts than when they failed to remember one of the

contexts, both of them or when they classified incorrectly an old image as a new one. There were no differences at frontal regions. Our results showed that theta in occipital region, specifically at O2, was associated only with the whole acquisition of the context, suggesting theta activity might be associated with the amount of information, and not with the type of context, encoded.

Title: Memory integration and separation during learning are mediated by distinct hippocampal and cortical networks

Authors: *M. L. MACK[1], B. C. LOVE[2], A. R. PRESTON[3]
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Univ. Col. London, London, United Kingdom; [3]The Univ. of Texas at Austin, Austin, TX

Abstract: Successful learning depends on encoding new information relative to existing knowledge. Neurobiological memory theories attribute such encoding to complementary functions of the hippocampus (HPC) and its interactions with neocortex. Specifically, HPC comparator processes that evaluate the overlap between new experiences and current knowledge trigger either pattern separation, wherein new memories are made representationally distinct from existing knowledge, or pattern integration, wherein new information is incorporated into existing memories. Recent behavioural and electrophysiological data suggest that the tendency of the HPC to trigger separation or integration may fluctuate on a moment-by-moment basis; yet, characterizing such moments of learning have proved challenging in humans given the lack of empirical methods to identify precisely when knowledge is created versus updated. Here, we overcome this challenge with SUSTAIN, a computational learning model that makes explicit predictions about when newly-encountered information is encoded through pattern separation or integration. During fMRI scanning, participants learned to categorize complex objects composed

of multiple features across four category learning tasks, with each task defined by different associations between category labels and combinations of object features. The learning model was fit to participants' behavior during the learning tasks to derive trial-by-trial predictions of when a new separated memory was formed versus when existing memory representations were updated. These model predictions were then leveraged in a fMRI regression analysis to characterize the neural circuits underlying moments of knowledge creation and integration. This approach led to two central findings: First, the creation of new memories was preceded by elevated activation in anterior HPC, consistent with HPC's role in detecting mismatch and triggering new encoding. A similar striatal signal also preceded new encoding. Second, distinct cortical networks were functionally coupled with HPC during the different encoding operations. We found a knowledge creation network involving higher-level visual representation areas including lateral occipital and ventral temporal regions, and a knowledge updating network comprised of the angular gyrus and regions of lateral prefrontal and frontopolar cortices. By leveraging a neurocomputational framework grounded in cognitive theory, our findings reveal the neural mechanisms of critical learning moments and characterize how new information is successfully reconciled with prior knowledge.

Title: Differential modulation of reward on memory encoding for objects and scenes is reflected in functional connectivity patterns

Authors: *J. YOO[1,2], H. SCHULTZ[2,3], D. MESHI[2,4], S. HAN[1], H. HEEKEREN[2]
[1]Dept. of Psychology, Yonsei Univ., Seoul, Korea, Republic of; [2]Dept. of Educ. and Psychology, Freie Univ. Berlin, Berlin, Germany; [3]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [4]Dept. of Advertising and Publ. Relations, Michigan State Univ., East Lansing, MI

Abstract: This study builds on two lines of research investigating long-term memory processing in the brain: (1) anterior and posterior medial temporal lobe (MTL) pathways process different stimuli categories—object-based and spatial-based (scene) memory, respectively, and (2) reward-induced stimuli value enhances long-term declarative memory for these stimuli, which is mediated by the MTL and the dopaminergic midbrain. Taken together, these two findings lead to the question: is reward-induced memory enhancement for stimuli mediated differentially, by these different pathways in the brain? We hypothesized differences in value-related encoding

between objects and scenes due to different functional connectivity patterns of the anterior and posterior MTL.
To address this, we recruited 25 participants (5 males, mean age=25) for a two-day fMRI experiment (Siemens 3T, 1.5x1.5x2 mm EPI sequence, TR=1.8s, multiband factor=2). On Day 1, they performed a memory encoding task in the scanner in which they were differentially rewarded (high/low) for correctly classifying stimuli with regard to color (blue/yellow) and category (object/scene). On Day 2, participants returned to perform a surprise retrieval, recognition-memory task. Behaviorally, we found an asymmetric memory enhancement due to reward, in which high-reward objects were remembered significantly better than any other condition. With regard to the analysis of neuroimaging data, we employed functional connectivity multivariate pattern analysis (fcMVPA) to test our hypothesis: a linear support vector machine was trained to classify pairwise cross-correlation coefficients (edges) of the weighted time-series of predefined regions of interest. fcMVPA iteratively classified edges weighted with object & high-value vs. scene & high-value as a function of the number of edges included, with a peak accuracy of 82.5% when the 104^{th} edge was included. To characterize the patterns for two conditions, we divided the 104 edges into two groups which showed stronger correlation when weighted with object & high-value and vice versa, and performed centrality analysis for each network. As a result, right lateral occipital cortex showed the greatest eigenvector centrality for 63 edges which showed stronger correlation in regard to object & high-value. For 41 edges showing stronger connectivity for high-value scenes, left parahippocampal gyrus acted as the central hub.
Our results demonstrate reward-enhancement of object and scene memory due to differential functional connectivity patterns, suggesting that when value and stimulus category interact, the information follows distinct neural pathways.

Title: The hippocampus and early visual regions are functionally connected during spatial memory encoding

Authors: *B. M. JEYE, S. D. SLOTNICK
Boston Col., Chestnut Hill, MA

Abstract: The hippocampus and contralateral early visual regions are known to be activated during spatial memory; however, there is no evidence in humans, to our knowledge, that these regions are functionally connecting during this cognitive process. In the current functional magnetic resonance imaging (fMRI) study, we assessed whether the hippocampus and early visual regions were functionally connected during spatial memory encoding. During the study phase, participants maintained fixation and viewed abstract shapes presented in the upper-right quadrant, the lower-right quadrant, the upper-left quadrant, or the lower-left quadrant. During the test phase, old shapes were presented at fixation and participants classified each shape as previously in the "upper-right", "lower-right", "upper-left", or "lower-left". Encoding of shapes in the left visual field (collapsed over visual field location to increase power) produced activity in a left posterior hippocampal region, while encoding of shapes in the right visual field produced activity in another left posterior hippocampal region. To identify the early visual regions that might be connected to each of these hippocampal activations, we conducted a functional connectivity analysis between each hippocampal region and the rest of the brain. A preliminary analysis revealed the hippocampal activation associated with the encoding of shapes in the right visual field had greater functionally connectivity to contralateral (left hemisphere) early visual regions, including V1, than ipsilateral early visual regions. The hippocampal activation associated with the encoding of shapes in the left visual field did not show this contralateral pattern of early visual area connectivity. These findings suggest that the hippocampus and early visual regions interact to support the encoding of spatial memories.

Title: Event segmentation of repeated information

Authors: *O. BEIN, L. DAVACHI
Dept Psychology, NYU, New York, NY

Abstract: Most of our everyday life events contain repetition. For example, we typically take the same route to the same building and office. Event segmentation theories posit that continuous experience is segmented into discrete episodes, or events, at event boundaries. Specifically, it has been hypothesized that an "event model" is maintained to guide behavior within each event or context and that 'event-boundaries' are encountered as a result of prediction-errors that signal the

need for a new event model (Zacks et al., 2007). But how is event segmentation influenced by repeated events as they become more predictable, as in our everyday life? Are events nevertheless segmented, in the potential absence of prediction error, or does repetition reduce segmentation processes and lead to more integration across event boundaries? While previous studies in the field have typically used once-presented lists, here we repeated the lists, and examined behavioral and neural effects of event segmentation using high-resolution functional magnetic resonance imaging (hr-fMRI). Participants viewed black-and-white objects superimposed on a color background. The background color changed every 4 objects, thus an event boundary was defined as a change in background color. Participants made pleasantness judgement on the object-color combination. Each list repeated 5 times, and was followed by an order memory test. Upon completion of all lists, participants were tested on their memory for object-color associations. Participants highly accurate in the order memory test, indicating that the indeed the lists were well-learned. Behaviorally, markers of event-segmentation previously found in once-presented lists (Heusser et al. 2018) persisted over repetition: reaction times (RTs) during the list-learning phase were greater for items presented at the boundary compared to non-boundary items. Interestingly, we observed this effect, and in similar magnitude, even when the lists repeated. Additionally, memory for the object-color association was greater for boundary items compared to non-boundary items. In our analyses of the hr-fMRI data, we examined the contributions of hippocampal subfields and medial temporal lobe regions to event-segmentation across multiple repetitions, as well as to potential integration mechanisms. These results are suggestive of the neural and cognitive processes underlying event segmentation over multiple repetitions. They suggest that even in repeated and well-learned experiences, events are still segmented in memory.

Title: Novelty processing associated with neural beta oscillations improves recognition memory across the lifespan

Authors: *T. K. STEIGER, A. SOBCZAK, R. REINEKE, N. BUNZECK
Dept. of Psychology, Univ. of Luebeck, Luebeck, Germany

Abstract: Background: Previous imaging studies in healthy young subjects could show that the anticipation of novelty recruits the mesolimbic system and drives subsequent recollection. Since the mesolimbic system undergoes age related changes, we expected that the effect of novelty

anticipation is diminished during healthy aging. **Method:** To test this hypothesis and the underlying neural oscillatory mechanisms, we used EEG in combination with a previously established paradigm in a group of healthy younger (18-31) and elderly (55+) subjects. Here, coloured cues predicted the subsequent presentation of either a novel or previously familiarized image (75% validity), and subjects indicated at outcome whether the cue-image combination was correct or incorrect. On the subsequent day, recognition memory for the novel images was tested using a modified remember/know procedure. **Results:** Overall recognition memory was significantly lower in the elderly subjects; however, novelty prediction improved recognition performance independent of age and memory quality (i.e. recollection and familiarity). At the neural level, expected vs unexpected novel images were accompanied by an increase in beta power (i.e. 13-25 Hz) peaking at around 1-1.5 s after stimulus onset. Importantly, this effect was observed in both age groups but significantly enhanced in the elderly. **Conclusion:** Our data provide further evidence that novelty anticipation improves recognition memory performance, and they suggest that this is not impaired during healthy aging. While beta oscillations appear to provide the underlying mechanism, the increased responses in the elderly suggest compensatory effects.

Title: Across-episode memory formation is facilitated by their conceptually-related overlapping content

Authors: *B. NICOLÁS BERENGUER, D. CUCURELL, L. FUENTEMILLA
Univ. de Barcelona, Barcelona, Spain

Abstract: Individual experiences often overlap in their content, offering the possibility to build links across separate events. However, in daily-life different episodes rarely occur within the same scenario (i.e., entrance of the Parc Güell) and links among them need to be created on the bases of more abstract overlapping features (e.g., parks in Barcelona). Here, participants engaged in a two-phase learning and generalization task, wherein they learned an intermixed set of associations (i.e., face-scene) that overlapped by same scene or by conceptually-related scene information and subsequently generalized to novel stimulus combinations. Participants successfully learned the associations and were capable to generate inferences in both conditions,

indicating that the emergence of across-episode memory representations can rely on overlapping content of conceptual nature.

Title: Selective attention to perceptual versus semantic features at encoding impacts neural engagement and memory behaviour

Authors: *S. VIJAYARAJAH, M. L. SCHLICHTING
Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: We know that attention impacts what we remember, yet the specific mechanism by which attention to different kinds of features influences memory for our experiences remains unclear. Prominent theories disagree as to whether attention to semantic or perceptual features at encoding should yield better memory, with empirical work supporting both claims. We propose that these mixed findings may be due to differences in the nature of the encoded representation—specifically, whether memories are maintained as separate or integrated into existing knowledge—across these states. Previous work has shown that the human brain can store both separated and integrated memory representations (Schlichting et al., 2015). Moreover, selectively attending to different features at encoding (room layout vs. paintings in an art gallery) both influences neural patterns and promotes memory for the attended information (Aly & Turk-Browne, 2016). Here, we build on this prior work with complementary behavioural and fMRI studies asking whether attending to semantic vs. perceptual features at encoding impacts representation of the event as a whole. In a 1-back task, participants viewed fairy tale illustrations that varied in semantic (story) and perceptual (artist) features while searching for either story or artist repeats across blocks. Behavioural results showed that participants were able to detect repeats along both semantic and perceptual dimensions. Moreover, fMRI revealed that semantic attention engaged parietal cortex (including angular gyrus) as well as lateral and anterior temporal regions. In contrast, perceptual attention activated visual regions (occipital pole, lateral occipital cortex) and lateral prefrontal cortex. Following the 1-back, participants completed a surprise memory test that included all illustrations seen in the 1-back (old), illustrations similar to those seen in the 1-back (lures), and new illustrations. Participants had

better memory for non-repeat illustrations encoded during semantic vs. perceptual attention. However, memory for repeats showed the opposite pattern: memory was better (more hits) for repeats encoded during perceptual attentional states and worse (more false alarms to lures) for repeats from semantic attentional states. These behaviours are consistent with perceptual attention promoting mnemonic separation and semantic attention facilitating integration of new experiences into existing semantic networks. Our findings suggest that attention to perceptual vs. semantic features shifts the neural networks engaged during encoding, providing a mechanism by which attention mediates memory representation.

Title: Disruption of verbal episodic memory encoding by epileptiform discharges is greatest in the left perirhinal and entorhinal cortex

Abstract: A comorbidity of epilepsy is memory impairment. It is thought that inter-ictal epileptiform activity in certain brain regions may interfere with memory formation. In this study, we asked if spikes and high-frequency oscillations (HFO) that spontaneously occur during word presentation in a free recall list learning task decrease the probability of recalling that word correctly. The patient cohort included 181 subjects who consented to undergo intracranial monitoring and participate in the task. Intracranial EEG was recorded at 500-1600 Hz and

analyzed using a spike and HFO detector utilizing a topographical analysis of the depth iEEG wavelet convolution. We quantified spike and HFO events during 118,892 word encoding trials, and confirmed spike and HFO detections using visual validation and annotation editing. The electrode sites were classified using co-registered pre-implant MRI and post-implantation CT images that were segmented on the basis of several published brain atlases. A naive Bayesian machine learning model was used to calculate the posterior probabilities of word recall given a spike or HFO, and the significance of this prediction was determined using bootstrapping. In the left hemisphere, but not the right, ripples ($p< 0.01$), fast ripples ($p<0.01$), and spikes ($p<0.01$) disrupted word encoding. In the left temporal neocortex, spikes in the middle temporal gyrus decreased the probability of correct word recall by 11.9% ($p<0.001$, n=1,379). In the left mesial temporal lobe, spikes did not disrupt verbal memory encoding in area CA1 ($p>0.05$, n=364) nor in the dentate gyrus ($p>0.05$, n=417). However, spikes in the left entorhinal cortex (prob= -54.2%, $p<0.001$, n=81) and perirhinal cortex (prob=-15.6%, $p<0.01$, n=167) did strongly disrupt memory encoding. Encoding was not disrupted by spikes in right mesial temporal lobe structures. These results suggest that normal physiological function in the left entorhinal and perirhinal cortices are required for verbal memory encoding. Also, verbal memory impairment in patients with mesial temporal lobe epilepsy may be attributed, in part, to inter-ictal epileptiform activity in the left entorhinal and perirhinal cortices.

Title: Functional-anatomical alignment between brains using a naturalistic stimulus in healthy individuals and a hippocampal amnesic

Authors: *X. ZUO[1], M. D. BARENSE[4], C. J. HONEY[2], J. CHEN[3]
[2]Psychological and Brain Sci., [3]Psychology, [1]Johns Hopkins Univ., Baltimore, MD; [4]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: MOTIVATION. A fundamental and persistent challenge in fMRI research is aligning brain areas and functional responses across individuals. This is particularly difficult when anatomical or functional reorganization may have occurred, as in many clinical populations. How can we compare the neural responses of healthy individuals to patients, when the anatomical relationship between their brains is uncertain? One solution is functional co-registration: define a correspondence between voxels in different subjects, based on each voxel's response profile to a wide range of stimuli (e.g., Haxby et al. 2011; Chen et al., 2015). However, functional alignment sometimes leads a single voxel in one brain to be associated with a weighted combination of widespread voxels in another brain; these alignments may be *a priori*implausible and difficult to interpret. Therefore, we set out to develop a more interpretable functional alignment method that (i) combines anatomical and functional constraints and (ii) establishes a one-to-one match for regions-of-interest across brains. **METHODS.** We establish baselines using healthy controls, then characterize anatomical/functional restructuring in a hippocampal amnesic patient's brain. 36 participants listened to a 7-minute audio story during fMRI. We also collected fMRI data using the same stimulus from an amnesic patient with bilateral medial-temporal lobe damage (Rosenbaum et al., 2008). We calculated inter-subject correlation between a) control subjects, and b) controls and patient, using Shen et al. (2013)'s resting-state parcellation. In a classification analysis, we split the control data in half and compared group average parcel timecourses parcel by parcel. **RESULTS.**Using 56 parcels, classification performance was 84.0% (chance = 1.8%), indicating high between-group correspondence of functional responses, i.e. anatomically corresponding parcels almost always exhibit the strongest correlation between groups.When classification was performed using each subject in one group compared to the other group mean, accuracy was also well above chance (22.9%). Our amnesic-to-control classification accuracywas still above chance (9.3%), but the parcel matching was substantially lower than between controls. **CONCLUSIONS and NEXT STEPS.** Visual inspection suggested that low patient-control correspondence of response was due, at least in part, to poor anatomical correspondence between their brains: portions of the patient brain might have shifted to accommodate damaged or missing tissue. Next, we will use control parcels to generate optimized parcel layouts of functional reorganization in the patient's brain.

Title: Curious connections: White matter microstructure correlates of types of curiosity

Authors: *A. VALJI, A. COSTIGAN[1,2], C. J. HODGETTS[1,2], M.-L. READ[1,2], K. S. GRAHAM[1,2], A. LAWRENCE[1,2], M. GRUBER[1,2]

Abstract: Curiosity - the desire to acquire new information - influences learning and memory. While fledgling neuroscience research has shed light on how state curiosity affects hippocampus-dependent learning, the effect of curiosity on learning is highly variable between individuals. The neuroanatomical substrates underpinning these individual differences in trait levels of curiosity are unknown. Furthermore, curiosity itself is a multifaceted construct, and thus may be supported by multiple neural systems. Here, we used diffusion-weighted imaging to investigate how specific white matter pathways (i.e., the fornix and the inferior longitudinal fasciculus [ILF]) relate to individual differences in distinct types of curiosity: epistemic curiosity (i.e., the desire to acquire new knowledge), social curiosity (i.e., curiosity in obtaining information about others), and perceptual curiosity (i.e., curiosity in an environment rich with novel stimuli). Given that the fornix supports exploratory behaviour and information seeking via hippocampal-striatal connections, we asked the question whether there would be a correlation between fornix microstructure and all three different types of curiosity. In contrast, given that the ILF is involved in networks supporting semantic processing, we predicted a correlation between ILF microstructure and specifically epistemic curiosity. Fifty-one female participants underwent a two-shell diffusion magnetic resonance imaging sequence and completed a set of well-validated questionnaires measuring different types of curiosity. Using deterministic constrained spherical deconvolution tractography, mean fractional anisotropy (FA) and mean diffusivity (MD) values for the fornix and ILF were extracted for each participant and correlated with the self-report measures of curiosity. In line with our predictions, we found a significant negative correlation between epistemic curiosity and MD of the ILF. In addition, fornix microstructure was found to significantly correlate with multiple aspects of curiosity, namely interest-based epistemic curiosity, general-based social curiosity and specific-based perceptual curiosity. The present findings suggest that curiosity is a multifaceted concept that relies on distributed but interacting structural brain networks where fornix microstructure is potentially associated with a variety of curiosity traits whilst the ILF is associated with epistemic curiosity.

Title: Theta coherent ensembles in the human anterior temporal lobe mediate episodic memory encoding

Authors: *R. HAQUE[1], S. INATI[2], K. A. ZAGHLOUL[3]
[1]Natl. Inst. of Hlth., Bethesda, MD; [3]Surgical Neurol. Br., [2]Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: The electrophysiological underpinnings of human episodic memory have been well characterized by measuring broadband high frequency activity in neocortical areas from macroscopic intracranial electrodes used to detect epileptic seizures. However, the role of narrowband oscillations in human memory formation, particularly in local neocortical circuits, is largely unknown. Here we measure spike-field coherence from micro-electrode arrays implanted in the human anterior temporal lobe in order to assess how local circuits contribute to memory processes. We find that anterior temporal lobe neurons are coherent with narrowband theta oscillations locally and across the cortical surface, and that spikes preferentially occur at a specific phase within the theta cycle. The extent of coherence and phase locking to narrowband theta during memory encoding was significantly greater when those memories were subsequently remembered versus those that were forgotten. These results suggest that theta-coherent networks in the anterior temporal lobe and across the cortical surface promote memory encoding.

Title: Imaging the consolidation of distressing memories: Dissociating voluntary versus involuntary recall

Authors: *R. M. VISSER[1,2], R. N. HENSON[1], E. A. HOLMES[3]
[1]MRC CBU, Univ. of Cambridge, Cambridge, United Kingdom; [2]Clin. Psychology, Univ. of Amsterdam, Amsterdam, Netherlands; [3]Clin. Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: A key question in emotional memory research is how a traumatic event may result in intrusive, involuntary memories of that event - the core clinical feature of psychological disorders such as post-traumatic stress. Previous behavioural work shows that the strength of voluntary recall of traumatic events is not necessarily related to the frequency or vividness of the involuntary recall of those events, a dissociation that is not readily explained by mainstream episodic memory theories. Here, we investigated whether the two types of recall may be associated with distinct neural profiles at the time of encoding and shortly after. For this, 32 healthy participants underwent functional Magnetic Resonance Imaging while viewing clips of distressing events (the so-called 'trauma film paradigm'), with periods of resting state in between consecutive clips. Next, we applied 'multi-voxel correlation structure' to assess the degree to which voxel-by-voxel connectivity profiles related to the encoding of a specific clip persisted during the immediately-following post-encoding rest period. In the hippocampus, higher similarity between post-encoding rest and encoding profiles, compared to immediately-preceding pre-encoding rest periods, predicted the voluntary recall (both verbal and visual recognition) of the distressing events, a week later. This neural profile was not however related to the frequency or variety of intrusive memories that participants recorded in a daily diary, which they kept for a week following film viewing. These findings corroborate behavioural observations and tentatively suggest that voluntary and involuntary memories of the same event may to some extent rely on separate neural systems.

Title: Medial prefrontal cortex has a causal role in selectively enhanced consolidation of emotional memories: A TMS-EEG study

Authors: *N. YEH[1], S. Y. KIM[2], J. PAYNE[4], N. S. ROSE[3]
[2]Psychology, [3]Dept. of Psychology, [1]Univ. of Notre Dame, Notre Dame, IN; [4]Psychology, Univ. of Notre Dame Dept. of Psychology, Notre Dame, IN

Abstract: Abstract Emotional aspects of episodic memory are preferentially benefited at the expense of co-occurring neutral aspects. This is known as the emotional memory trade-off effect, which is enhanced over consolidation delays that include a period of sleep. Previous fMRI research has shown a correlation between retrieval-related activation of medial prefrontal cortex

(mPFC) and memory for emotional (versus neutral) information after a night of sleep compared to after a day spent awake. Moreover, sleep has been proposed to exert its strongest effects on gist-based familiarity, rather than specific recollection of memory details. However, little is known about how mPFC activity during encoding interacts with consolidation processes to enhance emotional aspects of memories after a night of sleep. This study goes beyond correlational findings to casually investigate the role of mPFC activity during encoding in the enhancement of emotionally salient aspects of episodic memory. At encoding, healthy young adult participants (N = 22) viewed negative (e.g. snake) or neutral (e.g. chipmunk) objects placed on plausible neutral backgrounds (e.g. forest scene), while undergoing simultaneous EEG recording with 2s trains of intermittent theta burst stimulation (iTBS) to either the mPFC (i.e., experimental condition) or motor cortex (i.e., active control/sham condition) at 80% of active motor threshold. Memory was assessed with two delayed (i.e., 30 minutes, 24 hours) incidental recognition tests by decomposing the scenes into individually presented objects and backgrounds. The results replicated the emotional memory trade-off with negative objects better remembered than their neutral backgrounds after 30 minutes, with a more pronounced trade-off following a delay (24hr) that included sleep. Consistent with our hypothesis, iTBS to the mPFC led to enhanced gist memory for negative objects following a 24 hour delay that included sleep compared to control stimulation, despite equivalent false alarms rates. Thus, these findings suggest that iTBS to the mPFC during encoding may interact with consolidation processes to selectively preserve the gist of negatively salient information.

Title: Neural correlates underlying the effect of value on recognition memory encoding

Authors: *B. ELLIOTT, C. BLAIS, S. M. MCCLURE, G. A. BREWER
Arizona State Univ., Tempe, AZ

Abstract: The ability to prioritize and encode important or valuable information is an essential aspect of human memory. However, the processes underlying how value can affect memory are not yet well understood. One hypothesis is that value affects memory via top down executive control processes, where after recognizing that a stimulus is valuable, a participant would selectively engage an elaborative or effective rehearsal strategy. A second hypothesis is that value affects memory involuntarily through the dopamine system that determines reward valuation. Here we examined the behavioral and neurophysiological correlates of value-directed

recognition memory. Participants encoded words that were assigned varying point values (1,3,7, or 9) and were instructed that their goal was to maximize their score on a subsequent word recognition test in multiple study-test phases. Subjective states of recollection (i.e., "Remember") and familiarity (i.e., "Know") were assessed at retrieval. Words assigned higher values at study were discriminated more effectively than lower valued words. This difference was primarily driven by increases in Remember responses with no difference in Know responses. During encoding, we examined the extent to which an early parietal P3 component (450-650 ms post-stimulus) thought to index dopamine driven attention allocation and a late sustained frontal positivity (1000-2000 ms post stimulus) that has been related to elaborative rehearsal strategies and executive resources predicted the subjective state of recollection. Our data indicate that that the effect of value on recognition memory is primarily driven by the dopamine-driven reward valuation system as compared to more strategic selective rehearsal processes. Specifically, we found a positive relationship between the amplitude for the P3 component that scaled linearly with the value assigned to each word. Furthermore, this effect was also positively related to behavioral measures of each participants' sensitivity to value. No such relation was observed on the late sustained frontal positivity, and the amplitude of this component was not related to related to each participants' sensitivity to value. Together, these data suggest (1) a need for two distinct processes to support recognition memory decisions, and (2) that value-directed encoding results in a greater effect on subjective states of recollection.

Abstract: Development of a neural prosthetic for human memory requires an understanding of how mnemonic information is categorized and encoded for storage. Our recent report (Hampson et al. J. Neural Eng, 2018, 15:036014) showed that human memory could be successfully

facilitated by delivery of patterned electrical stimulation to CA1 electrode sites in human hippocampus. In prior studies, the patterns were derived by nonlinear multi-input, multi-output (MIMO) modeling of hippocampal CA3 and CA1 ensemble activity during the encoding phase of a visual delayed-match-to-sample (DMS) task. We now extend this study to derive and deliver patterned stimulation in a DMS+Delayed Recognition (DMS+DR) task, to facilitate memory of category content for DMS+DR visual stimuli.

In human patients undergoing Phase II invasive monitoring for intractable epilepsy, recordings from an initial DMS (training) session were employed to determine neuron firing patterns for five categories of images; animal, building, plant, tool, and vehicle. Previous use of a MIMO model only allowed stimulation of CA1 neurons based on CA3 activity. Calculation of category specific stimulation patterns prior to the stimulation session now allows for selection of both CA1 and CA3 neurons as stimulation targets. During a second (stim test) session, subjects received microelectrical stimulation on approximately 60% of trials during the sample phase of the DMS portion of the DMS+DR task. Stimulation trials were a combination of positive stim (stim category matches sample image category), negative stimulation (stim category does not match sample image category) and ambiguous stimulation (image during stimulation was a blank grey square) trials.

Positive stimulation trials for all patients resulted in a reduction of errors in three of the five categories, with the remaining stimulation category performance level near unstimulated performance. Negative stimulation resulted in reduction in errors for at least three of the twenty possible cross category combinations. Ambiguous trial stimulation also resulted in increased performance over chance. Analysis of the survey used to categorize images combined with stimulation results suggest that category stimulation works, but effectiveness is dependent on selection of images used during the recording session to derive category patterns. These results thus provide an important foundation for further design considerations for the current neural prosthetic to restore human memory damaged by injury or disease.

Abstract: In prior demonstrations of category stimulation by a neural prosthetic for human memory (Hampson et al. J. Neural Eng, 2018, 15:036014) we utilized models that were developed from a patient's own hippocampal CA3 and CA1 neural ensemble firing. With this technique, as long as there was a mixture of correct and error trials when the ensembles were recorded, it was possible to detect patterns of neural firing associated with correct memory performance, and utilize those patterns to facilitate performance within a delayed-match-to-sample + delayed recognition (DMS+DR) task. In the adjacent poster (Hampson et al. this meeting) we extended this technique to facilitate specific content categories within visual stimuli. Here we explore whether similar encoding for such categories exists across human subjects. Category patterns from other subjects performing the same DMS+DR task were tested to determine if stimulation patterns would have a shared effect between subjects. Stimulation patterns were matched between subjects through use of common channels on electrodes targeted for implantation in the same location of the hippocampus. This resulted in stimulation of analogous areas between subjects donating and receiving the stimulation pattern. Stimulation testing was performed the same as in the adjacent poster, with a combination of positive, negative, and ambiguous trials. Positive stimulation trials for all patients resulted in a reduction of errors in two of the four categories tested, with the remaining categories performance level near that of unstimulated performance. Categories that showed enhancement were the same as those that showed enhancement with individualized codes (Hampson et al. this meeting). Negative stimulation has resulted in no significant change in performance, while ambiguous trial stimulation has resulted in increased performance over chance in the one subject tested so far. Stimulation effects are similar to, but less effective than, when a subject's own codes are used, and indicate that there may be shared aspects of the neural codes for category representations between subjects. These results indicate that implementation of a neural prosthetic to restore human memory may also facilitate learning and/or rehabilitation via shared representations of memory encoding.

Title: Facilitating memory: An ensemble sparse classification model for decoding memory categories and features from hippocampal spike patterns recorded in epilepsy patients

Authors: *X. SHE[1], D. SONG[1], R. E. HAMPSON[3], G. NUNE[2], B. LEE[2], C. N. HECK[2], C. Y. LIU[2], V. Z. MARMARELIS[1], S. A. DEADWYLER[3], T. W. BERGER[1]

Abstract: To build hippocampal prostheses for enhancing memory functions, it is essential to understand how memories are encoded in the hippocampus. For this purpose, we have developed a multi-resolution, multi-trial (MRMT) sparse classification model to decode hippocampal spiking activities into memory labels. Mode inputs are spatio-temporal patterns of hippocampal CA3 and CA1 spikes collected from epilepsy patients performing a delayed match-to-sample (DMS) task. Model outputs are non-mutually exclusive memory labels describing categories and feature of sample images presented in the sample phases of the DMS task. The classification model consists of a B-spline filter bank with a large range of temporal resolutions and a sparse logistic regression classifier. Sparse model coefficients are calculated with multiple trials of 10-fold estimation and cross-validation, with different random partitioning of data into training and testing sets. Model performances are evaluated with a Matthews correlation coefficient (MCC). To ascertain the significance of decoding performance of the classification model, two additional classification models are estimated using the same procedure as negative controls. In the first control model, values of memory labels (model output) are randomly shuffled to remove the correlation between spike patterns and memory labels; in the second control model, the time window of spike patterns (model input) is shifted to be before the sample presentation event so the spike patterns contain no information about their corresponding sample images. Results show that the classification model yields significantly non-zero MCCs in predicting multiple memory labels in all patients (n = 8), while the two control models obtain zero-valued MCCs in all memory labels and a large majority of memory labels, respectively. These results indicate that (1) the ensemble MRMT sparse classification model effectively avoids overfitting even when the number of features is large (i.e., over a thousand) and the data length is short (i.e., 100 - 200),

and (2) spike patterns during sample response events of the DMS task encodes categories and features of sample images.

Title: Facilitating memory: Enhancing human memory function with endogenous hippocampal neural code predicted by a closed-loop nonlinear dynamical model

Authors: *D. SONG[1], X. SHE[1], R. E. HAMPSON[3], G. NUNE[2], B. LEE[2], C. N. HECK[2], C. Y. LIU[2], V. Z. MARMARELIS[1], S. A. DEADWYLER[3], T. W. BERGER[1]

Abstract: Hippocampal prostheses are biomimetic devices designed to restore and enhance memory functions. They bypass damaged hippocampal circuits by stimulating a downstream (output) hippocampal region using output signals predicted from upstream (input) hippocampal signals with a multi-input, multi-output (MIMO) nonlinear dynamical model. To build a MIMO model that restores normal input-output functions of the hippocampal circuit, intact input-output signals, which are impaired or even absent in the damaged hippocampus, are required. Similarly, to build a MIMO model that enhances memory functions, input-output signals underlying above-normal hippocampal functions are needed. One approach for solving this "missing data" problem is to obtain input-output data and MIMO model from different subjects, who have normal or above-normal memory functions. This memory transfer approach relies on the existence of similarities in neural recordings and encodings between subjects and thus can be challenging. In this abstract, we describe an alternative self-learning approach that allows building normal or above-normal MIMO models by exploiting the input-output data recorded from the same subjects. In this approach, memory states are assessed with a classifier that takes neural signals as inputs and memory strength as output. MIMO models are adaptively estimated from the input-output data controlled by the memory strength. When the memory strength is high, which reflects a strong memory state, MIMO models are updated using the strong-state input-output

data; when the memory strength is low, which indicates a weak memory state, MIMO model are used to stimulate the downstream regions to restore the strong memory codes learned during strong memory states. This closed-loop strategy essentially elevates weak memory states into strong memory states and thus enhances the overall memory functions of subjects. Our experimental-modeling studies in human subjects have shown that the outcomes (i.e., correct or error responses) of delayed match-to-sample (DMS) task, which result from the strength of memory states, can be predicted from the hippocampal CA3 and CA1 spike trains. Using MIMO models estimated from CA3-CA1 spiking data recorded during correct DMS trials (i.e., strong memory states) to drive stimulations to CA1 can improve memory performance of the DMS task. These results provide strong supports for the feasibility of building such a self-learning memory prosthesis for enhancing memory functions.

