Title: Pathological changes in microglia during cerebellar postnatal development in a mouse model of Niemann Pick type-C disease

Authors: R. S. ALTRECHE, B. R. BOYLE, *I. SOTO;
Rowan Univ., Glassboro, NJ

Abstract: Niemann Pick Type-C disease (NPC) is a lysosomal storage disease that is acquired by autosomal recessive inheritance. It is mostly caused by deficiency of the NPC1 protein, which transports cholesterol out of the lysosomes, therefore abnormal accumulation of cholesterol and other lipids in endosomes and lysosomes is a hallmark of NPC. Purkinje cells (PCs) in the cerebellum are hypersensitive to NPC1 deficiency, degenerating earlier and to a larger degree than other neurons in the brain. Previously, we found that in *Npc1^{nmf164}*mice activation of microglia is already detected at post-weaning age and precedes PCs degeneration, suggesting that NPC1 deficiency could alter microglia during cerebellar postnatal development. To determine the effects of NPC1 deficiency in cerebellar microglia during postnatal development, the migration, proliferation and maturation of developing microglia was studied using immunofluorescence and 3D image reconstruction analysis. It is known that during normal cerebellar postnatal development, microglia precursors migrate from the white matter region into the internal granule layer (IGL), then into the molecular (ML) and external granule layers (EGL). The location and number of microglia in the developing cerebellum was quantified; the number of microglia at the IGL, ML (where the dendrites of Purkinje cells reside) and the EGL was determined. We have found that in the first days of postnatal development there is a decreased number of microglia in the *Npc1^{nmf164}* mutant mice when compared to age-matched wild type (WT) mice. In contrast, we have found that overtime, there is an increase in the number of microglia in the ML of *Npc1^{nmf164}*mice when compared to age-matched WT mice. At 9-10 days, the number of microglia was remarkably higher in the ML of *Npc1^{nmf164}*mice than in WT mice. Similarly, at 14-15 days, the number of microglia was also higher in the ML of *Npc1^{nmf164}*mice than in the WT mice. Significant morphological differences between WT and *Npc1^{nmf164}*microglia were found, specifically shorter processes in the mutant microglia. Our findings suggest that microglia migration and/or proliferation may be delayed in *Npc1^{nmf164}* mice

during early postnatal days, however proliferative activity seems to be increased overtime in these mice when compared to WT.

Title: Precise integration of direct cell reprogramming - induced neuronal cells into adult neocortical circuits

Authors: *F. WANG[1], Y. LIU[2], X. LI[1], L. CHENG[2], X. ZHANG[1];
[1]State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China;
[2]Inst. of Neurosci. and State Key Lab. of Neurosci., Chinese Acad. of Sci., Shanghai, China

Abstract: Recent discovery of *in vivo* reprogramming of glia cells to neurons by defined neurogenic transcription factors in the adult brain has provided a new approach for neuronal replacement therapy. However, it remains completely unknown whether and how these direct cell reprogramming-induced neuronal cells (iNs) are functionally integrated into the existing neural circuits. We report here that in the adult mouse primary visual cortex (V1), the iNs, reprogrammed from astrocyte by a single transcription factor Ascl1, can develop proper distinct visual tuning functions and they are precisely integrated into the existing retinotopic map, compared to original counterparts. Matured iNs receive brain-wide afferent connections that are known to innervate the V1. They form fully-assembled structures of afferent and efferent synapses with pre-existing V1 neurons under electron microscopy. Thus, these *in vivo* findings strongly endorse promise for application of direct cell-reprogramming to the neural circuit reconstruction in a diseased or injured brain.

Title: Promoting oligodendrocyte differentiation in adult neural stem and progenitor cells by targeting G-quadruplex nucleic acid secondary structures

Authors: D. GOLDBERG[1], L. FONES[1], A. L. VIVINETTO[1], J. CAUFIELD[1], R. R. RATAN[2], ***J. W. CAVE**[2];
[2]Weill Cornell Med., [1]Burke Neurolog. Inst., White Plains, NY

Abstract: Neural stem and progenitor cells in the adult subventricular zone (SVZ) are a potentially important source of endogenous neural repair. Several different pathological conditions can stimulate this neurogenic niche to generate progenitors that migrate towards afflicted regions. This endogenous repair response, however, is usually inadequate to provide meaningful neuroprotection or repair. Thus, exploiting the SVZ neurogenic niche as potential source of endogenous repair requires the development of efficient methods to manipulate the proliferation and differentiation of SVZ derived neural progenitors. G-quadruplexes are nucleic acid secondary structures that are pervasive in the genomic DNA and RNA transcriptomes of mammalian cells. These structures regulate numerous cellular processes associated with gene expression and genome duplication, but their role in controlling the proliferation and differentiation of neural stem and progenitor cells is unexplored. In this study, we show that targeting nucleic acid G-quadruplex stability with small molecules can modify adult SVZ neural stem and progenitor cell proliferation and promote oligodendrocyte differentiation. We show that two related small molecules (pyridostatin and carboxypyridostatin) that differentially target DNA and RNA G-quadruplex stability reduce proliferation in the SVZ in vivo of adult mice. Using in vitro neurosphere cultures, however, our analyses reveal that targeting DNA G-quadruplex stability reduces proliferation by inducing DNA damage and apoptosis. By contrast, exclusively targeting RNA G-quadruplex stability with carboxypyridostatin does not induce cell death, but rather facilitates the production oligodenodrocyte progenitors when EGF and FGF2 growth factors are present. We also find that interperitoneal administration of carboxypyridostatin increases the number of Olig2-expressing cells in the cortex and corpus callosum of adult mice. Together, these findings suggest that RNA G-quadruplexes are an important, new class of molecular target for neural stem and progenitor cell engineering.

Title: A distinct role of polycomb group proteins in CNS myelination

Authors: *L. YANG, J. WANG, R. Q. LU;
Cancer and Blood Dis. Institute, EHCB, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Epigenetic regulation iscrucial for neural cell fate specification and maintaining proper cell identity. However, the epigenetic mechanisms that regulate oligodendrocyte lineage progression remain incompletely understood. The polycomb repressive complex 2 (PRC2) deposits the H3K27me3 mark on the promoters and enhancers of regulatory genes to silence their expression. Expression of H3K27me3 increases during the transition from oligodendrocyte precursors (OPC) to mature oligodendrocytes, while H3K4me3, which labels active chromatin, is enriched on OPCs. Eed and Ezh2, the core component of PRC2, are expressed in OPC and differentiated oligodendrocytes. Intriguingly, EED is detected in the nucleus of OPCs but in cytoplasm of mature oligodendrocytes. In vivo stage-specific conditional knockout indicates that Eed is necessary for maintaining OPC proliferation and differentiation, resulting in myelination defects, while deletion of Ezh2 impairs OPC differentiation but OPC proliferation. Though the mice with deletion of EED and EZH2 display oligodendrocyte differentiation defects at early developmental stages, EED knockout mice show sustained myelination defects in the developing CNS, while myelination defects in EZH2 knockout mice recovers at the adult stage, suggesting a non-redundant role of PRC2 complex components during oligodendrocyte development. Genomic occupancy analyses reveal thatEed targets Wnt and TGF-β signaling components, the negative regulators of OPC differentiation. Wnt and TGF-β signaling is upregulated in oligodendrocyte progenitors Eed mutant mice.Inhibition of Wnt and TGF-β signaling partially rescues oligodendrocyte differentiation defects caused by Eed loss. Furthermore, genetic deletion of Eed in OPCs impairs myelin repair after demyelinating injury. These data reveal a novel epigenetic regulated pathway and suggest an essential role for Eed in SVZ homeostasis and injury.Thus, our findings reveala distinct role of PRC2 complex proteins-mediated epigenetic regulation for myelination and maintenance of myelin homeostasis during CNS development and after injury.

Title: Altered fetal microglia phenotypes are associated with abnormal neurogenesis following maternal immune activation

Authors: M. LOAYZA, K. CARTER, L.-W. FAN, Y. PANG, *A. J. BHATT;
Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Maternal infection is a risk factor for Autism Spectrum Disorder (ASD). Although the underlying neuropathology remains largely unknown, neuroimaging studies consistently showed that there is a period of brain overgrowth in ASD infants, which may be caused by dysregulated neuronal growth. Given that microglia are critically involved in both neurogenesis and programmed neuronal death in homeostatic condition, whereas activated microglia are known to exhibit different phenotypes linked to either proinflammatory or anti-inflammatory functions, this study tested a hypothesis that lipopolysaccharide (*LPS)-activated fetal microglia altered neural development by promoting neurogenesis.* Time-pregnant C57BL/6J mice at E12.5 were injected with LPS (50 ug/kg body weight, i.p.) and controls received saline injection. On postnatal day 1 (P1) and P21, brain sections were prepared from mice pups for immunohistochemical analysis of microglia and neurons. Microglia phenotypes were assessed by flow cytometry on E15 and P4. We found that maternal LPS challenge significantly increased Iba1+ microglia in neurogenic regions including the subventricular zone (SVZ) of lateral ventricles and the dentate gyrus (DG) of hippocampus. The majority of microglia exhibited unique phenotype characterized with double positive immunostaining for CD86 and CD206 in the control E15 and P4 mice brain, which was significantly increased by LPS treatment. LPS exposure resulted in a marked increase of Ki67+ cells in the SVZ and DG, suggesting potential over-production of neurons. We also found that TGFb+ neurons, which were only observed in the deep (layer III-IV) but not the superficial layers (I-II) of control P1 mice, were distributed throughout cortical layers in LPS-treated pups. On P21, the total number of parvalbumin positive neurons in the medial prefrontal cortex was significantly lower in the LPS-exposed offspring mice than the controls. Overall, our data showed that a low dose maternal LPS exposure leads to enduring activation of fetal microglia, which is associated with increased neural progenitor cell proliferation and reduced PV+ neurons, and this may alter cytoarchitecture and local circuits in highly laminated structures such as the cerebral cortex and hippocampus.

Abstract: Recent developments have revealed the importance of lipids as biomarkers in different diseases and as indicators of the cell's homeostasis, in addition to their structural function. However, the limitations inherent to the assays used for lipidomic analysis hamper surfacing the complex relationships between lipid classes, lipid species and proteins. To overcome these handicaps, we developed cell membrane microarrays of different brain areas of non-human primate and rat to determine the lipid fingerprint of samples of different nature in a standardized and fast way, using MALDI mass spectrometry. Consecutive microarrays were also employed in enzymatic and immunohistochemical assays and the data obtained were analyzed together by supervised and unsupervised learning methods.
Several positive and negative correlations above 0.8 and below -0.8 were found between certain lipid species and even between some lipids and the expression of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and the activity of cholinesterases (ChE) and acetylcholinesterase (AChE). Some of these interactions between sulfatides, phosphatidylcholines (PC) and phosphatidylethanolamines (PE) or even ChE and AChE were equally high in rat and in non-human primate nervous system. In particular, an inverse relationship were determined in both species between [Sulfatide d42:2-H]- and [PC 32:0-H]-, characteristic lipids from white and grey matter respectively. Moreover, a good correlation was found between some sphingomyeline (SM) and sulfatide species and the GAPDH expression. Thus, these data indicate important relationships between cell membrane lipids and also proteins in the brain, although further research is required to determine the relevance of them in physiological and pathological conditions.

Title: Retinaldehyde dehydrogenase 2 is required for the production and maturation of oligodendrocyte precursors in the postnatal corpus callosum

Authors: *V. E. MORRISON, V. N. SMITH, J. K. HUANG;
Dept. of Biol., Georgetown Univ., Washington, DC

Abstract: Myelination of the central nervous system (CNS) relies on the production of oligodendrocytes (OLs) from oligodendrocyte precursor cells (OPCs). During the first month of postnatal life, OPCs that eventually populate the corpus callosum arise from neural stem cells (NSCs) in the dorsal subventricular zone (SVZ) of the lateral ventricle and then mature to generate myelinating OLs. However, the signals that regulate the production and maturation of OPCs in this region are not fully understood. In this study, we show that the retinoic acid (RA)-synthesizing enzyme retinaldehyde dehydrogenase 2 (RALDH2) is required for the production and maturation of postnatal OPCs in the corpus callosum. Deletion of RALDH2 in neural/glial antigen 2-positive ($NG2^+$) cells, including perivascular cells and OPCs, reduced total OL lineage cell number, disrupted OPC differentiation, and caused hypomyelination of the corpus callosum. Moreover, decreased OL lineage cell numbers coincided with reduced NSC survival and decreased sonic hedgehog (SHH) signaling in the SVZ. Additionally, astrocyte and cortical neuron numbers were reduced. Our work reveals a role for RALDH2-dependent RA synthesis by $NG2^+$ cells in regulating OPC development and myelination of the corpus callosum. Furthermore, we raise the possibility that paracrine RA signaling between $NG2^+$ cells and NSCs impacts neuro- and gliogenesis.

Title: Glial cell dysfunction as a result of 3D genome architecture changes in Trisomy-21 in iPSC and Ts65Dn mouse models

Authors: *E. R. LOCKSHIN[1], G. KUFFNER[2], H. MEHARENA[3], L.-H. TSAI[2];
[1]Picower Inst. For Learning and Memory, Cambridge, MA; [3]Picower Inst. for Learning and Memory, [2]MIT, Cambridge, MA

Abstract: Trisomy 21(T21) is a genetic disorder that results from triplication of chromosome 21, which causes genome wide disruption. Some of the phenotypes of T21 include intellectual disability, craniofacial abnormalities, hypocellularity of the brain, deficits in neurodevelopment,

and early onset of Alzheimer's disease (AD). TS21 has been shown to cause dysfunction in gene expression in different cell types, and the implications of T21 on glial cell function has not been investigated. Proper glial cell function is necessary for neurodevelopment, homeostasis, and healthy aging. Our primary focus is on astrocyte and microglia function. Astrocytes maintain the environment of the CNS for neural function and GABAergic signaling. As the resident immune cells of the CNS, microglia are responsible for synaptic pruning, responding to injury and pathogens. Dysfunctional microglia are implicated in many age-related diseases, including AD. Initial RNA-seq analysis of iPSC derived microglia and astrocytes indicates down regulation in gene expression for migration, cell cycle, neurodevelopment, and other pathways. We used iPSC derived glial cells to further investigate this cellular dysfunction, and compare them to an in-vivo model of Ts65Dn mice. Additionally, we looked at the changes in the 3D genome architecture of these cell types using Hi-C analysis. Understanding the physiological differences of these cell types in TS21 will allow future development of therapies for individuals with TS21.

Title: Using 3D brain organoids to model human astrocyte maturation and uncover the developmental origins of glioblastoma

Authors: *C. SOJKA[1], A. KING[1], A. TREVINO[2], G. CARSON[2], S. A. SLOAN[1];
[1]Emory Univ., Atlanta, GA; [2]Stanford Univ., Palo Alto, CA

Abstract: Astrocytes are the most abundant glial population in the human brain and yet we know little about their developmental origins and mechanisms of maturation. Further, although we are learning more about the role of astrocytes in guiding neural development, less is known about their own development and the implications of aberrant astrogenesis in neurodevelopmental disorders and oncogenesis. Human astrocytes undergo a profound maturation process during postnatal development that is evidenced by transcriptomic, morphological, and functional changes. In the case of glioblastoma (GBM), a brain cancer defined by uncontrolled astrocyte proliferation, astrocytes in the tumor core share a similar transcriptomic profile to that of fetal human astrocytes. We hypothesize that this similarity could either be a result of perturbed astrocyte development, abnormal astrocyte maturation, or aberrant astrocytic differentiation from other progenitor pools. Therefore, we sought to define the normal timeline of human astrocyte development, and to identify temporally-graded molecular drivers of astrocyte maturation and deviations of that process in instances of irregular astrocyte

development. One obstacle that has stymied attempts to study human astrocyte development has been lack of access to tissue samples at key developmental time points. To address this hurdle, we used 3D iPSC-derived brain organoids, supplemented with primary human fetal and adult cortical samples to define the genetic landscape throughout multiple stages of normal astrocyte maturation. Additionally, we analyzed the genetic landscapes of astrocytes purified from primary human GBM samples to determine the degree to which they deviate from normal astrocyte developmental trajectories and to pinpoint where on the maturation spectrum GBM astrocytes fall. Understanding the developmental origins of normal and neoplastic human astrocytes will help provide mechanistic insight into GBM formation and progression and uncover potential therapeutic targets for the treatment of GBM.

Title: Serotonin and brain plasticity in the hippocampus: The role of microglial cells

Authors: A. TURKIN[1,2], M. SIDOROVA[2], N. ALENINA[1], ***F. KLEMPIN**[1,3];
[1]Max-Delbruck-Centrum (MDC), Berlin, Germany; [2]Inst. of Life Science, Immanuel Kant Baltic Federal Univ., Kaliningrad, Russian Federation; [3]Charité Univ. Med., Berlin, Germany

Abstract: Microglia are resident immune cells of the adult brain and become activated in response to stimuli. Among the various functions, microglial cells release neurotrophins and cytokines to maintain homeostasis of neural circuits, but also express neurotransmitter systems. Serotonin (5-hydroxytryptamine, 5-HT) is a crucial signal in the neurogenic niche microenvironment of the hippocampus, involved in antidepressant action, and has recently been shown to enhance microglial response to injury in acute mouse brain slices. Genetically modified animal models that differ in their availability of serotonin, constitute powerful tools to study neuroplasticity and drug development. We took advantage of tryptophan hydroxylase 2 deficient (*Tph2*$^{-/-}$) rats, selectively depleted of brain serotonin, to determine the expression profile of various 5-HT receptors on microglial cells in the hippocampus and prefrontal cortex at postnatal day (P)8 and P21. In the presence or absence of brain serotonin, microglia cells of female and male transgenic rats and their littermates were FACS-sorted by flow cytometry for qPCR analysis. Surprisingly, we observed a significant increase in the population of CD11b-expressing

microglia in the dissected brain areas of *Tph2*$^{-/-}$ rats at P21, suggesting reduced serotonin-induced suppression of microglia activation in the absence of the neurotransmitter. Our data show high expression of 5-HT2b and 5-HT5a receptor subtypes, weak expression of 5-HT1b and 5-HT7. Furthermore, we analyzed mRNA levels of the brain-derived neurotrophic factor, BDNF- since we had shown previously that complete lack of brain serotonin induces BDNF signaling- and also of interleukin-6 upon microglia activation in *Tph2*$^{-/-}$ rats at P21. Together, our data indicate an important link between microglial cells and signals of the neurogenic niche, e.g. serotonin and BDNF, that could be employed as therapeutic targets.

Abstract: The mechanisms that drive the timing and specificity of oligodendrocyte myelination during development, or remyelination after injury or immune attack are not well understood. Recent work has shown that oligodendrocyte progenitors receive synapses from neurons, providing a potential mechanism for neuronal-glial communication. We hypothesize that these connections are important both for correct myelination of neurons during development and for myelination during neuronal plasticity. We utilize chemogenetic tools and viral monosynaptic circuit tracing to analyze these neuroglial connections and to examine OPC proliferation, myelination and neuronal-glial connectivity after altering neural activity *in vivo*.

Title: Histological and ultrastructural evidence of planarian myelin

Authors: *L. THOMPSON[1], M. SCOTTO[1], S. GUARIGLIA[2];
[1]St. Joseph By the Sea High Sch., Staten Island, NY; [2]New York State Inst. for Basic Res., Staten Island, NY

Abstract: Planarians are a small invertebrate flatworm which belongs to the class *Turbellaria*. They are hardy organisms and can be found in many environments throughout the world. In a laboratory setting, planarians are inexpensive and easy to maintain. To date, it is thought that planarians lack myelin, like other invertebrates. Recently, some studies have demonstrated that invertebrates do have myelin, although it is often structurally different than vertebrate myelin. Using whole mount preparations of planarian stained with fluoromyelin, a fluorescent dye that is used to stain myelin, we found robust staining in the brain and ventral cords of planarians. To confirm our finding, we prepared samples to be stained using Luxol Blue, the dye that is traditionally used to visualize myelin. We found the same staining pattern in our Luxol Blue stained planarian sections. We also immunostained the planarians using an avian Schwann cell marker, which reacted with the structures thought to be myelin. We then investigated the ultrastructure of the planarian brain, and found cells that resemble *Drosophila* glia. Finally, we exposed the planarians to cuprizone, the agent that is typically used to pharmacologically induce demyelination in vertebrate models. The planarians completely lost all fluoromyelin positive regions of brain and the ventral nerve cords. This finding suggests that the fluoromyelin positive regions which we identified are indeed myelin, as they are absent after an animal is treated with the demyelinating agent cuprizone. Our findings also suggest that planarian myelin is affected by cuprizone in the same manner that is found in vertebrates, which suggests that studies performed in planarians are translational to other organisms, making planaria a potential high throughput model for studying demyelinating conditions.

Title: Characterization of peripheral glia using single cell RNA-seq approach

Authors: O. E. TASDEMIR YILMAZ[1], *L. V. GOODRICH[2], R. A. SEGAL[1];
[1]Dana-Farber Cancer Inst., Boston, MA; [2]Harvard Med. Sch., Boston, MA

Abstract: The peripheral nervous system is comprised of multiple distinct sensory and autonomic ganglia. In all types of peripheral ganglia and peripheral nerves, glial cells are closely associated with neurons, and the number of peripheral glial cells is higher than the number of peripheral neurons. Although we know much about the diversity and function of neurons in these ganglia, the genetic profile and differences of the glial cells that associate with those neurons are still a mystery. In order to investigate the similarities and differences among these peripheral glial cells, we profiled the developing peripheral glia from two sensory ganglia, dorsal root ganglion (DRG) and spiral ganglion of the cochlea, using single cell RNA-seq approaches. From our dataset, we uncovered unique markers for subtypes of glial cells. In particular, we found that the glial progenitors have different dynamics in these distinct ganglia. Glial progenitors persist in DRG from embryonic development through the postnatal period, while the progenitor cell population in cochlea can be seen in early embryonic development but decrease rapidly and are not detected in the postnatal setting. This finding could have implications on the glial renewal differences in the two sensory ganglia. Interestingly, while the Schwann cells of the DRG and sciatic nerve closely resemble those found in the cochlea, the gene signature of satellite glia from DRGs and cochlea are clearly distinct from one another, satellite glia may serve different functions in the two ganglia. As both sets of satellite glia express astrocyte-like patterns of gene expression, satellite glia may modulate the development and function of the associated peripheral neurons and thereby contribute to sensory transduction.