Title: Facilitating memory: Localization of ensembles and neural correlates of encoding contributing to a neural prosthetic for human memory

Authors: *S. A. DEADWYLER[1], B. M. ROEDER[2], C. JOHNSON[3], A. S. DAKOS[1], R. T. WICKS[1], D. E. COUTURE[1], A. W. LAXTON[1], G. POPLI[1], C. T. WHITLOW[1], R. E. HAMPSON[1]

Abstract: Further development of the neural prosthetic for human hippocampal-dependent memory (Hampson et al. J. Neural Eng, 2018, 15:036014) requires refinement of electrode placement within the hippocampus which can be guided by anatomical localization and confirmed via neurophysiological recording characteristics. In this study we expanded hippocampal morphometric measurements to include normal subjects, subjects with a known history of epilepsy, as well as subjects tested with the neural prosthetic for hippocampal memory

(Hampson et al. & Roeder et al., this meeting). In addition we have analyzed neurons recorded from the human hippocampus to determine functional relationships of those neurons to memory function.
A morphometric survey was conducted using 3-T MRI scans of 100 hippocampi from normal subjects, 50 hippocampi from subjects with a known history of epilepsy, as well as more than 50 hippocampi from epilepsy patients who were eventually implanted with electrodes for Phase II diagnostic mapping of seizures (Wicks et al., 2018). Average dimensions of the hippocampus along typical implantation tracks within these populations were then utilized for localization of over 400 neurons recorded from anterior and posterior hippocampal CA3 and CA1 electrode sites in 16 subjects undergoing diagnostic mapping of seizures. Pairs of neurons from putative CA3 and CA1 sites were analyzed for correlation indicative of localization within the respective hippocampal cell fields, while single neurons and ensembles were analyzed for neural correlates of the memory tasks.
Hippocampal neural firing conformed to expected cross-correlation and task correlates predicted by preclinical studies in rodents and nonhuman primates. On average, neurons exhibited transient increased firing rate (i.e. firing peaks) immediately prior to the Sample (encoding) and Match (recall) responses within a delayed-match-to-sample (DMS) memory task. Further, ensembles showed distinct firing patterns on correct trials that were distinct from error trials. Notably, neurons exhibited peak and latency differences in both the encoding phase (i.e. predicting the error) as well as the recall phase of error trials, confirming that mnemonic errors resulted from failure to appropriately encode task-relevant information. These results provide an important foundation for understanding the neural principles underlying memory and contribute to advancement of the design of our neural prosthetic for human memory.

Title: Multivariate pattern analysis in psychotic-like experiences

Authors: *M. GUPTA[1], A. MOYETT[2], M. BLAIR[2], A. BARBER[2], K. KARLSGODT[1,2]
[1]UCLA, Los Angeles, CA; [2]Feinstein Inst. for Med. Res., Manhasset, NY

Abstract: There is a growing interest in using neuroimaging measures in conjunction with machine learning to classify individuals with schizophrenia (SCZ) from healthy controls (HC). Little research has investigated classifying individuals with high levels of psychotic-like experiences (H-PLE) symptoms from low (L-PLE). Here, a linear class-weighted support vector machine (LC-SVM) trained on structural magnetic resonance imaging (sMRI) measures, i.e. volume and thickness, achieved an accuracy of 71%, a sensitivity of 65%, and a specificity of 75% discerning between SCZ (n = 85) and HC (n = 101) groups split into a training and testing datasets. The five most important areas in the brain for classification were left pericalcarine, right pericalcarine, right middle temporal, left parahippocampal, and right fusiform. Next, we employed the same method to label H-PLE (n = 67) and L-PLE (n = 145) individuals from the Human Connectome Project (HCP), identified based on item scores in the Achenbach Self Report. Using a LC-SVM to H-PLE and L-PLE had an accuracy of 51%, a sensitivity of 55%, and a specificity of 46% using sMRI data. Using a stacked classifier achieved an accuracy of 58%, a sensitivity of 53%, and a specificity of 65% in the same group. The five most important areas in the brain for classification were the right middle temporal, right inferior temporal, left inferior parietal, right lateral orbital frontal, and right caudal anterior cingulate. This proof of concept shows it is possible to use neuroimaging measures to predict levels of PLE in a healthy population, although there may be differences in which regions are most predictive. Future analyses will include training a classifier to differentiate between SCZ and HC and then use it to classify H-PLE and L-PLE. In addition, the inclusion of other neural data such as resting-state MRI and/or diffusion tensor imaging (DTI) will improve the predictive power of the classifier and indicate if the same or different brain areas are important in other neural biomarkers.

Abstract: A key challenge in the field of neuropsychiatry lies in matching patients with effective treatments. Most studies operate under the canonical assumption that categorical diagnostic groupings and/or pre-existing clinical assessments are the 'gold standard' for describing behavioral and therefore neural variation in patients. Attempts to robustly characterize the neural substrates of these variables have yielded limited success, suggesting an inadequate mapping to neurobiologically meaningful variation. Notably, a great deal of heterogeneity exists even within groups of patients with the same diagnosis. Thus, understanding the mapping between specific behaviors and clinically meaningful variation in neural properties is critical to developing and ultimately administering effective individualized treatment.

Here, we describe a multivariate neuro-behavioral framework under which behavioral variation can be mapped to features of specific neural systems in a data-driven way. We leverage neural (fMRI-derived) and behavioral data from 436 psychosis-spectrum patients that are publicly available via the NIMH Data Archive as part of the Bipolar & Schizophrenia Consortium for Parsing Intermediate Phenotypes study. We first identify dimensions of behavioral variation in patients by performing a PCA across all behavioral measures. Importantly, these dimensions are not parallel to traditional symptom scales from pre-existing clinical instruments, and do not reflect conventional diagnostic boundaries. We then demonstrate that variation along these behavioral dimensions relates to variation in the global brain connectivity of specific neural systems. Critically, these robust neuro-behavioral relationships were not observed using either traditional diagnostic groups or *a priori* clinical scales. We also demonstrate the flexibility to embed both categorical and continuous features within the same generalized geometry. We further show that this framework can inform the identification of pharmacological targets for specific symptom profiles and may assist in selecting behavioral measures that precisely pinpoint neural variation at the individual level.

Characterizing how and which specific sets of symptoms map to neural circuitry is a key step towards developing targeted and effective treatments for psychiatric disorders. We propose the Neuro-Behavioral Relationships In Dimensional Geometric Embedding (N-BRIDGE) framework as a key step towards unified mapping between the geometry of behavioral variation and the geometry of neural variation, thus integrating both categories and continuous features in psychiatry.

Title: Reduced mismatch negativity reflects impaired deviance detection in schizophrenia

Authors: *D. KOSHIYAMA, K. KIRIHARA, M. TADA, T. NAGAI, M. FUJIOKA, K. USUI, T. ARAKI, K. KASAI
Dept. of Neuropsychiatry, Grad. Sch. of Med., The Univ. of Tokyo, Tokyo, Japan

Abstract: Background: Mismatch negativity (MMN) is a promising candidate of translatable biomarker for schizophrenia that can link preclinical animal studies to clinical studies. Previous studies have proposed stimulus specific adaptation and deviance detection as the mechanism underlying MMN. Recent animal studies are now revealing neural mechanisms underlying stimulus specific adaptation and deviance detection. Although many previous studies reported reduced MMN in patients with schizophrenia, there is no study to examine whether reduced MMN in patients with schizophrenia is due to impairments of stimulus specific adaptation or deviance detection. In this study, we measured MMN, evaluated effects of adaptation and deviance detection, and examined whether reduced MMN in patients with schizophrenia is due to impairments of adaptation or deviance detection. Methods: Patients with schizophrenia (N=25) and healthy comparison subjects (N=27) participated in this study. We recorded electroencephalography during an oddball paradigm and a many standards paradigm. We measured MMN and evaluated effects of adaptation and deviance detection on MMN amplitude. Results: MMN amplitude was reduced in patients with schizophrenia compared to healthy comparison subjects. Patients with schizophrenia showed no impairments in the effects of adaptation on MMN compared to healthy comparison subjects. On the other hand, patients with schizophrenia showed impairments in the effects of deviance detection on MMN compared to healthy comparison subjects. Impaired deviance detection was correlated with severe positive symptoms in patients with schizophrenia. Conclusion: We found that impaired deviance detection, but not adaptation, affected reduced MMN amplitude in patients with schizophrenia. In addition, the impaired deviance detection was significantly correlated with severe positive symptoms. These findings show that reduced MMN in patients with schizophrenia is due to impairments of not adaptation but deviance detection, and that impaired deviance detection is associated with positive symptoms in schizophrenia. Therefore, investigating neural mechanisms underlying deviance detection may be useful for revealing the pathophysiology of schizophrenia and developing new treatments for schizophrenia.

Title: Evaluating a potential marker of plasticity in schizophrenia: Perceptual learning in visual search

Authors: *E. A. REAVIS[1,2], A. MCCLEERY[1,2], J. K. WYNN[2,1], M. F. GREEN[1,2]
[1]Semel Inst. for Neurosci. and Human Behavior, UCLA, Los Angeles, CA; [2]Mental Illness Research, Educ. and Clin. Ctr., VA Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: Numerous forms of learning and memory are impaired in schizophrenia, and these impairments are strong predictors of functional disability in the disorder. Similarly, various abnormalities in visual perception exist in schizophrenia and predict individuals' level of functioning. However, little is known about potential impairments in perceptual learning, at the intersection of these two cognitive domains. In the present study, we adapted an established paradigm to rapidly induce and measure perceptual learning using a visual search task in both outpatients with chronic schizophrenia (N=31; mean age=49; 20 male/11 female) and matched healthy controls (N=17; mean age=47; 11 male/6 female). Across five 20-minute testing sessions completed over two days, participants viewed arrays of visual stimuli in which a target stimulus could be present (50% of trials) or absent (50%), among a variable number of similar distractor stimuli. All search stimuli were bisected disks with red and green halves; targets could be distinguished from distractors by the configuration of the two elements (e.g., red-left/green-right vs. green-left/red-right). Such searches are ordinarily slow and inefficient but tend to become more efficient with training in healthy undergraduates. Participants responded 'target' or 'no target' to each array, and reaction times were recorded. Search efficiency was quantified by assessing the relationship between the number of search stimuli and reaction time, from which the search time per item was inferred. Decreases in the search time per item were considered evidence of perceptual learning. Steady-state visually evoked potentials associated with search targets and distractors were also assessed using electroencephalography before and after training. Behavioral data from both groups showed an expected linear relationship between the number of search stimuli and reaction time, indicating that participants performed the task correctly and the data were valid. However, the two groups combined showed only marginally significant

perceptual learning (p=0.09), and there was no significant difference in the amount of learning between the two groups. This could suggest that this type of perceptual learning might be relatively impaired by mid to late adulthood in general, but not substantially different between people with chronic schizophrenia and matched community controls.

Title: Pyridoxamine, a novel treatment for negative symptoms of schizophrenia

Authors: *M. ARAI[1], M. MIYASHITA[2], K. TORIUMI[3], Y. HORIUCHI[4], A. KOBORI[4], M. ITOKAWA[4]
[1]Dept. of Psychiatry and Behavioral Sciences,, Tokyo Metropolitan Inst. of Med. Science,, Tokyo, Japan; [2]Project for Schizophrenia Res., Tokyo Metoropolitan Inst. of Med. Sci., Tokyo, Japan; [3]Project for Schizophrenia Res., [4]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: The aim of this clinical trial was to obtain proof of concept for high-dose pyridoxamine as a novel treatment for schizophrenia with enhanced carbonyl stress. Ten Japanese schizophrenia patients with high plasma pentosidine, which is a representative biomarker of enhanced carbonyl stress, were recruited in a 24-week, open trial in which high-dose pyridoxamine (ranging from 1200 to 2400 mg/day) was administered using a conventional antipsychotic regimen. Main outcomes were the total change in Positive and Negative Syndrome Scale score and the Brief Psychiatric Rating Scale score from baseline to end of treatment at week 24 (or at withdrawal). Decreased plasma pentosidine levels were observed in eight patients. Two patients showed marked improvement in their psychological symptoms. A patient who harbors a frameshift mutation in the Glyoxalase 1 gene also showed considerable reduction in psychosis accompanied with a moderate decrease in plasma pentosidine levels. A reduction of greater than 20% in the assessment scale of drug-induced Parkinsonism occurred in four patients. Although there was no severe suicide-related ideation or behavior, Wernicke's encephalopathy-like adverse drug reactions occurred in two patients and were completely suppressed by thiamine supplementation. High-dose pyridoxamine add-on treatment was, in part, effective for a subpopulation of schizophrenia patients with enhanced carbonyl stress. Further randomized,

placebo-controlled trials with careful monitoring will be required to validate the efficacy of high-dose pyridoxamine for these patients.

Abstract: Poor awareness that one has a psychotic disorder is common in schizophrenia, and negatively impacts clinical treatment and symptom management. Following our previous magnetic resonance imaging (MRI) study of schizophrenia patients, which was suggestive of poor connectivity being associated with unawareness, we hypothesized that the disruption of white matter integrity underlies poor insight. This study utilized diffusion tensor imaging (DTI) data from 1.5T MRI scans and data quantifying insight using the Scale for Unawareness of Mental Disorder-Revised (SUMD-R). Tract-Based Spatial Statistics (TBSS, part of FSL) were used to quantify regional differences in average fractional anisotropy (FA), which provides information about white matter microstructural integrity. A preliminary cross-sectional analysis of 35 subjects with first-episode schizophrenia showed that lower average FA values of the following white matter regions of interest were associated with unawareness of the patient's own reduced information processing speed: portions of the corona radiata, the corpus callosum (genu, body, and splenium), the tapetum, the uncinate fasciculus, the medial lemniscus, portions of the cingulum and fornix, portions of the internal capsule, and portions of the external capsule. These preliminary findings suggest that reduced white matter integrity may be associated with poor insight in individuals with first-episode schizophrenia. The significance of these findings lies in the value of creating a more complete neuroanatomical profile for insight in schizophrenia, both

for developing a better understanding of insight and to improve opportunities for successful clinical interventions and treatment.

Hosp. (CHUV), Univ. of Lausanne, Lausanne, Switzerland

Abstract: Exposure to childhood trauma (CT) increases the risk for psychosis and affects the development of brain structures, possibly through oxidative stress (OS). Since OS is also linked to psychosis, it may interact with CT, leading to a more severe clinical phenotype. In a cohort of 133 early psychosis patients (EPP), we explored the relationships between CT and hippocampal volume, blood antioxidant defense systems (glutathione peroxidases (GPx) and thioredoxin/peroxiredoxin (Trx/Prx), and psychopathological and neuropsychological outcomes. We found that in CT patients, the hippocampal volume correlated negatively with GPx activity, which was not the case for patients without CT. In CT patients with high GPx activity (High-GPx+CT patients), hippocampal volume was decreased compared with that in Low-GPx+CT patients and patients without CT who had similar hippocampal volumes. High-GPx+CT patients had more severe positive, negative and disorganized symptoms than the other patients. Interestingly, Trx levels and oxidized Prx levels correlated negatively with GPx only in Low-GPx+CT patients. Moreover, Low-GPx+CT patients perform better than other patients on cognitive tasks. Discriminant analysis combining redox markers, hippocampal volume, and clinical and cognitive scores allowed for the stratification of the patients into subgroups. In conclusion, traumatized EPP with high peripheral oxidation status (high GPx activity) had smaller hippocampal volumes and more severe symptoms, while those with a lower oxidation status (low GPx activity) showed better cognition and regulation of GPx and Trx/Prx systems. These results suggest that maintained regulation of various antioxidant systems allowed for compensatory mechanisms preventing long-term neuroanatomical and clinical impacts. The redox marker profile may thus represent important biomarkers for defining treatment strategies at early stages of psychosis.

Title: Dysrupted modulation of thalamus activation and thalamocortical connectivity during task performance in schizophrenia

Authors: *A. S. HUANG[1], B. P. ROGERS[2], N. D. WOODWARD[1]
[1]Psychiatry, Vanderbilt Univ. Med. Ctr., Nashville, TN; [2]Vanderbilt Univ., Nashville, TN

Abstract: Introduction: Modulation of thalamic connectivity with the prefrontal cortex (PFC), a region believed to be core to the pathogenesis of schizophrenia, is required for higher-order cognitive abilities, including attentional control, which are often impaired in schizophrenia. Despite considerable evidence finding that thalamus anatomy and connectivity are abnormal in schizophrenia, how these abnormalities are reflected in thalamus function during cognition is relatively understudied. To address this gap, we investigated how thalamic function and thalamus-PFC connectivity under different levels of cognitive demand may be dysrupted in schizophrenia.
Method: Thirty-nine participants (19 healthy individuals and 20 individuals with schizophrenia) underwent fMRI scanning while performing an event-related two-alternative forced choice task under Single and Dual Task conditions. In the Single Task condition, participants responded either to a visual cue with a well-learned motor response, or an audio cue with a well-learned vocal response. In the Dual Task condition, participants performed both tasks. Thalamic connectivity with task relevant regions of the PFC for each condition was measured using beta-series correlation.
Results: Individuals with schizophrenia demonstrated an ability to modulate PFC, but not thalamic activation by task demand, while healthy subjects showed modulation in both regions. They also failed to demonstrate the expected modulation of thalamus-PFC connectivity by task demand observed in healthy subjects.
Discussion: Individuals with schizophrenia showed a reduced ability to modulate both thalamic responses and thalamus-PFC connectivity with increased cognitive demand, while, in the current task, their ability to modulate PFC function appears to be maintained. It is possible that in schizophrenia, the thalamus may be dysrupted at lower levels of task demand than the PFC.

Title: Schizophrenia and semantic processing: Cognitive state and brain electrical activity

Authors: *F. A. ROBLES[1,2], L. R. ROMERO[1], V. VALDEZ VELASCO[1], D. L. CANELA[1], A. LARA ZARAGOZA[3]
[1]Lab. de Neurociencia Cognitiva, Colotlán, Jalisco, Mexico; [2]Neurol., Univ. of California, Irvine, CA; [3]Psychiatry, Integral Ctr. of Mental Hlth., Colotlán, Mexico

Abstract: Schizophrenia affects more than 21 million people worldwide (WHO, 2016). In Mexico, 11,553 are treated (WHO, 2016-2012). Studies have shown a progressive grey-matter loss from parietal and temporal to frontal lobes with overactivation of cortico-limbic circuits, correlated with early deficits in neuropsychological function (Pantelis *et al*., 2003). A core feature of Schizophrenia is the disorganized speech that aims to particularities in semantic processing. For example, N400 has shown an enhancement in amplitude for sentence priming tasks (Nestor *et al.* 1997) or a reduction of the N400-effect in the evaluation of congruity in sentence endings or priming words (Ohta, 1999; Kiang *et al.,* 2012), suggesting Schizophrenia patients exhibit distinct functional connections among concepts within semantic memory depending on the differences in controlled (decreased amplitudes at longer SOA) or automatic semantic processing (increased activation at short SOA) (Minzenber *et al.*, 2002; Ditman and Kuperberg, 2007). Cohn and Kutas (2015) proposed N400 frontal negativity probably indexes working memory instead of semantic processing. The present study evaluates Schizophrenia patients (n=10, 5 patients, 6 women, ages *M*=31.4*; t=1.67, p=0.13;* 8.6, Spanish speakers) that responded to three tasks: 1) semantic congruity (100 trials, 4-word phrase, “A cat can bark”); 2) visual sequences (80 trials with 4 images, 40 exchanged endings); 3) semantic matching (100 trials with 4 images, 50 with unrelated final stimuli). Trials began with a plus sign in a dark screen center for 400 ms, followed by 4 stimuli (1350 ms each), separated by a 200 ms dark screen. Last stimulus was preceded by an interrogation sign. ITI was variable (216.67-1366.67 ms). Patients presented normal-to-mild cognitive impairment (MMSE: *M*=27.40 *SD*=2.19; CI: *M*= 68.80, *SD*=14.44) and a prolonged time without treatment (*M*=9.76, *SD*=9.72 years). Patients were significantly slower (t=2.387; p=.04) and made more errors (t=3.819; p=.005) in semantic congruity. They also differ from controls in the number of errors in visual sequences (t=0.301; p=.01) but not in semantic matching (t=1.87; p=.09). This shows deficits in the semantic congruity seem related to sequential more than semantic processing in Schizophrenia patients. During tasks electrical activity was registered (19 electrodes, 10-20 system). N400 amplitudes and latencies will be shown. As typical antipsychotic medication provides modest-to-moderate gains in multiple cognitive domains (Mishara and Golberg, 2004), the delay in receive treatment in these patients adds to the cognitive deterioration.

Title: Update on a longitudinal pilot study to assess the effects of gamma neurofeedback on cognitive function in schizophrenia patients

Authors: Z. YANG[1], J. PINEDA[2], I.-W. SHU[1], J. ONTON[3], A. RIVAS[1], N. ZHEN[2], L. RING[2], M. BORDYUG[2], E. HERRERA[2], *F. SINGH[4,5]
[1]Psychiatry, [2]Cognitive Sci., [3]Inst. for Neural Computation, [4]UCSD, La Jolla, CA; [5]Psychiatry, Univ. of California at San Diego, La Jolla, CA

Abstract: Cognitive deficits are a common and recalcitrant symptom of schizophrenia (SCZ) spectrum disorders and have been associated with reduced gamma band (35-50Hz) responses (GBR) in frontoparietal regions of the brain. Neurofeedback (NFB) is an operant conditioning methodology used to train individuals to volitionally control brain oscillatory activity, and has been shown to influence frontoparietal neural circuitry in healthy populations. Therefore, we tested the feasibility of administering NFB to enhance GBR in patients with SCZ. The primary aim of the study is to assess target engagement, and determine whether GBR can be trained reliably in a SCZ population. A secondary aim is to determine whether changes in GBR influence downstream targets, including behavioral variables. We are conducting an open label study in adults between the ages of 18-65, who met DSM-V criteria for SCZ or schizoaffective disorder. All subjects will undergo 12 weeks of NFB, for 2 sessions a week. Brain function (EEG), neuropsychological variables and community functioning assessments are conducted at baseline and post-treatment. To date, 6 subjects have completed 4 weeks of NFB training. Preliminary data analysis indicates 1) target engagement as evidenced by changes in NFB training threshold, 2) changes in brain function as assessed by EEG, including increased gamma power in the resting state over frontal brain regions (F3, F4) and 3) and increases in Processing speed, attention/vigilance and visual learning. Additional analyses are underway to determine NFB's effects on event-locked brain activity, specifically in response to cognitive tasks.These early results indicate that patients with SCZ can implement operant conditioning approaches such as NFB, and that EEG can be used to detect brain changes as early as 4 weeks. Therefore, NFB has the potential to serve as a useful adjunctive treatment in clinical settings to help treat cognitive deficits associated with schizophrenia spectrum disorders.

Title: Bayesian inference explains frequency perception in humans: Neural correlates and relationship to psychosis

Authors: *E. LAGACHE[1], G. HORGA[2]
[1]New York State Psychiatric Inst., New York City, NY; [2]Psychiatry, Columbia Univ. Med. Ctr., New York, NY

Abstract: Bayesian models of perception posit that percepts result from an optimal integration of new sensory information and prior knowledge or beliefs. In turn, prominent models of altered perception in psychosis suggest that pathological illusions and hallucinations may represent percepts that are excessively biased towards prior beliefs. The current study represents an ongoing effort to determine the neural mechanisms underlying the integration of new sensory information and prior knowledge in healthy and pathological conditions.
To this end, we have designed a new magnitude-estimation task in which subjects reproduce the frequency (pitch) of tones drawn from uniform distributions with varying widths. In parallel, we are leveraging recent advances in population receptive field (pRF) models of functional magnetic resonance imaging (fMRI) to optimize tonotopic mapping of the primary auditory cortex (PAC). Finally, we are testing the ability of Bayesian models of perception to explain the behavioral data and changes in the individual tonotopic maps that may underlie interindividual differences in frequency-reproduction behavior.
In a pilot study in healthy individuals (n=10), frequency-reproduction behavior exhibits a significant characteristic signature of Bayesian perception. These individuals tend to overestimate frequencies lower than the mean of the sampled distribution and underestimate frequencies higher than the mean. This “central tendency” suggests integration of prior knowledge and can be well explained by a Bayesian model that seeks to minimize reproduction error by incorporating a central-tendency prior. Data collection for psychosis-prone individuals is in progress. We expect that psychosis-prone individuals will exhibit higher central tendency than socio-demographically matched healthy controls, indicating a greater bias toward prior beliefs. Interindividual differences in tonotopic maps in PAC derived from fMRI data in patients and controls are expected to match the interindividual differences in frequency-reproduction behavior.

In conclusion, our pilot results provide a first demonstration that models of Bayesian inference can be applied to frequency perception in humans. Leveraging this novel approach and pRF methods for tonotopic mapping may provide a fruitful avenue to understand the neural mechanisms of perceptual inference in the human brain. In turn, an improved understanding of these neural mechanisms may advance our understanding of pathological conditions characterized by perceptual abnormalities, including hallucinations in schizophrenia and those in other neuropsychiatric illnesses.

Title: Thalamo-cortical structural connectivity in schizophrenia and bipolar disorder

Authors: *J. CHO[1], J. C. THOMPSON[2]
[1]Psychology, [2]George Mason Univ., Fairfax, VA

Abstract: Schizophrenia (SZ) and bipolar disorder (BD) are debilitating mental illnesses with overlap in genetic, cognitive, clinical and functional brain connectivity characteristics. Recent resting-state (rsfMRI) connectivity studies have found a pattern of over-connectivity between the thalamus and sensory-motor regions but under-connectivity between the thalamus and prefrontal cortex in SZ as well as BD, but with attenuated effects. Structurally, abnormalities between the thalamus and cortex have been observed in SZ and BD but studies examining the structural relationship between the thalamus to frontal and motor cortices are sparse. The aim of this study was to investigate structural connectivity from specific thalamic nuclei to the cortex and its relationship to clinical symptoms.
All subjects were part of the UCLA Consortium for Neuropsychiatric Phenomics dataset freely shared online through the OpenfMRI project. First, masks of the prefrontal (PT) and motor (MT) regions of the thalamus were created using the Johansen-Berg et al, thalamic atlas in FSL to perform tractography between the thalamic regions and the fronal and motor cortices. Diffusion weighted images were preprocessed using FSL's FDT toolbox and underwent DTIFIT, BEDPOSTX and PROBTRACKX. Tracts were thresholded using the waypoint method and binarized to create a mask for extraction of fractional anisotropy (FA).
There was a significant difference between groups on tract FA as determined by a one-way MANCOVA after controlling for age, $F(4,428) = 2.701$, $p < 0.05$, *Pillai's* Trace = 0.049, partial $\eta 2 = 0.025$. Follow-up univariate tests revealed a significant difference between groups on PT to frontal tract FA, $F(2,214) = 3.340$, $p < 0.05$, partial $\eta 2 = 0.030$, but no difference between

groups on MT to motor cortex tract FA. A Tukey-kramer post hoc test showed significantly greater tract FA in HC (.144±0.90) compared to SZ (-.284±.142), $p < 0.05$). BD showed intermediate values between HC and SZ but no significant differences in pairwise tests. Correlation analyses revealed a significant positive correlation between PT to frontal FA and MT to motor cortex FA, ($r = .536$, $p < 0.05$) and a significant negative correlation between PT to frontal FA and negative symptoms ($r = .225$, $p < 0.05$) - patients with greater thalamo-frontal tract FA have less severe negative symptoms. We replicated findings that SZ is associated with abnormal structural connectivity between the thalamus and frontal cortex but not in BD. However, our cohort showed a relationship between the two thalamo-cortical tract FAs in addition to clinical symptoms. This might indicate that BD shares similar but reduced structural abnormalities with SZ.

Title: KCNH2-3.1 impairs neural connections between hippocampus and mPFC

Authors: *F. YANG, Z. HU, M. REN, D. R. WEINBERGER
Div. of Developmental Neurobio. and Functional Genomics, Lieber Inst. For Brain Develop., Baltimore, MD

Abstract: The KCNH2-1A potassium channel conducts delayed-rectifier potassium currents that have a rapid activation and relatively slow inactivation in deactivation kinetics. Our previous work has identified a novel primate isoform of KCNH2-1A channel, the KCNH2-3.1 potassium channel, in human brain that is upregulated in schizophrenia. Our previous studies also showed that KCNH2-3.1 transgenic mice exhibit alterations in neuronal structure and microcircuit function in the hippocampus and prefrontal cortex, areas affected in schizophrenia. It has been proposed that failure of functional integration and flow of information between hippocampus and mPFC results in cognitive deficits in schizophrenia patients. The possibility of synaptic impairments between hippocampus and mPFC as key pathophysiological mechanisms associated with schizophrenic phenotypes in KCNH2-3.1 mice has not been explored before. In this study, to investigate structural connectivity in these mice, we measured synaptic density on mPFC layer V pyramidal neurons innervated from hippocampal CA1 axonal terminals. To examine this, we injected AAV DJ-CaMKIIa-hChR2(H134R)-eYFP into the ventral hippocampus of KCNH2-3.1

and control litter mates, and used Imaris software to perform 3D reconstruction of confocal images to quantify the number of hippocampal CA1 axonal boutons in mPFC. Confocal imaging showed a substantial reduction of synaptophysin+ puncta density in the mPFC innervated from ventral hippocampal CA1 pyramidal neurons of KCNH2-3.1 mice. We further injected AAV DJ-syn-VAMP2-Flag into the ventral hippocampus of Thy1-eYFP-H/NSE/KCNH2-3.1 transgenic mouse, and used the Imaris software to quantify hippocampal CA1 VAMP2-Flag-expressing boutons over the YFP-expressed dendritic spine formation of layer V pyramidal neurons of mPFC in KCNH2-3.1 transgenic mice. Compared to control mice, pyramidal neurons in KCNH2-3.1 mice showed significantly decreased synaptic innervation, further confirming that overexpression of KCNH2-3.1 isoform impairs synapse formation of hippocampal CA1 axonal boutons onto mPFC layer V pyramidal neurons. These findings provide further insights into the precise alterations in hippocampal-mPFC connectivity observed in this schizophrenia-associated animal model, and could ultimately help elucidate the molecular and cellular basis underlying schizophrenia pathogenesis.

Title: Schizophrenia is characterized by reduced functional connectivity between memory and reward circuits during learning

Authors: *S. HASAN[1], M. HUQ[1], A. Z. CHOWDURY[1], J. A. STANLEY[1], A. ROBISON[2], K. N. THAKKAR[3], V. A. DIWADKAR[1]
[1]Dept. of Psychiatry, Wayne State Univ. Sch. of Med., Detroit, MI; [2]Neurosci., [3]Dept. of Psychology, Michigan State Univ., East Lansing, MI

Abstract: Background
Schizophrenia (SCZ) is characterized by altered dopamine sensitivity, which may in turn affect reward related processes that are omnipresent during task acquisition and processing (Gray et al.,1991). From this general framework, compared functional connectivity (FC) between three regions of the brain, the Nucleus Accumbens (NAcc), Ventral Tegmental Area (VTA), and the Hippocampus (Hipp) in a task-active state in SCZ and healthy controls (HC). Experimentally driven associative memory was induced using an established paradigm (Stanley et al., 2017). The three regions are noted for their roles in reward processing (NAcc & VTA) and memory (Hipp). Our interest was whether FC was significantly lower in SCZ. Alterations in FC between either of the NAcc and/or VTA and Hipp would suggest abnormal functional interactions between

memory and reward related circuits in SCZ.

Methods

fMRI data were acquired from forty one participants (22 SCZ, 19 HC; 3T Siemens Verio) while they performed an associative memory task. During the task they learned associations between nine object-location pairs (~13 minutes). fMRI data were processed using typical methods (SPM12) with epochs representing distinct task phases (Encoding, Rest and Retrieval). The sub-network of regions (NAcc, VTA, Hipp) were motivated using previously defined nodes (Kahn et al, 2013). Montreal Neurological Institute (MNI) coordinates used were: NAcc [-11 4 0]; VTA [-4 -15 -9]; Hipp [-26 -22 14]. Time series from these coordinates were forwarded for FC analyses. Correlation coefficient were computed and normalized to bivariate distribution curve (Fisher's Z) and were submitted for statistical inference. Independent sample t-tests were employed to assess differences between each of the sub-network pairs.

Results

SCZ participants were characterized by reduced FC between the Hipp and VTA ($p<0.02$), with marginally significant reductions between the NAcc and VTA ($p=0.05$, one-tailed).

Discussion

Because reward related processing is expected to underlie successful acquisition of complex tasks, it is expected that brain regions associated with reward and task processing will show functional integration. We proposed that impaired reward sensitivity in SCZ may mediate a loss of functional integration between task relevant regions (Hipp) and reward related regions (VTA and/or Nacc). Our results provide preliminary evidence for this effect, as well as a loss of integration within the reward circuit (VTA and Nacc). Impaired cognitive processing in SCZ may be integrally linked to impaired reward processing, and the disconnection between these underlying systems should be further investigated.

Title: Recovery of theta-gamma phase-amplitude coupling following single dose administration of amphetamine in patients with schizophrenia

Authors: *N. MURPHY[1], N. R. POLIZZOTTO[2], C. P. WALKER[1], N. RAMAKRISHNAN[1], R. Y. CHO[1]
[1]Psychiatry, Baylor Col. of Med., Houston, TX; [2]UTHealth, Houston, TX

Abstract: Background
Dopaminergic modulation of sensory cortical gamma oscillations in schizophrenia patients, through single dose amphetamine administration remediates impaired entrainment to levels closer to that of control subjects after placebo administration (Komek et al., 2012). However, it remains unclear whether this is linked also to any improvements of amplitude modulation by the phase of low frequency oscillations. Our aim was to investigate the link between dopaminergic drive and the modulation of gamma oscillations via cross-frequency coupling (CFC) in patients with schizophrenia.
Methods
N = 12 patients with schizophrenia and N = 12 healthy controls were presented with 40 Hz auditory click train stimuli (500 ms) during 129 channel electroencephalograph (EEG) recording. A double-blind crossover placebo-controlled design was used to test within groups effects of oral dextroamphetamine (0.5 mg/kg) on the auditory steady state response. Placebo and amphetamine visits were separated by a minimum of 5 days. We evaluated CFC at a region of interest (N = 10 electrodes) surrounding and including FCz estimated as the mutual information between gamma(40 Hz ± 14 Hz) band amplitudes and delta (2-4 Hz), theta (4-8 Hz), and alpha (8-14 Hz) phases during the stimulation period. Mutual information scores were normalized by Z-transformation using the distribution of 100 surrogate coupling values.
Results
In the placebo condition coupling was significantly lower in patients than controls for the theta-gamma comparison (p = .009). The net effect of amphetamine was to increase theta-gamma coupling in patients (p = .034) and to decrease theta-gamma coupling in controls (p = .031), with the overall change between conditions being significantly greater in patients (p = .003). Despite reduced control CFC there was no significant difference between groups in the amphetamine condition. No effects were detected for alpha-gamma and delta-gamma comparisons
Conclusions
Our findings suggest that dopamine modulation in schizophrenia can improve impaired CFC but in healthy controls can impair intact CFC. This pattern is similar to our prior findings of dopamine modulation of gamma power in patients vs. healthy controls (Komek et al, 2012), and consistent with prior reports of an inverted-U relationship between dopamine levels and cortical function (Williams & Castner, 2006). This suggests that dopamine modulation in patients not only can remediate gamma oscillatory activity in cortical circuits, but also help in restoring the CFC of such gamma activity with lower frequency rhythms.