Abstract: During adult hippocampal neurogenesis, the majority of newborn cells undergo apoptosis and are rapidly phagocytosed by resident microglia in order to avoid disturbing the surrounding neurons. Here, we propose that phagocytosis is not merely a passive process of corpse removal but has an active role in maintaining adult hippocampal neurogenesis. First, we found that neurogenesis was disrupted in mice chronically deficient for two microglial phagocytosis pathways (P2Y12, MerTK/Axl), but was transiently increased in mice in which MerTK expression was conditionally downregulated. We then followed an in vitro approach to perform a transcriptomic analysis of microglial phagocytosis and identified genes involved in metabolism, chromatin remodeling, and neurogenesis-related functions. Finally, we determined that the phagocytic microglia secretome limits the production of new neurons both in vivo and in vitro. Our data suggest that reprogrammed phagocytic microglia acts as a sensor of local cell

death, modulating the balance between cell proliferation and cell survival in the neurogenic niche, supporting the long-term maintenance of adult hippocampal neurogenesis.

Title: Zinc is essential for adult hippocampal neurogenesis

Authors: ***B. CHOI**[1], D. HONG[1], J. JEONG[1], B. LEE[1], J.-Y. KOH[2], S. SUH[1];
[1]Physiol., Hallym University, Col. of Med., Chuncheon, Korea, Republic of; [2]Neurol., Univ. of Ulsan Col. of Med., Seoul, Korea, Republic of

Abstract: Since the subgranular zone (SGZ) of the dentate gyrus (DG) is the most active neurogenic region and also the site where synaptic zinc is most highly concentrated in the mossy fiber terminals, we sought to explore the hypothesis that vesicular zinc is an important modulator for hippocampal neurogenesis. Our previous studies have demonstrated that chemical zinc chelation or dietary zinc deprivation both lead to reduced progenitor cell proliferation and impaired hippocampal neurogenesis. Both effects are reversed by zinc supplementation. To establish the role of zinc transporter 3 (*ZnT3*), a transporter of zinc ions from the cytoplasm into synaptic vesicles, in adult hippocampal neurogenesis, a genetic loss-of-function approach was employed using *ZnT3*$^{-/-}$ mice. Here we report that genetic deletion of *ZnT3* not only reduced progenitor cell proliferation and neuroblast production but also reduced neuronal maturation of newborn cells that survive in the DG. Furthermore, the present study also investigated the effects of zinc ($ZnCl_2$, 4 mg/kg), n-acetyl cysteine (NAC, 20 mg/kg) or $ZnCl_2$ plus 2NAC (ZN) supplement on hippocampal neurogenesis. Interestingly, compared to $ZnCl_2$ or NAC, administration of ZN was most effective in enhancing progenitor cell proliferation and neuroblast production. In addition, ZN supplementation reversed the *ZnT3* loss-associated reduction of neurogenesis via ERK and CREB activation. Therefore, the present study demonstrates for the first time that *ZnT3* and vesicular zinc are essential for adult hippocampal neurogenesis.

Title: Operant conditioning prevents the death of cells generated in the dentate gyrus of the adult rat

Authors: C. HUGGINS, *D. M. CURLIK, II;
Psychology, York Col. of Pennsylvania, York, PA

Abstract: Thousands of new neurons are produced each day in the dentate gyrus of the adult mammalian hippocampus. However, the majority of those cells die within weeks of their birth. The most effective way to prevent this cell death is through effortful and successful learning. Myriad studies have revealed that classical conditioning and spatial learning can prevent this cell death. However, little research has examined whether acquisition of an operant conditioning task with an appetitive reward also increases the number of surviving cells. Therefore, the current study was conducted to determine whether conditioning with an operant procedure would prevent the death of adult-born hippocampal cells. Adult male rats were trained with fifty trials of an operant discrimination procedure per day, for four consecutive days. In order to motivate animals to perform the task they were food restricted prior to conditioning, and food pellets were used as an appetitive reward during conditioning. Additional control animals were food restricted but not trained, or not food restricted and not trained. In order to ensure that exposure to food reward pellets did not alter neurogenesis, all animals received equal exposure to the pellets. Stereological analysis conducted approximately two weeks after training revealed that food restriction significantly decreased the number of surviving cells in the dentate gyrus ($p < 0.05$). However, training with the operant task prevented this decrease ($p < 0.05$). Together, these results indicate that food restriction decreased the number of surviving cells in the dentate gyrus, however training with an operant conditioning procedure was sufficient to attenuate that decrease.

Title: Galantamine prevents and reverses adolescent alcohol-induced deficits in hippocampal neurogenesis

Authors: *V. A. MACHT, R. P. VETRENO, F. T. CREWS;
Skipper Bowles Ctr. for Alcohol Studies, Univ. of North Carolina, Chapel Hill, NC

Abstract: Adolescent intermittent ethanol (AIE) exposure causes protracted reductions of hippocampal neurogenesis in adult rats. Previous studies have found AIE-induced reductions in neurogenesis are prevented by exercise, the non-steroidal anti-inflammatory drug indomethacin, and the HDAC inhibitor TSA, supporting the hypothesis that neurogenesis is reduced through long-lasting changes in proinflammatory/trophic gene expression in the hippocampal neurogenic niche. The current study expands on this hypothesis by testing whether the cholinesterase inhibitor galantamine (GAL), which has anti-inflammatory properties, can prevent and/or reverse decreases in hippocampal neurogenesis following AIE. In this study, we used a preclinical AIE model (5.0 g/kg/day i.g., 2-days on/2-days off from postnatal day [PND] 25-55) in male rats alone or combined with GAL. GAL (4.0mg/kg/day, i.p.) exposure was either 30 minutes before ethanol exposure (prevention) or daily following the cessation of AIE (reversal). On approximately PND 70, rats were euthanized and their brains were prepped for immunohistochemical staining for the neurogenesis marker doublecortin (DCX), the apoptotic marker cleaved caspase 3 (CC3), and the cell proliferation marker Ki-67. AIE reduced DCX+immunoreactivity (IR) by 37% and increased CC3+IR by 50% (p's < 0.05). GAL both prevented and reversed the AIE-induced reduction of DCX+IR (p's < 0.05). There was a main effect of GAL to increase Ki-67+IR by 56% (p < 0.05) indicating increased cell proliferation may contribute to restoration of AIE-induced reductions in hippocampal neurogenesis. Future studies will continue to probe mechanisms regulating AIE impaired neurogenesis. Supported by the Neurobiology of Adolescent Binge Drinking in Adulthood (NADIA) consortium of the NIAAA.

Title: Electrically stimulated hind-limb muscle contractions increase adult hippocampal neurogenesis in anesthetized mice

Authors: *J. C. GARDNER[1], S. DVORETSKIY[2], Y.-Y. YANG[1], D. A. LANGE[1], S. VENKATARAMAN[1], A. KATWALA[3], C. RENDEIRO[4], M. D. BOPPART[2], J. S. Sci., Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Regular exercise is crucial for maintaining cognitive health throughout life. Many exercise-induced neurological adaptations have been identified, particularly in the hippocampus, including increased numbers of new neurons in the dentate gyrus (DG). However, how exercise enhances hippocampal neurogenesis whether through factors released from contracting muscles that travel to the brain via the blood, or in response to acute activation of the DG from the physical exertion remains a mystery. The goal of this study was to test the hypothesis that muscle contractions alone, in absence of DG activation, are sufficient to increase adult hippocampal neurogenesis. Adult male, C57BL/6J mice were anesthetized, and exposed to bilateral hind-limb muscle contractions (both concentric and eccentric) via electrical stimulation (e-stim) of the sciatic nerve twice a week for 8 wk. Another group was treated similarly except without e-stim (sham control; n=16/group). BrdU was injected during the first 4 weeks to measure survival of new neurons in the DG at 8 wk. A follow-up experiment explored acute effects of e-stim on neuronal activation of DG. A group experienced one session of e-stim or sham treatment (n=8/group) and then was euthanized 90 min later to measure numbers of c-Fos-positive cells in DG. The chronic e-stim produced muscle adaptations including decreased fatigue and increased capillary density. Relative to sham control, the e-stim increased total number of BrdU cells in the DG by 26% and total volume by 10%. The sham and e-stim group displayed similar numbers of c-Fos positive cells. Results demonstrate that muscle contractions alone are sufficient to increase adult hippocampal neurogenesis, in absence of activation of DG, and while the animal is anesthetized. We speculate that specific chemical signals are released from the contracting muscles which pass into the brain from the blood to exert their influence on the brain.

Title: Effects of environmental enrichment on hippocampal circuitry and function

Authors: *M. FRECHOU, K. MCDERMOTT, E. WOOD, R. FERGER, J. GONÇALVES; Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Exposure to enriched environments (EE) improves performance in behavioral tasks that depend on the hippocampus, such as spatial memory and context discrimination. It also increases the number of newborn neurons added to the hippocampal dentate gyrus (DG) in the adult brain, which is thought to partly mediate its cognitive benefits. Conversely, decreasing adult neurogenesis results in cognitive deficits. Changes in connectivity patterns have been observed in the adult-born neurons (ABNs) of mice exposed to EE compared to mice housed in standard conditions. But overall, it is still unknown how the circuit properties of the DG change in EE, and which mechanisms underlie these changes. We hypothesize that exposure to behavioral experience during adult neuronal development results in changes in the functional patterns of ABN, resulting in altered spatial encoding and local network activity in the DG. To evaluate this, we use in vivo two-photon calcium imaging in head-fixed mice on a self-propelled treadmill to record the activity and spatial tuning of DG neurons, in mice exposed to EE compared to standard housing controls. Our goal is to parse out the effects of EE-dependent changes on the hippocampus and the contribution of ABNs to the observed effects. Understanding these changes and their underlying mechanisms will provide a novel framework for understanding how behavioral manipulations can have long-lasting effects on cognitive function.

Title: The effects of anesthesia on adult hippocampal neurogenesis in adult rats

Authors: J. L. KIM, N. E. BULTHUIS, *H. A. CAMERON;
Section on Neuroplasticity, NIMH/NIH, Bethesda, MD

Abstract: Following anesthesia and surgery, some patients show symptoms of cognitive dysfunction that can last months after their procedure. While it is still debated whether these cognitive deficits result from anesthesia or other aspects of surgery, studies have recently shown that prolonged sedation of rats with isoflurane or propofol impair performance on memory tasks, like the radial arm maze and fear conditioning, days or even weeks later. One proposed mechanism by which anesthesia may alter memory is by decreasing hippocampal adult neurogenesis. Although several studies have seen a reduction in cell survival after anesthesia in rodents, most studies have focused on vulnerable populations, like neonates and aged rodents. Currently, it's still unclear to what extent sedation affects neurogenesis in young adults. We therefore examined the effects of sedation on proliferation and survival of new neurons in the adult dentate gyrus. In addition to isoflurane and propofol, we included two sedatives commonly used for moderate sedation, midazolam and dexmedetomidine. Because few studies has examined the effects of sedation on neurogenesis in females, we compared male and female rats. All animals were sedated for 4 hours and sacrificed 24 hours later. Control rats of both sexes remained in their home cages until time of sacrifice. Three different cell populations were analyzed: the permanent, distinguishable birthdate markers EdU and BrdU were administered one week and one month prior to anesthesia, respectively, to identify immature and mature neurons, while PCNA was used to identify dividing precursor cells and assess cell proliferation at time of sacrifice. None of the drugs altered cell proliferation or the number of immature neurons in the DG in either sex, and most had no effect on mature neurons. However, female rats treated with propofol (M=368.1, SE=50.1) had fewer BrdU+ cells than propofol males (M=608.5, SE=37.0) and control female (M=550.4, SE=34.5) and male (M=611.7,SE=37.0) rats (p<0.05). These findings suggest that there is no general effect of sedation on new neurons in the dentate gyrus but that propofol reduces adult neurogenesis, with greater effects in females than males. Future studies will include behavior to determine whether propofol-induced changes in neurogenesis have cognitive effects. Taken together, these studies will help elucidate possible

mechanisms by which sedation may alter ongoing production of new neurons to impair cognitive functions.