Title: Resting state functional connectivity abnormalities in schizophrenia

Authors: *E. SEFIK[1], A. ABBAS[1], S. KEILHOLZ[1,2]
[1]Emory Univ., Atlanta, GA; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Functional connectivity (FC) is a measure of the temporal correlation among anatomically distinct brain regions underlying large-scale brain networks. It has been widely demonstrated that patients with schizophrenia (SZ) show FC abnormalities throughout the brain. Yet, it is not clear from the current literature whether resting state dysconnectivity continues to deteriorate with disease progress.
Methods: We first investigated FC differences between healthy controls (HC) (n=18) and SZ patients (n=25), with high demographic selectivity: males with a strict SZ diagnosis, stable medication adherence and a similar age of disease onset. Second, we probed the effect of disease progress on FC in SZ subjects between two age groups: early (n=8) versus late 20s (n=8). Finally, in order to isolate the effects of disease progress from normal aging, we investigated FC differences in HCs between two age groups: early (n=6) versus late 20s (n=6). Seed based and parcellation based analysis techniques were used to calculate the Pearson's correlation between the time-courses of each brain region of interest (ROI).
Results: We identified significant FC differences in 365 ROI-pairs between SZ and HC, 135 ROI-pairs between old and young SZ, and 40 ROI-pairs between old and young HC. Results showed dysconnectivity in SZ across the entire brain, primarily in the default mode network (DMN), thalamo-cortical and cerebello-cerebral connectivity. Specifically, the DMN showed hyperconnectivity in SZ patients. Additionally, we found interhemispheric FC abnormalities in SZ, primarily in somato-motor regions, the cingulate gyrus and the inferior parietal lobe. Taken together, our findings demonstrate inter-regional and inter-hemispheric FC abnormalities in SZ. We further found a disease-progress driven exacerbation of FC in as short a period of time as early versus late 20s. This exacerbation was mostly evident in PFC connectivity to thalamus,

cerebellum, precuneus and limbic regions. Hyperconnectivity of the DMN was significantly higher in older patients. This effect was insufficiently explained by aging related factors alone. **Conclusion:** These results extend prior literature indicating that brain networks measured by resting state fMRI are abnormally organized in SZ, with a disease progress driven exacerbation. Higher FC abnormalities seen in older patients -despite stabilization on antipsychotic treatment- may be evidence of the inefficacy of currently available pharmacologic interventions in treating negative and cognitive symptoms. Our findings further demonstrate the clinical potential of resting state FC as a biomarker for early diagnosis and treatment of SZ.

Title: The prefrontal cortex follows the respiration-coupled rhythm during waking and REM-sleep, but not during slow-wave sleep

Authors: *R. MOFLEH, B. KOCSIS
Harvard Med. Sch., Boston, MA

Abstract: Breathing in rodents normally appears in a wide range of frequencies, overlapping with delta and theta oscillations in brain activity. Recent studies reported that the respiratory rhythm, mediated by monitoring nasal air movement by the olfactory bulb (OB), may promote synchronous oscillations globally in the brain including higher-order brain networks, such as prefrontal cortex (PFC) and hippocampus (rev. Tort et al., 2018). It remains important to clarify, however, what these networks use respiratory synchrony for—as well as when, how, and why. In the present study we investigated the relationship between respiratory rhythm and PFC oscillations, and the contribution of OB to it, in rats during two different stages of sleep, REM-sleep and slow-wave sleep (SWS), as well as two awake states, quiet (QW) and active waking (AW), also identified as non-theta and theta states. Local field potential (LFP) was recorded from OB, PFC, and hippocampus along with neck muscle EMG in undisturbed freely behaving rats while respiratory rhythm was monitored by direct recording of diaphragmal activity (EMG). We found that the prominent PFC oscillations in the delta range synchronize with respiratory rhythm in a state-dependent manner. Coherence between diaphragmal EMG and PFC (dia-PFC) was significantly ($p<0.04$) lower in SWS (0.12+0.03) than in any other state (between 0.37 and 0.68 in AW, QW, REM). Respiratory-OB coherence (dia-OB) did not necessarily show this

relationship, it was not significantly different for example between SWS and REM sleep (p=0.34). Furthermore, within states, dia-PFC did not significantly correlate with dia-OB (R2 between 0.0005 and 0.2534 in SWS, QW, AW and 0.675 only in REM) indicating that OB transfer of respiratory rhythm to PFC was strongly modulated by inputs mediating the level of arousal. Accordingly, dia-PFC and OB-PFC strongly correlated in theta states (0.87 in REM and 0.57 in AW) and less in non-theta states (0.03 in SWS, 0.37 in QW).The prefrontal cortex (PFC) contributes to different cognitive functions and is highly interconnected with various cortical and subcortical structures. Specifically we have shown the importance of a 2-5 Hz rhythm in this communications (Roy et al., 2017). The results of this study indicate that respiratory synchronization may also be involved in generating state- and task-dependent PFC outputs.

Title: Loss of dendritic inhibition in pharmacological and genetic mouse models related to schizophrenia

Authors: *F. ALI, D. M. GERHARD, R. S. DUMAN, A. C. KWAN
Dept. of Psychiatry, Yale Sch. of Med., New Haven, CT

Abstract: Schizophrenia (SZ) is a major psychiatric disorder, generally thought to involve an imbalance in excitation and inhibition. However, the precise circuit mechanisms underlying such imbalance are unclear. Here, we uncovered a cortical dendritic disinhibition phenotype involving deficits in somatostatin-positive interneurons (SOM-IN) in two different mouse models related to schizophrenia. We first injected adult mice with systemic ketamine (KET model), an NMDA receptor antagonist that is also a psychotomimetic drug widely used as an acute pharmacological model related to SZ. Combining this with *in vivo* two-photon calcium (GCaMP6) imaging, we found elevated spontaneous calcium transients in layer 1 apical dendritic spines of excitatory neurons (EXC) in dorsomedial portion of prefrontal cortex (dmPFC - Cg1/M2). The same hyperactive spine calcium phenotype was also observed in dmPFC of *Shank3*-R1117X (*Shank3* model) mice with a rare, highly penetrant SZ-related mutation in the *Shank3* gene important for

glutamatergic synapses. We further found that this EXC spine hyperactivity was associated with reduced activity of dendrite-targeting SOM-IN in layer 2/3 and their layer 1-projecting axons in both the KET and *Shank3* models. Together, our convergent results in mouse models suggest reduced SOM-IN activity that releases the dendritic spines from inhibition i.e., disinhibition. Because layer 1 is an important site of cortico-cortical processing, we further examined the consequences of dendritic disinhibition on long-range cortical information processing via two experiments in the KET model. First, we electrically stimulated the retrosplenial cortex (RSC), which sends dense projections to dmPFC layer 1 while imaging the dendritic spines in layer 1 of dmPFC. We found that ketamine increased the response of EXC dendritic spines to long-range RSC inputs, particularly at high stimulation frequency regimes. In the 2nd experiment, we recorded local field potentials (LFP) simultaneously in RSC and dmPFC, finding an increased field-field coherence between the two areas after ketamine injections. Overall, our imaging experiments provide a potential circuit basis for the widely-found hyperconnectivity phenotype in SZ: a hypofunction in dendrite-targeting SOM-IN associated with disinhibition of dendritic spines, leading to long-range hyperconnectivity. We hypothesize that loss of SOM-IN activity is due to a deficit in NMDAR function, reducing excitatory drive to SOM-IN. We are currently testing this hypothesis using viral strategies and pharmacological manipulations in both KET and *Shank3* models during *in vivo* imaging and behavior.

Title: Maternal immune activation alters cortical catecholaminergic function and induces cognitive impairment in offspring

Authors: *B. PEREZ-PALOMAR[1,3], J. E. ORTEGA[3], J. J. MEANA[3], J. G. MCCALL[2]
[2]Anesthesiol., [1]Washington Univ. in St. Louis, Saint Louis, MO; [3]Pharmacol., The Univ. of the Basque Country, Leioa, Bizkaia, Spain

Abstract: Schizophrenia is a chronic and disabling mental disorder with an early onset. Cognitive deficits start early and are present together with classical schizophrenia symptoms. The dorsolateral prefrontal cortex (DLPFC) is the main anatomical pathway modulating cognitive activities and is critical for executive function. Interestingly, the postsynaptic alpha-2 adrenoceptors located on pyramidal cells of the DLPFC, that maintain basal cognitive activity, seem to be underactive in schizophrenic patients. Importantly, one of the most significant environmental risk factors for the development of schizophrenia is prenatal exposure to infection. Indeed, maternal immune activation (MIA) in animals produces behavioral and neurochemical aberrations considered relevant in models of schizophrenia. The aim of this study was to evaluate a MIA model mimicking prenatal viral infection by the administration of poly(I:C) to pregnant dams (7.5 mg/kg ip, gestational day 9.5). We evaluated cognitive impairments of adult offspring by the novel-object recognition test (NORT) in the presence and absence of either the alpha-2 agonist (guanfacine 0.1 mg/kg ip) or the alpha-2 antagonist (MK-912 0.05 mg/kg ip). In addition, we measured extracellular dopamine and norepinephrine (NE) concentrations in prefrontal cortex (PFC) by microdialysis. Poly (I:C) mice showed decreased novel object discrimination in the NORT compared with controls, demonstrating a cognitive deficiency. Interestingly, both the alpha-2 agonist (guanfacine) and the alpha-2 antagonist (MK-912) were able to reverse that deficiency in the Poly (I:C) offspring. Therefore, the cognitive impairment produced by MIA in offspring could be related to alterations in the noradrenergic pathways of the PFC that control cognitive processes. To determine the sufficiency of increased PFC noradrenergic tone in reversing the MIA-induced cognitive impairment, we sought to selectively manipulate this projection in vivo. To do so, we genetically targeted channelrhodopsin-2 to only locus coeruleus noradrenergic (LC-NE) neurons used local photostimulation to increase LC-NE terminal activity in the PFC following MIA. Together these results suggest that noradrenergic tone is important for regulating cognitive function in the Poly (I:C) model of maternal immune activation. This approach provides a promising translational animal model for the study of cognitive dysfunctions present in schizophrenia.

Title: Adolescent stress during critical periods alters the developmental trajectory of hippocampal parvalbumin (PV) interneurons and recapitulates circuit dysfunction implicated in schizophrenia

Authors: *X. ZHU[1,2], F. V. GOMES[1,2], A. A. GRACE[1,2]
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Univ. of Pittsburgh Dept. of Neurosci., Pittsburgh, PA

Abstract: Adolescence is characterized by enhanced neuroplasticity and responsivity to external events. While this period facilitates many beneficial learning processes, it is also a vulnerable period with respect to detrimental environmental impacts. Indeed, our prior studies indicated that unregulated stress during adolescence is able to induce long-term behavioral deficits and circuit dysregulation leading to an adult condition analogous to schizophrenia (SCZ). Based on these observations, we evaluated the hypothesis that adolescence is both a sensitive period and a critical period for environment to modulate pathophysiological process of SCZ. Specifically, male Sprague-Dawley rats were submitted to a 10-day combined footshock (FS) and restraint stress (RS) during two stages (PD21-30 or PD31-40) during adolescence or at adulthood (>PD75). Using *in vivo* electrophysiology, the long-term effects (>PD75 and 5-6 weeks post-stress) on dopamine (DA) neuron activity in the ventral tegmental area (VTA) were evaluated. Parvalbumin (PV) intensity and PV neuron number were also evaluated in prefrontal cortex (PFC) and ventral hippocampus (vHipp) subregions 1, 10, 20 days post-stress and in adulthood. Our results showed that adolescent stress during PD21-30 or PD31-40 resulted in comparable DA system hyperresponsivity in the adult, and produced persistent PV cell loss in the ventral subiculum of vHipp and transient (only at 1 day post-stress) PV loss in the prelimbic regions of PFC. These effects were not observed for groups exposed to the same 10-day stress paradigm in adulthood. To examine whether adolescence may also be a critical period for attenuating pathophysiology, we used the methylazoxymethanol acetate (MAM) developmental disruption model of schizophrenia, and tested whether environmental enrichment (EE) during PD21-40 could ameliorate or prevent DA circuit dysregulation and structural abnormalities in adults. Our preliminary results suggested that adolescent EE is able to ameliorate the structural deficits in the vHipp and the DA hyperresponsitivity in the VTA, an effect not detected with adult EE (>PD75) groups. Altogether, this study suggests that early adolescence is perhaps both a sensitive and a critical period for deleterious as well as protective effects of the environment on schizophrenia.

Title: M4 muscarinic acetylcholine receptor leads to antipsychotic and precognitive efficacy in rodents

Authors: M. POPIOLEK[1], A. ROSSI[2], *Y. MANDELBLAT-CERF[3], D. YOUNG[4], S. LOTARSKI[2], L. ZHANG[2], C. BUTLER[2], R. KOZAK[4]

Abstract: Preclinical and clinical data suggest that muscarinic acetylcholine receptor activation may be therapeutically beneficial for the treatment of psychosis and cognitive impairment. This is best exemplified by clinical observations with xanomeline, whose efficacy is thought to be mediated through co-activation of the M1 and the M4 muscarinic acetylcholine receptors (mAChRs). Here we examined the impact of treatment with a novel M4 mAChR selective activator on striatal dopamine terminals in vivo. Through fiber photometry we observed attenuation of striatal dopamine activity. Outcome of the striatal mechanistic study was consistent with antipsychotic-like efficacy in behavioral assays including reversal of amphetamine locomotor activity and amphetamine prepulse inhibition. In addition to antipsychotic efficacy, we also found M4 mAChR to enhance rodent performance on attentional and cognitive readouts including the sustained attentional task under distractor condition (d/SAT/SAT) and the continuous trial-unique to nonmatching-to-location task (cTUNL). Taken together we concluded that xanomeline's clinical efficacy may, at least in part, be attributable to activation of the M4 mAChR.

Title: Adeno-associated virus mediated inhibition of 14-3-3 proteins in the hippocampus induces schizophrenia-like behaviors in mice

Authors: *J. ZHANG[1], K. GRAHAM[1], H. QIAO[2], Y. WU[1], Y. ZHOU[1]
[1]Florida State Univ., Tallahassee, FL; [2]Shaanxi Univ. of Chinese Med., Xianyang Shi, China

Abstract: The 14-3-3 family of proteins is involved in a number of neuronal processes, and is genetically linked to several psychiatric disorders such as schizophrenia. Existing 14-3-3 knockout models, including our 14-3-3 functional knockout (FKO) mice that express an isoform-nonspecific 14-3-3 inhibitor primarily in the forebrain, exhibit behavioral endophenotypes corresponding to the core symptoms of schizophrenics. Prior human studies have implicated key forebrain regions, such as the prefrontal cortex (PFC) and the hippocampus (HP), in the pathophysiology of schizophrenia. However, 14-3-3 deficiency in these specific brain regions has not been examined in mouse models as a potential cause of schizophrenia-associated behaviors. In this study, we used an adeno-associated virus (AAV) which delivered shRNA to knock down the expression of the 14-3-3 inhibitor transgene in the 14-3-3 FKO mice, thus selectively restoring the function of 14-3-3 within targeted brain regions. We found that expression of the shRNA in both the PFC and HP is necessary to attenuate psychomotor agitation of the 14-3-3 FKO mice. Furthermore, to determine whether regional inhibition of 14-3-3 is sufficient to induce schizophrenia-associated behaviors, we constructed an AAV to express the 14-3-3 inhibitor. We found that AAV-mediated 14-3-3 inhibition in both the PFC and HP can trigger psychomotor agitation in wild type mice. Interestingly, when assessing the two brain regions separately, we determined that AAV-mediated 14-3-3 inhibition is sufficient to induce several behavioral and cognitive deficits including hyperactivity, impaired associative learning and memory, and reduced sensorimotor gating. In addition, we found that acute 14-3-3 inhibition results in decreased post-synaptic NMDA receptor levels and dendritic spine density. Together, findings from this study directly link 14-3-3 inhibition in the HP to certain schizophrenia-associated endophenotypes. Further study is underway to investigate how 14-3-3 deficiency in the HP induces these behavioral deficits.

Title: *In vivo* electrophysiology in the 14-3-3 functional knockout mouse model of schizophrenia

Authors: *Z. B. JONES, J. ZHANG, Y. WU, Y. ZHOU
Biomed. Sci., Florida State Univ., Tallahassee, FL

Abstract: Schizophrenia is a chronic and disabling psychiatric disorder that affects approximately 1% of individuals worldwide. Patients with schizophrenia exhibit diverse cognitive and behavioral deficits, yet the neurobiology underlying these deficits remains poorly understood. In particular, elucidating the circuit and network level changes that occur in schizophrenic brains may provide crucial insights into the development and treatment of this highly intractable disorder. Several psychiatric disorders, including schizophrenia, feature perturbations in rhythmic oscillations at various frequencies as part of their pathophysiology. In addition, defects in both local and long-range neural synchrony have long been observed in schizophrenic individuals. To further examine altered network activity in an animal model of schizophrenia, here we use a 14-3-3 functional knockout (FKO) mouse line that our lab has recently developed. These mice transgenically express a 14-3-3 peptide inhibitor with a neuronal-specific promoter to disrupt the endogenous functions of 14-3-3 proteins in an isoform-independent manner. We have previously shown that these 14-3-3 FKO mice recapitulate several schizophrenia-related behavioral phenotypes and exhibit impairments in learning, memory, synaptic activity and plasticity. This study aims to determine whether this FKO model also recapitulates the oscillatory and neural synchrony defects that manifest in patients with schizophrenia. To begin addressing this question, we implanted monopolar electrodes into prefrontal and hippocampal areas of our 14-3-3 FKO mice and their wild-type littermates and recorded local field potentials under resting state conditions. Through comparisons of these two groups in specific measures such as band power (particularly in the gamma frequency range), coherence, and phase synchrony, we expect to identify specific 14-3-3 mediated electrophysiological defects and correlate those defects to schizophrenia-associated behavioral endophenotypes. Future work will seek to determine the mechanisms driving these network changes in the brain as well as the temporal and regional specificity of 14-3-3 mediated dysfunctions at the cellular, network, and behavioral levels.

Title: Brain morphological abnormality in schizophrenia: Voxel-based morphometry and surface-based morphometry using CAT12

Authors: *Y. KYURAGI, N. ORIBE, S. FUKUSHIMA, N. NAKAYAMA, R. HAYASHIDA, Y. MIYAKE, K. OTA, T. UENO
Natl. Hosp. Organization Hizen Psychiatric C, Saga, Saga, Japan

Abstract: Introduction: Previous brain image studies and postmortem brain studies have reported that gray matter volume decreases mainly in frontal lobes, temporal lobe, and limbic system in schizophrenia. By using the Voxel-based morphometry (VBM) method, abnormal brain structure volume can be detected by searching the whole brain. Moreover, by using the Surface-based morphometry (SBM) method, the form of the cerebral cortex can be evaluated in more detail. We examined gray matter volume and morphological abnormality of the cerebral cortex in schizophrenia using Computational Anatomy Toolbox (CAT12) which became newly available in Statistical Parametric Mapping (SPM12).Methods: We covered 30 patients with schizophrenia hospitalized and treated at our hospital and 30 healthy, age and sex matched individuals. We compared the gray matter volume using the 3D T1-weighted images by the VBM method, and detailed structure evaluation was performed on the cerebral cortex region, which showed the gray matter volume decrease in schizophrenia, by SBM method. We calculated the cortical thickness, gyrification index and sulcal depth in the target cerebral cortex region and its surrounding structures using Aparc.a2009s atlas and compared between groups.Results: In the VBM analysis, there was a decrease in gray matter volume in schizophrenia in left superior temporal gyrus, right frontal operculum, left middle occipital gyrus, right thalamus, both side calcarine cortex, left anterior cingulate gyrus, left frontal operculum (p&lt0.05, FDR corrected; whole brain). In the SBM analysis, the surrounding structures of the left superior temporal gyrus showed a decrease in gyrification index in the left planum polare and a decrease in sulcal depth in the left transverse temporal sulcus, the left posterior limb of the lateral fissure, and the left superior temporal fissure (p&lt0.05). Abnormality in the SBM analysis could be confirmed for the other volume decrease regions seen in the VBM analysis.Conclusion: Decreased gray matter volume and morphological abnormality of the cerebral cortex were observed in schizophrenia. These abnormalities may be involved in the pathology of schizophrenia.

Title: Severe symptomatic schizophrenia showed smaller local gray matter volume

Authors: *T. UENO[1], Y. KYURAGI[1], R. HAYASHIDA[2], N. ORIBE[2], N. NAKAYAMA[2], K. KAWAKAMI[2], M. ONOUE[2], H. KUGA[3], S. FUKUSHIMA[4], Y. MIYAKE[1], T. YUZURIHA[1]
[1]Hizen Seishin Iryo Ctr., Kanzaki-Gun, Japan; [2]Hizen Seishin Iryo Ctr., Saga, Japan; [3]Johns Hopkins Univ. Sch. of Publ. Hlth., Baltimore, MD; [4]1-1 Nijigaoka, Nagasaki, Japan, Kouseikai Michinoo Hosp., Nagasaki / Nagasaki, Japan

Abstract: Introduction; Several studies investigated that the gray matter volume in schizophrenia patients were reduced than the normal control subjects. However, the location of the reduction is not clearly understood. Neckelmann et al. showed that the hallucination score was related to the gray matter volume in the temporal lobe. They used Brief Psychiatric Rating Scale (BPRS) to access the clinical feature. Although they accessed the clinical impairments, the group consisted of severe symptom and not so severe symptom. This study aimed to investigate the gray matter volume reduction in severe symptomatic schizophrenia patients. Methods; One hundred and twenty one schizophrenia patients were recruited from Hizen Psychiatric Center. They met to the DSM-5 criteria diagnosed by two independent psychiatrists. All participants signed informed consent forms according to the ethical committee of the Hizen Psychiatric Center. The exclusion criteria were alcohol/drug abuse, brain hemorrhage/ infarction, or thyroid dysfunction.BPRS (24 factors) was used to assess the clinical condition of each patient. Sixteen schizophrenia patients were chosen out of this group by symptomatic state with the scale of Unusual thought, Bizarre behavior, and Conceptual disorganization in the BPRS scale. They had 6(severe) or 7(very severe) points rated. Sixteen normal age matched normal control were recruited from Hizen Psychiatric Center by Ads . All participants were scanned by 1.5T MRI machine (Philips) to get the T1 weighted structural brain images in 6 minutes. Resolution was 1mm x 1mm x 1.2 mm. All the images were segmented to the gray matter images and converted to the normalized images with the canonical brain image in MNI coordinate with the DARTEL method in SPM software (Ashburner 2007). General linear model was used to investigate a gray matter volume reduction rather than normal control. General linear model has covariates of age and sex. Cutoff was under 0.001 (P value) of each point of brain, and 0.01 (P value) of spatial extent with Gaussian random field model to exclude the type 1 error.Results; Schizophrenia patients showed smaller volume in right medial temporal lobe, left anterior cingulate, and left orbitofrontal lobe. No voxels were survived in the analysis of volume excess rather than normal control.Discussion; Severity in schizophrenia patients might be related to temporal lobe and anterior cingulate, and orbitofrontal lobe. However, left temporal lobe were not detected in this study. Further investigation would be needed.References: Neckelmann G, Specht K, et al(2006) , Int J Neurosci 116(1):9-23Ashburner, J. (2007). Title: Abnormal diffusion across the brain in schizophrenia compared to autism

Authors: *S. M. HAIGH[1], S. M. EACK[2], T. KELLER[1], N. J. MINSHEW[3], M. BEHRMANN[1]
[1]Psychology, Carnegie Mellon Univ., Pittsburgh, PA; [2]Sch. of Social Work, Univ. of Pittsburgh, Pittsburgh, PA; [3]Professor of Psychiatry and Neurol., Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Autism and schizophrenia share many behavioral characteristics such as social and communication problems and sensory abnormalities, despite the differences in diagnostic criteria. This has led to investigations into the underlying pathophysiology that may help differentiate between the two conditions. In the current study, we used Diffusion Tensor Imaging (DTI) to investigate the integrity of white matter tracts across the brain. We directly compared 23 adults with Autism Spectrum Disorder (ASD) to 15 adults with schizophrenia, and to 14 healthy age- and gender-matched controls. Measures of fractional anisotropy (FA) were similar across the three groups, but the adults with schizophrenia showed greater mean diffusivity (MD) in both radial and axial directions compared to the adults with ASD and controls. There were no significant group differences in head motion and brain volume, and even when these factors were included in the analyses, the effects in MD still held. The results suggest that although the integrity of white matter tracts as measured by FA is similar in the three groups, the microstructure of white matter in schizophrenia has fewer barriers to restrict water diffusion overall, compared to that in autism and in typically developing individuals. Together, this indicates that white matter tracts may be subtly impaired in schizophrenia, and may be helpful in differentiating the pathological differences between these two conditions.

Title: The effects of oral tryptophan challenge on blood kynurenines, cerebral blood flow, and cognition in schizophrenia

Authors: *L. M. ROWLAND, R. W. BUCHANAN, D. L. KELLY, C. F. KILDAY, F. M. NOTARANGELO, M. A. R. THOMAS, R. SCHWARCZ
Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Elevated brain levels of kynurenic acid (KYNA), a metabolite of the kynurenine pathway of tryptophan (TRYP) degradation, are observed in schizophrenia (SZ) and are thought to be causally involved in the cognitive deficits observed in the illness. Increases in brain KYNA levels cause behavioral impairments in rodents reminiscent of SZ, but this effect has not been investigated in humans. Therefore, we administered oral TRYP to increase production of brain KYNA in patients with SZ and healthy controls and assessed blood kynurenines, brain blood flow, and cognition. Thirty-one participants (14 controls and 17 patients) consumed a slurry of 6 g TRYP or placebo and completed blood draws, a neuroimaging session consisting of arterial spin labeling (ASL) for cerebral blood flow measures, and neuropsychological tests of verbal and visual memory, attention, and working memory. Results revealed a robust increase in blood kynurenine and KYNA following TRYP but not placebo administration in both groups ($p<0.05$). With respect to cerebral blood flow, there was a significant drug by group interaction such that prefrontal cortical blood flow during TRYP versus placebo was higher in healthy controls and lower in patients ($p < 0.05$). This is important since we and others have shown that lower cortical blood flow is related to poorer cognitive function in patients with schizophrenia. Our results suggest that an increase in KYNA may be causally involved in this phenomenon. Finally, verbal learning performance was significantly poorer during TRYP compared to placebo in the healthy control group. These results provide strong support for the hypothesis that increased KYNA may be related to the pathophysiology of cognitive impairments in SZ. The results also highlight the methodological utility of a TRYP challenge to increase the production of kynurenines in humans.

Title: Dual-color volumetric imaging of neural activity of cortical columns *in vivo*

Authors: *S. HAN[1], W. YANG[1,2], R. YUSTE[1]
[1]Biol. Sci., Columbia Univ., New York, NY; [2]Dept. of Electrical and Computer Engin., Univ. of California, Davis, Davis, CA

Abstract: To capture the emergent functional properties of neural circuits, high-speed volumetric imaging of neural activity at cellular resolution would be ideal. Although two-photon calcium imaging is a powerful tool to study population activity *in vivo*, conventional two-photon microscopes only image two-dimensional planes. Expanding it to three-dimensions while maintaining a high spatiotemporal resolution appears necessary. We developed a novel two-photon microscope with dual-color laser excitation that can image neural activity in a 3D volume in mice cortex *in vivo*. We use 920 nm and 1064 nm lasers to image, at the same time, neurons labeled with GCaMP6 in layer 2/3, and with jRGECO in layer 5, respectively. To enable volumetric scanning, an electrically tunable lens or a spatial light modulator was implemented in the beam path to enable fast sequential or simultaneous scanning of different focal planes. Using this beam multiplexing strategy, we image the neuronal activity of cortical circuits at high speed in primary visual cortex from awake mice (600 μm deep volumes at 10 vol/s). Using these data, we analyze the orientation tuning properties of cells in cortical columns, as well as the spatial structures of visually-evoked neuronal ensembles. We also demonstrate fast volumetric calcium imaging of layer 1 apical dendrites and layer 2/3 somata in local V1 circuits, as well as long-range projections from PFC and layer 2/3 somata in V1. We are optimizing our system to image functional neural circuits through the entire depth of a cortical column.

Title: Improving quality of optical fiber-based endoscopy for *in vivo* brain imaging

Authors: *T. TUCKOVA, M. HONS, P. JAKL, M. SILER, E. DRAZANOVA, L. KRATKA, J. TRÄGÅRDH, T. PIKALEK, S. SIMPSON, T. TYC, H. UHLIROVA, T. CIZMAR

Abstract: Optical fibers have been used in the past to image in locations deep in the scattering tissue which are not accessible through optical microscopy. Recently, the endeavor to minimize tissue damage has motivated the use of multi-mode fibers which allowed for high-resolution imaging with significantly smaller cross-section than single-mode fibers or GRIN lenses. Only recently the first successful functional imaging of neuronal calcium in vivo has been demonstrated in the mouse brain [1, 2]. These efforts represent a huge leap forward in MMF-based endoscopy, yet the quality of the detected functional calcium signals in vivo is still far from the state-of-the-art standards set by confocal and multi-photon microscopy. We introduce here computational and technological advancements to improve the quality of fiber-based imaging potentially important for brain endoscopy.

Title: A new method for measuring GABA using enzymatic reactors and fluorometric detection

Authors: *C. M. PÉREZ[1], A. A. RUÍZ-GARCÍA[1], A. MORALES-VILLAGRÁN[2], J. C. SALAZAR-SÁNCHEZ[2]

Abstract: γ-Aminobutyric acid (GABA) is a non-proteic amino acid recognized as the major inhibitory neurotransmitter in the mammalian central nervous system. GABA has been a widely studied molecule, despite the difficult that its measurement represents. Several methods have been developed for this purpose; most of them use HPLC and with minor frequency fluorescence methods. We present a methodology to quantify GABA in micro and sub-micro molar range using fluorometric detection coupled to a customized flow system developed in our laboratory to allow continuous measurements. In this methodology GABA standards and samples were treated with an enzymatic reactor that contained GABAse to convert the GABA to glutamate, and glutamate oxidase to produce hydrogen peroxide which reacts with Amplex^{TM} Red and horseradish peroxidase (HRP) producing resorufin as a fluorescence derivate. The detection system uses a laser beam of 532 nm to excite the resorufin, which produces fluorescence at 590nm, which is proportional to GABA concentration. The light emitted was captured in a silicon photomultiplier coupled to an Arduino data acquisition system, afterwards, numerical values were recorded. GABA standards concentrations were also measured with an HPLC with electrochemical detection to validate this new method. The lower concentrations tested with this technique was 500nM, obtaining linear R^2 coefficient values higher than 0.95. This method provides the alternatives for detecting both low and high quantities of GABA present in fluid samples, such as in tissue extract or microdialysates. It offers the possibility to run a large number of samples in a single trial due to its immediate detection and the short time needed between individual readings.

Abstract: The brain mediates our interaction with the external world by performing complex computations undertaken by highly interconnected regions spread across several centimeters. To understand how computations occurring globally mediate behavior, we need tools to measure and manipulate the activities of these widespread brain regions at the single cell resolution, and at multiple timescales. Currently, appropriate tools to access large brain regions while simultaneously sampling information at high rates are not available. The ability to perform such multi-scale imaging in the context of neural perturbation of localized regions of the brain would be very powerful. To this end, we have developed “See-Shells”, digitally generated transparent polymer skulls, that enable wide-field sub-cellular resolution optical access to the whole dorsal cortex in mice. We used a motorized stereotax to map the skull surface of a 9-week old C57/BL6 mouse at 85 points to generate a 3D point cloud. We used this point cloud to interpolate a general 3D surface that accurately mimicked the morphology of the skull and subsequently used the interpolated surface as a template to digitally design skull replacements using computer aided design (CAD, SolidWorks) software. The See-Shells consist of a 3D printed PMMA frame bonded to a transparent, thin and flexible polymer, Polyethylene terephthalate (PET) using an adhesive epoxy. See-Shells were implanted on 16 C57/BL6 mice, 2 Thy1-YFp mice, and 27 Thy1-GCaMP6f mice by adapting previous window implantation protocols. See-Shells were chronically implanted and allowed optical access for over 100 days. We demonstrate the ability to image sub-cellular structures such as dendrites and dendritic spines at depth *in vivo* using two-photon (2P) microscopy. We also performed wide-field imaging of mesoscale activity in awake head-fixed animals, as well as imaged the activity of individual neurons in localized cortical regions spread across several millimeters using 2P microscopy. Perforating the PET allowed us to introduce probes for intra-cortical stimulation of the motor cortex while performing cortex wide imaging. We observed that localized stimulation of the motor cortex causes global activation of the whole cortex in both anesthetized and awake animals. Thus, See-Shells enable us to chronically interface with the cortex at high spatial and temporal resolution, at both mesoscale and cellular levels, in the awake animal.

Abstract: Regulation of gene transcription is essential for long-term plasticity in the brain. However, it has not been possible to monitor *in vivo* the dynamics of neuronal transcription and to correlate them to the activity patterns in a large ensemble of cells over time. To address this, we developed a technique to image *in vivo* the activity of cAMP response element binding protein (CREB), an activity-dependent transcription factor important for synaptic plasticity, using 2-photon fluorescence lifetime imaging (2pFLIM) in combination with new FRET biosensors. This technique allowed for a long-term simultaneous imaging of CREB and neuronal activity in layer 2/3 cortical neurons in awake animals. We found that, on average, CREB activity is positively correlated with behavioral performance in a motor learning task. Further, we performed chronic dual-imaging of CREB and neuronal activity in the primary visual cortex and identified a correlation between CREB and neuronal activity dynamics following sensory deprivation. This approach will allow researchers to unravel transcriptional dynamics underlying experience-dependent plasticity in the brain.

Abstract: Single neuron and local field potential electrophysiological tetrode recordings of fast dynamic electrical activity and large ensemble neural oscillations have enabled researchers to begin deciphering functional aspects of deep brain regions where optical methods struggle due to scattering effects. This lack of optical access prevents imaging single cell calcium dynamics and spatial localization of cells. Methods exist to increase optical imaging depth, but even with 3-photon excitation imaging beyond 2mm is difficult. To overcome this limitation, it is possible to image through implanted GRIN lenses: rod shaped glass lenses of small diameter. Here, we describe a GRINtrode, a deep brain implant that combines optical and electrophysiological recording in a single, compact design.
The GRINtrode is designed for dual imaging/electrical recording in the hippocampus but can be modified using different length GRIN lenses for a variety of deep brain regions. The device includes a drive to allow manual vertical translation for fine-tuning the recording location.

Title: Light in the dark! Shedding light on the suitability of novel BOPIDY dyes for voltage sensitive imaging of neurons in the stomatogastric ganglion of cancer pagurus

Authors: *J. BUTCHER[1], J. A. TICKLE[2], D. SIRBU[4], A. C. BENNISTON[4], P. E. ANDRAS[3]
[1]Sch. of Computing and Mathematics, Keele Univ., Newcastle Under Lyme, United Kingdom; [2]Sch. of Life Sci., [3]Sch. of Computing and Mathematics, Keele Univ., Keele, United Kingdom; [4]Sch. of Chem., Newcastle Univ., Newcastle, United Kingdom

Abstract: Voltage sensitive dyes (VSDs) allow the activity of 100s-1000s of neurons to be monitored simultaneously providing fast temporal dynamics, making single action potential events observable. However, VSDs suffer from poor signal to noise ratio (SNR), where typically it is ~10 times less than that of calcium sensitive dyes. This work aims to improve the SNR of VSDs while maintaining their temporal dynamics by building on previous work using a new generation of VSDs derived from BOPIDY dyes. These dyes were recently shown to be viable alternatives to standard VSDs [1] such as Di4-ANEPPS [2].
The stomatogastric ganglion (STG) of *Cancer pagurus*, which controls the movement of muscles in the gastric system, produces a robust and stable pyloric rhythm (PR), making it well-suited for testing VSDs. As a result, optical imaging of the STG using VSDs is well documented (e.g. [3]). The toxicity (indicated by the increase in PR frequency) of several novel dyes was assessed and compared to Di4-ANEPPs. The STG was removed and desheathed to allow for optical recording followed by a 20 minute bath application of each dye and a 20 minute washout. For each dye, the duration of light shone onto the STG ranged from 20s to 5 minutes in increments of 20s as described before [1]. Each of the dyes tested showed low toxicity when measuring the change in the PR frequency. The SNR of each dye, measured by the change in fluorescence of a cell when intracellularly injected with a current of 0.1 nA, showed that the new dyes offered a similar SNR when compared to Di4-ANEPPS.
Future work involves the further validation of these dyes, assessing toxicity and SNR in crab and mammalian tissue, the results of which will feedback into the refinement of the structure of suitable novel dyes in the future.

Abstract: In recent years fiber photometry [1, 2] gained popularity among neuroscientists as a method for causal investigation of neural circuitry *in vivo* [3, 4]. The knowledge of the spatial characteristics of the light collected by the implanted waveguide is a key aspect for the analysis of data related to calcium or voltage dynamics. Here we present a method to measure light collection properties of flat cleaved optical fibers based on laser scanning two photon microscopy (LS2PM). The setup is shown in Fig 1(a): one facet of the optical fiber is immersed into a fluorescent medium, while the light emitted by the distal facet is conveyed on a PMT. Via a volumetric raster scanning of the fluorescence excitation, the light collected from the optical fiber is measured point by point. By combining the two images acquired from the system, the fraction of light collected from the optical fiber can be assessed. A meridional section of the light collection diagram of a 0.39NA/200µm core fiber in PBS:fluorescein solution is shown in Fig.

1(b), and the respective three dimensional reconstruction is shown in Fig. 1(c) (isosurfaces at 10%, 20%, 40%, 60% and 80% of the maximum). In typical *in vivo* experiments, fluorescence is excited and detected through the same waveguide; hence, the signal gathered from a specific position depends on the intensity of excitation. The pinhole detection path in the optical setup allows to measure the distribution of the light emitted by the waveguide. Fig. 1(d) depicts a meridional section of the light emission diagram (Fig. 1(d1)), the light collection diagram (Fig. 1(d2)), and their combination in a photometry efficiency parameter (Fig. (1d3)), obtained as a pixel by pixel product) of a 0.39NA/200µm core fiber in a fluorescent mouse brain slice.
The method proposed here potentially represents a rapid tool for the performances characterization of various photometry devices.

Title: Dynamic ratio-metric imaging of cytosolic free Ca^{2+} in skeletal muscle cells using 340/380 nm light emitting diode illuminators

Authors: *M. CHENCHILIYAN[1], A. DEUTSCH[2], E. PEWZNER[2], D. FIXLER[1]
[1]Engin., Bar-Ilan Univ., Ramat Gan, Israel; [2]Prizmatix Ltd., Givat-Shmuel, Israel

Abstract: Calcium-sensitive fluorescent indicator falls broadly into two categories, ratio-metric (dual-wavelength) or single-wavelength indicators based on their response to a calcium elevation. Ratio-metric indicators shift either their excitation or their emission wavelengths in response to calcium, allowing the concentration of intracellular calcium to be determined from the ratio of fluorescence emission or excitation at distinct wavelengths. Fura-2 is one of the most common ratio-metric fluorescent Ca^{2+} indicator, which has an emission maximum at 510 nm whereas its excitation maxima change from 380 nm to 340 nm in response to calcium binding. Historically, a combination of arc lamp and monochromators have been used as the light source for Fura-2 ratio-matric fluorescence microscopy. In recent years different combinations of LEDs such as 350/380 nm or 360/380 nm have been used to excite Fura-2. To precisely match the Fura-2 excitation, in this study we built a fast switchable 340/380 nm LED (Prizmatix Ltd., Israel) excitation light source. The newly constructed light source has been exploited in Fura-2 ratio-metric calcium imaging of skeletal muscle cells. The spontaneously elicited Ca^{2+} transients in the cells were recorded with a high temporal resolution (1 ms). The light source utilized for the demonstrated instrumentation in this report optimally matches the excitation wavelengths of either calcium-free or bound states of Fura-2. The high-intensity stability and fast switching of the 340/380 nm LED illuminator indicates their potential as a preferred light source for Fura-2 ratio-metric calcium imaging over the existing light sources.

Title: Improved automated imaging of mouse mesoscale cortical circuits and behavioral analysis

Authors: *T. H. MURPHY[1], J. BOYD[2], J. LEDUE[2], F. BOLANOS[5], M. BALBI[3], M. P. VANNI[4]

[1]Univ. British Columbia, Vancouver, BC, Canada; [3]Psychiatry, [4]Dept. of Psychiatry, [2]Univ. of British Columbia, Vancouver, BC, Canada; [5]Psychiatry, UBC, Vancouver, BC, Canada

Abstract: We have reported a system to voluntarily head fix (autoheadfixation) and images cortices of adult group-housed mice (Murphy et al. 2016 Nature Comm) that are identified using RFID tags (Bolanos et al. 2017). We replaced noisy solenoids with servo fixation which results in > 10-fold higher head fixation rates and use both male and female mice C57bl6. Mice are water restricted and can complete as many trials of head fixation per day as they desire to obtain water. Any mouse not performing the task will be given supplemental water. To facilitate a behavioral task, we have added automated lick detection and synchronization of the head fixation system with multiple behavioral cameras using an internet-based UDP trigger. This triggering system ensures that animal specific time stamp information is passed between different Raspberry PIs controlling head fixation or video imaging clearly associating videos with a specific mouse RFID tag and time stamp. To train animals for future head fixation and behavioral tests we employ multiple stages. The first stage, which typically lasts about a week involves an animal entering the head fixation tube (only ~35 mm) and receiving what are called "entrance rewards" from an elongated water spout. The water spout is shortened over the next 3-6 days. The animal then proceeds further down the tube and trips an IR sensor which will initiate a program of brain imaging or behavioral task, but is not associated with head fixation (3-6 days). We then gradually add head fixation over the next week. We then sequence the animals to full voluntary head fixation (not >2 min in duration) and integration with a licking based reward task (over an additional 3 days). Stages of task engagement first involves auditory feedback for inappropriate licking. We find that animals will tend to lick spontaneously while head fixed. We give auditory feedback if licking occurs at too high a frequency and in the absence of rewards. This imposes a condition where the lick rate needs to subside before rewards are delivered. Once the licking rate subsides for period of 1-2 seconds we then present a vibration stimulus and they need to lick within a time window to receive a reward. 18 mice were trained in this manner and greater than 50% were able to respond with tone-based lick suppression and then licked when given a go-trial vibrational cue leading to reward. While the integration between behavior and brain imaging is still being done (and analysis pipeline developed), we anticipate that improved training regimens and behavior readouts will facilitate more complex and automated homecage tasks leading to robust longitudinal animal models of human disease.

Title: Brainwide optical circuit interrogation at the cellular level guided by online analysis of neuronal function

Authors: *C. WANG[1], N. VLADIMIROV[1], B. HOECKENDORF[1], Y. MU[1], M. TANIMOTO[1], J. WITTENBACH[1], J. FREEMAN[1,2], S. PREIBISCH[1,3], P. KELLER[1], M. AHRENS[1]
[1]Janelia Res. Campus, Ashburn, VA; [2]Chan Zuckerberg Initiative, San fransico, CA; [3]Berlin Inst. of Med. Systems Biol., Berlin, Germany

Abstract: Understanding the brain requires measuring and perturbing neuronal activity. Tools for this have advanced rapidly, and are typically applied locally, but behavior is generated by the coordinated activity of neurons widely distributed across the brain. Thus, ideally we want to measure activity patterns of all neurons in the brain during behavior, use this information to decide which neurons to perturb, and record the brainwide effects of the perturbation. We developed an experimental and computational system that enables such experiments at the brainwide scale. In behaving larval zebrafish, we measure neuronal activity in the entire brain during behavior using light-sheet imaging. Concurrently, through fast distributed computational analysis, we generate whole-brain functional maps relating neuronal activity to stimuli/behavior. Any subset of neurons can be selected from the maps and then optically ablated/activated with a two-photon laser. Deleting specific functional neuron types from any of these nuclei has profound, distinct effects on brainwide responses consistent with a distributed implementation of the sensorimotor transformation. We extend the method to cellular-resolution targeted optogenetic activation during whole-brain imaging. These open-source methods allow for concurrent whole-brain activity and causality mapping in the same animal, which will enable delineating the contributions of neurons to brainwide circuit dynamics and behavior.

Title: Stable, flexible positioning for *in vivo* imaging of neural activity in the awake macaque monkey

Authors: *J. CHOI[1], V. GONCHAROV[3], J. KLEINBART[2], A. L. ORSBORN[2], B. PESARAN[2]
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY; [3]Janelia Res. Campus; Howard Hughes Med. Insitute, Ashburn, VA

Abstract: Two photon imaging of neural activity in the awake monkey has the potential to offer important insights into the cellular organization of neuronal population dynamics during complex cognitive behaviors. However, large-scale cellular resolution imaging in macaques is complicated by large movement artifacts and the expansive curvature of the cortical surface, spanning 80 degrees of angle and centimeters. Automatically positioning a microscope objective to multiple areas of the macaque cortical surface remains an unsolved problem. Doing so accurately and repeatably is necessary for localizing neurons across days and reducing aberrations due to poor alignment with glass cranial windows. Additionally, physiological pulsations and bodily movements can cause artifacts on the order of millimeters if left unstabilized. To address these concerns, we designed an implant and robotic positioning system to optically align the objective lens with a set of defined imaging sites, specifically in the visual and somatosensory cortices. The positioner adds five motorized degrees of freedom providing enough flexibility to move the objective into precise optical alignment with any target on the dorsal convexity of cortex. To track the moving elements, a set of computer vision markers attached to the microscope and the imaging chamber implant(s) allow their relative pose to be monitored and adjusted. Stability is ensured by a set of lockable reinforcing posts that rigidly fix the implant in relation to the microscope's optical table when a suitable imaging position has been found. A novel custom designed skull ring implant rigidly fixes the implant in three places to the head fixation apparatus. In addition to providing stability, this provides a watertight enclosure for imaging chambers placed within the ring. An easily replaceable two-photon chamber insert provides a sealed, incompressible interface between the brain and glass window, limiting pulsation artifacts. While testing the system to image a patch of cortex expressing GCaMP6s in an awake macaque, the resulting motion from all sources was measured to have a maximum deviation of 5 μm in the imaging plane and less than 1 um during periods of quiet wakefulness. The marker tracking error was measured to be less than 0.5 mm in position and less than 0.11 degrees in rotation. These results demonstrate stable and repeatable functional imaging of cellular activity in the awake macaque monkey sufficient for the analysis of large-scale neural population dynamics.

Title: Simple low cost system for optical intrinsic signal imaging of the mouse cortex

Authors: *H. E. LOPEZ-VALDES[1,2], C. NOLLA-SALTIEL[2], H. MARTÍNEZ-CORIA[1,3], M. X. MENDOZA-ROJAS[2], J. F. MENDOZA-VICTORINO[2]

Abstract: Optical intrinsic signal imaging (OISI) is a technique to map brain activity by measuring intrinsic activity-related changes in tissue reflectance. Main related changes detected are increased in cerebral blood flow and hemoglobin oxygenation changes. OISI have been commonly used to map the visual, olfactory and somatosentory cortices under physiologic and pathological condition. We develop our system taking advantage of open source hardware and software. Our OIS system was made with inexpensive electronic, mechanical and optical parts available from commercial suppliers and some custom-made components. A solid aluminum optical breadboards was used to set a stage for surgery with inhaled anesthetic, a stereo microscope, a homoeothermic blanket system, a CCD monochrome camera with a tandem lens, a three color led ring and a stimulus isolator. Male mice (28-32 g) were anesthetized with isoflurane and temperature maintained at 37℃. Images were obtained through the intact skull under red light using a 8-12 bit CCD camera connected to a tandem lens (50 mm, mounted front-to-front). To generate forepaw functional maps, electrical stimulation (50 Hz, 0.001 seconds pulse width, 0.14 to 0.22 mA) was generated by a custom-made pulse stimulator, connected to a custom-made stimulus isolator, and delivered to the tissue through a pair of subdermal needle electrodes (27 GA; Rochester Electro-Medical, Tampa, FL, USA), which were inserted 2mm apart under the proximal and distal walking pads of the right forepaw. 1 second stimulation was delivered 5 seconds after the start of each trial and the total duration of one trial was 25 seconds. For image analysis, a square region of interest of 2.00 mm was centered 2.12 mm lateral and 0.04 mm anterior to bregma. Maps were generated by thresholding at 50% of the maximal response. All the significant pixels in the region of interest were summed and then converted to millimeter to obtain the activated area. The control of electrostimulation and data acquisition was written in Visual Studio 2010. Image analysis was performed using either plugins or custom routines written for ImageJ 1.5.1A (NIH, Bethesda, MD, USA).

Title: Single-step implants for microendoscopic calcium imaging - enabling higher yield experiments with more consistent and standardized imaging performance

Authors: *J. J. NASSI, D. CHENG, M. J. SCHACHTER, M. TRULSON, S. MALANOWSKI, A. TAJIK, K. VISSCHER, S. L. OTTE
Inscopix, Inc., Palo Alto, CA

Abstract: Head-mounted, single-photon miniature microscopes coupled to implanted microendoscopic GRIN lenses enables unprecedented access to large-scale neural circuit calcium dynamics in behaving rodents. In order to accelerate mass adoption of this powerful technology, there is a need for a simple and reliable surgical workflow associated with preparation of animals for imaging, which currently requires three separate surgeries to inject virus, implant a GRIN lens and attach a microscope baseplate to the skull. Here we present a single-step solution for surgical preparation in mice which entails GRIN lenses coated at their distal end with GCaMP-expressing AAV coupled to the latest miniature microscopes featuring liquid lens based electronic focusing (nVista 3.0; Inscopix, Inc.). This solution reduces the number of required surgeries from three to one, reducing the time, cost and risks associated with the standard surgical workflow. We have additionally developed a suite of cellular calcium metrics that allows for the quantification of GCaMP performance and overall imaging quality longitudinally for a given animal and across animals at specified time-points. Serial dilution studies utilizing these in-vivo performance metrics, along with histological analysis, aid in determining the optimal number of viral particles with which to coat the lens and thereby allow for the standardization of AAV-coated lenses and the in-vivo imaging performance they enable. These single-step implants, along with key improvements to the focusing and docking mechanisms of the miniature microscope, should significantly increase experimental yield and enable more consistent and standardized imaging performance within and across labs, thereby lowering the barriers for mass adoption of this technology and rapidly advancing breakthrough discoveries in the brain sciences.

Title: Z-scanning in volumetric 2P-microscopy with a fast voice coil driven remote focus system

Authors: F. HUHN[1], C. SCHULZE[2], *T. G. OERTNER[2], G. RAPP[1]
[1]Rapp OptoElectronic GmbH, Wedel, Germany; [2]Inst. for Synaptic Physiol., Hamburg, Germany

Abstract: Fast volumetric sampling of biological specimens with laser scanning microscopes is required in many fields of neurobiology and medicine. When image acquisition in the lateral (x,y) plane reaches frame rates up to 100 Hz by means of resonant scanner systems, a jump between two z-layers in the image stack should also be performed in a few milliseconds, a time scale that cannot be reached by moving the objective or the specimen. Several proposed remote focusing systems only translate a small mirror with a mass below 1g and therefore rely on fast linear positioners.
We present measurements with a fast remote focusing system on a two-photon-microscope using a voice coil driven linear stage that we developed. The voice coil stage has a travel range of 1000 µm, a 10 µm step response time of 1ms and position accuracy better than 1 µm (Fig. 1). We characterize the dynamic properties of the voice coil stage and describe the remote focus system. As proof of concept, we show its applicability for 2-photon calcium imaging of neuronal activity in the CA1 region of rat hippocampus. The remote focusing system is compatible with the open-source software ScanImage (HHMI Janelia Research Campus / Vidrio Technologies, LCC).

Title: Reconstruction of single neuron resolution spiking activity from simulated diamond nitrogen-vacancy center vector magnetometric maps

Authors: ***M. PARASHAR**[1], K. SAHA[3], S. BANDYOPADHYAY[2]
[1]Sch. of Biosci., [2]Dept. of Electronics and Electrical Communication, Indian Inst. of Technol. Kharagpur, Kharagpur, India; [3]Dept. of Electrical Engin., Indian Inst. of Technol. Bombay, Mumbai, India

Abstract: Spikes, each a rapid (1-2 millisecond) neural membrane potential fluctuation, need to be detected in neurons at single cell resolution, possibly from any structure of the brain, in order to advance microscale understanding of brain structure and function. Currently, no technique

(fMRI, MEG, Electrophysiology) other than in-vivo two-photon calcium imaging achieves the desired resolution, however only within <1mm from the brain surface. Nitrogen-Vacancy centers (NVC) in diamond allow biomagnetic field (like action potential associated magnetic field; APMF) imaging, due to its ultrahigh magnetic field sensitivity, microscale spatial and temporal resolution and room temperature operation. We perform theoretical and computational analysis to find achievable spatial and temporal resolution in 2-Dimensional (2D) vector magnetic field measurements obtained from widefield diamond NVC imaging of mammalian cortical pyramidal neurons. We simulate AP propagation in cortical pyramidal neuron, taking into account detailed neuronal geometry and ion channel densities. Magnetic field vector has been calculated from voltage propagation simulations. We find ~1pT peak-to-peak magnitude of APMF of cortical pyramidal neurons. Different values of mammalian APMF magnitude have been reported in the range of 1pT-1nT in other studies. Therefore, we simulate magnetic field values by application of Biot-Savart law on a cable-theory based multi-compartment neuronal model, with minimal assumptions. The above framework has been used to simulate 2D NV magnetometric maps (NVMMs). Our results show that AP propagation through different regions of the pyramidal neuron, like axon hillock, action initial segment, myelinated regions and nodal regions, form different and computationally identifiable signatures in the 2D NVMMs. Further, we solve the inverse problem of reconstructing location of spiking neurons by developing a reconstruction algorithm. We find that APMF from different neurons, present in the plane parallel and perpendicular to the 2D diamond NV layer, can be separately identified in 2D NVMMs, even in case of simultaneous firing. These results suggest that the inverse problem in diamond NVC based images can be solved using the algorithm developed here. The expected resolution depends on occupancy of the 3D volume of interest, sparseness of activity, pixel scan size of diamond NV widefield imager, acquisition time and sensitivity of the imaging setup. Therefore, we show that diamond NV magnetometry is a realistic and promising tool for detecting single neuron resolution spiking activity in mammals.

Title: Facilitating the adoption of oxygen partial pressure imaging with two-photon microscopy

Authors: *S. SAKADZIC[1], T. V. ESIPOVA[2], M. A. YASEEN[1], A. DEVOR[1,3], S. A. VINOGRADOV[2], D. A. BOAS[1,4]

Abstract: The assessment of brain oxygenation on the microscopic level has the potential to transform our understanding of important clinical problems, such as stroke, Alzheimer's disease, dementia, chronic hypertension, and brain cancer, facilitating the development of new therapies and helping to improve clinical imaging and treatment protocols. Until now, no technology has been capable of microscopic oxygen imaging in the brain with high spatial and temporal resolution. Over the past several years we have developed a method, termed two-photon phosphorescence lifetime microscopy of oxygen (2PLM), which has the unique capability of fulfilling this niche. This is the only imaging method that allows high resolution mapping of brain oxygenation in real time.
2PLM of oxygen is a combination of state-of-the-art two-photon enhanced phosphorescent probes and a unique variant of two-photon laser scanning microscopy. The transformative power of 2PLM of oxygen has been demonstrated in several high-impact publications [1-7], producing great interest in the neuroscience community. With the help of NIH R24-NS092986 grant, we are in a process of setting up a self-sustaining resource that promotes widespread use of the two-photon oxygen imaging technology, making this new powerful method available to a broad group of neuroscience researchers.

Abstract: Swept confocally aligned planar excitation (SCAPE) microscopy is a light-sheet based imaging technique that permits very high speed volumetric imaging of cellular structure and function through a single, stationary objective lens. We have developed second generation SCAPE microscopes that further extend the capabilities of this approach to cover sub-cellular and very high speed (>100 VPS) imaging, meso-scale field of view volumetric imaging, two-photon excitation for fast volumetric imaging deeper into the mammalian brain, and a system optimized for high throughput imaging of cleared tissues. Working with collaborators, we have applied SCAPE to imaging a wide diversity of samples relevant to modern neuroscience including the freely crawling Drosophila larvae, awake behaving flies, larval zebrafish, C. Elegans worms, intact olfactory epithelium, awake behaving mice and cleared and expanded brain tissues. In these samples, we have used SCAPE to address a range of biological questions, made accessible by SCAPE's unique features, for example characterizing the sequential firing patterns of proprioceptive neurons throughout the crawling Drosophila larva. In turn, these

applications have highlighted the data analysis challenges of datasets exceeding 100's of Gbs. We will also report on progress towards dimensionality reduction and denoising, 4D registration and cell tracking and the application of big-data analysis techniques for information extraction and modeling of activity in the context of real time behavior.

Abstract: Sheet Illumination microscopy is a well developed tool in the bio-imaging community due to its many inherent advantages. Increased photonic efficiency allows for lower power light sources to be used, which in turn reduce phototoxic damage at the sample over time. High fidelity, high SNR data can be collected from these systems due to their optical sectioning capabilities, and as such, many have been designed to operate within a limited parameter space. These instruments often follow traditional design logic, for specialization in a single imaging condition, for the observation of a single type of neuroscientific data. This mentality yields high resolution results for a particular type of data, yet is limited in terms of flexibility. Here, the design and development of a user-configurable light sheet microscope is discussed, which uses a spatial phase modulator to dynamically shape and optimize the incident light sheet to perform

highly in a number of temporal and spatial scales. Optical performance and stability is assessed using fluorescent microspheres for PSF evaluation before conducting calcium imaging experiments on *C. elegans* and *Danio rerio.* The result is a general purpose microscopy platform that can adapt to the observation of many neuroscientific phenomenon in numerous spatial and temporal scales.

Title: An expanded open-source toolbox for widefield calcium imaging in freely behaving animals

Authors: *D. P. LEMAN[1], I. A. CHEN[2], W. W. YEN[1], A. CRUZ-MARTIN[1], N. PERKINS[3], W. A. LIBERTI[5], T. J. GARDNER[1], T. M. OTCHY[3], I. G. DAVISON[4]
[1]Biol., [2]Biomed. Engin., [4]Dept. of Biol., [3]Boston Univ., Boston, MA; [5]UC Berkeley, Berkeley, CA

Abstract: The combination of genetically encoded Ca^{2+} indicators and miniaturized, head-mounted fluorescence microscopes ("miniscopes") now offers the ability to record the activity of large neural populations in freely moving animals such as mice, rats, and songbirds. The freedom of movement afforded by miniscopes has enabled imaging during a wide range of naturalistic behaviors. However, current systems are limited to single-color imaging, and rely on gradient-index lenses that restrict their field of view to less than ~1mm^2. Here, we present an expanded-capability miniscope toolbox based on our open-source FinchScope project that helps overcome these limitations.
First, we have developed a dual-color system that uses multiplexing of excitation wavelengths to image spectrally distinct fluorescent reporters. This approach should enable identification of genetically specified cell types within circuits broadly labeled with single-wavelength activity sensors, as well as imaging of different cell classes labeled with different activity reporters, including specific subpopulations identified by retrograde labeling from different target areas. Tools for dual-color imaging will allow improved access to the activity of functionally distinct ensembles within heterogeneous neural circuits.
Second, we have developed an enlarged field-of-view system capable of imaging brain areas up

to 3 X 4 mm^2 in behaving mice. Using a 3D printed housing and off-the-shelf components, our optical design provides resolution of approximately 10μm and field curvature of less than 200μm. Combined with a high-resolution 5MP sensor, this resolution should be sufficient for single neuron imaging. Our large-area system is well suited for capturing distributed neural representations, such as sensory maps within olfactory bulb or single cortical areas. It should also allow visualization of functional interactions across multiple sensory and motor cortical regions. Methods for large-area imaging in freely moving animals will offer further insights into sensory coding, navigation, and sensory-motor coupling.
Overall, our low-cost, easily modifiable open-source system provides new imaging capabilities that complement advances in genetically encoded Ca^{2+} indicators, creating further opportunities for neural circuit imaging in naturalistic environments.

Title: OpenCortex: An integrated platform of cortex-wide imaging and deep-brain modulation for measuring cellular functional connectivity in behaving mice

Authors: *B. S. HUANG[1], L. GROSENICK[2,3], T. SPELLMAN[1], N. YADAV[1], A. TOADER[1], C. LISTON[1]
[1]Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY; [2]Statistics, Columbia Univ., New York, NY; [3]Simons Fndn., New York, NY

Abstract: Cognitive functions, such as memory encoding/retrieval, involve distributed functional connectivity networks spanning the cortex, with concurrent interplay with subcortical structures such as the hippocampus. Past work has largely focused on separate brain regions in isolation, while mechanisms of large-scale cortical-subcortical interactions as an integrated functional network remain unclear. Current barriers in acquiring cortex-wide cellular-resolution activity in mice include: 1) limited chronic whole-cortex recording access with cellular

resolution, 2) difficulties in capturing the multiple spatial and temporal scales involved, and 3) lack of techniques for concurrent cortical and subcortical recording/manipulation, which could facilitate the interpretation of cortical network activity. To overcome the first challenge, we have developed an *open-skull cortex-wide cranial window* in mice that provides optical access to the entire dorsal cortical surface, by surgically replacing the skull with a 10-mm-diameter glass coverslip. In addition, these windows can be fused with micro-prism implants for imaging deep medial cortical regions, such as the medial prefrontal and retrosplenial cortices. For the second challenge, we took a multiscale imaging approach (combining one-photon widefield imaging and 2-photon microscopy at different magnifications in the same brain) to acquire multi-level dynamic functional connectivity at both global and single-neuron levels. For the third challenge, we combined the cortex-wide window with chronically-implanted multi-functional fiber-probes and deep-imaging optical elements within the same brain, using newly-developed lateral-entry strategies to gain access from the side of the skull, while preserving the dorsal surface for cortex-wide imaging access. Here we demonstrate how the *OpenCortex* platform enables cortex-wide recording of cellular-resolution network activity with simultaneous monitoring and modulation of subcortical inputs in head-fixed behaving mice engaged in higher-order cognitive tasks. Long-term stability of the cortex-wide windows and implanted devices allows repeated recordings from the same animal-subject over days and months, thus enabling longitudinal studies of changing cellular circuits and networks across learning and development, in addition to supporting continuous iterations between theory and experimentation to test causal models of network mechanisms underlying cognition.

Title: Visualization of neuromodulation action at single synapse resolution

Authors: *S. KRUESSEL[1], D. LEE[2], J. HYUN[1], H.-B. KWON[1]
[1]Max Planck Florida, Jupiter, FL; [2]Dept. of Anat., Korea Univ., Seoul, Korea, Republic of

Abstract: Neuromodulators influence characteristics of cells and circuits. They change intrinsic properties of neurons by modulating ionic channels and also change plasticity threshold by altering ionotropic receptor functions. However, most of previous studies analyzed changes via

recording at cell body, which lacks the precise origin of neuromodulation-induced changes. In this study, we develop a synapse version of iTango2, named “Syn-iTango2”, and test whether the neuromodulation action can be monitored in real-time in local dendritic regions. Proof of principle was performed in HEK cells using Western Blot analyses, in vitro organotypic mouse slices applying dopamine agonist quinquirole and in acute slices of the nucleus accumbens activating dopaminergic terminals arising from the VTA via channelrhodopsin. This innovative technique will open the feasibility of studying neuromodulation circuits at subcellular resolution in behaving animals.

Title: Volumetric imaging of neural activity using a fast-switching spatial light modulator

Authors: *R. LIU, N. BALL, J. BROCKILL, J. ZHUANG, L. KUAN, C. WHITE, A. LEON, D. SULLIVAN, C. SLAUGHTERBECK, C. FARRELL, P. SAGGAU

Abstract: Large-scale *in vivo* recording of neural dynamics from mammalian brains at physiologically relevant temporal resolution is essential for our mechanistic understanding of brain function and its disorders. Multi-plane imaging is a conceptually straightforward approach to achieve volumetric recording of neural activity by utilizing the laminar structure of neocortical columns. However, the scanning trajectory and speed for traditional PZT-based multi-plane imaging is limited by mechanical inertia. Here, we report our recent advances in developing a microscope platform using a high-speed liquid crystal spatial light modulator. This novel imaging system allows for inertia-free multiplane functional imaging of awake and behaving animals at physiologically relevant frame rates. Using our approach, we recorded neural activity from the neocortex of awake and behaving mice at a volume of $500 \times 500 \times 200$ μm^3 at a rate of ~7 Hz (i.e., 500×500 μm^2 at each plane and a separation of ~40 μm between planes). In addition, imaging planes can be arbitrarily arranged at different depth within a column of neocortex, allowing us to record from multiple cortical layers (i.e., layer II/III, layer IV, and layer V) in a quasi-simultaneous manner during the same behavioral state.

Abstract: In non-degenerate two-photon excitation (ND2PE) microscopy the required energy for transition from the ground state to the excited state is delivered via absorption of two photons of different energies - NIR and IR - from two pulsed laser beams (Fig1(a)). ND2PE microscopy has the following advantages: (i) an increase in the IR power can be used to compensate for the loss of NIR power due to scattering and absorption; (ii) under ND2PE, fluorophores exhibit an increase in the absorption cross section; (iii) ND2PE can be used to mitigate out-of-focus excitation, which limits depth penetration of two-photon microscopy, when the NIR and IR wavelengths are chosen outside of the fluorophore excitation spectrum and are spatially displaced outside the focal plane. First, for each considered fluorophore, we obtained a 2D map of the absorption cross-section. Figure 1 shows a Jablonski diagram for ND2PE (a) and a cross-section map for EGFP (b); each value was normalized to the maximum degenerate absorption cross-section. Based on these results, we selected the combination of NIR and IR wavelengths that gave us significant cross-section enhancement and implemented these wavelengths for imaging of neurons in mouse cerebral cortex *in vivo*. As predicted, we observed an increase in the image brightness (Figs 1(c-d)). Finally, by spatially displacing the beams outside of the focal plane, we reduced the out-of-focus fluorescence, in phantoms and *in vivo*, while achieving high spatial resolution comparable to that of conventional two-photon microscopy.

Abstract: We developed Gradient Light Interference Microscopy (GLIM) as a label-free method for studying thick, strongly scattering specimens, such as acute brain slices. GLIM combines DIC microscopy with phase-shifting interferometry to suppress multiple scattering and attaches as an upgrade module to an existing microscope. GLIM enables quantitative studies of mesoscale structures that are hundreds of microns thick. Nevertheless, many such biological samples are not transparent, or otherwise incompatible with transmitted light imaging (e.g., high well count microplates). Thus, we designed a new epi-illumination GLIM microscope (epi-GLIM), which is now compatible with bulk tissues, including mm-thick brain slices and model organisms (e.g., zebrafish). We present the principle of operation, performance in terms of resolution and contrast and proof of concept applications to imaging thick specimens and tomographic reconstructions.

Title: Virtual manipulation of model organisms with rapid volumetric and neural activity feedback

Authors: *J. CARMONA, JR[1], B. A. MADRUGA[2], A. C. ROBERTS[3], K. ARISAKA[1]
[2]Physics, [1]UCLA, Los Angeles, CA; [3]Psychology, CSUF, Fullerton, CA

Abstract: Surveillance of environmentally unaware organisms is the primary objective of neuro-fields. The unconstrained mobility of organisms is the best possible method to solving questions in regards to how and why brains operate in their enigmatic manner. For this reason, rapid cellular resolution volumetric imaging and macro behavioral tracking of animals can be decoded and translated from complex static connectomes to sequential and theoretically defined processes. This was achieved using a line scanning confocal microscope operating at user discretion volumetric rates from ultra fidelity volumes (450 um x 450 um x 100 um) to rapid > 30 volumes/second (200 um x 100 um x 100um) and a low magnification tracking microscope. In addition, various virtual environments are created using spatiotemporally controlled electromagnetic sources (electric fields, magnetic fields, near ultraviolet, 405 nm, and infrared, 1490 nm) and chemical sources (salt concentrations) to which organisms have developed sensors for including, chemical, photoreceptors and thermoreceptors as cardinal for survival. Furthermore, optogenetic applications and laser ablation techniques were embedded into the

system for manipulation of neural networks with closed loop control. The system was applied to nematode Caenorhabditis elegans (C. elegans) and the more complex vertebrate Danio rerio (Zebrafish) and observed behaviorally and neuronally (via the GCaMP6 calcium dependent fluorescent protein) while mobile and immobilized; confirming previous research and yielding novel results.