Title: Chronic hypercaloric diet modifies the hippocampal neurogenesis and behavior in the adult rat

Authors: *V. VARGAS, C. VIVAR, I. JIMÉNEZ-ESTRADA;
Fisiology Departament, CINVESTAV-IPN, Mexico City, Mexico, Ciudad de Mexico, Mexico

Abstract: Obesity is a public health problem around the world. Studies in humans and animal models suggest that high-calorie diets have negative effects on brain physiology, particularly in the hippocampus. This brain area is important for learning and memory, and it is one of the few regions of the brain where neurogenesis continues during postnatal life. The hippocampus and adult neurogenesis are susceptible to nutritional changes in early and later stages of development. However, the effect of chronic exposure, from perinatal to adulthood, to a high-calorie diet has not been evaluated. Here we evaluated the effects of chronic high-calorie diet on adult neurogenesis and hippocampus-mediated learning and memory. Adult female Wistar rats were fed either with a normal diet (standard chow diet, (3.8 Cal/g) or a high-calorie diet (5 Cal/g) before mating, throughout pregnancy and lactation. After weaning, all offspring male were fed under the same maternal diet until the end of the experimental procedure. At 23-weeks-old, the cognitive function of offspring rats was evaluated using hippocampus-dependent behavioral tasks. Additionally, in a separate group, adult neurogenesis was also evaluated using 5-bromo-2-deoxyuridine (BrdU; 50mg/kg, ip). Results showed that the chronic high-calorie diet increased energy intake, body weight gain, perivisceral adipose tissue, and modified the glycemic regulation compared to the control group. Quantification of BrdU-NeuN double-labeled cells showed that the chronic high-calorie diet significantly decreased the number of adult-born hippocampal neurons, which correlated with the impairment in spatial learning and memory in the Barnes maze task. Altogether suggests that the effects of chronic high-calorie diet, from the maternal environment to adulthood, induces a dysfunction in both hippocampal neurogenesis and learning and memory processes.

Title: Functional recovery by enriched environment in neonatal white matter injury: Evidence from morphological and electrophysiological assessments

Authors: A. HATTORI, *N. TAJIRI, Y. UEDA, A. ISHIDA, T. SHIMIZU, H. HIDA;
Dept. of Neurophysiol. & Brain Sci., Nagoya City Univ., Nagoya-city, Aichi, Japan

Abstract: Hypoxia-ischemia (H-I) in preterm infants occasionally results in neonatal white matter injury (NWMI) associated with neurodevelopmental disabilities such as paralysis and cognitive dysfunction. Enriched environment (EE) that contains increased motor activity, social interaction and exploration is known as a good method to improve disturbed motor function. To investigate whether EE during the period of development effects on the recovery of disturbed motor function in NWMI, rat model of NWMI made by H-I at postnatal day 3 (P3) was grown in either condition of EE or standard environment (SE) for 5 weeks from P25 to P70. Four tests of hindlimb retraction, beam walk ability, horizontal ladder, and rotarod were performed at P25, P35, and P70, and immunohistochemical assessments and electrophysiological investigations were then carried out at P70. NWMI model exhibited significant deficits of four tests compared with sham-operated control at P25. EE for 5 weeks resulted in significant improvements of the behavior except for rotarod in NWMI at P70. However, NWMI-SE group did not show any improvements. The effects on EE was shown as early as P35 in NMMI. Although the sensorimotor cortex is thinner in the ipsilateral side of NWMI at P70, EE caused in the recovery of cortical thickness that is comparable to the opposite side and sham-control. To know if cortical motor map and electrical responsiveness in the sensorimotor cortex of the NWMI are changed by EE, intracoritical microstimulation was performed at P70. Although significant differences of the cortical maps and the responsiveness were detected in the NWMI, EE also caused in significant recovery of the cortical maps and the thresholds of the hip joint and hindlimb. These data suggest that EE during the period of development has significant effects on disturbed motor function in NWMI, accompanied with significant changes of the cortical motor map and the responsiveness in the sensorimotor cortex.

Title: The effect of environmental enrichment on hippocampal neuroplasticity-related genes in Hatano rats

Authors: *H. ASANO[1], H. OKAWA[1], A. NAKAYAMA[1], H. TOKUOKA[1], W. KASAI[1], R. OTA[2], M. KAWAGUCHI[1];
[1]Sch. of Agriculture, Meiji Univ., Kawasaki, Japan; [2]Hatano Res. Institute, Food and Drug Safety Ctr., Kanagawa, Japan

Abstract: Low neuroplasticity in the hippocampus can be a factor in neuropsychiatric disorders, such as Alzheimer's disease, depression and anxiety disorder. It may be possible to treat these disorders by improving neuroplasticity, but first it is necessary to examine neuroplasticity-related genes and identify possible improvement factors. Environmental enrichment can improve neuroplasticity in rats' hippocampus, for example by introducing a running wheel, novel object, or a combination of these. Hatano low avoidance (LAA) and high avoidance (HAA) rats are inbred strains selected from Sprague-Dawley (SD) rats by active avoidance test. Studies have shown that environmental enrichment decreased anxiety-like behavior in LAA rats but not in HAA rats. Moreover, HAA have a smaller hippocampus than LAA, which suggests that there may be different neuroplasticity activity HAA and LAA rats. Therefore, investigating the relationship between environmental enrichment and neuroplasticity in the hippocampus of HAA and LAA Hatano rats could shed light on the treatment of neuropsychiatric disorders. Here, we investigated the effect of environmental enrichment on neuroplasticity-related genes in Hatano rats. At 4 weeks of age, the animals were introduced into either a standard environment cage (200×410×250mm) or a larger environmentally enriched cage (440×660×398mm) that contains a running wheel (350×170×370mm), a plastic tunnel (Φ77, length 163mm) and a wood house (200×170×300mm). Hippocampus were sampled at 15 weeks of age and the gene expressions levels of Brain-derived neurotrophic factor (Bdnf) exon9 and Wingless-type MMTV integration site family member 3a (Wnt3a) gene expression levels were measured by RT-qPCR. There was no significant difference in Wnt3a mRNA. Bdnf exon9 mRNA showed significantly higher gene expression in LAA than in SD and HAA, and only in SD showed significantly higher gene expression levels in environmental enrichment than in standard. These results suggest that the effects of environmental enrichment on neuroplasticity-related gene expression may affected by strain. Moreover, Bdnf forms eight mRNAs, so it is still possible that there could be differences in the expression levels in other exons and BDNF protein.

Title: Effect of voluntary running on aberrant seizure-induced neurogenesis and cognitive deficits associated with chronic pentylenetetrazole kindling in rats

Authors: K. POST, M. GILCHRIST, L. BRANDT, C. COLE, H. LEHMANN, *N. M. FOURNIER;
Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Chronic epileptic seizures are well known to increase levels of hippocampal neurogenesis. As these new neurons develop, they integrate abnormally within existing networks forming synaptic connections that enhance hippocampal excitability and contribute to cognitive dysfunction. Physical exercise is a robust stimulator of neurogenesis in rats and increases performance on behavioural tasks that require normal hippocampal function. It is also well known exercise can produce neuroprotective effects against seizures. In this study, we set out to investigate whether voluntary running could reduce aberrant hippocampus neurogenesis and cognitive deficits associated with repeated seizures induced by pentylenetetrazole (PTZ) kindling. Long-Evans male rats were individually housed in cages equipped with or without a running wheel for the entire duration of the study. Following a short habituation period, rats were repeatedly administered saline or the chemoconvulsant PTZ every two days for 24 days. After kindling, rats underwent a series of tests that measure cognitive and affective behaviours (e.g., open field test, elevated plus maze, forced swim test, object recognition, object location, context fear and trace fear learning). Our preliminary findings showed that both non-kindled controls and PTZ runners performed significantly better then the PTZ non-runners on trace fear learning and object location memory. Interestingly, PTZ runners also showed greater exploratory activity in the elevated plus maze and would venture further into the distal end of the open arms then non-kindled controls and PTZ non-runners. Finally, while PTZ kindled seizures increased doublecortin-positive immature neurons in the dentate gyrus of both runner and non-runner groups, running appeared to reduce the number of ectopic hilar cells and promoted greater dendritic growth and complexity in newborn neurons located in the granule cell layer. Together,

these findings provide evidence that physical exercise can improve cognitive outcome and reduce aberrant hippocampal neurogenesis that accompany repeated seizures.

Title: Mild traumatic brain injury in the mouse induces a transient increase in neurogenesis and sustained survival of newborn neurons

Authors: *L. R. CLARK[1,2], P. L. KUMAR[1,2], N. K. ACQUAH[1,2], R. C. COSTA PAIXAO[1,2], S. YUN[1,2], H. METHENY[1], A. S. COHEN[1,2], A. J. EISCH[1,2];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The majority of the 2.8 million traumatic brain injuries (TBIs) that occur annually in the US are classified as mild. Mild TBIs (mTBIs) can induce long-lasting impairment in memory and attention. Contextual memory is disrupted after mTBI, and is critically dependent on adult dentate gyrus neurogenesis. There are conflicting results about how TBI affects neurogenesis, with very little work examining the impact of a mild injury. We asked the question, how does a mouse model of mTBI influence the dynamic process of adult hippocampal neurogenesis? Male C57BL/6J mice (6-8 weeks) received either sham surgery or mTBI via lateral fluid percussion injury (LFPI), and dentate gyrus neurogenesis was measured via stereology at early (3 days post-injury, dpi), intermediate (7 dpi), and late (31 dpi) time points. Mice received a single injection of BrdU (150mg/kg i.p.) 3 dpi to label proliferating cells. Brains from each time point were assessed with markers for DG neurogenesis and reactive glia: proliferation [Ki67+, BrdU+ (2hr post-BrdU)], differentiation (DCX+), survival [BrdU+(4 wks post-BrdU)] and microglia (Iba1+). Additionally, GCL volume was assessed in brains from the early and late time points. At the early time point, GCL volume was not different between Sham and LFPI mice. LFPI mice had ~50% more Ki67+ SGZ cells relative to Sham mice, and the same number of DCX+ SGZ/GCL cells as Sham mice. In contrast, at the intermediate time point, LFPI mice had ~30% more DCX+ SGZ/GCL cells than Sham mice, but the same number of Ki67+ and BrdU+ cells. At the late time point, Ki67+ and DCX+ cell numbers were the same between LFPI and Sham mice, but LFPI mice had ~70% more BrdU+ SGZ cells than Sham mice. GCL volume was also not

different between Sham and LFPI mice at the late time point. These data suggest a transient increase in proliferation of neural precursor cells shortly after LFPI, which may relate to the subsequent transient increase in immature neurons and to a bolus of adult-born granule cell neurons that persist 1 month post-injury. Ongoing work is testing this hypothesis with additional immunohistochemical analyses (phenotyping of BrdU+ cells at intermediate and late time points; DCX+ cell morphological analyses), and exploring how these cells influence hippocampal anatomy and function on both the circuit and behavioral level.