Title: Multi-plane two-photon imaging of the piriform cortex in freely-behaving mice

Authors: *B. OZBAY[1], G. L. FUTIA[2], M. MA[3], D. RESTREPO[4], E. A. GIBSON[2]

Abstract: Two-photon microscopy is used as a common technique for acquiring neuronal data from multiple neuronal layers in head-fixed mice. As the miniaturization of electronics and optics improve, it is becoming more feasible to use advanced microscopy techniques in head-mounted devices for the imaging of naturally-behaving mice. In this work, we show deep-brain imaging of the piriform cortex in a mouse using a two-photon fiber-coupled microscope (2P-FCM). A coherent imaging fiber-bundle is used for lateral imaging and an electrowetting tunable lens is used for rapid axial focusing with no mechanically moving parts. The 2P-FCM weighs 2.5 g, with a lateral resolution of 1.5 µm and an axial resolution of 10 µm. We show imaging of a cylindrical volume of ~150 µm diameter by ~150 µm depth. The 2P-FCM is coupled to a GRIN lens implanted in the anterior piriform cortex for the imaging of GCaMP6s-expressing neurons. Behaviorally relevant neuronal activity is observed in multiple neuronal layers as female mice explore an environment with both their own bedding and unfamiliar male bedding. We show that the overall level of neuronal activity in the piriform cortex increases with decreasing distance to unfamiliar bedding. We could identify the responsiveness of specific neurons to each type of bedding. This setup can potentially be used for the multi-plane single-neuron imaging of high-level olfactory processing as mice track odorant plumes, which is currently not feasible under head-fixed conditions.

Title: Two-photon calcium imaging of the hippocampus in transgenic rats under voluntary head fixation

Authors: *P. D. RICH[1], B. B. SCOTT[1], S. Y. THIBERGE[1,2], A. SONG[1,3], C. GUO[4], D. G. TERVO[4], C. D. BRODY[1], A. Y. KARPOVA[4], N. D. DAW[1], D. W. TANK[1,2]

Abstract: Optical access to cortical and subcortical structures in task-performing animals has become an essential tool in neuroscience. Large ensembles of neurons can be recorded simultaneously and subsets of those can be silenced or stimulated. In rodents, this approach has been mainly been used in mice, however rats are often the first choice for the study of cognitive functions. Our goal was to record calcium dynamics from the hippocampus of awake rats; large ensembles of simultaneously recorded cells will help advance our understanding of how neural activity relates to the hippocampus' proposed role in navigation and planning.
Multiphoton imaging in rodents requires stability and optical access to brain; one such approach is to use voluntary head restraint with a table-top microscope (Scott et al., 2013, 2017). Voluntary head restraint also enables precise stimulus presentation whilst allowing free spatial behaviour during other periods of a behavioural task.
We visualized calcium dynamics of dorsal CA1 neurons in transgenic rats expressing GCaMP6f under the control of Thy-1 promoter with 2-photon microscopy (Dombeck 2010). Furthermore we developed a new head positioning system that is entirely passive and allows rats to engage and break fixation instantly, at any point, at will. We incorporated a magnetic bearing mechanism to the existing kinematic alignment system. In the new system, magnets retain the headplate with sufficient force to ensure stable imaging, whilst still allowing the animal to pull away at any point during imaging.
We trained animals to initiate and retain head fixation for brief periods (1-5s) before a reward was delivered. Stability within and registration accuracy across fixations allowed the imaging of calcium dynamics of large populations of hippocampal neurons across multiple trials and between sessions. We altered the task to present rewards continuously at a random rate of 0.2/s

for as long as the animal held fixation. We were able to achieve fixations, with recorded calcium dynamics, for up to 1 minute.
We are currently developing tasks that combine the controlled conditions of head fixation with free spatial behaviour in order to investigate the hippocampal contributions to navigation and planning.

Title: Neuromorphic neural networks: Converging globally, acting locally

Authors: *D. GARDNER
Physiol. & Biophysics, Joan and Sanford I Weill Med. Col. of Cornell Univ., New York, NY

Abstract: In 1993, The Neurobiology of Neural Networks (Gardner, D., MIT Press) presented parallels between artificial neural networks (ANN) and neuronal circuitry and offered neuromorphic implementations or extensions. In the following 25 years, advances in both neurobiology and ANNs extend parallels and possibilities. Current computationally capable ANNS include not only classic perceptron-derived feed-forward parvo-layered nets, but also magno-layered convolutional ‘deep learning’ ANNs and recurrent nets including LSTMs. ANNs evolve function by tuning synaptic weights across layers, including hidden layers; two years ago at SfN Gardner and Gardner (2016) noted hidden-layer-like responses in several systems. Contemporary synaptic physiology offers multiple mechanisms for plastic alteration of synaptic strength compatible with useful ANNs. Such models also need selective propagation of information along and across network levels in order to alter specific synapses. Neurobiology offers examples of global modulation as well as biophysically-plausible mechanisms to use transmitted information to adjust local plasticity. Transported signals from neuronal somas can selectively alter locally-tagged synapses, providing sites for convergence of cell-wide and synapse-local information. Presynaptic inhibition and facilitation can use remotely-originating

information to alter specific synapses. Two very general properties of nervous systems offer potential molecular mechanisms for supervised control of local plasticity. Many synapses are spanned by protein-protein links including membrane-spanning cell-adhesion molecules with cytoskeletal connections. Astrocytes and microglia may mediate both short-term and long-term actions specific to individual synapses, potentially controlled by both local and global factors. Invertebrates offer additional examples of neuromorphic mechanisms. Aplysia buccal ganglia provide a simple, well-characterized example of a minimal yet functional hidden layer, a narrow channel consisting of two neurons (B4 and B5) with identical structural connectivity but with different neuromodulatory co-transmitters, signals, and potential for differential programmability. This network also offers evidence for postsynaptic, and therefore retrosynaptic, specification of transmitter release. Fly olfaction relies on ANN-like organization and synaptic modulation. Enhanced communication and collaboration by neuroscientists and ANN developers has great potential both for new and neuromorphic ANN designs and also for analyses of the computations performed by neural networks formed by real neurons.

Title: Achieving context-dependent processing in neural networks through human-level continual learning

Authors: *Y. CHEN, JR[1], G. ZENG[2], B. CUI[3], S. YU[4]
[1]Brainnetome Ctr., Inst. of Automation, Chinese Acad. of Scienc, Beijing City, China; [2]Inst. of Automation, Chinese Acad. of Sci., Beijing, China; [3]Inst. of Automation Chinese Acad. of Sci., Beijing, China; [4]Brainnetome Ctr., Inst. of Automation, Chinese Acad. of Sci., Beijing, China

Abstract: One of the hallmarks of high-level intelligence is flexibility. Humans can respond differentially to the same stimulus according to contexts, such as different goals, environments, and internal states. The prefrontal cortex (PFC), which is highly elaborated in primates, is pivotal for such an ability. The PFC can quickly learn "rules of the game" and dynamically apply them to map the sensory inputs to different actions in a context-dependent way. This is quite different compared to the current artificial deep neural networks (DNNs). DNNs are powerful for recognition and classification tasks as they learn sophisticated mapping rules between the inputs and the outputs. However, the rules that current DNNs can learn are typically stereotyped. This limits the network's ability to work in more complex and dynamical situations in which the mapping rules themselves are not fixed but constantly change according to contexts, such as different environments and goals. Inspired by the role of the prefrontal cortex (PFC) in mediating context-dependent processing in the primate brain, we propose a novel approach, involving a learning algorithm named orthogonal weights modification (OWM) with the addition of a PFC-like module, that enables networks to continually learn different mapping rules in a context-dependent way. We demonstrate that with OWM to protect previously acquired knowledge, the networks could sequentially learn up to thousands of different mapping rules without interference, and needing as few as ~10 samples to learn each, reaching a human level ability in online, continual learning. In addition, by using the PFC-like module to properly mix sensory and contextual information, a network could sequentially learn different, yet context-specific mapping rules for identical sensory inputs. Taken together, these approaches allow us to teach a single network numerous context-dependent mapping rules in an online, continual manner. This enable highly compact systems to gradually learn myriad of regularities of the real world and eventually behave appropriately within it. Our model would offer an alternative option to explain how new information are integrated into neural systems, shed light on the potential role of replay of experiences in the learning process and show how sensory information can be modulated by context signals in PFC.

Title: A mechanism for synaptic copy between neural circuits

Authors: *L. TAO[1], B. WANG[2], Y. SHAO[2], A. T. SORNBORGER[3]
[2]Ctr. for Bioinformatics, [1]Peking Univ., Beijing, China; [3]Dept. of Mathematics, Los Alamos Natl. Lab., Los Alamos, NM

Abstract: Cortical oscillations are central to information transfer in neural systems. Experimental evidence supports the idea that coincident spike input can allow the neural threshold to be overcome, and spikes or firing rates to be propagated downstream in a circuit. Therefore, an observation of oscillations in neural circuits would be an indication that repeated synchronous spiking is enabling information transfer and processing. However, for memory transfers, in which synaptic weights must be being transferred from one brain region to another, the underlying dynamical and circuit mechanisms remain unclear. Here, we present a synaptic transfer mechanism whose structure provides some understanding of the phenomena that have been implicated in memory transfer, including nested hippocampal, thalamo-cortical and slow cortical oscillations. We construct a circuit that uses pulse-gating to guide graded information through Hebbian synapses to learn (encode) a covariance matrix from input data. Using pulse-gating we then copy the synaptic strengths encoding the covariance to a second set of Hebbian synapses. The dynamics that emerges is similar to those observed experimentally, i.e., nested oscillations at various frequencies, that accompany memory consolidation and memory transfer. We show that there are a number of gating schemes capable of performing the transfer, all based on generating bases and basis transforms that may be gated between sets of synapses.

Title: Hierarchical selective recruitment: A control-theoretic framework for goal-driven selective attention

Authors: *E. NOZARI[1], J. CORTES[2]
[1]Univ. of California San Diego, LA Jolla, CA; [2]Univ. of California, San Deigo, La Jolla, CA

Abstract: The ability to prioritize relevant over irrelevant sensory information according to endogenous desires (and not stimulus salience) is commonly referred to as goal-driven selective attention (GDSA). A long lasting debate in the study of GDSA concerns the point in the thalamocortical information-processing hierarchy at which the selection occurs, culminating in

the idea that the locus of selection is task-dependent and distributed along the hierarchy [1]. Nevertheless, a full understanding of how this distributed multi-level selection arises from network dynamics is still lacking.
Using a model-based approach, we provide a unified framework to explain GDSA termed hierarchical selective recruitment (HSR). In HSR, the sensory hierarchy is decomposed into discrete layers with inter-layer timescale separation and intra-layer dynamics described by recurrent networks with nonlinear rate dynamics. The network at each layer is further decomposed into a subnetwork representing relevant information and another representing distractions which are, respectively, recruited and inhibited by the layer above. This results in a multiple-timescale, arbitrarily large, complex nonlinear dynamical system that is remarkably flexible and capable of explaining the principles of GDSA across different modalities.
These properties, however, depend on the network structure, i.e., the pattern and efficacy of synaptic connections. Using linear-threshold nonlinearities for intra-layer dynamics and tools from systems and control theory, we derive several necessary and sufficient conditions on network structure that guarantee HSR. These conditions have in turn direct implications for thalamocortical networks that support selective attention. For instance, we show that the effective size of the recruited subnetwork at each layer has to remain bounded, posing restrictions on the stimuli that can be simultaneously attended to. We apply our framework to a case-study of selective audition in rats, using simultaneous recordings of prefrontal cortex and primary auditory cortex from [2]. We show that our proposed network structure with only 4 nodes per region and less than 20% of possible synaptic connections can explain more than 85% of the rate dynamics in both regions, which is significantly higher than random structures with the same number of nodes and sparsity level. These analytical and computational results thus support HSR as a generic mechanism for GDSA.

Title: A roadmap for multi-scale and multi-subject analysis of human functional brain networks

Authors: *R. BETZEL[1], M. A. BERTOLERO[1], D. S. BASSETT[1,2,3,4]
[1]Dept. of Bioengineering, [2]Dept. of Physics and Astronomy, [3]Dept. of Electrical & Systems Engin., [4]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Brain networks can be partitioned into sub-networks known as “modules.” Modules expose patterns in the brain’s wiring, delineate groups of functionally related brain areas, and serve as biomarkers of development and disease [1]. Despite this, principled methods for characterizing inter-individual variation in the brain’s modular structure remain elusive. Most current approaches make strong assumptions about the scale at which modules are defined (their number and size) or their stability across individuals. These assumptions go against prevailing beliefs that brains exhibit multi-scale and hierarchical modules and weaken the generalizability of module-based biomarkers. Developing a deeper understanding of how modules are organized within individuals and how they vary across individuals requires new analytic tools and approaches. Here, we present a novel approach for module detection that allows for assumption-free comparisons across subjects. Based on advances in multi-layer network analysis, our method represents individual’s networks as single layers in a multi-layer ensemble, whose layers are clustered simultaneously [2]. Separate parameters allow users to interrogate modules at different topological scales and to flexibly accommodate different hypotheses about the stability of modules across individuals. Critically, because module labels are preserved across layers, inter-individual comparisons can be carried out with no additional heuristics, facilitating inter-individual module comparisons with unprecedented straightforwardness and certainty. We apply this approach to connectivity data from the Human Connectome Project (HCP) and the Midnight Scan Club (MSC). We find evidence across datasets that modules vary along different modes with distinct spatial patterns and topological scales. We further examine each mode at the level of individual subjects in the HCP dataset, observing that the correlation of module similarity across subjects is differentially associated with subjects’ performances on tasks requiring working memory, language, social, and relational processing. Finally, using MSC data, we find that intra-individual module variability exhibits distinct modes but is subject-specific. In summary, we propose a novel, assumption-free method for module detection and comparison. We demonstrate this method’s utility by applying it to two datasets, uncovering novel brain-behavior associations, and revealing the multi-scale nature of functional brain networks.

Title: A neural network model of predictive smooth pursuit eye movement in primates

Authors: *H. J. KASHYAP[1], G. DETORAKIS[2], N. DUTT[1], J. L. KRICHMAR[2], E. NEFTCI[2]

Abstract: Primates utilize smooth pursuit eye movement to track a moving target. Due to sensory and processing delays of 80-100 milliseconds in the primate visual pathway, zero lag smooth pursuit is not achievable solely using retinal slip (RS) as feedback. Instead, the brain uses a predictive mechanism to calculate eye velocity from the delayed RS input, which allows zero lag pursuit and tracking of a target during occlusions. If a target’s motion is predictable, the primate vision system rapidly learns the spatiotemporal sequence of target velocity. Herein, we propose a recurrent neural network (RNN) based model that rapidly learns a visual target’s velocity on-the-fly and demonstrates the predictive behaviors of the primate smooth pursuit system. The proposed model is able to i) gradually eliminate the initial lag between eye and target velocities, ii) track a target with nonlinear velocity during occlusions, iii) adapt to unpredictable perturbation and phase shift in target velocity, and iv) qualitatively reproduce the typical initial pursuit acceleration observed in experiments. Although pursuit experiments on primates suggested that an internal model of target motion may be used for pursuit prediction, the neural mechanism to create and maintain such an internal model was not known. Our work shows how the internal model of target velocity is learned and updated rapidly by a neuron population using a delayed RS signal as the error. We propose that the frontal eye fields area of the primate brain is comparable to our RNN, based on their common predictive activities during smooth pursuit and location on the pursuit pathway.

Title: Enhancing computational model discovery via network visualization and analysis

Authors: *T. M. MORSE[1], R. A. MCDOUGAL[2]
[1]Neurosci., Yale Univ. Sch. Med., New Haven, CT; [2]Neurosci., Yale Univ., New Haven, CT

Abstract: ModelDB, a database for sharing and discovering computational neuroscience work, contains the source code for over 1300 published computational models including over 400 network models. To facilitate assessing these models for research relevance and potential reuse, we are expanding ModelDB's search and ModelView visualizations with data obtained from semi-automated network model analysis. To ensure simulator independence, we assume the availability of a specification of the network's inhibitory, excitatory, and gap junction connections in the NeuroML standard.For NEURON models using common naming conventions, a semi-automated analysis tool uses simulator introspection to identify inhibitory, excitatory and gap junctions between pre- and post-synaptic neurons and encodes this information in the NeuroML standard. A separate script reads the connectivity information from the NeuroML file to generate summary statistics which are stored and made searchable in the database. ModelView for network models is extended to support displaying the default connectivity information in various formats such as is shown in the figure for Short et al., 2016 (modeldb.yale.edu/183300, red excitatory, blue inhibitory). Note that each model may support being run in multiple configurations; for Short et al., for example, in other configurations the model has more cells and connects the ET cells. Our initial development focuses on NEURON network models because NEURON has a semi-automated analysis tool that uses simulator introspection to extract network connectivity from models that follow common naming conventions. In principle, developers of other simulators could add such analysis tools to their own software.Our first-stage work initially focuses on supporting NEURON network models because that is the most commonly used simulator for ModelDB entries and because we previously had single-cell model visualization for these models. Since the remaining steps use data stored in NeuroML, they are simulator-independent.

Title: Drift-diffusion balance generates asynchronous irregular activity in networks of conductance-based neurons

Authors: *A. SANZENI[1], M. H. HISTED[1], N. BRUNEL[2]
[1]NIH/NIMH, Bethesda, MD; [2]Neurobio., Duke Univ., Durham, NC

Abstract: In the balanced model, the irregular firing observed in cortical neurons is explained through a cancellation of mean excitatory and inhibitory inputs to the cells of the network, which lead to a `balanced state' in which firing is due to fluctuations in synaptic inputs. In current-based models, where inputs do not depend on membrane potential, such state emerges dynamically in the strong coupling limit (large number of synaptic connections per cell K), provided that synapses are of order 1/sqrt(K), so to produce fluctuations large enough for the membrane potential to cross threshold. While these models have successfully reproduced a number of experimental observations in cortex, it is still unclear to what extent they apply to real cortical networks, in which synaptic inputs are due to conductance changes and are therefore voltage dependent. In particular, in networks of conductance-based neurons, the balanced state does not produce irregular firing because, in the large K limit, mean excitatory and inhibitory synaptic inputs are constrained to remain at finite distance from threshold, while fluctuations become negligible. Using a mean field approach, we show that asynchronous irregular activity emerges in these networks thanks to a new mechanism: rates dynamically adjust to balance the contributions of input mean, which suppresses firing, and fluctuations, which facilitates firing. As in the classical balanced-state model, the state is characterized by a linear network transfer function, CV of the inter-spike intervals close to one, and an approximately lognormal distribution of firing rates. The different operating mechanism manifests itself, as the coupling strength increases, in two ways. First, to preserve firing, synaptic efficacy should scale as 1/log(K), i.e. synapses are stronger than the 1/sqrt(K) found in current-based models. Second, compared to the current-based model, the operating regime of networks of conductance-based neurons is significantly more robust to heterogeneities in input connectivity.

Title: The role of striatal tonically active neurons in reinforcement learning: A modeling study

Authors: *I. A. RYBAK[1], T. KIM[2], K. C. HAMADE[1], W. H. BARNETT[4], R. A. CAPPS[5], E. M. LATASH[6], S. N. MARKIN[3], Y. I. MOLKOV[4]

Abstract: The striatum is an important part of the basal ganglia which is critical for reinforcement learning. Cholinergic tonically active neurons (TANs) in this structure are thought to gate the dopaminergic input to medium spiny neurons for action selection and reinforcement learning. TANs exhibit a context-dependent pause in their activity. During the pause, the dopamine (DA) concentration in the striatum varies to encode the reward prediction error (RPE), i.e. the difference between the expected and actual reward. Despite multiple previous experimental studies, the role of TANs in reinforcement learning remains poorly understood. In the present study, we used computational modeling to investigate the possible role of TANs in reinforcement learning and their involvement in the control of DA release in the striatum. Our model is based on the following concepts synthesized from existing literature data. During tonic firing, TANs control the level of DA by releasing acetylcholine (ACh) onto nicotinic receptors at the axon terminals of dopaminergic neurons (DANs) projecting to the striatum. Via this mechanism in presence of cholinergic input, the striatal DA concentration stabilizes at a baseline level. In response to an excitatory stimulus, putatively originating in the thalamus, TANs generate a short burst followed by a prolonged pause in their activity lasting for several hundred milliseconds. During this pause, the cholinergic input to the DANs disappears, and DA release is solely controlled by DAN activity that encodes the RPE thus enabling the reinforcement learning. In the model, the mechanism of the pause in TAN activity is defined by the electrophysiological properties of TANs. Specifically, the short burst in TAN activity is followed by a slow after-hyperpolarization (sAHP) current lasting for several seconds. Another current, the hyperpolarization-activated h current, allows quick recovery from sAHP. The h-current in these neurons is suppressed by DA via D2 receptors. In summary, the TAN pause is produced by the sAHP current, and the pause duration is controlled by the h-current which in turn depends on DA concentration. Our model predicts that the RPE encoding depends on dynamic interactions

between DA release and TAN activity in the striatum. To evaluate the behavioral consequences of this interaction, we have incorporated our proposed striatal micro-circuitry into a previously published model that performs reward-based motor learning. The model allowed us to investigate the effects of the striatal DA deficiency on non-error-based motor adaptation as observed in Parkinson's disease (PD) and the effects of L-DOPA treatment for PD patients.

Title: A computational analysis of the voltage sensitive dye imaging data of the rodent hippocampus

Authors: *J. KANG[1,3], K. JUNG[1,3], H. BAHNG[1,3], H.-J. PARK[1,3,2]
[1]Dept. of Nuclear Med., [2]Brain Korea 21 PLUS Project for Med. Sci., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [3]Ctr. for Systems and Translational Brain Sciences, Inst. of Human Complexity and Systems Sci., Yonsei Univ., Seoul, Korea, Republic of

Abstract: Voltage-sensitive dye imaging (VSDI) reflect the membrane potentials of ensembles of neurons. Since the VSDI technique provides us high temporal and spatial resolution data in both of in vitro and in vivo, this technique is an important neurophysiological technique to investigate the dynamics of the brain. However, due to the complexity of the VSDI signal, to analyze the connectivity across neural populations, computational analysis is essential.
In this study, we applied the dynamic causal modeling (DCM) [1] to analyzed VSDI data of the hippocampal slices of mice in the open dataset [2]. In this framework, the computational model consisted of two parts; neural activity and observation models, and all these model parameters were simultaneously estimated to minimize prediction errors with observed VSDI data by Bayesian inferences.
In the experiment, the temporoammonic pathway was stimulated four times with 100 ms intervals. The VSDI data was recorded for 10 and 8 brain slices of the wild type and the epileptic Arx conditional knock-out mutant mouse, respectively. In the wild type, hyperpolarization after the stimulation was observed in CA1 region for the first stimulation, and this inhibition was reduced for the latter stimuli. On the other hand, in the mutant, reduction of the hyperpolarization was suppressed.

To describe adaptive properties of the neural spikes, we employed extended Jansen and Rit model with an additional memory term for the neural model. For the observation model of VSDI signals, we used a weighted sum of three sub-populations. To construct DCM, we extracted VSDI signals at the Hilus, CA1, and CA3 regions of the hippocampus, and systematically explored 512 patterns of effective connectivity.
As a result, the most fitted DCM successfully reproduced VSDI signals in both wild type and mutant mouse. Our results suggested that the adaptive parameter of the DCM plays an essential role to understand different responses in the mutant from those of the wild type. In this way, the DCM for the VSDI could be used for the investigation of the mesoscale brain dynamics.

Title: An optimization principle for the emergence of the grid cell system

Authors: *T. MA, I. FIETE
Univ. of Texas At Austin, Austin, TX

Abstract: Individually, grid cells are defined by their periodic responses as a function of animal location in 2D spaces. Collectively, the grid cell system is defined as a collection of individual cells that can be grouped into a small number of disjoint sets (modules) with different spatial periods across sets and the same spatial periods within sets [Stensola12]. Grid cell tuning can spontaneously emerge through unsupervised learning using spike-time dependent plasticity in recurrent circuits [Widloski14] or using Hebbian-like learning on feedforward weights from a set of place cell inputs [Derdikman16, Kropff08]. These are mechanistic models of how plasticity could lead to the self-organization of a single grid cell module, but do not consider the functional reasons for the emergence of grid cell tuning. On the other hand, there are models of grid cell emergence based on training a network to learn a spatial task; however, the cells exhibit a single spatial period [Cueva18]. Theoretically, it has been hypothesized and demonstrated through analytical methods [Fiete08, Fiete11, Fuhs06, Herz12] that the multi-periodic structure of the grid cell system enables exponentially high capacity coding in the number of grid modules. At the same time, models show that grid cells can function as path integrators [Burak09,Burgess07],

and experimental results are consistent with the low-dimensional continuous attractor dynamics hypothesized for path integration in some of these models [Fyhn07, Yoon13]. What has remained unclear, however, is what combination of functional and biological constraints are sufficient to give rise to the grid cell system. To address this question, we define cost functions and set up neural network training schemes to optimize these constraints. We find that maximizing the number of unique coding states while fulfilling the path integration requirement with simple mechanisms are essential elements for the emergence of periodic single-neuron responses and the emergence of multiple discrete modules.

Title: Converting correlation codes into firing rate codes via nonlinear dendritic integration

Authors: *R. GRGURICH[1], H. T. BLAIR, IV[2]
[1]Psychology, [2]Dept Psychology, UCLA, Los Angeles, CA

Abstract: A population of spiking neurons can encode information about a stimulus using a *firing rate code*, which maps values of the stimulus onto patterns of neural firing rates, or using a *correlation code*, which maps values of the stimulus onto patterns of temporal correlations among spike trains. Here, we show how a correlation code can be converted into a firing rate code by a single layer of neurons that performs nonlinear integration of synaptic inputs onto its dendrites. To demonstrate this, we simulated spike trains generated by a population of head direction (HD) cells, where each individual HD cell fired maximally when a rat's head faced toward that cell's preferred azimuth angle. As the rat turns its head, the dynamics of head movement induce temporal correlations among HD cell spike trains which depend upon the angular head velocity; so in addition to storing a firing rate code for head angle, the population of HD cells also generates a correlation code for the angular head velocity. We show that this correlation code for velocity can be converted into a firing rate code for velocity by a single layer of neurons that uses nonlinear dendritic integration to compute "co-firing rates" between pairs of HD cell spike trains. We used the NEURON simulator to show how this process of nonlinear dendritic integration can be performed by NMDA receptor currents in a multicompartmental neuron model with morphology similar to a pyramidal or stellate cell. Based upon these results, we propose that dendritic mechanisms for converting correlation codes into firing rate codes may

underlie the brain's ability to perform a variety of useful computations such as neural differentiation (that is, extracting velocity signals from position signals, which may account for some firing properties of "speed cells" in hippocampal networks), measuring phase alignments between neural oscillators to decode information encoded within patterns of neural synchrony, and encoding different spatial contexts by detecting spike train correlations among hippocampal place cells that arise from the unique adjacency relationships among place fields in each context.

Title: Deriving binocular spontaneous neural activity by optimizing depth perception in an innate learning model of visual development

Authors: *S. SENDELBACH[1,2], M. V. ALBERT[1,2]
[1]Dept. of Computer Sci., [2]Neurosci. Program, Loyola Univ. Chicago, Chicago, IL

Abstract: Spontaneous, patterned neural activity occurs prenatally in the early visual system. This work tests the results of alternate neural activity patterns on simulated animal visual performance using the efficient coding paradigm. The goal was to better understand the precise nature of correlated binocular spontaneous activity in the LGN and V1 by observing the derived ability of an animal to perform an ecologically relevant visual task - depth discrimination. Spontaneous neural activity in the retina presents as amorphous, spatiotemporal patterns that have been directly observed; although LGN and V1 spontaneous activity is only partially observable, our results qualitatively match with what is known about correlated activity between eye layers. But the question remains, why these patterns? Why so similar across distinct species? This work is a continuation of an "innate learning" paradigm in which spontaneous neural activity prepares an animal for adult vision in a similar way to learning that occurs after the eyes open. To study this activity, we implemented a two eye-layer percolation model for activity generation. The parameters of the model resemble abstractions from retinal wave modeling: fractions of recruitable cells, dendritic field sizes, surrounding activity thresholds, and additionally a probability of transmitting activity between eye-specific layers. Simulated neural activity in a range of candidate parameter choices were tested. These activity images were provided as inputs to a V1 efficient coding strategy to derive candidate receptive fields. These derived binocular V1-like receptive fields were then used in a series of depth perception tasks on autostereograms, and scored accordingly. For each set of activity parameters, 2000 binocular filters were generated from the derived images and used for depth estimation and scoring.

Optimal parameters for depth perception produced simulated activity that closely resembled spontaneous activity measured in vivo. This work demonstrates how an ecologically relevant goal, like binocular depth estimation, can be used to directly estimate properties of binocular visual development.

Title: A software framework for simulating large-scale population dynamics of growth transform spiking neural network

Authors: *D. MEHTA, A. GANGOPADHYAY, J. HA, K. AONO, S. CHAKRABARTTY
Washington Univ. In St Louis, Saint Louis, MO

Abstract: The process of neural spike generation and transmission expend relatively large amounts of energy; therefore, neurobiological systems have evolved to use neural codes that are energy optimized for different information processing tasks. Current spiking neural network models, however, do not capture the process of spike generation and encoding from the perspective of energy-minimization; instead treat the energy costs as a constraint. In contrast, we study spike generation and neural coding in a network of spiking neurons by designing an energy functional (fig. a), which when minimized under realistic physical constraints, produces emergent spiking dynamics (Gangopadhyay & Chakrabartty, TNNLS '17, fig. b). At the core of this formulation is a growth transform (GT) based neuron model that follows a trajectory in a dual optimization space, while the network follows a trajectory in a high-dimensional primal space (fig. c). These high-dimensional trajectories are guaranteed to be stable, interpretable and have been found to be consistent with population dynamics that have been observed in neurobiology (Saha & Raman, NatNeuro '13).
For disseminating this concept to the scientific community, we have developed two versions of open source software for simulating an arbitrary network of GT neurons. The network is capable of handling asymmetrical excitatory and inhibitory connections between neurons. The MATLAB^{TM} based provides an intuitive introduction to the GT Neuron Network. Input currents, objective function parameters and the connection matrix can be dynamically updated, and the

neuronal responses can be continuously visualized. An optimized C++ code that can simulate more than million neurons, can be used as a tool for large-scale simulation using sparse matrix representations and libraries. The software can be mapped onto GPU based computational platforms. Users can create hierarchical network models and present different forms of complex stimuli. These toolboxes are available through the web-portal https://aimlab.seas.wustl.edu/.

Title: Addressing analysis questions for a nonlinear synaptic system as a model for ictogenesis

Authors: *S. KARAMINTZIOU, K. J. STALEY
Harvard Med. School/Mgh, Charlestown, MA

Abstract: Seeking to understand and control the conditions that lead to seizure initiation, we simulate the hippocampal CA3 region as a network of integrate-and-fire neurons with an anatomical synaptic topology that is modulated by use-dependent synaptic depression and recovery. The network exhibits high-dimensional, third-order nonlinear dynamics. The cornerstone of the modeling approach is short-term synaptic plasticity, that is, the modification in transmitter release probability, a process demonstrated experimentally to exhibit first-order depression and recovery kinetics. This type of synaptic plasticity may also underlie elements of activity-dependent disinhibition arising from depression of excitatory glutamatergic inputs to interneurons. Using this model we look for parameters that are within experimentally described

ranges and that generate both stable interictal network activity and occasional ictal transitions. A preliminary analysis is performed within a system-theoretical framework.

Title: Models of recurrent networks in hippocampus encode temporal order

Authors: *C. D. COX, B. G. GUNN, G. LYNCH
Anat. and Neurobio., Univ. of California Irvine, Irvine, CA

Abstract: There has been considerable discussion about the possible contributions of the hippocampus in the encoding of sequential and temporal information. Relatedly, a great deal of evidence indicates that the structure plays a central role in the organization of the flow of experience into episodic memories. Field CA3 is a component of hippocampus including a dense collateral system that is seemingly appropriate for processing temporal information. To evaluate the properties of the hippocampal CA3 across biologically relevant timescales to ordering within episodes, we developed a realistic simulation composed of ~1000 simple biophysical neurons. Based on previous studies, the model was wired to create neighborhoods, favoring local over global connectivity; CA3 interneurons provided local feedback and global feed-forward connections. We previously showed that simulations of this type generate sharp waves with properties comparable to those found in field recording of slices. This previous model was updated in several ways, including stronger neighborhood linkages. A brief (100ms) physiologically realistic activation led to continual firing lasting 10 seconds. The activity was eventually terminated by slowly building effects of local inhibition. The firing was found to be extremely vulnerable to disruptions: small increases in inhibition or loss of 5-10% of excitatory synapses caused model collapse. Increases in connectivity or reduction of inhibition produced runaway activity. By adding multiple inputs, a plasticity rule, and sparse long range connections the model was found to be capable of storing and retrieving the proper order of a sequence of cues over biologically relevant timescales. Essential elements of this model were verified with in vitro physiological preparations.

Title: A method of online learning with neuromorphic computing network

Authors: *R. SCORCIONI, Q. JANG, S. SKORHEIM, N. STEPP, V. DE SAPIO, P. PILLY
HRL Labs., Malibu, CA

Abstract: One of the most challenging issues in online learning is to learn from a small set of training samples because it is difficult to have a large set of training samples for an online learning system, which is generally required to achieve real-time computing and in many applications, a large set of training samples may not be available or too expensive to obtain. Another challenge in online learning is to learn new things without fully retraining the learning system because the requirement of real-time computing prevents online learning systems to fully retrain the system when they have to learn new things. In our approach, our learning system is able to perform unsupervised learning automatically in real-time; different objects in the input data are clustered into different categories by the unsupervised learning; and only a small set of training samples is needed to label the categories in supervised learning. When new objects are input into the system, new categories will be formed by the unsupervised learning process and only a small set of new training samples is needed to label the new categories so that the system is able to learn new categories without fully retraining the system. Since our online learning system is based on neuromorphic computing network, it is computationally much efficient compared to deep learning based methods.

Title: Neural coding via spike-timing self-information

Authors: *M. LI[1], K. XIE[2], J. LIU[3], D. WANG[2], G. FOX[2], F. ZHAO[2], J. Z. TSIEN[2]
[1]Harvard Univ., Cambridge, MA; [2]Augusta Univ., Augusta, GA; [3]Dept. of Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Cracking brain's neural code is of general interest. Here, we examine the "Neural Self-Information Theory" that the interspike-interval (ISI) carries self-information that is inversely proportional to its variability-probability. Specifically, higher-probability ISIs convey minimal information because they reflect the ground state, whereas lower-probability ISIs carry more information, in the form of "positive" or "negative surprisals," signifying the excitatory or inhibitory shifts from the ground state, respectively. These surprisals serve as the quanta of information to construct temporally coordinated cell-assembly ternary codes representing real-time cognitions. Accordingly, we devised a general decoding method and unbiasedly uncovered 15 cell assemblies underlying different sleep cycles, fear-memory experiences, spatial navigation, and 5-choice serial-reaction time (5CSRT) visual-discrimination behaviors. We further revealed that robust cell-assembly codes were generated by ISI surprisals constituted of ~20% of the skewed ISI gamma-distribution tails, conforming to the "Pareto Principle" that specifies, for many events—including communication—roughly 80% of the output or consequences come from 20% of the input or causes. These results demonstrate that real-time neural coding arises from the temporal assembly of neural-clique members via silence variability-based self-information codes.