Title: Neuroanatomical correlates of socioeconomic status in infancy

Authors: L. M. BETANCOURT[1], H. HURT[1], T. NICHOLS[2], O. ELCI[1], B. AVANTS[2], ***M. J. FARAH**[3];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. Pennsylvania, Philadelphia, PA

Abstract: Socioeconomic status (SES) has long been associated with differences in mental health and cognitive ability. Understanding these differences is an important goal for public health and social equity. Given the brain's central position in causal pathways linking genes and experience to psychological outcomes, the neuroanatomical correlates of SES have become the subject of active study. Most such research focuses on people of school age and older. Our 2015 study analyzed brain structure in a group of 47 1-month-old healthy African American baby girls, whose family SES ranged from very low (sub-poverty line) to middle class (Betancourt et al., Developmental Science). We found cortical grey and white matter volume to correlate positively with SES, measured as a composite of family income-to-needs ratio and maternal educational attainment. Here we report the results of follow-up imaging, accomplished at least once at ages 1 and/or 2 years, using mixed model analyses to answer two questions: (1) Does the influence of SES grow, shrink or stay the same over the first two years of life? (2) Does brain volume differ globally or are differences regionally localized? Mixed model analysis, with variables SES, age and age^2 found significant effects of all three: higher SES brains had larger volumes, older brains had larger volumes, and the effect of age was nonlinear, with less growth in the second year. Regarding (1), the influence of SES neither grew nor shrank as tested by adding interactions SESxage and SESxage^2 to the model. (Interpretation is qualified by the low

power for testing interaction effects in this sample, and the possibility that rate of brain growth may differ across SES, such that 1 year and 2 year scans may assess volumes at different points in the developmental trajectory.) Regarding (2), SES predicted frontal and temporal lobe volumes. It also predicted overall white matter volume and cortical grey matter volume, with a borderline significant effect on parietal volume and no significant effect on occipital lobe volume or deep grey matter volume. Given SES differences in prenatal environment, and known effects of stress and toxins on fetal development, prenatal processes may be responsible for early SES brain differences.

Title: Early-life iron deficiency anemia is associated with alterations in microbiome maturation and reduction of cortical volume in infant rhesus monkeys

Authors: *D. N. RENDINA[1], G. R. LUBACH[1], R. M. VLASOVA[2], M. LYTE[3], G. PHILLIPS[3], M. A. STYNER[2], C. L. COE[1];
[1]Harlow Ctr. for Biol. Psychology, Univ. of Wisconsin, Madison, WI; [2]Departments of Psychiatry and Computer Sci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Dept. of Vet. Microbiology and Vet. Med., Iowa State Univ., Ames, IA

Abstract: Iron-deficiency anemia (ID) is the most common micronutrient deficiency, and young infants are especially vulnerable to negative neurodevelopmental, cognitive, and metabolic outcomes that can persist beyond infancy. While iron availability is known to dynamically modulate the intestinal microbiota, the extent to which host iron status influences microbial colonization, and the neurobehavioral consequences of the resulting dysbiosis, are not known. **Methods**: Twenty-nine infant rhesus monkeys (*Macaca mulatta*) were evaluated at 2-month intervals for the first year of life, and 12 naturally became iron deficient around the time of weaning (6-8 months of age). Blood was collected for hematology and iron indices, and fecal microbial community structure and diversity were determined by gene amplicon sequencing and taxonomic classification of the V4 region of the bacterial 16S rRNA gene. Mother-infant interactions were observed between 2-4 months to evaluate infant behavioral maturation. At 12 months, magnetic resonance imaging data were obtained on a 3T scanner. Gray matter (GM) and

white matter (WM) volumes were determined for major cortical regions using an automatic segmentation and parcellation pipeline, and volumes of several subcortical structures were evaluated. **Results:** The microbial colonization of the infant gut was distinct in ID infants with respect to bacterial phylogeny and abundance (p=0.044) and was characterized by decreased evenness (p=0.06), suggesting delayed microbiome maturation. In contrast to iron sufficient infants, the overall community structure in ID infants was stable between 4-6 months of age. However, the genera *Megasphaera* was consistently enriched in ID infants and its relative abundance at 4 and 6 months of age was predictive of low hemoglobin at 6-months. Despite subsequent iron treatment, the infants that were ID at 6 months of age had diminished total brain volumes (TBV) at one year. This impact on brain growth was most apparent in bilateral reductions in basal ganglia and amygdala volumes and decreased GM in the prefrontal cortex. ID infants also exhibited more motor activity and fewer behavioral interactions with the mothers during observations at 4 months of age. **Conclusion:** Differences in the gut microbiome preceded and were coincidental with infantile anemia, and associated with smaller brain volumes at one year of age. These findings highlight the importance of iron biology for understanding host-microbe interactions and indicate that ID during infancy can have enduring neurodevelopmental effects that were evident in spite of the administration of iron when anemia was detected.

Title: Changes in cultured adult neural stem cell physiology following sublethal exposure to silver nanoparticles

Authors: D. W. KIPPS, K.-C. K. PATTERSON, *N. SPITZER;
Dept. of Biol. Sci., Marshall Univ., Huntington, WV

Abstract: Silver nanoparticles (AgNPs) are an environmental contaminant of emerging concern due to their widespread use in the production of consumer goods including toothpaste, socks, and cosmetics. AgNPs released from these items could potentially be ingested or inhaled, crossing biological barriers due to their unique surface properties. Animal studies indicate that oral exposure to AgNPs leads to bioaccumulation in tissues including the brain. Although the efficacy

of AgNPs as antimicrobials and biosensors is well documented, their effects on mammalian cells at environmentally relevant low levels are unclear. We previously found that low-level (1μg/mL) AgNPs disrupt cytoskeletal function, leading to formation of f-actin inclusions and disrupting neurite dynamics in cultured adult neural stem cells. In addition, AgNPs disrupt β-catenin intracellular signaling mechanisms in these cells. Here, we investigated interactions of AgNPs with two other intracellular signaling pathways, MAPK/ERK and Akt, both of which are involved in regulation of neuronal cell differentiation. We exposed differentiating cells to AgNPs in combination with specific pharmacological agents to activate or inhibit the pathways, and then assessed cytoskeletal dysfunction. Neurite dynamics were examined with time-lapse microscopy where we found that the inhibition of Akt and MAPK/ERK stimulated neurite extension. However, pharmacological inhibition of these pathways was not able to rescue the neurite collapse resulting from low-level AgNPs exposure. Inhibition of MAPK/ERK signaling leads to an increase in f-actin inclusion formation that may be additive with AgNP-induced inclusions, while inhibition of Akt did not alter inclusion formation. Pharmacological activation of MAPK/ERK in combination with AgNPs indicated a more complex interaction of mechanisms regarding f-actin disruption. This was supported by immunoblot assessment of signal protein phosphorylation after AgNP exposure. These data suggest a more indirect or downstream connection between Akt or MAPK/ERK pathways and AgNPs. Finally, we investigated changes in electrical properties of cultured adult neural stem cells after exposure to sublethal AgNPs, measured by whole cell patch clamp electrophysiology. This work will help us to understand chronic effects of low-level AgNP exposure from consumer goods on brain cell function. Our work in neural stem cells is especially applicable to children, whose brains are still developing, and therefore depend significantly on neural stem cell function.

Title: Examining running-induced structural plasticity in the ventral hippocampus in relation to cognitive enhancement and anxiety regulation

Authors: *E. A. TAWA, B. A. BRIONES, E. C. COPE, E. J. DIETHORN, S. MURTHY, E. GOULD;
Princeton Univ., Princeton, NJ

Abstract: Previous findings of cognitive enhancement and anxiolysis after long term aerobic exercise raise the possibility that the neural mechanisms supporting exercise-induced cognitive improvement also operate in brain circuits involved in anxiety regulation. Because the rodent ventral hippocampus (vHIP) is important for anxiety regulation and has recently been found to contribute to some types of learning and memory, it is a likely candidate region for mediating these effects. Previous studies have shown that running stimulates widespread structural plasticity throughout the hippocampus, including the formation of large numbers of new neurons; however, it remains unresolved whether running-induced structural plasticity in the vHIP promotes cognition and dampens anxiety. Furthermore, a large number of parvalbumin-expressing (PV+) cells in the hippocampus are enwrapped in specialized extracellular matrix (ECM) structures, called perineuronal nets (PNNs), which are known to regulate plasticity. While there is some suggestive evidence that PNN formation can be affected by experience, no studies have investigated whether new neurons generated during running form microcircuits with PNN+ PV+ cells, thus inducing reduced anxiety/enhanced cognition states. Here, we study the potential roles of new neurons and PNNs in the optimizing effects of physical activity on anxiety and cognition in adolescent mice. By testing both males and females, we explore previously unaddressed questions regarding plasticity mechanisms underlying brain optimization during the transition into adulthood, when hormone levels are changing and sex differences may emerge. We replicated the anxiolytic effects of running in male mice on both the elevated plus maze and novelty suppressed feeding tasks, and also found a higher discrimination ratio on the object location test, suggesting cognitive improvement. We have also found anxiety reduction and cognitive improvement on the aforementioned tasks in group-housed mice using a vertical wheel in a larger home cage, compared to pair-housed mice using a disc wheel in a smaller home cage. These findings implicate that the home cage environment and running set-up play important roles in assessing behavioral differences. The relationship of these behavioral changes to alterations in new neurons, inhibitory interneurons, and PNNs is under investigation.

Title: Sex-specific effects of early life stress on hippocampal neurogenesis in the pig

Authors: *K. DURGA[1], N. DUQUE-WILCKENS[2], A. MOESER[1], A. ROBISON[1];
[2]Physiol., [1]Michigan State Univ., East Lansing, MI

Abstract: Depression is a leading cause of disability worldwide, yet available treatments are ineffective for nearly half of treated patients. Mood disorders like depression have been linked to early life adversity and are exacerbated by chronic or traumatic stress, so uncovering how stress affects mood-related brain regions is critical to improve our understanding of depression etiology and potentially improving treatment. Depression patients often display reduced hippocampal volume, and many animal models of depression display a reduction in hippocampal neurogenesis that is reversed by chronic exposure to antidepressants like fluoxetine. Using a pig model, we assessed whether exposure to early life adversity affects hippocampal neurogenesis and gene expression. Early weaned (15 days post partum) or late weaned (28 days post partum) female, castrated male, and intact male pigs were euthanized at 20 weeks of age and brain tissue was immediately harvested. We performed immunohistochemistry in the dentate gyrus to detect the protein doublecortin, a marker of differentiating neurons. We found a significant reduction in doublecortin labeled cells in early weaned females compared to the late weaned females in the dentate gyrus, indicating a sex-specific reduction in neurogenesis not dependent on adult circulating testosterone. We also used western blot to detect expression of the *FosB* gene, which controls hippocampal gene expression and is necessary for neurogenesis in mice. We found that early weaned females had an increased level of hippocampal FosB and ΔFosB, while these *FosB* gene products were reduced in the early weaned castrated males. Ongoing studies are assessing FosB and ΔFosB in the prefrontal cortex and the nucleus accumbens, as well as examination of neuroinflammation throughout the brain. Together, these data suggest that early weaning has sex specific effects on hippocampal neurogenesis and gene expression later in life, perhaps driving susceptibility to mood disorders in adulthood.

Title: Connectivity of adult-generated dentate granule cells in a mouse model of fetal alcohol spectrum disorder

Authors: *K. C. GUSTUS, L. LI, J. NEWVILLE, L. A. CUNNINGHAM;
Neurosciences, Univ. of New Mexico Sch. of Med., Albuquerque, NM

Abstract: Fetal Alcohol Spectrum Disorders (FASDs) are associated with impaired hippocampal function. Using a limited access voluntary drinking paradigm, we previously demonstrated that prenatal alcohol exposure (PAE) leads to impaired hippocampal neurogenesis in response to enriched environment (EE) in adult mice, which is associated with impaired performance on a neurogenesis-dependent contextual discrimination task, and increased excitatory synaptic input as assessed by patch clamp electrophysiological recordings in adult-generated dentate granule cells (aDGCs) (Choi et al., 2005; Kajimoto et al., 2013, 2016). Here, we test whether these structural, behavioral and electrophysiological parameters are associated with altered dendritic structure using a limited-access drinking-in-the-dark PAE paradigm for gestational alcohol exposure (maternal BEC=80-90mg/dl; Brady et al. 2012). PAE and Sac control Nestin-CreER^{T2}:tdTomato mice were used for sparse labeling of aDGCs by single tamoxifen injection (60mg/kg i.p.) on postnatal day (PD) 48. Mice were randomly assigned to standard housing (SH) or EE for 3 or 6 weeks post-tamoxifen. Confocal image stacks of tdTomato^{+} aDGCs were reconstructed using Imaris^{tm} 3-D software for Sholl analysis of dendritic complexity. Preliminary data (n=4 EE EtOH, 2 EE Sac) shows an interaction of treatment and Sholl intersections ($F_{27, 25} = 2.514$; $p=0.0116$ with increased basal dendrites (60-70μm) in 6 week old aDGCs of EE PAE mice, suggesting sustained increased connectivity of the inner molecular layer (IML). One method to explore this is through monosynaptic afferent connectivity studies. We performed a feasibility study on male C57Bl6 mice (n=7), in which each received stereotaxic injection of retrovirus conferring expression of an avian receptor TVA, rabies glycoprotein (G), and nuclear localized GFP at PD42 and a second injection of EnvA ΔG MCherry rabies with restricted infection to TVA^{+} hippocampal aDGCs at PD77. One week later mice were sacrificed and the distribution/quantification of MCherry^{+} cells relative to dual-labeled aDGCs was determined (hilus=0.9098±0.3617; granule cell layer= 0.3255±0.1451; molecular layer=0.2197±0.08522). The highest ratios are from populations that innervate aDGC proximal regions, making this technique useful for future determination by which EE-mediated dendritic morphology is modified in PAE. These data demonstrate an EE-mediated increase in proximal dendritic complexity of matured aDGCs, and further support subsequent elucidation utilizing the dual vector afferent tracing strategy.

Title: Intermittent Hypoxia (IH) increases HIF1a signaling in TBR2+ intermediate progenitors through a reactive oxygen species mechanism

Authors: *C. SZUJEWSKI[1], M. A. KHUU[2], T. NALLAMOTHU[2], A. J. GARCIA, III[3]; [1]Neurobio., [2]Univ. of Chicago, Chicago, IL; [3]Emergency Med., The Univ. of Chicago, Chicago, IL

Abstract: Neurocognitive decline is a frequent consequence of sleep apnea, commonly associated with intermittent hypoxia (IH). Oxygenation is an important factor influencing adult neurogenesis. We have recently shown that IH disrupts this process in the dentate gyrus. Hypoxia inducible factor 1 (HIF1a), is a transcription factor regulated by the state of oxygenation and is important in stem cell development. However, the role of IH-dependent HIF1a signaling in neural stem cell (NSC) development and differentiation is unclear. This study examines how IH-dependent HIF1a signaling affects hippocampal adult neurogenesis. We tested the hypothesis that IH-dependent HIF1a signaling promotes survival of NSCs during IH. Immunohistochemical studies were performed on hippocampal tissue from young adult mice (>P36) exposed to room air (control) or 10 days of IH (IH_{10}). While IH_{10} did not change the number of proliferating NSCs ($KI67^+/SOX2^+$), the number of intermediate progenitors (INPs, $TBR2^+$) was reduced. IH_{10} also decreased the number of $HIF1a^+$ NSCs yet increased the number of $HIF1a^+$ INPs. Antioxidant administration during IH_{10} prevented both the loss of INPs and the upregulation of $HIF1a^+$ in this cell type. These findings suggest that IH-dependent HIF1a signaling does not promote NSC survival yet is upregulated through a reactive oxygen species-dependent mechanism in $TBR2^+$ INPs. Ongoing experiments are investigating the impact of IH-dependent HIF1a signaling INPs.

[3]Dept. of Pediatrics and Human Develop., Michigan State Univ., Grand Rapids, MI

Abstract: Maternal immune activation (MIA) has emerged as an environmental risk factor for various neurodevelopmental disorders (NDDs), including autism and schizophrenia. Animal models of MIA provide the opportunity to identify the molecular signaling pathways that initiate the disease process and lead to NDD-related neuropathology and behavioral deficits. The preclinical polyinosinic-polycytidylic acid (polyI:C) model has become one of the most widely used approaches in MIA research, however the progression of pathological changes in the fetal brain remain uncharacterized. To identify changes in fetal mouse cortex across a time course following mid-gestational MIA via poly(I:C) injection, we applied transcriptional profiling and neuroanatomical characterization in MIA offspring across embryonic brain development. To reduce variability, we determined the effective dose of poly(I:C) to induce reproducible levels of immune response. Female mice were bred and injected with saline or poly(I:C) at E12.5. Cortices were dissected from E12.5 +6h, E14.5, E17.5 and P0 from MIA and control offspring and processed for RNA-seq, histology, and/or protein analysis. We identified strong transient transcriptional signatures in fetal cortex that included an initial acute signature suggesting activation of stress response pathways in the fetal brain, followed by alterations to proliferation and neuronal differentiation that emerged at E14.5 and peaked at E17.5. MIA-associated transcriptional changes were greatly diminished by birth (P0), though gene expression across several pathways remained elevated. We used immunohistochemistry and Western blot at E17.5 to examine dysregulated genes involved in a range of developmental processes. We validated proliferative populations, altered cortical lamination patterns, precocious astrogenesis and altered maturation on interneuron populations. In summary, the validated transcriptomic maps provide novel insights into the molecular and developmental processes linking MIA pathology and neurodevelopmental sequelae.

Title: Modeling glaucomatous neurodegeneration of human pluripotent stem cell-derived retinal ganglion cells

Authors: K. B. VANDERWALL[1], K.-C. HUANG[1], C. M. FLIGOR[1], S. S. LAVEKAR[2], Y. PAN[3], T. R. CUMMINS[4], ***J. S. MEYER**[5];
[1]Biol., IUPUI, Indianapolis, IN; [2]Biol., IUPUI, Indianapolis, MA; [3]Program in Med. Neuroscience, Paul and Carole Stark Neurosciences Res. In, Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Dept Biol. SL306, Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [5]Indiana Univ., Indianapolis, IN

Abstract: Human pluripotent stem cells (hPSCs) can serve as powerful tools for the *in vitro* analysis of human neurodegenerative diseases, as well as a platform for pharmacological screening of these diseased cells . Retinal ganglion cells (RGCs) serve as the essential connection between the eye and the brain, with this connection disrupted in blinding disorders such as glaucoma. As such, when derived from patients with inherited forms of the disease, the opportunity exists to study cellular phenotypes associated with glaucomatous neurodegeneration. However, in order to serve in this capacity, differentiated hPSCs must fully recapitulate the features of the affected *in vivo* cell type, including the ability to exhibit mature neuronal characteristics. Thus, efforts of the current study were initially focused upon the functional maturation of hPSC-derived RGCs based upon morphological and functional properties. Subsequently, the ability to derive RGCs from hPSCs was applied to an *in vitro* model of glaucoma using patient-derived cells. Using this system, it was hypothesized that when grown from hPSC-glaucomatous sources, RGCs would exhibit deficits in neuronal complexity and functional deficits, leading to increased apoptosis. hPSC-derived RGCs from healthy control sources demonstrated increased neurite complexity, functionality, and expression of synaptic

proteins over time in culture. These features were significantly enhanced and accelerated when grown in the presence of astrocytes, similar to what is observed in the retina and optic nerve. When grown from glaucomatous sources, hPSC-derived RGCs matured similarly during early stages but at later stages of development, they exhibited significant reductions in their morphology and neurite complexity. These morphological features were associated with an increased level of apoptosis exhibited specifically within the RGC population. Furthermore, RGCs derived from glaucomatous sources were found to be more highly excitable by patch clamp analysis, suggesting a potential role for excitotoxicity in the deficits observed in glaucomatous RGCS. The results of this study are the first of its kind to extensively study the functional and morphological maturation of RGCs *in vitro*, with important implications for the contributions of glial cells to RGC development and maturation. More so, glaucomatous hPSC-derived RGCs exhibited disease deficits, with the opportunity to explore the unknown mechanisms causing RGC death in glaucoma as well as explore areas of therapeutic intervention including pharmacological screening and cell replacement therapies.

Abstract: While embryonic rodent pyramidal neurons have been extensively used for modeling neuronal development, interspecies differences, including alterations in developmental timings, mean that not all results are readily recapitulated in human models. There is a pressing need for *in vitro* models to fully capture the mechanisms and molecular pathways specific to human neural development and disorders including cortical gyrification, autism, and schizophrenia. To meet this objective, we describe a protocol for generating low density human iPSC-derived forebrain neurons and compare the development of various morphological features in human versus rodent-derived neurons. Using specific markers for developmental milestones, such as Tau-1 to mark axon formation, in conjunction with high content imaging, we observe that human derived neurons follow a similar pattern of development to rodent neurons, but with a prolonged

time course. We use pharmacological treatments targeting the cytoskeleton to demonstrate that robust molecular mechanisms for neurite growth and polarization are preserved in human and rodent neurons. For example, myosin inhibition using Blebbistatin increased axon outgrowth and arborization in both rodent and in human neurons. Our findings indicate that while robust mechanisms for neuronal development are preserved, human iPSC-derived neurons follow a delayed growth pattern *in vitro* that can be used to explore nuanced mechanisms specific for human brain development.

Abstract: Differentiation of human pluripotent stem cells (hPSCs) into ectoderm provides neurons and glia useful for research, disease modeling, drug discovery, and potential cell therapies. In current protocols, hPSCs are traditionally differentiated into ectoderm after 6 to 10 days *in vitro* when protected from mesendoderm inducers. This protracted timing has made ectoderm a difficult germ layer to access and manipulate, hindering development of efficient differentiation protocols for ectoderm-derived cell types. Here we report efficient and serum-free differentiation of hPSCs into ectoderm within 24 hours using specific pathway modulation. This method is greater than 70% efficient, is broadly applicable to a panel of five independent hPSC lines, and accelerates the emergence of downstream intermediate and terminal neurodevelopmental landmarks. Given its rapid and flexible nature, we expect this method to democratize the development and execution of significantly more efficient protocols for the differentiation of ectoderm-derived cell types from hPSCs.