Title: Pairwise interactions among different brain regions organize large scale neural networks for information processing

Authors: *W. NIU[1], X. HUANG[2], K. XU[3], T. JIANG[4], S. YU[5]
[1]Brainetome Ctr., Inst. of Automation,Chinese Acad. of Sci., Beijing City, China; [2]Inst. of Automation,Chinese Acad. of Sci., Beijing, China; [3]Inst. of Automation,Chinese Acad. of Sci., BeiJing, China; [5]Brainnetome Ctr., [4]Inst. of Automation, Chinese Acad. of Sci., Beijing, China

Abstract: Spatially separated brain areas do not function independently. Instead, they interact with each other to form networks with coordinated activities, supporting various brain functions including perception, motion and cognition. It is well known that higher order interaction (HOI), such as Exclusive Or operation, is necessary for a system to be computation universal, i.e., to be able to perform all possible computations. However, currently it is unclear whether HOI is present in large scale neural networks when these networks are actively involved in information processing. To address this question, we analyzed functional magnetic resonance imaging data collected from human subjects when they were executing various tasks including perception, language, working memory, etc (the HCP data set). Our results demonstrated that the strength of HOIs in large scale neural networks, such as the default mode network, the frontal-parietal network, etc., were very weak, indicating that the computations underlying major brain functions do not rely on HOIs at the level of brain areas. Further, we examined the activities of a neural network model with dynamic features similar to the actual brain. No strong HOI were observed even when the model was stimulated, suggesting that the lack of HOIs is intrinsic for networks with neural dynamics similar to the brain. Our results revealed the dominance of pairwise interactions in organizing coordinated activities among different regions to support key functions of the brain. It also suggest- that human like, highly versatile artificial intelligence system can be built based on pairwise interactions among different functional modules, which greatly simplifies the complexity of the design and training of such systems.

Title: White matter network architecture guides direct electrical stimulation through optimal state transitions

Authors: *J. STISO[1], A. N. KHAMBHATI[1], T. MENARA[2], A. E. KAHN[1], J. M. STEIN[1], S. DAS[1], R. GORNIAK[3], B. LITT[1], K. A. DAVIS[1], F. PASQUALETTI[2], J. TRACY[4], T. H. LUCAS[1], D. S. BASSETT[1]

Abstract: Electrical brain stimulation is currently being investigated as a potential therapy for neurological disease. However, opportunities to optimize and personalize such therapies are challenged by the fact that the beneficial impact (and potential side-effects) of focal stimulation on both neighboring and distant regions is not well understood. Here, we hypothesize that the effects of simulation will propagate along white matter tracts to affect change in the activity of distal regions. Specifically, we use network control theory to build a formal model of brain network function that makes explicit predictions about how stimulation spreads through the brain's white matter network and influences large-scale dynamics. We test these predictions using combined electrocorticography (ECoG) and diffusion weighted imaging (DWI) data from patients with medically refractory epilepsy undergoing evaluation for resective surgery, and who volunteered to participate in an extensive stimulation regimen. We posit a specific model-based manner in which white matter tracts constrain stimulation, defining its capacity to drive the brain to new states, including states associated with successful memory encoding (as defined by a previously trained and validated classifier). In a first validation of our model, we find that the true pattern of white matter tracts can be used to more accurately predict the state transitions induced by direct electrical stimulation than the artificial patterns of a topological or spatial network null model. We then use a targeted optimal control framework to solve for the optimal

energy required to drive the brain to a given state. We show that, intuitively, our model predicts larger energy requirements when starting from states that are farther away from a target memory state. We then suggest testable hypotheses about which structural properties will lead to efficient stimulation for improving memory based on energy requirements. We show that the strength and homogeneity of edges between controlled to uncontrolled nodes, as well as the persistent modal controllability of the stimulated region, predict energy requirements. Our work demonstrates that individual white matter architecture plays a vital role in guiding the dynamics of direct electrical stimulation, more generally offering empirical support for the utility of network control-theoretic models of brain response to stimulation.

Title: A circuit-level model of reward learning under uncertainty

Authors: *A. SOLTANI[1], S. FARASHAHI[2], A. IZQUIERDO[3]
[1]Psychological & Brain Sci., [2]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [3]Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: Though neural correlates of expected uncertainty have been found in many species' brains, we still do not know how these signals contribute to or are influenced by volatility in the environment. To accurately estimate volatility of the environment, or how rapidly reward conditions change, decision-makers should take into account estimates of outcome probabilities. However, most normative models of learning under uncertainty assume a hierarchical representation of expected and unexpected uncertainty (volatility) in which the estimation of volatility is independent of estimates of outcome probabilities. Similarly, it is unclear how volatility could influence learning in reinforcement learning models that update reward values based on reward prediction error. Thus, none of the predominant models of value-based learning provides plausible neural mechanisms for or testable predictions about how the computations of expected uncertainty and volatility are performed, and importantly, how they interact with each other. We have recently shown that reward-dependent metaplasticity provides a plausible mechanism for both computation of value under uncertainty and the estimation of volatility. Here we propose a circuit-level model for computation of expected and unexpected uncertainty and how the two interact. The model consists of three areas; two areas that estimate reward

probabilities using plastic and metaplastic synapses, and one area that estimates volatility based on the output of metaplastic synapses. Volatility is estimated using the output of the metaplastic system on a trial-by-trial basis. This signal is then sent back to both plastic and metaplastic systems to make them more adaptable when volatility is high. Based on previous findings, we hypothesized that anterior cingulate cortex (ACC) and striatum compute reward probabilities using metaplastic and plastic synapses, respectively, whereas volatility is computed in basolateral amygdala (BLA). First, we show that feedback using the volatility signal in BLA, based on input from ACC but not striatum, can improve performance in probabilistic reversal learning. Moreover, we show that inhibition of connections from ACC to BLA reduces learning more strongly than inhibition of BLA to ACC connections. Overall, our circuit-level model proposes a plausible mechanism for interactions between computations of expected and unexpected uncertainty. In addition, it provides specific testable predictions about the contributions of different areas and their connections to learning and choice under uncertainty.

Title: The GABAA receptor binding SCN is more related to ion channel activity-related TBN than cortical thickness SCN

Authors: *F.-T. WONG[1], N. W. DUNCAN[2]
[1]GIMBC, Taipei Med. Univ., Taipei, Taiwan; [2]GIMBC, Taipei Med. Univ., Taipei, Taiwan

Abstract: The gamma-aminobutyric acid (GABA) neurotransmitter system plays an important role in our mental function and health. Here we investigate the relationship of multimodal network topologies associated with GABA system. Firstly, a structural covariance network (SCN) from positron emission tomography (PET) measures of GABAA receptor binding was generated based on 23 participants. Secondly, with the same 23 participants plus 4 participants, SCN based on MRI measures of cortical thickness was generated. Thirdly, applying the GABA receptor-related and ion channel activity-related gene expression maps from human adult brain microarray datasets provided by the Allen Institute for Brain Science (AIBS), transcriptomic brain networks (TBN) were definded by estimating gene co-expression between pairs of cortical regions matched to the nodes of the SCN.
The GABAA receptor binding SCN reveals the topological properties such as small worldness,

rich club, and compact modular structure. However, comparisons of the SCN between GABAA receptor binding and cortical thickness show significant differences in the degree of small world propensity and distribution of connection. By thresholding the 85 percent strength of connection, a majority of preserved overlapped connections is observed in visual cortex across the 4 topological structures. In addition, the regional GABAA receptor binding level is negatively correlated with the regional GABA receptor-related gene expression while positively correlated with ion channel activity-related gene expression. Furthermore, the results of a multivariate dimension-reducing technique of partial least squares (PLS) to explore the associated components between all 20,737 genes and PET level at the SCN nodes demonstrates that the second independent partial least squares component (PLS2) represented a significant association with the gene profile related to regulation of neurotransmitter receptor activity, membrane potential, and glutamate receptor signaling pathway.
The evidence suggested that the GABAA receptor binding SCN has stronger topological relationship with ion channel activity-related TBN than cortical thickness SCN.

Title: The underlying mechanism of the alteration of il-bla connectivity by stimulation:A computational perspective

Authors: *Z. CHEN[1], F. FENG[1], E. BLACKWOOD[2], M.-C. LO[2], A. S. WIDGE[2], S. NAIR[1]
[1]Electrical Engin. and Computer Sci., Univ. of Missouri Columbia, Columbia, MO; [2]Psychiatry, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Synchrony of low-frequency theta (4-8 Hz) oscillations between infralimbic cortex (IL) and basolateral amygdala (BLA) has recently been shown to impact the regulation of fear-behavior and may be a target for brain stimulation paradigms. Open-loop and closed-loop electrical stimulation have been shown to alter IL-BLA connectivity and coherence, implying alteration of inter-area oscillatory synchrony between IL and BLA. However, the underlying mechanisms that cause the these changes are unknown. Such an understanding will also help with the development of improved stimulation schemes to further enhance coherence between the BLA and IL regions. To address these questions and obtain a mechanistic understanding of its functioning, we developed a biophysical 1460-cell computational model of the IL-BLA network using a Hodgkin-Huxley formulation. The network model was developed using the known physiological and anatomical properties of the BLA and IL, specifically different single

cell types and their neurophysiology, synaptic current dynamics, spatially heterogeneous spatial connectivity, short- and long-term plasticity and neuromodulatory inputs. The model replicated several known features of IL-BLA network. The IL region consists of layer II and layer V with 380 pyramidal cells (PNs) and 80 interneurons (ITNs). The BLA region consists of 900 PNs and 100 ITNs. We used realistic connectivity between different types of neurons in IL and BLA and also the inter-area connectivity between IL and BLA. The average firing rates of PNs and ITNs in BLA are 0.5 Hz and 25 Hz respectively, consistent with biological data. Furthermore, the firing rate of PNs and ITNs in IL are 4-6 Hz and 10-20 Hz respectively. Moreover, simulated LFP signals are recorded in model BLA and IL. Single-pulse evoked potential response (ERP) in BLA given current injections into IL neurons was found similar to in vivo recordings. On-going work examines the role of short-term plasticity in connectivity change. Further work will be to investigate how intrinsic and extrinsic theta oscillation are involved in the synchrony alteration.

Title: Precision neurology: Cellular mechanisms of Alzheimer's disease

Authors: *A. SOLODKIN[1], J. ZIMMERMANN[2], V. K. JIRSA[3], A. R. MCINTOSH[4], P. RITTER[5], M. J. BREAKSPEAR[6]
[1]Anat. & Neurobio., UC Irvine Hlth., Irvine, CA; [2]Rotman Res. Inst., North York, ON, Canada; [3]Inst. De Neurosciences Des Systemes, Marseille, France; [4]Baycrest Ctr., North York, ON, Canada; [5]Charite, Univ. Med. Berlin, Berlin, Germany; [6]Queensland Inst. of Med. Res., Herston, Australia

Abstract: Introduction: Brain function can be measured across multiple spatial scales, from individual cells, to large-scale networks. Within each scale, meaningful signals are mixed across several time scales. There is presently no single experimental technique that can acquire data across these scales. The problem is exacerbated by nonlinearities inherent in the brain, where a vast number of spatiotemporal features at one level support emergent features at another. In this work we use our computational framework, ***TheVirtualBrain (TVB)*** that enables us to integrate data across multiple scales and identify general principles of their interactions. Previous results in Alzheimer's disease (AD) based on simulations of rsfMRI showed local changes on the

inhibition/excitation balance and global changes where local dynamics within regions were stronger than between regions. Here, we focus on functional mechanisms at a cellular level by simulating Local Field Potentials (LFP) in limbic regions as they relate to **G** (Global coupling) to understand basic mechanisms of brain synchrony in AD.
Methods: Behavioral data acquired for 79 participants from the Sydney Memory and Ageing study (MAS) were stratified based on cognitive performance in four groups: 16 super normal controls (SNC), 16 healthy controls (HC), 31 amnesic MCI (aMCI), and 16 Alzheimer's Disease. Simulation of LFP with TVB, determined the value of G (G critical) associated with oscillations of the LFPs. We also measured the range of G values associated with the oscillations along their location, frequency and amplitude finally determining their relationship with cognition.
Results: Can be summarized in 4 points: a) Oscillatory signals in the LFP so robust in super normal controls, gradually decreased as cognition decreased; b) Oscillations were found exclusively in the posterior cingulate region; c) Additional metrics derived from the oscillations (e.g., amplitude, frequency and presence of spikes) showed that their relationship with cognition was either linear (increase or decrease), or U-shaped with an increase in NC and MCI before decreasing in AD representing perhaps a compensatory reaction. d) In parallel, there was also a decrease in synchrony between regions;
Summary: This work establishes an essential new capacity for the neuroscience community to merge the wealth of multiscale data acquired in an evolving computational architecture. Our results represent a new generation of biomakers that are related directly to disease mechanisms, are individualized for each patient and are related to clinical phenotype. As they represent brain dynamics, they can be an invaluable tool for developing novel therapies.

Title: Modeling brain dynamics in brain tumor patients using the virtual brain

Authors: *D. MARINAZZO[1], H. AERTS[2], M. SCHIRNER[3], B. JEURISSEN[4], D. VAN ROOST[2], E. ACHTEN[2], P. RITTER[5]
[1]Dept. of Data Analysis, Ghent Univ., Gent, Belgium; [2]Ghent Univ., Ghent, Belgium; [3]Freie Univ. Berlin, Berlin, Germany; [4]Univ. of Antwerp, Antwerp, Belgium; [5]Charite, Univ. Med. Berlin, Berlin, Germany

Abstract: Presurgical planning for brain tumor resection aims at delineating eloquent tissue in the vicinity of the lesion to spare during surgery. To this end, non-invasive neuroimaging techniques such as functional MRI and diffusion weighted imaging fiber tracking are currently employed. However, taking into account this information is often still insufficient, as the complex non-linear dynamics of the brain impede straightforward prediction of functional outcome after surgical intervention. Large-scale brain network modeling carries the potential to bridge this gap by integrating neuroimaging data with biophysically based models to predict collective brain dynamics. As a first step in this direction, an appropriate computational model has to be selected, after which suitable model parameter values have to be determined. To this end, we simulated large-scale brain dynamics in 25 human brain tumor patients and 11 human control participants using The Virtual Brain, an open-source neuroinformatics platform. Local and global model parameters of the Reduced Wong-Wang model were individually optimized and compared between brain tumor patients and control subjects. In addition, the relationship between model parameters and structural network topology and cognitive performance was assessed. Results showed (1) significantly improved prediction accuracy of individual functional connectivity when using individually optimized model parameters; (2) local model parameters can differentiate between regions directly affected by a tumor, regions distant from a tumor, and regions in a healthy brain; and (3) interesting associations between individually optimized model parameters and structural network topology and cognitive performance.

Title: Toward a standard network model of musical improvisation

Authors: *S. E. FABER, A. R. I. MCINTOSH
Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Music and language are sophisticated communicative mediums that share many commonalities in the brain. Both rely on acoustic cues, both have form and are bound by culturally-defined rules, and both are social behaviours. The neural correlates of music and speech perception have been extensively quantified. These correlates include an auditory processing network common to both behaviours, and analogous networks for parsing semantic and syntactic content. Researchers have now begun studying productive, spontaneous speech and music-making, adding networks for executive control and goal-directed movement to the perceptual foundation, but the field has yet to reach consensus. This poster will present a new model of social music-making that includes its underlying neural correlates based on previous neuroimaging studies of the perception and production of language and music. I will make recommendations on future directions for the study of social music-making, including research with clinical populations, and discuss the challenges posed by such endeavours.

Title: Characterization of interictal epileptogenic brain networks: Mechanistic insights from large-scale computational modeling using the virtual brain

Authors: *J. COURTIOL[1,2], S. PETKOSKI[1], V. K. JIRSA[1]
[1]Inst. de Neurosciences des Systèmes, Marseille, France; [2]Charité, Univ. Med. Berlin, Berlin, Germany

Abstract: Epileptogenic brain networks are associated with changes in functional connectivity even at rest during the interictal period (i.e., between seizures). Although some algorithms can nowadays robustly detect these changes, findings so far are inconsistent and the mechanism by which these changes occur is still largely unknown. Large-scale computational modeling carries the potential to bridge this gap by investigating the dynamical characteristics of the interictal epileptogenic brain networks during resting-state, in order to study their effects on the resulting functional connectivity. To achieve this, we virtualized 15 individual healthy and epileptic subjects' brain by using the neuroinformatics platform The Virtual Brain. Personalized virtual brain model was built based on a phenomenological neural mass model for resting-state and unfolding over subject-specific brain anatomical connectivity. We investigated how the global brain dynamics leading by the control model parameters (excitability and global coupling) changed between healthy and epileptic subjects by estimating them from functional empirical data and identifying the optimal dynamic working point of each subject's brain. Compared with healthy subjects, epileptic patients showed similar topology of resting-state functional connectivity. Suggesting that brain anatomical connectivity did not differ significantly between the two groups. We then progressively incorporated in the brain model, the patient-specific interictal epileptogenic networks, identified by the pre-surgical evaluation, by systematically altering the underlying local excitability model parameter of the corresponding nodes. The model showed a linear global increase of functional connections and variability along with the increase of excitability parameter and size of the interictal epileptogenic networks. However, the significantly increased were located in the epileptogenic networks followed by a diminished level of complexity. These findings provide a possible underlying mechanism explaining the empirical interictal functional connectivity changes observed in epileptic patients during resting-state, namely a local shift of the brain's dynamic working point of the brain regions involved in the seizure, leading to increased connectivity and decreased complexity.

Title: Effects of fMRI preprocessing choices on functional connectivity in children and adolescents with and without autism spectrum disorder

Authors: *A. K. EASSON, S. C. STROTHER, A. R. MCINTOSH
Baycrest Hlth. Sci., North York, ON, Canada

Abstract: Autism spectrum disorder (ASD) is a highly heterogeneous disorder that has been described as a developmental disconnection syndrome. It has been suggested that ASD is characterized by reduced functional connectivity (FC) between frontal and posterior brain regions, increased FC among local regions with concurrent decreases in FC between distant regions, and an atypical trajectory of FC development. However, there has yet to be a framework describing the nature of FC in ASD that is supported consistently. This inconsistency can be attributed, in part, to heterogeneous samples, but also due to heterogeneity of fMRI preprocessing steps across studies.

The aim of this study is to address the heterogeneity of preprocessing methodology by evaluating the effects of different fMRI preprocessing choices on group differences in FC observed between participants with and without ASD.

Resting state fMRI data from 19 participants with ASD (M=10.25 years, SD=1.51 years) and 16 typically developing (TD) participants (M=9.97 years, SD=1.70 years) were obtained from the ABIDE-II database. Participants were matched for age, IQ, and head motion. Using *Optimization of Preprocessing Pipelines for NeuroImaging* (OPPNI; Churchill et al., 2015) software, the following steps were varied: temporal detrending (orders 0-6), lowpass filtering, global signal removal using PCA (GSPC), WM and CSF signal regression (CUSTOMREG), and motion censoring. Time series of 82 cortical ROIs were extracted. FC was defined by Fisher z-transformed Pearson correlations for each ROI pair across all time points. Further, structural connectivity (SC) matrices were constructed from DTI data using The Virtual Brain pipeline. Simulations of resting-state data were performed in TVB. Effects of preprocessing on FC, correlations between each subject's SC and FC matrices, and correlations between simulated and empirical FC, were examined.

CUSTOMREG and GSPC led to diffuse reductions in FC. Further, interactions between pipelines and groups were observed. However, a set of connections showed consistent group differences across all pipelines, with primarily reduced FC in ASD. Across pipelines, there were significant differences in SC-FC correlations and correlations between simulated and empirical FC, which were particularly prominent when GSPC, CUSTOMREG, and lowpass filtering were turned off.

Our results highlight the sensitivity of FC to different preprocessing strategies, especially when comparing groups.

Abstract: We demonstrate how computational multi-scale brain modeling (1) supports revealing potential disease mechanisms in Alzheimer's disease (AD). Central to our research is The Virtual Brain (TVB; thevirtualbrain.org) platform (2,3). TVB allows connectome-based simulation of whole brain dynamics. Recent work with AD patients, healthy controls (HC) and persons with mild cognitive impairment (MCI) from the Sydney Memory and Aging Study confirms the benefit of using the model parameters to characterize cognitive status (4). We here build on this proof of concept and apply advanced methods to a cohort from the Alzheimer's Disease Neuroimaging Initiative (ADNI, adni.loni.usc.edu). We used a refined processing pipeline (5) for patients with MCI (n=41), AD (n=17) and HC (n=91). We implemented the processing standards of the Human Connectome Project (HCP, humanconnectome.org) with multimodal parcellation in 379 cortical and subcortical regions (Fig.1). We demonstrate how pathological candidate mechanisms reveal their systems effects in brain network models (BNM's) using TVB. Detailed spatial information derived from person-specific positron emission tomography (PET) with AV-45 and AV-1451 tracing amyloid beta and tau protein was mapped to the individual BNMs (Fig.1). We model the tau burden as a reduced local degree of structural connectivity and the amyloid beta burden as an increased E/I balance. We demonstrate how individual models can explain inter-subject variability of functional activity and cognitive performance.
Figure 1. A,B) MSM parcellation of an ADNI brain showing the right and left pial surfaces. Color: myelin map (A) and cortical folding (B). C,E) Distributions of tau protein and D,F) amyloid beta taken from individual PET data projected to surfaces of cortical/subcortical structures in AD. Registeration to the Glasser group template. Title: Creating a macaque connectome for large-scale network simulations in TheVirtualBrain

Authors: *K. SHEN[1], S. EVERLING[2], A. R. MCINTOSH[1]
[1]Baycrest Ctr., North York, ON, Canada; [2]Physiol., Univ. Western Ontario, London, ON, Canada

Abstract: Linking cellular and circuit-level neural activity with signals collected using noninvasive imaging techniques remains a significant challenge to understanding the underlying mechanisms associated with BOLD-fMRI and M/EEG signals. TheVirtualBrain (TVB) is a software platform developed to meet this challenge through simulations of whole-brain network dynamics constrained by multimodal neuroimaging data. TVB models link biophysical parameters at the cellular level with systems-level functional neuroimaging signals. Multi-scale data available from animal models can provide vital constraints for the linkage across spatial and temporal scales. Here, we describe the development of a macaque structural connectome as an initial step towards establishing a comprehensive multi-scale macaque model in TVB. A whole-brain connectivity matrix of 82 ROIs was first generated from the CoCoMac database of tract tracing studies. The resulting matrix included information on the directionality of fiber tracts, but lacked details on fiber tract capacities and tract lengths, variables critical for describing the space-time relationships in large-scale networks. We enhanced this connectome with diffusion-weighted imaging data collected from 10 adult male macaque monkeys (9 *Macaca mulatta*, 1 *Macaca fascicularis*) at 7T. For each animal, probabilistic tractography was performed only for connections specified in the CoCoMac-derived matrix to generate individual estimates of fiber tract capacities and tract lengths. Tractography parameters for each animal were chosen so as to optimize overall accuracy based on an independent tract tracing dataset. Fiber tract capacities were estimated as the probability of detecting streamlines between each ROI pair. Estimates were then averaged across animals to produce 1) a weighted and directed connectivity matrix, and 2) a corresponding tract length matrix. Preliminary simulations of population activity using this macaque connectome yielded networks akin to known resting-state networks in macaques. Further development will allow simulations to be fit to resting-state BOLD-fMRI data collected from the same subjects. This work is a crucial first step to incorporating structural and functional constraints to multi-scale models of brain dynamics in humans.

Title: Disentangling the effects of aging related network changes for unimanual motor learning - An fMRI/EEG study

Authors: *S. CHETTOUF[1], J. ZIMMERMANN[2], A. DAFFERTSHOFER[3], P. RITTER[1,4,5]
[1]Neurol., Brainmodes Group, Berlin, Germany; [2]Rotman Res. Inst., North York, ON, Canada; [3]Amsterdam Movement Sci. & Inst. for Brain and Behavior Amsterdam, Amsterdam, Netherlands; [4]Bernstein Ctr. for Computat. Neurosci., Berlin, Germany; [5]Berlin Inst. of Hlth. (BIH), Berlin, Germany

Abstract: Motor learning requires orchestration across sensorimotor networks that can be impaired with age-related neurodegeneration, in particular in the corpus callosum[1]. As a consequence, motor learning may become challenging. We hypothesize that imbalance of inter-hemispheric (excitation) and intra-hemispheric (inhibition) connectivity between PM1 and M1 leads to decreased motor learning capabilities with age[2,3]. We examined 20 young (20-25y) and 20 older (59-70y) healthy right-handed participants who learned to perform a rhythmic perceptual motor task with their right hand, while being monitored with simultaneous EEG-fMRI[4] at Charité Berlin. We quantified behavioral performance by the strength of frequency locking between visual cues and exerted manual force. Improved performance appeared in both groups ($F(4.44,79,96)=2.56$, $p<.05$), but more pronounced in the younger. A 24h follow-up retention test confirmed motor learning in both groups (young $p=.003$, older $p=.007$). Moderate differences occurred in motor-correlated fMRI between groups (peak right cingulum *$T=5.23$ $p<.001$)*. Artifact corrected and motor correlated EEG β-band (15-30Hz) beamformers were lateralized in both groups albeit stronger in the young with left M1 peak ($T=12,95$ $p<.001$). An additional ipsilateral component in the older was found ($T=6,01$, $p<.001$*)*. For both groups motor-task related β-band de-synchronization in left M1 was correlated with behavioral improvement ($r=0.310$, $p<.001$). Our results point at an age-related functional re-organization possibly reflecting an imbalance of inter- and intra-hemispheric pathways. To clarify this further, we will use source-reconstructed EEG in contralateral M1 as regressors for fMRI. This will discern (bilateral) M1 and dorsal PM, which both contribute to motor output[2]. Resulting patterns are expected to differ not only in their lateralization but also in the intra-hemispheric activation. This and future simulations with TheVirtualBrain, will refine our findings that do already support the hypothesis of the need for interhemispheric and intra-hemispheric connectivity for motor performance and learning.

Abstract: One of the fundamental functions of our brain is to learn and adapt to our environment, yet little is known about the inter-subject learning variability. In this study we investigate the relation between changes in human electroencephalogram (EEG) oscillations and improvement in tactile acuity. Therefore 26 healthy individuals underwent EEG recordings as well as psychophysical measurements. Perceptual learning was measured via a two-point discrimination task before and after a 30 min repetitive-sensory stimulation of the right index finger. Changes of resting-state upper alpha band oscillations in sensorimotor areas contralateral to the stimulated finger pre versus after stimulation predict the improvement of tactile acuity. This effect sits on top of state-dependent learning outcomes demonstrated previously. In other words, resting state upper alpha (~10-12 Hz) changes over sensorimotor areas contralateral to stimulation are predictors of learning. Using a physiologically-inspired computational model we identify possible neural mechanisms for observed empirical phenomena. Our model combines macro- and microscale characteristics. It simulates cortical activity of primary somatosensory

and motor cortex driven by a thalamic input. Local regions are made of recurrently connected inhibitory and excitatory spiking neurons. Learning is implemented via spike-dependent plasticity kernels and detection rate measured via the phase-locking index of cortical oscillations to thalamic spikes. We systematically explore the effect of the parameters local recurrent inhibition strength and thalamic input frequency on neural frequency changes and learning. An increase in local inhibition and decrease in the thalamic input frequency reproduce the empirical finding of negative correlation between alpha power change and improved tactile acuity.

Title: Automatically generating HPC-optimized code for simulations using neural mass models

Authors: *A. PEYSER[1], S. DIAZ[1], M. WOODMAN[2], V. K. JIRSA[2]
[1]IAS, JSC, HPC in Neurosci., Forschungszentrum Juelich, Jülich, Germany; [2]Inst. de Neurosciences des Systemes UMR1106, Marseille, France

Abstract: High performance computing (HPC) is becoming more accessible and useful as a neuroscientific tool. Simulations of brain networks and analysis of medical data can now be performed at larger scales and with higher resolution. However many current neuroscientific software tools can't utilize yet the full power of supercomputers, GPUs and other computational accelerators.

The Virtual Brain (TVB: Sanz et al 2013) is a validated and popular choice for the simulation of whole brain activity. With TVB, the user can create simulations using neural mass models spanned in 3D space and generate forward solutions for common brain imaging signals (EEG, MEG, fMRI, etc). TVB allows scientists to explore and analyze simulated and experimental signals and contains tools to evaluate relevant scientific parameters over both types of data (Saenz, 2015). Internally, the TVB simulator contains several models for generating neural activity at the region scale. Most of these models are efficiently described using groups of coupled differential equations numerically solved over large spans of simulation time. Currently the models simulated in TVB are primarily written in Python and haven't been optimized for parallel execution or deployment on HPC architectures. Moreover several elements of these models can be abstracted, generalized and re-utilized, but the right abstract description for these models hasn't been implemented yet.Here we present early results from porting several TVB workflows to HPC accelerators. To reduce the required effort to utilize different HPC platforms, we've developed an automatic code generation tool to define abstract models at all stages of simulation, and then translate them to hardware specific code. Our simulation workflows involve different neural mass models (Kuramoto 1997, Wong 2006, etc) as well as pre-processing and post-processing kernels (Balloon model: Buxton 1998, correlation metrics, etc). We discuss strategies used to keep code portable between several architectures yet optimized for each platform, including benefits and limitations. We also show performance comparisons and show what can be achieved with the new code in terms of scalability and simulation times. Implementation of efficient hyperparameter optimization for complex models in TVB such as the epileptic seizure propagation model (Jirsa et al 2017, Proix et al 2018) is a current focus. We discuss implementation of Bayesian Inference techniques used for this purpose and results of initial runs on the HPC infrastructure in Jülich.

Title: Optimal surgical options considering inoperable zones for epilepsy patients: A computational approach using the virtual brain

Authors: *S. AN[1], F. BARTOLOMEI[1], M. GUYE[2], V. JIRSA[1]
[1]Aix Marseille Univ, INSERM, INS, Inst. Neurosci Sys, Marseille, France; [2]CNRS, CRMBM UMR 7339, Aix Marseille Univ., Marseille, France

Abstract: At present, more than 30% of epilepsy patients suffer from drug-resistant seizures, and surgical intervention is considered as the effective method able to control the drug-resistant seizures. Current studies on epilepsy surgery mostly have focused on localizing the epileptogenic zone (EZ) and effectively removing it. However, in a significant number of patients, EZs are distributed in distinct brain regions and involve eloquent areas that cannot be surgically eliminated due to the risk of neurological complications. Therefore, it is important to develop alternative surgical methods able to induce seizure relief by suppressing seizure propagation to other brain regions, even if they do not prevent the occurrence of seizures in EZs. The method should have no significant impact on normal brain functions. In this study, we propose an in silico surgical approach able to suggest effective and safe surgical options for each patient in case there are inoperable EZs. Our method employs modularity analysis using structural brain connectivity from each patient, which derives target brain regions and target fiber tracts, considering inoperable zones (IZs), for resection and disconnection surgeries, respectively. The effectiveness and the safety of the derived target zones (TZs) are evaluated by brain network simulations using The Virtual Brain (TVB) platform. In a patient-specific network model constructed by a neural mass model, structural brain connectivity and clinical estimation for EZs, characteristics of seizure propagation are simulated. In particular, changes of seizure-recruited regions after removing the TZs are observed in the worst-case where seizures spread to most brain regions. Moreover, the impact of the TZs on normal brain functions has been minimized using a metric developed to assess the integrity of the transient spatiotemporal trajectory following electrical stimulation at certain zones. This approach is aimed at preserving the information transmission capacity before and after eliminating the TZs. We apply this novel feedback approach comprising modularity analysis and network integrity preservation to a total of 7 drug resistant epileptic patients and identify the optimized surgical options for each individual patient. This study demonstrates the possibility of using computational approaches deriving optimal surgical options suitable for each patient and predicting the surgical outcomes.

Title: Explaining seizure onset patterns by computational modeling of a seizure spread on a cortical surface in The Virtual Brain

Authors: *V. SIP[1], M. GUYE[2,3], F. BARTOLOMEI[1,4], V. K. JIRSA[1]
[1]Aix Marseille Univ, INSERM, INS, Inst. Neurosci Sys, Marseille, France; [2]Aix Marseille Univ, CNRS, CRMBM, Marseille, France; [3]Assistance Publique – Hôpitaux de Marseille, Hôpital de la Timone, CEMEREM, Pôle d'Imagerie Médicale, CHU, Marseille, France; [4]Assistance Publique – Hôpitaux de Marseille, Hôpital de la Timone, Service de Neurophysiologie Clinique, CHU, Marseille, France

Abstract: Among the most commonly observed patterns in intracranial electroencephalography (iEEG) recordings of focal epileptic seizures is the so-called fast activity pattern (FA). This pattern is characterized by fast oscillations (8-30 Hz) and gradually increasing amplitude. Looking through the optics of dynamical system analysis, such onset resembles a nonlinear system going through a supercritical Hopf bifurcation, which may thus be the primary candidate to model the onset dynamics. Here we investigate a different mechanism that can mimic such FA onset pattern through the mechanism of traveling neural fields on a folded cortical sheet. At a given location, the neural field shows a rapid transition via saddle-node bifurcation from silent state to seizure state. The activity of the sheet is observed through the generated local field potential recorded on the contacts of a depth electrode. In this scenario, the gradual amplitude increase on the recorded signals is caused by the translation of the neural field and the subsequent spatial averaging of the source activity. We use The Virtual Brain platform to simulate the spread of the epileptic seizure on a piece of a cortical surface located in the vicinity of the intracranial electrode of interest. The highly resolved triangulated cortical surface is derived from the neuroimaging scans of a patient with a temporal lobe epilepsy. The Epileptor field model is employed to represent the source dynamics, and a dipole model of the cortical surface is used to calculate the iEEG signals from the source activity. Similarly as the iEEG recordings from the real patient, the simulated iEEG signals exhibit the typical feature of the FA onset pattern - slowly increasing amplitude of the oscillations. The comparison of the recorded and simulated signals in terms of the timing of the apparent seizure onset and the duration of the period of amplitude increase show also quantitative consistency, demonstrating the plausibility of the mechanism on the realistic spatial and temporal scales. The results show that it is not necessary that a dynamical model switches to a seizure state through a Hopf bifurcation; other bifurcations may produce the same onset pattern on the electrodes via the here described field effects. Because the choice of the bifurcation type has important consequences for the dynamical behavior of the system (e.g. for the response to stimulation), the obtained results underscore the importance of the appropriate model choice and suggest more dynamic interpretations of the concept of Epileptogenic Zone.