Title: Creation of inducible dCas9-effector iPSC-derived cortical organoids to study human astrocyte development

Authors: *S. N. LANJEWAR, A. T. KING, S. A. SLOAN;
Emory Univ., Atlanta, GA

Abstract: Astrocytes are the most numerous glial population within the central nervous system and play critical roles in neurodevelopment and maintenance of normal brain function. Due to their role as active choreographers of neural circuit formation, their own development, maturation, and function is critical to understand. However, limited access to human tissue at these key developmental stages makes this particularly challenging. Therefore, we utilize two approaches to study human astrocytes: primary astrocytes isolated from fetal and adult human brain tissue and human cortical organoids differentiated from induced pluripotent stem cells (iPSCs). Cortical organoids recapitulate key features of human cortical development, including the development and maturation of human astrocytes, which coexist alongside neurons in a complex 3D cytoarchitecture. An additional advantage of this platform is the ability to use the vast genetic toolset that is available to *in vitro* systems. We are particularly interested in developing new tools to artificially drive specific gene expression changes in human astrocytes to better understand the mechanisms that drive astrocyte development, maturation, and function. To accomplish this goal, we are using nuclease-dead Cas9 (dCas9) tethered to transcriptional activators (CRISPR activation) or inhibitors (CRISPR interference) to specifically modulate gene expression in our system. Our goal is to develop stable iPSC lines that contain tetracycline-inducible dCas9-effector systems with the intent of developing these into human cortical organoids. In the presence of specific guide RNAs, we plan to selectively modulate astrocyte gene expression to ask two fundamental questions: (1) what are the key regulators of astrocyte development, and (2) what are the functional roles of astrocytic genes in neurodevelopmental disorders? Additionally, this approach will allow us to determine how altering gene expression of

neurons and/or astrocytes affects developing neural circuits. Ultimately, these tools will help to study the roles of astrocytes in human brain development and how dysregulation of astrocytes contributes to the pathogenesis of neurodevelopmental disorders.

Title: Neuroepigenetic regulation of the imprinted gene GRB10

Authors: *A. M. JUAN[1], M. BARTOLOMEI[2];
[1]Neurosci., [2]Cell and Developmental Biol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Imprinted genes are a subset of mammalian genes that are exclusively expressed from either the maternal or paternal chromosome. Dysregulation of imprinted gene expression is associated with various human disorders, including the stunted growth disorder Silver-Russell syndrome (**SRS**). This disorder is associated with the abnormal inheritance of two maternal copies or alleles of the imprinted gene Growth Factor Receptor Bound Protein-10 (**GRB10**). Although most somatic cells express *GRB10* exclusively from the maternal allele, alternative promoters on the paternal allele drive *GRB10* expression only in neurons. However, the regulatory elements that coordinate this remarkable epigenetic "switch" of *GRB10* expression in development are unknown. This proposal will test the requirement of (1) allele-specific DNA methylation sequences and (2) zinc-finger protein **CTCF** binding in normal neuronal *GRB10* expression using relevant mouse models and CRISPR-edited neurons. By analyzing these epigenetic elements in a neuronal differentiation system and *in vivo*, we are the first to demonstrate how *GRB10* is epigenetically regulated. These findings will elucidate the mechanisms for allele and tissue-specific gene expression in the brain. Our results may also provide insight into the molecular basis of SRS, which could prompt epigenetic etiology screening and therapeutic options.

Title: Enhancement of human embryonic stem cells culturing conditions by the formation of spheroids in a three-dimensional microenvironment

Authors: M. VIDIGAL[1], M. C. DECARLI[2], M. H. T. NAGAHARA[2], P. R. G. KEMPE[1], S. KYRYLENKO[3], J. V. L. SILVA[4], A. M. MORAES[2], ***A. L. OLIVEIRA**[1];

Abstract: Culturing of stem cells in two-dimensional (2D) conditions has become standard and widely used. It allows *in vitro* expansion of multi and pluripotent stem cells for various research and therapeutic purposes. Nevertheless, 2D culturing is considered highly artificial, since native cell physiology and behavior can be significantly altered, affecting many aspects of comparisons to the *in vivo* scenario. Over recent years, we have been studying neuroprotective and immunomodulatory effects of human embryonic stem cells (hESCs) following spinal cord injury by transplanting 2D cultured cells *in vivo*. Brain and glial-derived neurotrophic factors (BDNF and GDNF, respectively) are expressed by hESCs, particularly when engrafted nearby the lesion site, what is interpreted as a mechanism for rescuing axotomized motoneurons. With the perspective of enhancing the neuroprotective potential of cultured hESCs, we cultured cells in a 3D spheroid setup, using a micromolded nonadhesive hydrogel developed by our team. This method standardizes spheroid time frame formation and size. The cells were cultured in three different cell densities under standard conditions (mTeSR™1 feeder-free maintenance medium for human ES, STEMCELL Technologies), and evaluated at days 0, 2, 4 and 7 by phase contrast microscopy. 2D cultures were carried out as comparison counterparts. After seven days of culture, the formed spheroids were fixed in phosphate buffer containing 4% paraformaldehyde and processed for immunocytochemistry using anti-BDNF, GDNF, laminin, MHC I, β2-microglobulin and LILRB2 antibodies. Pluripotency was evaluated by flow cytometry with the BD Stemflow™ Analysis Kit. The results show that all three cell density conditions yielded the formation of spheroids, being those of 300μm in diameter the best, based on size, stability, and cell density. Immunolabeling (7 days of culturing) revealed striking BDNF staining, but not

GDNF, combined with robust laminin expression, which were detected in the extracellular matrix milieu. Undifferentiation state is suggested by the low levels of MHC I and β2-microglobulin, in line with high expression of Stage-specific embryonic antigen-4 (SSEA-4; 2D - 90.6%; 3D - 99.8%), obtained by flow cytometry. LILRB2 upregulation indicates that hESCs express MHC I ligand, what may in turn influence immunomodulatory processes and interaction with immune and glial cells as well as neurons. Overall, the present results indicate that 3D culturing of hESCs allows successful spheroid formation, providing potentially better neuroprotective support than the 2D counterpart when used for regenerative medicine approaches.

Abstract: Central Nervous System (CNS) disorders are widely recognized as major economic, emotional and physical burden to patients, their families and society. Although progress has been made in the basic neuroscience research, there are still several challenges to overcome to find novel therapies and treatments for CNS diseases. One major limitation in current neurological research and drug discovery is the lack of human neuronal disease models which are biological relevant, scalable and reproducible. The advent of induced Pluripotent Stem Cells (iPSCs) technology has offered new opportunities for disease modeling and drug discovery as patient derived iPSCs and their derivatives represent more relevant disease models. Although methods for iPSCs generation have been well established, protocols for a highly consistent and scalable iPSCs neuronal differentiation still need further optimization to produce cost effective and reproducible neuronal cells. Charles River has performed molecular and functional characterization of human cortical, striatal and glutamatergic neurons differentiated from human stem cells using traditional differentiation protocols optimized from literature (Shi et al, Nat Prot

2012; Telezhkin et al., Am J Physiol Cell Physiol., 2016) or the forward reprogramming technology developed by Elpis BioMed (M Pawlowski et al. Stem Cell Rep, 2017) . Preliminary immunocytochemistry and branched DNA data showed expression of pan neuronal markers (betaIIItubulin and MAP2) in Elpis glutamatergic (eNeuron/glut) neurons already after 3 days in culture compared to the 23 days of neurons differentiated with traditional protocols. Moreover functional multi electrode array (MEA) data showed the presence of spontaneous activity in Elpis eNeuron/glut neurons at day 21 of differentiation compared to day 37 and 42 of striatal and cortical neurons. Finally when applying to high trough put (HTS) applications (TR-FRET assay) including cytotoxicity assay (Cell Titer Glo) Elpis eNeuron/glut neurons plated in 384 microplates and treated with tool compounds showed good assay statistic and higher suitability for HTS compared to neurons differentiated with traditional protocols.

Title: Cortical neurons from human embryonic stem cells derived and maintained on the human amniotic epithelium

Authors: *D. AVILA-GONZÁLEZ[1], W. PORTILLO[2], A. MOLINA-HERNÁNDEZ[1], G. GARCÍA-LÓPEZ[1], N. F. DÍAZ[1];
[1]Inst. Nacional de Perinatología, Ciudad de México, Mexico; [2]Inst. de Neurobiología, Querétaro, Mexico

Abstract: Human embryonic stem cells (HESC) are derived from the epiblast and have a pluripotent potential (ability to differentiate into all the cell types that conform an organism). However, the conventional culture of HESC using a feeder layer of mouse embryonic fibroblasts (MEF) for their derivation and maintenance has several drawbacks, including the risk of xeno-contamination. Also, it has been suggested that culture of HESC in this standard condition is an artifact and does not correspond to the *in vitro* counterpart of the epiblast during human embryonic development. Besides, our previous studies demonstrated the use of an alternative feeder layer of human amniotic epithelial cells (HAEC) to derive and maintain HESC. In recent

years, different research groups have demonstrated that HAEC are specified from the epiblast prior to implantation, so the culture of HESC on HAEC could represent a different pluripotent stage, being more suitable to recapitulate development early processes, such as neural induction and formation of cortical layers of the forebrain. Here, we differentiated HESC on HAEC or standard conditions (on MEF) to derive cortical neurons. For neural induction, we used a dual SMAD signaling inhibition protocol during 12 days (D12); subsequently, the cells were detached and cultured in N2B27 medium. At the end of the neural induction stage, we found neural rosettes constituted by $SOX2^{+}$/$PAX6^{+}$ and $NESTIN^{+}$ neural stem cells (NSC). From D16 to D30, the first $TUJ1^{+}$ immature and $MAP2^{+}$ mature neurons were detected. Later, the cortical phenotypes of deep layers were identified at D40 using the specific markers CTIP2 and FOXP2; while from D50, $GAD67^{+}$ and $CALRETININ^{+}$ interneurons emerged. Interestingly, there was an increase in all the neural markers evaluated when HESC were induced to form neural lineage under the condition of HAEC as feeder layer, in contrast when were maintained on MEF. These data suggest that HESC maintained on the alternative feeder layer of HAEC are able to derive NSC and differentiate towards neuronal cortical phenotypes.