Title: TVB-epilepsy: A software tool extending the virtual brain to predict patient specific seizure propagation

Authors: *D. PERDIKIS[1], M. M. WOODMAN[1], P. POPA[2], L. DOMIDE[2], J. MERSMANN[3], V. K. JIRSA[1]
[1]Inst. de Neurosciences des Systèmes UMR INSERM 1106, Aix-Marseille Univ. Faculté de Médecine, Marseille, France; [2]S.C. Codemart S.R.L., Cluj-Napoca, Romania; [3]Codebox Computerdienste GmbH, Stuttgart, Germany

Abstract: TheVirtualBrain (TVB) is an open source neuroinformatics platform for full brain network simulations using biologically realistic connectivity (see http://www.thevirtualbrain.org). Based on generative model simulation, TVB links the anatomical structure of an individual's brain large-scale networks, obtained via Diffusion Tensor Imaging (DTI), to observable functionality, i.e., neuroimaging signals (functional MRI, EEG, MEG and intracranial EEG) measured experimentally or clinically. Thus, TVB enables the model-based inference of neurophysiological mechanisms across different brain scales that underlie healthy as well as pathological brain function.
One of the most developed and pioneering clinical applications of TVB technology is to be found in epilepsy, a chronic non-communicable disorder of the brain that affects tens of millions of people of all ages worldwide. The current surgery success rate for drug resistant epilepsy (DRE) patients ranges from 30% to 70%, depending on the type of epilepsy, and has remained unchanged in the last fifty years. One of the most daunting challenges of DRE treatment using neurosurgery is the identification of the epileptogenic zone (EZ) responsible for the origin and propagation of an epileptic seizure in the brain.
Here we introduce TVB-epilepsy, a TVB module that extends TVB functionality with statistical inference techniques, aiming at facilitating the use of TVB for epilepsy applications by academic

and clinical researchers alike. Building on recent research on the dynamical mechanisms of seizure onset and propagation via permittivity coupling, TVB-epilepsy uses TVB to construct a dynamical brain network model of seizure energy propagation from patient's (d)MRI data. TVB-epilepsy extends the dynamical brain network model to a probabilistic model and inverts it by contrasting its predictions to (intracranial) EEG clinical data. Thus, TVB users can fit neurophysiologically relevant network parameters, the most important of which, namely the pathological excitability of each brain region, directly points to the EZ. For statistical inference, TVB-epilepsy includes an interface to STAN, a state-of-the-art platform for statistical modelling and high-performance statistical computation (see mc-stan.org). We present TVB-epilepsy's architecture and illustrate its basic workflow along use cases of patients with temporal-lobe DRE.
In summary, TVB-epilepsy enables the clinical and academic researcher to use concepts and state-of-the-art brain network models for patient-specific epilepsy research in a dedicated software environment.

Title: Relationship of EEG and music features through low dimensional manifolds

Authors: *S. SHAKIL, S. FABER, A. R. MCCULLOCH, T. M. BROWN, K. SHEN, A. R. MCINTOSH
Baycrest Hlth. Sci., Toronto, ON, Canada

Abstract: Background: Music influences mood, and this influence can be associated with musical features. 'Pleasant' music elevates mood and 'sad' music decreases mood. However, the relationship of these features to brain function and states is not well-studied. Here, we explore the relationship between musical features and brain states extracted from EEG data. **Methods**: For this study, we used EEG data from nine healthy subjects (19-35 years old) listening to 40 second excerpts from 25 pieces ranging from Renaissance to contemporary classical. Data was collected using a 64+10 Biosemi Active Two System at a sampling rate of 512 Hz and was preprocessed in EEGLAB. Afterwards, we formed one EEG matrix for each subject by concatenating all music pieces for all electrodes. We also grouped the music pieces in six groups

(very sad, sad, very angry, angry, tender, and happy) based on the valence and arousal features extracted from the musical excerpts. The EEG matrix of each subject was mapped onto a two-dimensional manifold using non-linear dimensionality reduction technique t-Distributed Stochastic Neighbor Embedding (**t-SNE**). Finally, we mapped the music groups onto the t-SNE manifolds. **Results**: Fig. 1, shows the results of the music group mappings on a 2D manifold of EEG data for three subjects. Here, each data point is the brain state at a particular time point based on the EEG data. We observed that the EEG time points for similar music features tend to cluster together (in similar states) as is evident from same color clusters. Furthermore, the sad and very-sad (blue and red) groups extracted from music are close. We do not find such state similarity for very-angry and angry states (yellow and pink), which may suggest that additional musical features should be taken into account in data grouping. **Conclusions**: Different types of music may induce unique brain activity in many states, which may explain music's effectiveness in mood regulation or in therapeutic settings. The relationship between brain states and music features needs to be explored more in order to effectively employ music as a therapeutic tool.

Title: Decoding music induced emotions

Authors: A. GHANI[1], J. ZHANG[1], A. MCLNTOSH[2], K.-R. MÜLLER[3], *P. RITTER[1]
[1]Charite, Univ. Med. Berlin, Berlin, Germany; [2]Rotman Res. Inst., Toronto, ON, Canada;
[3]Machine Learning, TU Berlin, Berlin, Germany

Abstract: We study how music alters our emotions on a subjective level. Total 18 subjects (9 females) listened to 30 classical musical excerpts while EEG data was recorded and continuous rating from participants was acquired on a two-dimensional scale of valence and arousal. Data were analyzed a) using PLS[1], b) the source separation framework SPoC[2], and c) classification via cross-frequency coupling features. Results: a) PLS analysis results in two significant variables. Unpleasant- relaxing pieces were related to high alpha-beta 10-20Hz ($p= 0.009$) whereas pleasant -stimulating were related to high gamma 40-80Hz ($p=0$). b) Participants who listen to music to regulate mood have more sensitivity to valence and less to arousal in their EEG ($p<0.05$). Shy and reserved personalities had lesser modulation of EEG ($p<0.01$). c) Two forms of CFC, namely PSI (phase synchronization index) and PAC (phase amplitude coupling) were applied to classify the emotional states, and compared with normally used methods PSD (power spectral density) and DLAT (difference in left-right laterality direction). The results showed that the best performance was obtained by features derived from PAC_4Hz at mean accuracies of 93.49% 92.42% separately for valence and arousal binary classification. Both in valence and arousal level, all the EEG coupling features outperformed the performance of feature types PSD and DLAT. Cross-frequency coupling was more sensitive to characterize the EEG variation in response to emotional states. Since mood is typically described as having either positive or negative valence, our results from b) corroborate that participants who use music to regulate their mood have higher weights for valence compared to arousal, i.e. their EEG is stronger modulated by valence. To capture the interaction of emotion network during musical listening we will combine EEG with fMRI and use the neuro-informatics platform The Virtual Brain (TVB, thevirtualbrain.org) for connectome based multi-scale brain simulations[3]. With TVB we reconstruct the information flow within the brain network and reveal processes that are not directly accessible from brain recordings.

Title: The virtual brain to characterize brain dynamics before and after MR guided interstitial thermal ablation for childhood epilepsy

Authors: *M. M. VANDEWOUW[1], A. G. WEIL[2], G. M. IBRAHIM[3]
[1]Sickkids Res. Inst., Toronto, ON, Canada; [2]Pediatric Neurosurg., Univ. de Montréal, Montreal, ON, Canada; [3]Neurosurg., Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Introduction. Epilepsy is a brain disorder characterized by seizures affecting approximately 1-2% of children worldwide, and is associated with significant medical, psychological, and social burdens. Magnetic resonance imaging (MRI)-guided laser-induced thermal ablation has been shown to be an effective and non-invasive treatment for those with refractory epilepsy. Although neuroimaging techniques are used to guide the ablation surgery, the complexity of brain dynamics makes it difficult to predict seizure outcome post-ablation. Whole-brain network modeling combining detailed biophysical information with global dynamics has the potential to better predict changes pre- and post-ablation.
Methods. We obtained data on 12 children with refractory epilepsy. Prior to surgery, while under sedation, the children underwent T1-weighted structural imaging, diffusion-tensor imaging (DTI), and resting-state functional imaging according to site-specific protocols. T1-weighted and resting-state images were also collected immediately after surgery. Post-operative structural T1-weighted images were used to generate ablation volumes. We simulated the pre-ablation large-scale brain dynamics using The Virtual Brain (TVB), inputting each participant's structural connectivity and individually optimizing local and global biophysical parameters according to their pre-ablation functional connectivity. Structural connectomes were then modified according to the ablation volume, and parameters were re-optimized using the post-ablation functional connectivity.
Results. Individualized local and global model parameters were able to accurately simulate pre-ablation brain dynamics. Furthermore, the re-optimized parameters specific to the ablation-modified structural connectome more accurately predicted post-ablation functional connectivity. Each participant's parameters differed between pre- and post-ablation.
Conclusions. Modeling complex brain dynamics with The Virtual Brain can help to further understand the effects of thermal ablation surgery for refractory epilepsy, and the local and global biophysical parameters are altered after ablation.

Title: Measuring causality in simulations of large scale brain networks using the virtual brain

Authors: *M. MANNINO[1], S. L. BRESSLER[2]
[1]Florida Atlantic Univ., Miami, FL; [2]Florida Atlantic Univ., Boca Raton, FL

Abstract: Inferring causal relations between the nodes of large-scale brain networks can reveal network topology, connectivity, and function, and help uncover the neurobiological basis of cognition. Appropriate methodologies for measuring dynamic causality in large-scale brain networks remain varied and elusive. In this project, we seek to infer causal relations in large-scale brain networks using a nonlinear neural mass model to generate time series data of a local field potential (LFP) signal, and use both the linear autoregressive modeling technique of Granger causality (GC) and the information-theoretic method of transfer entropy (TE), detecting nonlinear relations to analyze the data. Data are generated from two coupled oscillatory neural masses in The Virtual Brain (TVB). We previously provided theoretical and empirical analyses of probabilistic causality in LFP data of a large scale brain network, recovering the causal conditions using a popular variation of GC, in a unique manner. Here we extend the analysis in several ways: 1) we vary the control parameters and thus change the intrinsic dynamics of each node in the model to explore their distinctive effects on causality, 2) we use TE in a unique manner, to remain consistent with the GC results, and 3) we use TE and GC to recover a range of *a priori* parameterized conduction delays set in TVB. TE and GC are widely validated methods in neuroscience, and have been shown to be theoretically equivalent under certain conditions. Here, we empirically validate that equivalency.

Title: Multivariate distance correlation features of functional connectivity improve the reliability and power of connectome-based predictive modeling

Authors: *K. R. YOO[1], M. D. ROSENBERG[2], S. M. NOBLE[3], D. SCHEINOST[4], R. T. CONSTABLE[5], M. M. CHUN[4]
[1]Psychology, [2]Dept. of Psychology, [3]Interdepartmental Neurosci. Program, [5]Dept Diagnos. Radiol, [4]Yale Univ., New Haven, CT

Abstract: FMRI studies have shown that multivariate spatial activity patterns across voxels reflect mental states of the brain (Haxby et al. 2014). An open question is whether multivariate voxel-wise timecourses can better characterize region-by-region interactions (functional connectivity) compared to univariate approaches, typically measured with Pearson's correlations (r). We investigated the utility and reliability of multivariate functional connectivity estimated by multivariate distance correlations (dCor; Székely et al. 2007), a measure of multivariate dependency between two sets of variables, estimating both linear and non-linear associations. We examined the utility of multivariate functional connectivity in two ways using data from the Human Connectome Project (S1200 release; n=563 after exclusion; 7 task and 2 rest scans/individual; 160 TRs/scan). First, we assessed the identifiability of individual connectomes (Finn et al. 2015), and second, we used these features to predict an individual's fluid intelligence, using connectome-based predictive modeling methods (Finn et al., 2015; Rosenberg et al., 2016; Shen et al., 2017). Prior work relied on Pearson's r to measure functional connectivity, and basically, this study tested whether dCor features may produce superior performance. Multivariate functional connectivity measures using dCor achieved a higher identification rate (97%; Pearson:82%) between individuals' two resting-state scans. Identification rates with dCor were higher among every pair of fMRI scans (97±2%; Pearson:58±15%;). Predictive models constructed using dCor better predicted individuals' fluid intelligence (correlation between predicted and observed scores: 0.242; Pearson:0.156; $p<0.05$ with 10,000 bootstrap). We then assessed the test-retest reliability of dCor in a dataset previously used to evaluate the reliability of functional connectivity estimated by Pearson correlations (n=12, Noble et al. 2017). Multivariate functional connectivity measured with dCor was more reliable than univariate functional connectivity measures with Pearson correlation. dCor had a higher edge-wise reliability (0.43±0.13 for a single 6-min scan; Pearson:0.18±0.13) and higher connectome-wise reliability (0.45; Pearson:0.22). Furthermore, dCor provided higher perfect separation rate than Pearson's r. In conclusion, our findings suggest that multivariate estimates of functional connectivity are more reliable than univariate estimates, providing more powerful information about an individual's functional brain organization and its relation to cognitive skills.

Title: Blast-related mild traumatic brain injury in chronic phase: A diffusion tensor imaging study with machine learning

Authors: *P.-Y. HSU[1,2], R. THEILMANN[2], A. ANGELES-QUINTO[2], A. ROBB-SWAN[2], S. NICHOLS[2], D. HARRINGTON[2], A. DRAKE[4], T. SONG[2], M. DIWAKAR[5], R. CLIFFORD[2], R. LEE[2], C.-K. CHENG[2], A. MANDELL[2], D. BAKER[2], M. HUANG[3]

Abstract: Individuals exposed to blast-related mild traumatic brain injury (bmTBI) often experience long-term neurological and cognitive disorders. Yet no optimal treatments have been developed specifically for bmTBI, owing in part to the heterogeneity of injuries. In this regard, sensitive neuroimaging techniques combined with multivariate statistical analyses might help elucidate the mechanisms underlying bmTBI and ultimately, potential treatment targets. In the present study, deployed service members with combat exposure were recruited, including 19 healthy controls (HC) and 20 individuals with chronic bmTBI. Participants underwent diffusion tensor imaging (DTI) and neuropsychological (NP) testing. Voxel-wise statistical analyses of DTI data were carried out using Tract-Based Spatial Statistics (TBSS), and regions that showed significant group differences in various diffusion metrics were then utilized as variables in a support vector machine (SVM) analysis to identify the linear combination of aberrant diffusion metrics that optimally distinguished bmTBI patients from HC participants. The TBSS analysis revealed significantly increased fractional anisotropy (FA) and reduced radial diffusivity (RD) in bmTBI compared to HC participants, but no group differences in mean diffusivity or axial diffusivity (AD). The SVM model achieved 94% classification accuracy of bmTBI and HC participants in cross-validation experiments based on FA and AD/RD ratio. Regions in the genu and body of the corpus callosum and bilateral anterior corona radiata, anterior and posterior limb of the internal capsule, and the superior corona radiata were identified as potential markers of bmTBI. These results provide important evidence that persistent neurological and cognitive

symptoms associated with a history of blast-exposure sustained during combat is related to subtle, yet long-term changes in the underlying neuropathophysiology of the brain.

Title: Scan path modeling using marked point processes

Authors: *R. SHIBUE, M. YONEYA
NTT Communication Sci. Labs., Atsugi-shi, Kanagawa Pref., Japan

Abstract: A scan path is a time series of where the eye is looking. When modeling a scan path, it is necessary to consider the strong non-linearity arising from saccades. Without considering such non-linearity, estimation errors may occur and the estimate may become unreliable. This non-linearity also makes it difficult to model scan path distribution. Previous studies focused on partial features extracted from scan paths, such as the fixation map, saccade shapes and saccade transitions. These approaches disregard the relationships between partial features of scan path and it may result in loss of information.
In this presentation, we propose a new probabilistic generative model for scan paths. In our model, we use a marked point process determined by the superior colliculus structure to express a saccade occurrence and give a new definition of the saliency map. The marked point process is a stochastic process that is used for modeling series of events. It enables us to handle the non-linearity due to saccades without any preprocessing procedure and specify the scan path distribution directly.
We assume that the observed scan path is generated from the model and calculate the posterior of hidden variables by using variational inference approach. Distributions of partial features of a scan path can be obtained by marginalizing the estimated scan path distribution; our method can detect saccades, denoise a scan path measured by an eye tracker, estimate saccade shapes and calculate a fixation map simultaneously. Previous studies carried out these procedures in separate steps, which may cause errors and loss of information. On the other hand, our method avoids such problems by expressing these elements in a unified generative model.

Title: Pseudo-quantitative deconvolution of neuronal-related BOLD events with unknown timing

Authors: *J. GONZALEZ CASTILLO[1], C. CABALLERO-GAUDES[2], P. BANDETTINI[3]
[1]SFIM/LBC/NIMH/NIH, Bethesda, MD; [2]Basque Ctr. for Brain, Cognition and Language, San Sebastian, Spain; [3]Lab. of Brain & Cog/Sect Function Imag, NIMH-NIH, Bethesda, MD

Abstract: Multi-echo (ME) fMRI results in K time-series per voxel; each acquired at a different TE. Well-known differences in TE dependence profiles for BOLD (linear dependence) and non-BOLD (no dependence) fluctuations can be exploited to automate denoising of ME fMRI time-series. Here, we propose a novel ME formulation of the Sparse Free Paradigm Mapping[(SPFM) algorithm that by combining a hemodynamic response model, the above-mentioned TE-dependence model and L1-norm regularized estimators, produces voxel-wise quantitative estimates of time-varying changes in the transverse relaxation ($\Delta R2^*$) and the net magnetization ($\Delta S_0/ S_0$). All this, without prior information about the timing of experimental events. To evaluate this method, we computed histograms of $\Delta R2^*$ estimates accompanying five distinct tasks (auditory, finger tapping, reading, viewing of houses and viewing of biological motion patterns). In most instances, estimates fell within physiologically plausible limits of neuronally-driven $\Delta R2^*$ at 3T. Figure 1.A shows ME-SPFM $\Delta R2^*$ maps for one representative subject. There is good agreement between traditional GLM (1.A) and ME-SPFM $\Delta R2^*$ maps (1.C); with areas of positive activation in the GLM maps being dominated by negative changes in $\Delta R2^*$ in ME-SPFM maps. Figure 1.B shows the histograms of ME- SPFM $\Delta R2^*$ for all intracranial voxels, where most $\Delta R2^*$ estimates fall in the range [-0.74, 0.74] s^{-1} of physiologically plausible values for neuronal activation. Also, Figure 3.C shows the histograms for only voxels with significant positive response according to GLM (pFDR<0.05), where ME-SPFM $\Delta R2^*$ estimates are mostly negative (e.g., [-0.74,0] s^{-1}). This demonstrates how ME-SPFM yields physiologically plausible quantitative estimates of $\Delta R2^*$, and only few voxels (red circles in Figure 1.C) exhibited excessively large $\Delta R2^*$ to be mislabeled as neuronal-related events.
These results indicate ME-SPFM provide a viable method to estimate $\Delta R2^*$ time-series with

interpretable units, even when experimental event timing is missing (e.g., naturalistic, resting-state).

Title: Classification of schizophrenia patients and healthy controls based on gray matter volumes using support vector machines

Authors: *M. YAMAMOTO[1], E. BAGARINAO[2], I. KUSHIMA[1,3], R. SUZUKI[1], A. BRANKO[1], T. INADA[1], T. IIDAKA[2], N. OZAKI[1]
[1]Dept. of psychiatry, Nagoya Univ., Nagoya-Shi, Japan; [2]Brain and Mind Res. Ctr., Nagoya, Japan; [3]Inst. for Advanced Research, Nagoya Univ., Nagoya-Shi, Japan

Abstract: Objective
Gray matter (GM) volume changes in schizophrenia patients (SCZ) have been demonstrated by meta-analyses of structural magnetic resonance imaging (MRI) studies, which indicated the possibility of classification of SCZ and healthy controls (CON) using patterns of GM volume changes. Therefore, we aimed to explore the use of a support vector machine (SVM) to classify two groups using structural MRI data.
Method
Fifty SCZ (26 males, mean age 38.8 years) and 51 CON (29 males, mean age 36.5 years) were scanned using a 3.0 T MR scanner (Siemens Magnetom Verio). All subjects provided written informed consent to participate in the study. The Nagoya University Graduate School of Medicine and Nagoya University Hospital ethics review committee approved this study. The acquired T1 images were preprocessed using Statistical Parametric Mapping and the VBM8 and smoothed (full-width at half-maximum = 8 mm), and modulated GM images were generated. These images were used in the classification analysis using linear SVMs with regularization parameter set to 1. A whole-brain mask was applied to the images and only voxels within the mask were included in the analysis. To reduce the dimensionality of the data, a principal component analysis was performed. The classification performance of trained SVMs was evaluated using a 10-fold cross validation approach. In addition to the classification accuracy, we also evaluated several classification measures including sensitivity, specificity, positive predictive value, and negative predictive value. The significance of each voxel's contribution in the classification performance was evaluated using a permutation test with 5000 iterations. All analyses were performed using in-house Matlab scripts and the LIBSVM software package (http://www.csie.ntu.edu.tw/~cjlin/libsvm).
Results
The classification accuracy was 76.2% (specificity; 76.4%, sensitivity; 76.0%). Regions contributing to the classification accuracy included not only decreased GM volumes in SCZ, such as the bilateral rectal gyrus, anterior cingulate gyrus, temporal pole, insula, and left occipital gyrus, but also increased volumes in the bilateral putamen and globus pallidus.
Conclusion
These regions were largely consistent with the findings of a previous large-scale analysis of a linear SVM (Rozycki et al., 2017). The current results indicated that our SVM method could detect the volume changes that classify the two groups in relatively small sample sizes.

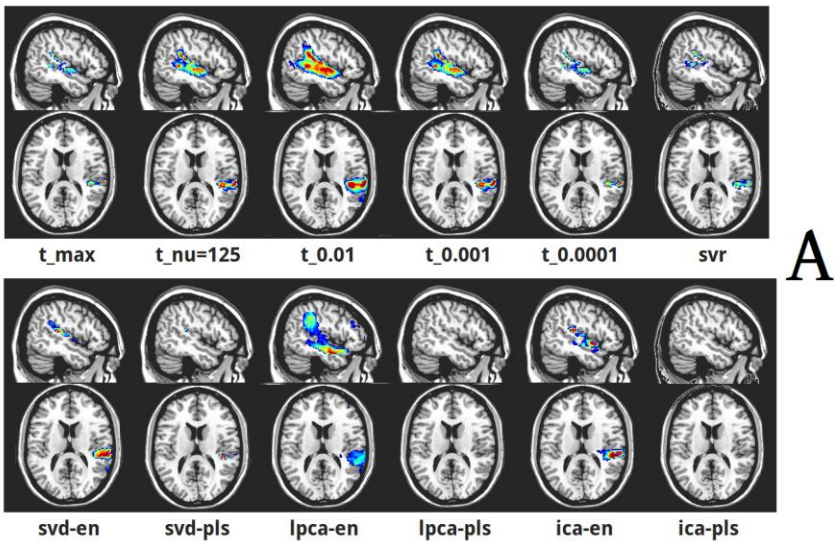
Title: Comparison of univariate and multivariate lesion symptom mapping methods for the analysis of brain-behavioral relationships

Authors: *T. J. HERRON[1], M. V. IVANOVA[2], N. F. DRONKERS[2], B. CURRAN[2], C. LUDY[2], A. ZHONG[2], A. U. TURKEN[2], J. V. BALDO[2]
[1]Neurology, Res., VA Northern California Hlth. Care Syst., Martinez, CA; [2]Res., US Dept. of Veterans Affairs, Martinez, CA

Abstract: Lesion symptom mapping (LSM) tools identify brain regions critically associated with neurologic and cognitive deficits in brain-injured patients. There have been many recent discussions comparing the advantages of multivariate (MV) versus univariate (V) LSM methods, with a notable direct comparison appearing recently [Pustina et al 2018]. Here we conducted a companion simulation study of the limits of detection reliability and spatial accuracy of artificial brain-behavior relationships (BBR) in gray matter (GM) using real lesion masks.
We first analyzed single parcel, proportional BBR conditions (% of target lesioned ~ % of behavioral deficit) in the left middle cerebral artery territory over a fully crossed design:
* 16 GM parcels as BBR targets
* Lesion masks from 2 different sites
* 12 lesion symptom mapping methods
* 4mm lesion mask smoothing vs. none
* patient sample sizes from 32 to 128
* multiple spatial accuracy measures.
We also tested "network" BBRs involving two cortical locations, both a redundant network and a dependent network, under the same crossed design. Lastly, we processed Western Aphasia Battery (WAB) data from 209 stroke patients to compare selected LSM contrasts.
Results from the single parcel BBRs showed good spatial accuracy for VLSM and most of the MVLSMs (see Table 1). Simulation results from the two-parcel "network" BBRs showed clear superiority of two data reduction MVLSM techniques and the cluster-size-threshold based maps (Table 2). The Figure shows two WAB analysis results.



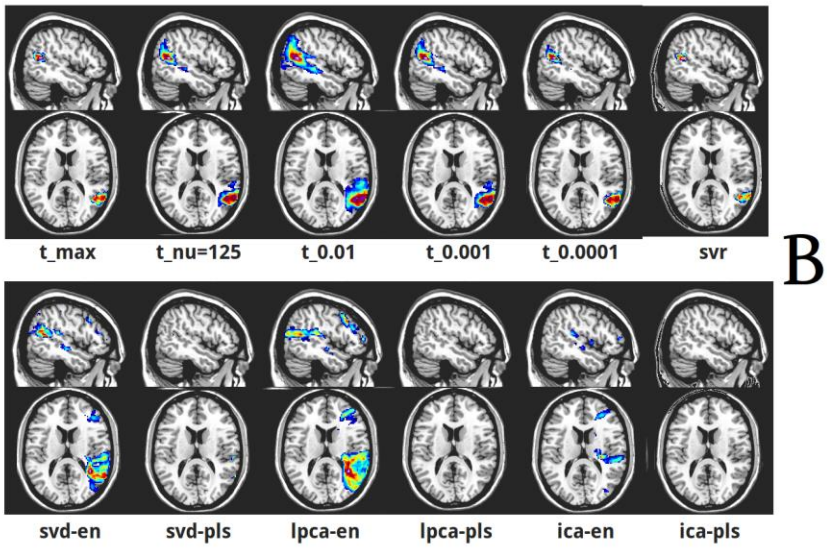


Figure: LSM results for the (A) repetition and (B) comprehension scores from the WAB where lesion size, age, education, months post event, and the other 3 WAB subscores were covaried out.

t_max: maximum regression value thresholded by permutation test
t_nu=125: same as t_max but using the 125th largest regression value [Mirman et al 2017]
t_0.01: cluster-size-based permutation test at fixed 0.01>p regression threshold (similarly t_0.001 t_0.0001)

-en: elastic net regression solution [Hastie et al 2103 ; glmnet toolbox]

ANOVA factor/interaction	F and partial ω^2	Details
LSM Type	$F_{11,165}=133$; $\omega^2=0.90$	DR+Elastic Net & SVR & VLSM good
Smoothing of Masks	$F_{1,15}=71$; $\omega^2=0.82$	4mm Gaussian FWHM smoothing +6.2 t
Number of Patients	$F_{6,90}=141$; $\omega^2=0.90$	Steep improvement: from 32 to 64 patients
LSM Type x Smoothing	$F_{11,165}=5.6$; $\omega^2=0.24$	SVR+VLSM most improved by smoothing
LSM Type x # Patients	$F_{66,990}=6.2$; $\omega^2=0.26$	SVR needs 64 subjects to do well, VLSM & some DR MVLSM only need 48 to do well.

Table 1: Single GM parcel proportional brain-behavior relationship (BBR) effects and interaction over the t-test difference between above-threshold LSM values inside vs. outside the target parcel. Only $p<0.0001$ effects and interactions shown. DR = data reduction.

ANOVA factor/interaction	F and partial ω^2	Details
LSM Type	$F_{11,165}=425$; $\omega^2=0.97$	DR+Elastic Net and small p cluster-size-based VLSM are good
Network Type	$F_{2,30}=96$; $\omega^2=0.86$	Redundant networks are the hardest to detect.
Number of Patients	$F_{3,45}=643$; $\omega^2=0.98$	Need 100+ patients in general to detect networks
Parcel	$F_{15,225}=12.1$; $\omega^2=0.43$	Main variability in detection is with lesion overlay edge parcels
LSM Type x # Patients	$F_{33,495}=35$; $\omega^2=0.70$	DR+Elastic Net might work with just 80 patients
LSM Type x Parcel	$F_{165,2475}=6.2$; $\omega^2=0.26$	No LSM works when one of parcel pairs is on the mask edge.
LSM Type x Network Type	$F_{22.330}=22$; $\omega^2=0.59$	SVD-EN best at identifying redundant networks.
# Patients x Network Type	$F_{6,90}=8.0$; $\omega^2=0.32$	Need 128+ patients for detecting redundant networks, usually
LSM x Network x # Pat.	$F_{66,990}=6.9$; $\omega^2=0.28$	$p<0.01$ cluster-size-based VLSM does OK in detecting most networks.

Table 2: Paired, networked GM parcels proportional brain-behavior relationship (BBR) effects and interactions over the t-test difference between LSM values inside vs. outside the target parcel pair. Only $p<0.0001$ effects and interactions shown. DR = data reduction.

Title: Alternation in hemispheric asymmetry of morphological brain network for Alzheimer's disease

Authors: *Y.-H. CHOI, S. BANG, J.-M. LEE
Dept. of Biomed. Engineering, Hanyang Universit, Seoul, Korea, Republic of

Abstract: The asymmetry of the human brain has been widely studied in the neuroscience field. It is well known that the left hemisphere is specialized for language and handedness and the right hemisphere is dominant for some nonverbal functions such as spatial attention and the processing of faces. Asymmetry of volumetric measures such as cortical volume, surface area and cortical thickness using the structural magnetic resonance imaging (MRI) has been reported to have globally and regionally hemispheric difference with more pronounced leftward than right asymmetry. Importantly, neuropsychiatric and neurological diseases such as schizophrenia, Alzheimer's disease (AD) exhibit significant changes in hemispheric asymmetries. In recent years, graph-theoretical approach has been applied to allow capturing various topological properties of complex brain network such as functional segregation, integration. Many studies have utilized the theoretical framework of graph theory to investigate brain networks in AD through different neuroimaging techniques. These studies have reported altered local and global graph properties of morphological brain network in AD. However, the methodology of these previous studies limited the investigation of graph properties to group-level analyses. Despite the advances in morphological brain network research for AD, however, little is known about whether there are differences in the topological organization of brain depending on disease. In the this study, the intracortical similarities of cortical thickness between two regions were estimated by calculating the Jensen-Shannon divergence, across subjects. Hence, the morphological hemispheric brain network was obtained from a group of individuals. And then, we applied graph theoretical approaches to quantify the global and nodal properties for hemispheric morphological networks. Finally, we investigated whether hemispheric and disease related differences in the morphological hemispheric brain network exists or not.

Hemispheric and Group effects on global network metrics revealed by two-way repeated-measures ANOVA

		Clustering coefficient	Characteristic path length	Normalized clustering coefficient	Normalized characteristic path length	Global efficiency	Local efficiency

Title: Using simulations to investigate the prevalence of false positives in data-driven forms of partial least squares analysis

Authors: *R. P. ROBERTS, D. R. ADDIS
The Univ. of Auckland, Auckland, New Zealand

Abstract: Partial least squares (PLS) is a multivariate technique commonly used with neuroimaging data to detect similarities and differences in i) brain activity (task PLS) and/or ii) brain-behavior correlations (behavior PLS) across groups and conditions (pls.rotman-baycrest.on.ca). PLS can be run in a data-driven fashion, in which orthogonal latent variables (LVs) are produced identifying a combination of i) contrasts between condition, groups, and/or behaviors and ii) spatial patterns across the brain expressing this contrast. The number of LVs produced in data-driven analyses increases as the "dimensionality" (i.e. number of groups, conditions, and/or behaviors) of a design increases. An alternative user-driven approach involves imposing *apriori* contrasts on the data (one LV for each contrast). The significance of each LV is assessed by permutation testing, determining how likely the observed effect is to occur from random noise. In this study, we varied design dimensionality in fMRI simulations to assess the

likelihood of getting significant effects (α=.05) for data-driven and user-driven PLS methods using data that should produce null results. For task PLS, on each simulation, we used resting-state data from the Human Connectome Project (N=50), pseudo-randomly assigned conditions to blocks and calculated mean percent signal change for each condition. For behavior PLS, we used task data (N=46) with 2 conditions (task and rest), and random vectors were generated on each simulation to act as behaviors. In task PLS, dimensionality was manipulated by changing the number of conditions in the design (2-6); in behavior PLS, we changed the number of conditions (1-2) and behaviors (1-4). For each design, 1000 data-driven PLS simulations were run, and the *p*-value of the LV explaining the most variance (i.e., LV1) was recorded for each simulation. These results were compared to 1000 user-driven simulations. Results for data-driven PLS showed that while false positive rates were ~5% (i.e., α) for designs with low dimensionality (i.e., task PLS with 2 conditions; behavior PLS with 1 condition and 1 behavior), it monotonically increased as dimensionality increased. For task PLS with 6 conditions, 71% of simulations produced $p < .05$ effects. For behavior PLS with 2 conditions and 4 behaviors, 85% produced significant LVs. Importantly, this was not true for user-driven PLS (false positive rate of ~5% regardless of dimensionality). These results suggest user-driven forms of PLS more effectively minimize type-I error rates, and that, if data-driven forms of PLS are used, significance should be assessed with more stringent methods (e.g. split-half resampling).

Title: MEG estimates of connection stationarity differ between schizophrenic and normal control subjects

Authors: *S. E. ROBINSON[1], A. J. MANDELL[2]
[1]MEG Core Group, NIH/NIMH, Bethesda, MD; [2]Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: Temporo-dynamic symbolic transfer entropy (tdSTE) was developed to study the time-course of event-related and spontaneous information transfer between pairs of brain regions. It employs symbolic states based upon rank order in the selected phase space and implemented using a leaky integrator that maintains a running estimate of the marginal and joint

probability density functions (PDFs) as a function of time. The *1/e* decay rate of the PDFs must be short enough to reveal the information transfer fluctuations while being long enough to obtain statistically stabile transfer entropy (TE) estimates. For a 3-dimensional phase space, information transfer increases with faster decay rates for both experimental data as well as for random surrogate data. We observe that the excess transfer entropy (eTE), i.e., the difference between TE of the data and that of the random surrogate) as a function of decay rate reflects the stationarity of communication between a given pair of brain regions. The maximum of this function represents the time-scale that information transfer is most stationary. The shape of this curve reflects the dispersion of stationarity for information exchanges between a given pair of brain regions. We computed excess kurtosis (g2) as a measure of dispersion of eTE versus decay rate. We evaluated this measure for 7 normal control (Nc) and 7 schizophrenic (Sz) resting MEG datasets. The source waveforms for each of 26 regions of interest (ROIs) were computed using an extended source LCMV beamformer in a 70-185 Hz bandpass, resulting in 1300 forward and reverse pairs. For each pair, we computed eTE for 40 decay rates, in log steps, ranging from 50 ms to 5 seconds. The false discovery rate (FDR) of the g2 differences (Sz minus Nc) were computed for all ROI combination. We find significant differences between Sz and Nc subjects for pairs connecting prefrontal, frontal, temporal, and parietal regions. The results for pairs of regions with p(FDR) < 0.05 are shown in the table. These results suggest that the the decay rate of information transfer can be used to study neurological and neuropsychiatric disorders.

Title: Studying genetic influences on brain structure and functional connectivity using twin brains

Authors: *G. HWANG[1], A. KULKARNI[2], V. A. NAIR[3], B. B. BENDLIN[4], V. PRABHAKARAN[3], E. MEYERAND[1]
[1]Med. Physics, [2]Biomed. Engin., [3]Radiology, [4]Med., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Differentiating between genetic and environmental influences on the human brain using data from monozygotic (MZ) and dizygotic (DZ) twins allows for a better understanding of individual differences in brain and behavior. Here we use MRI data from the Human Connectome Project (HCP) with a unique approach to investigate this problem. 70 MZ (28.8±3.5 years, 39 Female), 67 DZ (29.1±3.5 years, 39 F), 67 sibling (28.4±3.3 years, 35 F, 1-3 years age difference), and 70 control (28.8±3.3 years, 39 F) pairs were analyzed. MRI images were acquired with 3T Siemens Skyra scanners using magnetization prepared gradient echo sequence (TR=2400ms, TE=2.14ms, 0.7 mm isotropic) for T1w, and simultaneous multislice imaging (8 bands, 72 slices, TR=720ms, TE=33.1ms, 2.0 mm isotropic, four 15-minute eyes fixated runs) for resting state functional scans. Data were processed with the HCP minimal processing pipelines. From the T1w images, 254 FreeSurfer features were extracted and normalized. Resting images, after standard processing steps, were further processed by independent-component-analysis X-noiseifier (FIX) correction. Bandpass filtering was applied (0.01-0.1Hz). Time series from 360 cortical regions from HCP's Glasser parcellation and 19 FreeSurfer-based subcortical regions were extracted. Pearson's correlations were computed to generate the connectivity matrices. For a given pair, the differences were calculated in the structural and functional features. To account for the arbitrariness in the order of subtraction, every difference was duplicated with its opposite sign value. The resulting difference features were compared between groups using the F-test, with Benjamini-Hochberg corrections. Only features that did not show significant differences between DZ and sibling groups, while showing significance in all other 5 comparisons (genetic comparisons) were considered to be influenced by the genetics. Many global volume measures and subcortical volumes, such as caudate, putamen, and cerebellum showed strong genetic influence ($p<0.01$ in genetic comparisons, while $p>0.2$ between DZ and sibling). Overall variances in the functional features were also the smallest in the MZ (0.039), then DZ (0.045), sibling (0.049), and control (0.058) groups. 15 resting connections, many of which from the visual or auditory cortices, showed significance. No structural or functional features that were consistently significant in all genetic comparisons showed significance

between DZ and sibling groups. High resolution HCP data with a careful method revealed the genetic influence in shaping the overall brain structures, subcortical volumes and functional connectivity.

Title: Interhemispheric similarities between diffusion measures of human brain white matter tracts

Authors: *G. LERMA-USABIAGA[1], T. GLOZMAN[2], B. A. WANDELL[1]
[1]Psychology Dept., [2]Electrical Engin. Dept., Stanford Univ., Stanford, CA

Abstract: Background. Vertical midline symmetries are characteristic of human body and brain structures. These symmetries extend beyond structure to tissue properties. In human white matter, for example, group level analyses show that MRI diffusion measures in homologous right and left hemisphere tracts are more similar (correlated) than measures between non-homologous tracts (Wahl et al., 2010, Li et al., 2012). These similarities have the potential to inform us about phylogenetic, ontogenetic, and functional properties; deviations from these similarities, particularly when observed in individuals, can detect, diagnose and predict pathologies. **Methods.** We analyzed diffusion weighted imaging data in seven datasets (N=1200). The measurements were made on a variety of scanners using different acquisition parameters. We developed quantitative measures of left-right similarities, at the individual subject level, of micro- and macro-structural properties of the white matter tracts. We compared the within subject left-right similarities to similarities between a participant and other individuals. **Results.** (A) There are significant differences in the diffusion data depending on MR scanner vendors, scanning sites and diffusion acquisition parameters. (B) A partial least square regression (PLSR) model that relates data from the two hemispheres eliminates site and sequence differences; the measurements in one hemisphere calibrate the model prediction for the other hemisphere. (C) The PLSR model explains about 90% (± 8%) of the variance between left and right hemisphere measured within participants and about 64% (± 12%) of the variance between a participant and the group mean; this value differs somewhat between tracts. (D) Most importantly, left-right

similarity indices can be calculated on individual participants, and these indices can diagnose an individual whose indices are inconsistent with the population distribution. **Conclusion.** We developed a fully automated site-independent tool to assess the similarity between diffusion measured in the major left-right tracts. These single-subject level MRI indices can be used to screen for anomalies in clinical and research settings.

Title: Consistency across brain normalization algorithms in DTI analyses

Authors: *H.-W. YEH[1], M. BERGAMINO[1], S. KHALSA[1,2], M. PAULUS[1]
[1]Laureate Inst. for Brain Res., Tulsa, OK; [2]Univ. of Tulsa, Tulsa, OK

Abstract: Reproducibility is an essential foundation of science. Various factors may contribute to inconsistent findings and we researchers should do our best to control them as much as possible. In research using diffusion tensor imaging (DTI), an important pre-processing step is normalizing individual brain maps to a consensus template for group analyses. Currently, multiple algorithms or software are available for normalization but little is known about the impacts of using different algorithms. In this work, we evaluated the consistency of five normalization algorithms (AFNI, ANTs, DARTEL, FSL, and SPM) in DTI skeletonized and voxel based analyses (VBA).
A sample of 154 subjects consisting of three groups, 50 healthy controls (HC) (26 F, age mean (SD): 33 (11) y, PHQ9: 0.68 (1.1)), 59 moderately severe and severe depression (HD) (36 F, age: 36 (11) y, PHQ9: 18.5 (3.1)), and 45 mild depression (LD) (26 F, age: 38 (11) y, PHQ9: 8.5 (1.6)), underwent DTI acquisition and their fractional anisotropy (FA) values were normalized by each of the five normalization algorithms. For skeleton analysis, a consensus mask was generated to cover skeleton areas shared by the five algorithms. Consistency was evaluated by ICC(3,1) statistic (ICC henceforth) from two-way mixed-effects (random subject + fixed algorithm) model.
For all algorithms and groups together, voxels in skeletonized analyses showed a median ICC (mICC) of 0.52 and inter-quartile range (IQR) (0.37, 0.66), and mICC 0.38 (0.29, 0.50) in VBA. Removing each algorithm at a time (i.e. using four algorithms) only slightly altered mICC, ranging from 0.51 (without SPM) to 0.56 (without DARTEL) in skeletonized and from 0.35

(without SPM) to 0.41 (without ANTs) in VBA. Similar consistency was observed across the five algorithms within each group, with mICC 0.54, 0.55, and 0.51 for HC, LD, and HD in skeletonized analyses and 0.39, 0.42, and 0.37 for HC, LD, and HD in VBA, respectively.
In summary, consistency was poor to fair across normalization algorithms, and no single algorithm was substantially less or more consistent than the others; consistency was slightly lower in HD group than the other groups. Note that (a) ICC only indicates to what extent the algorithms are consistent, but not which algorithm is most valid (close to ground truth); (b) our findings refer to consistency "across" algorithms, but not "within" algorithms, which require repeated DTI scans. Further investigations are needed to achieve more consistent results. In conclusion, we suggest practitioners and reviewers bearing this information in mind when they compare results obtained from different normalization procedures or analysis methods.

Title: Robust fMRI hyperalignment based on repeated movie stimuli

Authors: *H. MANDELKOW, J. DE ZWART, J. DUYN
NIH / NINDS / LFMI / AMRI, Bethesda, MD

Abstract: The imprecision of anatomical alignment methods commonly limits the spatial resolution and sensitivity of conventional fMRI analysis based on the univariate general linear model. Recently proposed machine-learning methods circumvent the between-subject alignment problem using various forms of common factor analysis, which compute a linear projection of the fMRI signal from each subject's anatomical space to a common albeit abstract "functional" space [1]. Such "*hyperalignment*" methods achieve highly significant classification accuracies in all published experiments, although their sensitivity is often boosted by aggregating multiple consecutive fMRI volumes to create larger, more distinctive patterns at the expense of temporal (stimulus) specificity [2].
We recently demonstrated that PCA-LDA classifiers achieve high classification rates for individual fMRI volumes of the fMRI response to naturalistic movie stimuli presented repeatedly to the same subject [3]. Using *hyperalignment* based on a constrained PCA of the global BOLD signal patterns from multiple subjects, we now confirm that the same classifiers also achieve high classification accuracy in between-subject classification, distinguishing even single fMRI

volumes 2s apart. Both within- and between-subject classification seems to rely primarily on large-scale fMRI signal patterns that are robustly reproduced across experimental runs and subjects. Our data show that the optimal fMRI resolution for such experiments is relatively low (~3mm) and that within-subject averaging of the training data in conjunction with dimensionality reduction by PCA most effectively increases classification accuracy. We conclude that a judicious choice of fMRI resolution, repeated training stimuli and robust classification algorithms based on PCA and the Mahalanobis distance are key to making fMRI hyperalignment robust enough for practical applications in detecting cognitive or psychiatric conditions on a single-subject basis.

Title: Cluster failure or power failure? Balancing the scale with sensitivity

Authors: *S. M. NOBLE[1], D. SCHEINOST[2], R. T. CONSTABLE[2]
[1]Interdepartmental Neurosci. Program, [2]Radiology and Biomed. Imaging, Yale Univ., New Haven, CT

Abstract: Summary: Pioneering work in human neuroscience has relied on the ability to map activations using task-based fMRI, but recent work posed a major challenge to the field. Conventional methods for performing multiple comparisons corrections (MCC) were shown to yield insufficient specificity. However, that study's emphasis on specificity, although important, is incomplete. The accuracy of a method depends not only on its specificity but also its sensitivity, yet little research has been done on the sensitivity of MCC methods. As a first step, the present study extended publicly available scripts to perform a simulation of simple synthetic activations in real, resting-state data. The sensitivity of several procedures were assessed, as well as the spatial distribution of detected effects. **Methods:** For each grey matter voxel, an activation was synthesized using each combination of effect size (Cohen's *d*=small, medium, large), radius (r=8mm, 12 mm), and diffuseness (+/- smoothing). A subset of previously tested MCC methods were used to assess for activations: AFNI OLS (based on simulation of smoothness) and FSL

Perm (nonparametric). A previously untested, threshold-free method was added: FSL TFCE+Perm. To perform multiple tests at each of 10,000 voxels, scripts were parallelized for the Amazon cloud. To confirm the real-world relevance of this work, analyses will be repeated in task data. **Results:** At typical thresholds (CDT p=0.01), sensitivity of conventional methods to large effects was less than 5%, while sensitivity of TFCE was more than three times greater. In comparison, without correction, sensitivity is expected to be 80%. However, using a more stringent CDT increased sensitivity to levels about four times greater than TFCE. Across all tests, sensitivity to small effects was less than 1%. Spatial distributions of true and false positives were nonuniform and moderately correlated with one another (except for TFCE), though weakly or not correlated with the underlying smoothness. **Conclusion:** While we aim to confirm these results in real data, this work suggests that the power to detect effects using conventional MCC methods may be unreasonably low for the purposes of most studies. In addition, power is systematically even lower in many areas, suggesting a literature biased against detecting effects in many areas and a need to adopt spatially non-uniform corrections. Recently proposed strategies to improve sensitivity are crucial because optimizing for specificity, without considering sensitivity, undermines the accuracy and reproducibility of neuroimaging research. The present work adds to mounting evidence that it is time to balance the scale.

Title: Links between brain connectivity and cognitive performance in temporal lobe epilepsy

Authors: *R. RODRÍGUEZ CRUCES
Inst. of Neurobio., Natl. Autonomous Univ. of Mexico, Queretaro, Mexico

Abstract: Temporal lobe epilepsy (TLE) is the most common focal drug-resistant epilepsy and has been associated with white matter (WM) damage that extends beyond the epileptic focus (Otte el al; Epilepsia 2012). Neuropsychological evidence of structure-related cognitive impairments in TLE suggests that widespread structural anomalies relate with inter-individual cognitive performance differences in TLE (Rodriguez-Cruces et al; Epilepsy&Behavior 2017). Identification of specific patterns of network changes related to a particular cognitive profile is

highly relevant for the prognosis and adequate diagnosis in a progressive chronic disease such as TLE. We sought to relate cognitive performance to structural connectome in an integrative analysis. Our overall goal is to establish a particular pattern of white matter connectivity associated with a specific ensemble of clinical and neuropsychometrical features in TLE patients. We acquired structural magnetic resonance imaging (MRI) from 33 drug-resistance temporal lobe epilepsy patients and 25 -age and -sex matched healthy controls using a 3 T scanner. All subjects completed a full battery of cognitive tests (WAIS-IV & WSM-IV). A subject-level brain parcellation was estimated using a cortical (freesurfer) and subcortical segmentation tools (Manjón and Coupé 2016); which constituted the network nodes. Edge connection strength was calculated with streamline counts derived from anatomically constrained tractography and spherical deconvolution informed filtering of tractograms between two nodes (Smith, 2016). We obtained a 162x162 structural connectome matrix for each subject. Cognitive data were normalized to control using a z-score transformation and sorted into ipsilateral/contralateral to the seizure focus. Relationships between cognitive and connectome was established using canonical correlation analysis with strict control to avoid false positives.The current study explore cutting-edge methodology on a clinical population like TLE were we seek specific patterns of structural brain connectivity that relates to a particular cognitive profile in a multivariable manner.

Title: Network analysis in disorders of consciousness: Four problems and one proposed solution (exponential randomgraph models)

Authors: *J. DELL' HALIA[1], M. JOHNSON[2], M. M. MONTI[2]
[1]Los Angeles, CA; [2]UCLA, Los Angeles, CA

Abstract: In recent years, the study of the neural basis of consciousness, particularly in the context of patients recovering from severe brain injury, has greatly benefited from the application of sophisticated network analysis techniques to functional brain data. Yet, current graph theoretic approaches, as employed in the neuroimaging literature, suffer from four important shortcomings. First, they require arbitrary fixing of the number of connections (i.e.,

density) across networks which are likely to have different “natural” (i.e., stable) density (e.g., patients vs controls, vegetative state vs minimally conscious state patients). Second, when describing networks, they do not control for the fact that many characteristics are interrelated, particularly some of the most popular metrics employed (e.g., nodal degree, clustering coefficient) - which can lead to spurious results. Third, in the clinical domain of disorders of consciousness, there currently are no methods for incorporating structural connectivity in the characterization of functional networks which clouds the interpretation of functional differences across groups with different underlying pathology as well as in longitudinal approaches where structural reorganization processes might be operating. Finally, current methods do not allow assessing the dynamics of network change over time. We present a different framework for network analysis, based on Exponential Random Graph Models (ERGM), which overcomes the above limitations and is thus particularly well suited for clinical populations with disorders of consciousness. We demonstrate this approach in the context of the longitudinal study of recovery from coma. First, our data show that throughout recovery from coma, brain graphs vary in their natural level of connectivity (from 10.4% to 14.5%), which conflicts with the standard approach of imposing arbitrary and equal density thresholds across networks (e.g., time-points, subjects, groups). Second, we show that failure to consider the interrelation between network measures does lead to spurious characterization of both inter- and intra-regional brain connectivity. Finally, we show that Seperable Temporal ERGM (STERGM) can be employed to describe network dynamics over time revealing the specific pattern of formation and dissolution of connectivity that accompany recovery from coma.

Title: A method for conducting fMRI-guided, electric field optimized transcranial magnetic stimulation at any cortical site

Authors: *N. L. BALDERSTON, C. ROBERTS, E. MASI, Z.-D. DENG, T. RADMAN, B. LUBER, S. H. LISANBY, M. ERNST, C. GRILLON
Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Transcranial magnetic stimulation (TMS) is a noninvasive method to stimulate the cortex using time-varying magnetic pulses. With the advent of neuronavigation and figure-8

coils, researchers can target specific cortical regions with sub-centimeter accuracy. Capitalizing on this spatial specificity, it is possible to target specific ongoing cognitive processes with a high-degree of functional specificity. Although there are many existing TMS targeting methods, many of these do not account for individual differences in head size/shape or neural anatomy or are not generalizable to regions of the brain without obvious behavioral outputs (e.g. prefrontal cortex). Functional magnetic resonance imaging (fMRI), a widely used method to study brain activity, can deliver subject-specific, high-resolution maps of the entire brain that reflect changes in metabolic activity due to task demands. Recent advances in electric-field (E-field) modeling have made it possible to estimate the current induced in the brain, given a coil location, geometry, and orientation, and this process can be iterated across possible orientations to identify the optimal configuration. In this work, we combined these tools to create a generalizable workflow for subject-specific TMS targeting, capable of optimizing both the site of stimulation, and the coil orientation. We tested the algorithm using data from an ongoing repetitive TMS study using working memory related BOLD activity to target the right dorsolateral prefrontal cortex. We used 3 different a priori target definitions (anatomical, functional, and meta-analytical) compared to no a priori target definition. We found that constraining the fMRI targeting using any of the a priori regions of interest: 1) reduced variability in the location of the fMRI target across subjects, 2) reduced the overall scalp-to-cortex distance of the TMS target and hence the stimulation intensity, 3) reduced the variability in optimal coil orientation across subjects based on iterative E-field modeling. Together these results suggest that fMRI data can reliably identify functional neural targets for TMS, given a priori target definitions. Additionally, by combining this approach with iterative E-field modeling, our pipeline can determine both the optimal site and coil orientation for stimulation. Finally, because this approach relies only on an a priori target region and a task to activate the target region, it is generalizable to other cognitive neuroscience paradigms and regions of interest.

Title: Testing emotional attachment and mutuality (team) fmri task for studying dyadic interactions

Authors: *K. BURROWS[1], K. L. KERR[2,1], D. C. DEVILLE[3,1], E. L. RATLIFF[2,1], K. T. COSGROVE[3,1], J. BODURKA[1,4], M. P. PAULUS[1], A. S. MORRIS[1,2], W. K. SIMMONS[1,5]
[1]Laureate Inst. for Brain Res., Tulsa, OK; [2]Human Develop. and Family Sci., Oklahoma State Univ., Tulsa, OK; [3]Dept. of Psychology, The Univ. of Tulsa, Tulsa, OK; [4]Stephenson Sch. of Biomed. Engin., Univ. of Oklahoma, Tulsa, OK; [5]Janssen Res. & Development, LLC., LaJolla, CA

Abstract: The Testing Emotional Attachment and Mutuality (TEAM) task is a cooperative game designed to assess brain hemodynamic responses in each member of a dyad when the other member makes a costly error. The TEAM aims to probe and measure how brain circuitry underlying attachment and mutuality responds when the 'other' has let that individual down. During task trials, a sequence of 4 colored arrows is displayed two times for 6 seconds, after which the subject has 4 seconds to reconstruct the sequence by pressing colored buttons on a response box. This is followed by a 6-second 'reveal'/feedback period, in which the subject sees his/her own response and a pre-generated response for the other member of dyad. On true feedback trials, the subject is shown his/her response and feedback that the other person's response was correct. On enforced error trials, the feedback is pre-generated to reveal that the other person's response was incorrect, resulting in a loss of money for both subjects. A 6-second 's' detection trial was used as an active baseline condition, in which subjects were instructed to look for letter "s" from a random 20-letter string. No money was at stake during the 's' detection trials. Three runs of the TEAM task were created based on optseq2, with each run containing 14 true feedback, 3 enforced error, and 14 's' detection trials.
Prior to scanning, subjects were instructed on how to perform the TEAM task together and told that they would start out with $50 as a team, and that $5 would be deducted from their earnings for each error made while performing the TEAM task, regardless of which subject made the error. However, subjects are not aware that they are not completing TEAM task together and that the feedback regarding the other member's performance has been pre-programmed.
22 healthy adults (2 male, age: 30 - 53 years) and 25 adolescents (9 boys, age: 14 - 16 years) completed the TEAM task while being scanned concurrently on two 3T GE MR750 MR scanners as part of a parent-child interaction study. Using AFNI, the beta values derived from the contrast of enforced error versus true feedback were extracted for each subject, then included in a one sample t-test for adults or adolescents. All statistical maps were corrected for multiple comparisons at $p < 0.05$ with a voxel-wise $p < 0.005$.
Anterior insula, caudate, thalamus, hypothalamus, ventral tegmental area, ventral pallidum and striatum, inferior frontal and precentral gyrus, medial and superior frontal gyrus were activated in response to enforced error compared to true feedback in both adult and adolescent subjects. Results show the TEAM task successfully recruitment of brain emotional processing and regulation circuitry.

Abstract: Maintaining ecological validity within fMRI neuroimaging paradigms continues to be a significant challenge in conducting research with human participants. Social constructs, such as how parent-child interactions may affect child development, can be particularly difficult to study and quantify. The Dyadic Inter-Brain Signaling (DIBS) Project aims to understand how parents' emotion regulation affects adolescents' emotion regulation as well as to identify the neural basis (e.g., brain neurocicuitry) underlying these dyadic influences. In order to examine these fundamental constructs in an ecologically valid manner, parents and their adolescent children completed a conflict resolution task while undergoing fMRI hyperscanning. The task is divided into two parts. First, the parent-child dyad is prompted to describe a specific conflict that they have reported occurs often between them (e.g., "chores at home") for 2 minutes. This is followed by a prompt to resolve the conflict through collaborative problem solving for another 2 minutes. Using fMRI, each dyad was scanned simultaneously to measure the neural responses underlying these interactions. Dyads communicated via headphones and microphones. Participants completed three scanning runs, with a different conflict presented in each run. The audio files from each run were then transcribed and coded for emotionally valenced statements. Statements made by participants were coded based on 11 different categories; 5 positive categories (e.g., validation) and 6 negative categories (e.g., derisive humor). In previous studies done outside the scanner, the transcriptions have been broken up into 10-second "talk-turns" which are then coded into a specific category. To accommodate fMRI, coding has been adapted to record the onset and duration of each individual coded statement in order to use these variables as regressors in fMRI data analysis. To date, transcriptions from 17 dyads have been coded. To insure internal validity, 71% of the transcriptions have been coded twice or cross-checked with 81% reliability. The acceptable level of reliability for traditional behavioral tasks is 85% with 25% of the total transcriptions cross-checked. The introduced method of behavioral coding holds great potential

for a wide range of neuroimaging studies, and demonstrates advancement in ecological validity for fMRI.

Title: A free-speech paradigm for studying dyadic interactions with fMRI hyperscanning

Authors: *K. L. KERR[1], A. J. MOORE[2,1], M. MISAKI[2], E. L. RATLIFF[1,2], K. T. COSGROVE[3,2], D. C. DEVILLE[3,2], K. BURROWS[2], S. F. TAPERT[4], W. K. SIMMONS[5], J. BODURKA[2,6], A. S. MORRIS[1,2]

Engin., The Univ. of Oklahoma, Norman, OK

Abstract: Human cognition, behavior, and development are all significantly influenced by relationships and social interactions. The vast majority of neuroimaging studies to date, however, involve the presentation of stimuli to individual participants while their brain responses are measured in isolation, with limited ecological validity. The study of social interactions is critical for understanding adolescence, as relationships with parents and peers significantly shape development at this stage. We therefore developed a paradigm in which parents and their adolescent children can interact while both are undergoing concurrent fMRI scanning (e.g., hyperscanning) at 3 Tesla with a 32-channel head coil (image resolution of $2.5x2.5x2.9mm^3$). Parents and their adolescent children were scanned simultaneously and asked to discuss specific conflicts that they have with each other. Participants communicated via active noise cancellation headphones and a microphone while in the MRI scanners. To address and suppress the speech-related motion artifacts in acquired fMRI data, we employed a continuous-speech 'de-noising' procedure developed by Xu et al. (2014). This procedure uses a dual-mask spatial independent component analysis method to pinpoint imaging artifacts based on their extracerebral spatial origins. An automated independent component classifier is then used to identify noise components, and the dataset is reconstructed by subtracting the noise components from the time

series. The de-noising procedure significantly reduced speech-related artifacts (reduction in average motion from 0.34 to 0.03, based on AFNI's 'enorm' value). For task-based fMRI analyses, participant speech was transcribed and coded for specific types of emotionally valenced statements in order for coded statements to be used for regressors of interest in task-based analyses. The quality of parent-adolescent interactions while in the MRI scanner is similar to what has been observed in prior studies that have used this task outside of the scanner, with an average number of 28 codable statements made by each member of the dyad over 3 scanning runs (total discussion time of 12 minutes). Results demonstrate that it is possible to successfully study real-life social situations, such as conflict discussions between parents and their children, while participants undergo fMRI scanning. Importantly, this methodology has wide applicability to study the neural bases of many social constructs with advanced, non-invasive neuroimaging.

Title: Multi-scale topological impairments of brain networks characterized by centralities in SCD, aMCI and AD

Authors: *L. JIANG[1], K. QIAO[2], Y. HAN[3], X.-N. ZUO, SR[2]
[1]Cognitive and Developmental Psychology, Inst. of Psychology Chinese Acad. of Sci., Beijing City, China; [2]Inst. of Psychology Chinese Acad. of Sci., Beijing, China; [3]XuanWu Hosp. of Capital Med. Univ., Beijing, China

Abstract: Evidence suggests that there were topological impairments in brain networks of Alzheimer's disease (AD) patients. However, few studies were performed in the perspective of multi-scale topology and across the entire AD progression. In the present study, four network centrality analyses at different scales of topology were performed with resting state functional Magnetic Resonance Imaging (rs-fMRI) on 32 subjective cognitive decline (SCD), 37 amnestic mild cognitive impairment (aMCI), 30 AD and 40 normal controls (NC): Degree Centrality (DC)

at local scale, Subgraph Centrality (SC) at meso-scale, Eigenvalue Centrality (EC) and Page-rank Centrality (PC) at global scale. All scans were acquired on a 3.0 T Siemens scanner (Erlangen, Germany) at Xuanwu Hospital, Capital Medical University. And all the images were preprocessed using Connectome Computation System (CCS) in our laboratory. Our results revealed that SCD, aMCI and AD all displayed multi-scale topological impairments in multiple brain regions, and SC in the left limbic network in SCD correlated with episodic memory positively. Decreased meso-scale centrality in SCD, bidirectional alterations in multiple scale centralities in aMCI and increased meso-global scale centralities in AD indicated that the deterioration process of AD might be associated with the increase of network topology scale. Such systematical clinical dimension across the entire AD progression as well as multiple scale topological characterization within intrinsic functional connectome of human brain, would supply new insights into the elucidation of neuroimaging pathology of AD.

Title: Individual brain charting, a high-resolution fMRI dataset for cognitive mapping of the human brain

Authors: *A. L. PINHO, B. THIRION
INRIA Saclay, Gif Sur Yvette Cedex, France

Abstract: Mapping functional neuroanatomy of the human brain has become a central challenge in cognitive neuroscience and it constitutes an essential step toward linking brain systems and behavior. While there is a rich literature on the neural correlates underlying task performence, little is still known about the overall functional organization of the brain and how it can be translated into cognition. Neuroimaging techniques, such as Functional Magnetic Resonance Imaging (fMRI) have contributed to the investigation of brain regions involved in a variety of cognitive processes. However, to date, no data collection has systematically addressed the functional mapping of cognitive mechanisms at a fine spatial scale. The Individual Brain Charting (IBC) project stands for a high-resolution (1.5mm) multi-task fMRI dataset that intends to provide the objective basis toward a comprehensive functional atlas of the human brain. The data refer to a cohort of 12 participants performing many different tasks. The large amount of task-fMRI data on the same subjects yields a precise mapping of the underlying functions, free from both inter-subject and inter-site variability. Here, we present the first release of the IBC dataset, which comprises a dozen of tasks, addressing both low- and high- level cognitive functions. The corresponding data-descriptor article is currently in press (Pinho et al., 2018) and the source data plus derivatives are publicly available in the OpenfMRI repository (ds000244) and NeuroVault (id2138), respectively. Future outcomes concern to the development of a neurocognitive atlas derived from the dataset, which will rely on the functional signatures of the tasks and their mutual cognitive components. They can be inferred from maps of brain activation, using mega-analytic approaches. Particularly, data-driven methods will be herein employed for the extraction of the fundamental networks that represent the neural basis of such cognitive components. The atlas will account for a full revision of the neural correlates associated with behavior. It can thus provide a better understanding of cognition in the human brain and its regulation by brain functioning across individuals.

Title: Topological brain network changes in psychiatric disorders

Authors: P. RAZAEINIA[1], *R. M. CARTER[2]
[1]Univ. of California San Diego, San Diego, CA; [2]Dept. of Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Brain network analysis has shown promise for characterizing psychiatric disorders but commonly employed graph measures confound network shape and efficiency. Previously described network efficiency changes could occur in all or only part of the brain network. To improve characterization of brain networks in psychiatric disorders we utilize hitting time to resolve existing confounds in functional brain network measures and identify theoretically important information processing structures. We show that skewness of the hitting-time distribution correlates with the presence of path-like features similar to sensory processing subnetworks common in the brain. Using a publicly available dataset, we find evidence that skewness in the distribution of hitting times of functional connectivity decreases as the sensory network is engaged in a task. Skewness is also greater in resting-state networks of individuals with schizophrenia and bipolar disorder providing potential public health relevance.

Title: Deep gray matter volume and intrinsic functional connectivity following complex perioperative critical care for noncardiac congenital anomalies: Pilot study

Authors: C. R. L. MONGERSON[1], D. J. HODKINSON[1,3], D. ZURAKOWSKI[1,3], R. W. JENNINGS[2,3], *D. BAJIC[1,3]
[1]Dept Anesthesiol., [2]Surgery, Boston Children's Hosp., Boston, MA; [3]Harvard Med. Sch., Boston, MA

Abstract: Objective. There is a fundamental gap in our understanding of how complex perioperative critical care in *full-term* infants affects brain development. *We hypothesized that critically ill premature patients <1 year old, compared to full-term patients and healthy infants, would exhibit (1) smaller deep gray matter (DGM) volumes and (2) altered intrinsic functional connectivity following complex noncardiac perioperative critical care, as determined by MRI.* Methods. Full-term (n=13) and preterm (n=12) patients, and healthy controls (n=10), <1 year corrected age underwent non-sedated MRI scans following completion of surgery and critical care management for noncardiac gastrointestinal congenital anomalies (e.g. long-gap esophageal atresia), as per IRB approval at Boston Children's Hospital. 3T MRI scanner with a 32-channel receive-only head coil (Siemens, USA) acquired high-resolution structural images using FSE sequence [TR/TE= 12430/110 ms; FA 120°; 2 mm slices; 0.35 mm^2 voxels]. Resting-state functional MRI (rs-fMRI) data were acquired using BOLD sequence [GE-EPI, TR/TE = 1830/36 ms; 2 mm^3 voxels; FA 65°; 280 volumes]. Morphologically Adaptive Neonatal Tissue Segmentation tool was used to segment T2-weighted structural images to obtain DGM volumes, presented as absolute (cm^3) and normalized (% total brain volume) measures. Rs-fMRI data was preprocessed using customized scripts written in MATLAB, including a participant-level motion scrubbing strategy excluding volumes with framewise displacement > 0.25 mm. Intrinsic networks were evaluated using independent component analysis. Components reflecting *basal ganglia, thalamic-cerebellar,* and *salience networks* were further analyzed. Statistics was performed using a general linear models regression approach to compare groups with corrected age at scan as a covariate. Results. Absolute DGM volumes were decreased in patients (irrespective of the gestational age) compared to controls (i.e. main effect of group; $F(32,2)=6.9$, $p=0.003$), but not when normalized to total brain volume ($F(32,2)=1.9$, $p=0.169$). Preliminary rs-fMRI analysis showed significantly higher functional connectivity within the *basal ganglia network* of patients, but no group differences for thalamic-cerebellar and salience networks. Conclusions. Our preliminary data suggest complex perioperative critical care in infancy is associated with structural and functional changes in DGM development regardless of gestational age at birth. Future studies should evaluate basal ganglia volumes, as well as possible long-term neurobehavioral sequelae including pain sensitivity, motor function and emotional processing.

Title: Explainable deep learning of neuroimaging reveals key structural deficits in schizophrenia

Authors: *A.-C. YANG[1], C.-K. PENG[2], C.-P. LIN[3], S.-J. TSAI[4]
[1]Div. of Interdisciplinary Med. and Biotech., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Div. of Interdisciplinary Med. and Biotech., Beth Israel Deaconess Med. Center, Boston, Boston, MA; [3]Inst. of Brain Sci., Natl. Yang-Ming Univ., Taipei, Taiwan; [4]Dept. of Psychiatry, Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Background: Deep neural network (DNN) has facilitated the record-breaking of classification accuracy in fields such as speech or visual object recognition. However, limited studies have investigated the applicability of DNN to three-dimensional neuroimage data, and the interpretation of deep learning model remains like a black box. Here, we present an explainable DNN framework to identify key structural deficits in schizophrenia. **Methods:** Structural brain magnetic resonance images (MRI) were obtained from 200 schizophrenic patients and 200 age- and sex-matched healthy control subjects. The brain MRI images were normalized and segmented into gray matter (GM), white matter (WM), and cerebrospinal fluid (CSF) space. We introduced an original KL-L1 regularization method as a feature selection layer in the DNN to reduce dimensionality of neuroimage data and automatically identify key brain voxels without prior knowledge of brain pathology. **Results:** The DNN classifier with KL-L1 regularization achieved an average test accuracy of 91.7% in WM, an average of 87.5% in GM, and 75.5% in CSF. The key GM voxels identified by the DNN were within brain regions including insula, precuneus, and superior temporal pole; WM voxels were associated with neural tracts, such as cingulum/hippocampus, splenium of corpus callosum, and posterior corona radiata. **Conclusions:** The present study shows that the DNN with KL-L1 regularization can identify key structural deficits that are effectively related to the known structural pathology of schizophrenia. We anticipate that this explainable deep learning approach may provide a useful framework for the search of objective biomarkers of mental illness in future studies.