Title: Otic vesicle maturation into inner ear organoids requires extracellular matrix

Authors: *S. E. HOCEVAR[1], L. LIU[2], R. K. DUNCAN[2];
[1]Neurosci. Grad. Program, [2]Dept. of Otolaryngology, Kresge Hearing Res. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: Inner ear organoids derived from pluripotent stem cells could be a useful model system to study disease and regeneration. However, there is heterogeneity in size, morphology, and efficiency of organoids derived from otic vesicles. Some of this may due to cues from non-otic cells in the surrounding cellular aggregate. Greater control of the microenvironment surrounding the otic vesicle could decrease heterogeneity and increase the yield of organoids. Animal-derived otic vesicles show some autonomy during development and can differentiate into cochlear and vestibular domains in mesenchyme-free ex vivo culture. Therefore, we investigated whether stem cell-derived otic vesicles can autonomously generate cyst-like

organoids. To accomplish this, R1/E mouse embryonic stem cells were treated with factors to induce the formation of non-neural ectoderm, otic placode, and then otic vesicles. Vesicles were isolated from the rest of the aggregate on day 10 (D10) to D14, when the Pax2+/Sox2+ vesicles are clearly defined from the rest of the aggregate. Isolated vesicles were embedded in 100% Matrigel and grown in organoid maturation media to test their ability to differentiate into organoids. The D10 isolated vesicles grew in diameter but their thickness decreased, giving them a cyst-like morphology. Some vesicles remained smaller and thicker, whereas approximately 60% became larger, thinner, and cyst-like. No matter when the vesicles were isolated, the same percentage became cyst-like. Cysts contained MyoVIIa+ cells with phalloidin-labeled hair bundles. Therefore, we concluded that the maturation of vesicles into inner ear organoids was autonomous and independent of the non-otic cells that remained in the aggregate. In order to further investigate cues from the microenvironment that could be impacting otic fate, we investigated whether hydrogel stiffness or composition impacted the ability of vesicles to mature into organoids. Vesicles were grown in maturation media containing only 2% v/v Matrigel. This concentration produced little polymerization while exposing vesicles to about 200 μg/ml of extracellular matrix. We found that isolated vesicles could still develop into cysts with MyoVIIa+ cells. In the absence of Matrigel, vesicles collapsed and failed to produce cysts. Additionally, further immunohistochemistry of aggregates revealed that vesicles stained positive for laminin and collagen IV, indicating that the presence of these proteins, which are major components of Matrigel, may influence the development of organoids. Together, our results may help to define factors that influence organoid maturation.

Title: BC box motif in Sox6 induced differentiation to GABAnergic neuron of somatic stem cell

Authors: *T. YOSHIZUMI, H. KANNO, M. SINONAGA;
Neurosurg., Intaernational Univ. of Hlth. and Welfare Atami Hosp., Atami-city, Japan

Abstract: Previously, we demonstrated BC-box motif-mediated neuronal differentiation. Neuronal differentiation of somatic stem cells is induced by intracellular delivery of a peptide composed of the amino acid sequences encoded by a neuronal differentiation domain (NDD), and the NDD contained the BC box motif corresponding to the binding site of elongin C of BC box protein like Von Hippel Lindau tumor suppressor protein or suppressor of cytokine signaling (SOCS) protains. Especially, the NDD containing the BC-box motif in SOCS-6 protain advances

selective differentiation into GABAnergic neuron of somatic stem cell. And, it is reported SOCS protains mediate Janus kinase-2(JAK2) ubiquitination. From this, we here propose the mechanism of the GABAnergic neuronal differentiation of somatic stem cell mediated by the peptide of the BC-box motif in SOCS-6 protain. Immunoprecipitation with anti-JAK2 followed by immunoblotting showed the compound that contained the peptide from SOCS-6 has activity as an E3 ubiquitin ligase and mediates JAK2 ubiquitination. According to the result of western blotting, JAK2 and STAT3 are degraded. These result suggests that the GABAnergic neuronal differentiation of somatic stem cell mediated by the peptide of the BC-box motif in SOCS-6 is related to JAK2 ubiquitination. This GABAnergic neuronal differentiation of somatic stem cell using the BC-box motif in SOX-6 might contribute to the treatment of neuropathic pain and spasticity following spinal cord injury.

Title: Impact of OPRM1 A118G on ethanol sensitivity in stem cell derived human neurons

Authors: *M. S. SCARNATI[1], M. JOEL[1], M. SWERDEL[2], J. A. TISCHFIELD[3], R. P. HART[2], Z. P. PANG[1];
[1]Neurosci., Child Hlth. Inst. of New Jersey, New Brunswick, NJ; [2]Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ; [3]Dept. of Human Genet., Human Genet. Inst. of New Jersey, Piscataway, NJ

Abstract: Alcohol use disorders (AUDs) are among the most prevalent mental disorders worldwide. Yet, the mechanism(s) that can promote dependence in humans, in addition to the synaptic basis of AUDs in the context of opioid signaling, remains poorly understood mainly due to the difficulty in obtaining and studying live human tissue. This is critical in the context of genetic variants, including single nucleotide polymorphism (SNP) rs1799971 (*OPRM1*A118G) in the μ-opioid receptor (MOR). This SNP results in an amino acid substitution in the MOR by replacing an Asparagine (N) with Aspartate (D) at position 40. While the involvement of N40D MOR variants in AUDs remains highly debatable, alcoholic individuals with D40 variants gained more therapeutic effects when administered naltrexone. Work performed in heterologous expression systems and in rodents found altered ligand binding affinities for MOR and decreased

N’-glycosylation in the D40 variant, resulting in altered receptor trafficking, signaling and expression. Unfortunately, these studies have not revealed the correlation of D40 with alcohol reinforcement, possibly due to species specific differences in MOR function in humans. This makes it particularly important to assay the cellular and molecular mechanisms responsible for MOR function in the D40 variant in the context of *human* neurons. The *objective* of this project is to utilize human neuronal cells generated from induced pluripotent stem (iPS) cell lines to study the molecular, cellular, and synaptic mechanism(s) of MOR N40D in a *human* neuronal context. We have discovered a defect in N’-glycosylation in human MOR N40D peptide. The *working hypothesis is that the D40 variant of MOR impairs MOR trafficking, ligand binding, and expression, resulting from defective N’-glycosylation ultimately altering opioid and alcohol sensitivity on synaptic regulation, increasing the likelihood to develop an AUD.*Acute application of EtOH caused a significant increase in sIPSC and mIPSC frequency for N40 harboring iNs, while only a modest increase was observed in D40 human iNs. Interestingly, application of the MOR agonist DAMGO, following acute EtOH treatment, reduced the frequency of inhibitory events to a greater extent in D40 containing iNs. These data in combination with paired pulse stimulations suggest that iNs containing D40 MOR allelic variants have a lower initial synaptic release probability, and a higher affinity for opioid agonists. Finally, EtOH treatment alone indicates a differential sensitivity to acute treatment between genotypes. These results may provide a more mechanistic understanding of the interaction between alcohol and opioid signaling in humans.

Title: Optimal culture conditions for human induced pluripotent stem cell neurons

Authors: *J. LEVY, I. LORENZINI, M. NAVARRETE, S. MOORE, B. RABICHOW, M. ROBERTS, C. BURCIU, R. SATTLER;
Barrow Neurolog. Inst. at St. Joseph's Hosp, Phoenix, AZ

Abstract: Human induced pluripotent stem cells (hiPSCs) have shown to be valuable models for neurodegeneration, neurodevelopmental or neuropsychiatric research. Co-culturing hiPSC derived neurons on top of primary cultured astrocytes support the maturation, functionality and

neural synchronization. Additionally, the neurons adhere better and spread out more evenly when astrocytes are present. Our laboratory utilizes hiPSC derived motor neurons and cortical neurons to study the mechanisms of neurodegeneration in both amyotrophic lateral sclerosis (ALS) and frontotemporal degeneration (FTD). Even though co-culturing human iPSC derived motor neurons on top of primary cultured mouse astrocytes is optimal for neuronal maturation and function, many times astrocytes obscure neuron specific data when performing image, biochemical and/or molecular analyses. However, plating hiPSC neurons without the astrocytes leads to clumped and less functional neurons that slightly attach to glass coverslips or detach from the glass coverslip over time. In an effort to decrease astrocyte background and improve the even adherence and neuronal function of these hiPSC neurons, we tested six different combinations of extracellular coatings and six different neuronal medias to see which would support the best neurite outgrowth, synapse formation, and electrical communication. Each of the six coating combinations were paired with each of the six media types. For coating materials onto coverslips we used the following: PEI/Laminin; PDL/Geltrex; PLL/Laminin; PLO/Laminin; PDL/Matrigel and Collagen/Astrocytes. For culture medias, we used astrocyte conditioned media (ACM) supplemented with fresh growth factors (GFs), neuronal differentiation media (NDM) or BrainPhys supplemented with freah GFs and a 1:1 mixture of fresh NDM or BrainPhys and ACM with fresh GFs. To determine which pair of coating and media was most effective in promoting cell adherence and development, hiPSCs neurons were assessed for dendritic arborization, synaptic protein expression, and electrical activity. Even though neurons show the best results when they are plated on top of a monolayer of astrocytes, our results suggest that hiPSCs neurons plated without astrocytes with an optimized combination of coating and media leads to improve cell morphology and function over time.

Title: Glycolytic suppression enhances iPSC differentiation to NPC

Authors: *E. SZABO[1], **Y. KAM**[1], N. JASTROMB[1], K. SINGH[2];
[1]Agilent Technologies, Lexington, MA; [2]McMaster Univ., Hamilton, ON, Canada

Abstract: Cellular metabolism is an emerging critical factor suggesting that the metabolic status of cells and the environment can alter the differentiation trajectory of stem cells. In this study, we performed sequential metabolic profiling during induced pluripotent stem cell (iPSC) differentiation toward neuronal progenitor cells (NPCs). We found that a simple replacement of glucose, as the major carbon source, with galactose in the differentiation media enhance emergence of NPC in both quality and yield. Cellular metabolic profiling enabled the early detection of the metabolic shifts as a result of the carbon source switch. In order to facilitate *in vitro* tracking of changes in the metabolic phenotype during the early differentiation, we exploited 2D-monolayer culture method using singularized iPSCs, which is highly compatible with the Agilent Seahorse XF analyzer system allowing real-time cellular metabolic profiling of the differentiation time course from an iPSC to a NPC. The singularized iPSCs successfully differentiated to NPCs within 10 days. Interestingly, the NPC differentiation and overall yield was significantly improved by glucose replacement with galactose, which promoted selective reduction in glycolytic activity without affecting mitochondrial respiration. More homogeneous and rapidly growing NPCs were obtained in the presence of galactose, while a significant amount of non-NPC-like cells remained in the presence of glucose. The XF analysis also revealed a significant difference in the metabolic profiles between the two groups, which showed more stable and persistent mitochondrial function in galactose supplemented condition. The difference in metabolic profile appeared as early as two days after the onset of differentiation, while the expression pattern of the NPC molecular marker, nestin, was already distinguishable after four days of differentiation. These results support the importance of the carbon sources during metabolically dynamic processes, such as lineage specification/differentiation of stem cells. The study demonstrates that alterations of mitochondrial function even early during the differentiation from iPSCs, which are highly glycolytic, can drive stem cell differentiation programs. In addition, the analysis suggests that a sequential or on-time metabolic profiling can be a useful readout for evaluating *in vitro* differentiation towards predicting trajectory and quality of the differentiation process.

Title: Multifunctional biodegradable porous microspheres to act as a delivery platform and three-dimensional model for neurological disease

Authors: *E. S. SANDHURST[1], D. ENGEBRETSON[1], K. R. FRANCIS[2];
[1]Univ. of South Dakota, Vermillion, SD; [2]Cell. Therapies and Stem Cell Biol. Group, Sanford Res., Sioux Falls, SD

Abstract: Optimization and improvement of stem cell survival and differentiation represent a critical barrier to both the modeling of nervous system development and utilization of stem cell derivatives for patient therapies. Our approach seeks to provide a 3D matrix that facilitates cell-cell interaction, differentiation, and functional activity within a chemically defined environment. To achieve this, we prepared 3D porous polymer microspheres to act as carriers that were seeded with human neural stem cells (NSCs) derived from induced pluripotent stem cell (iPSC) models. Using a double emulsion and porogen leaching technique, defined amounts of poly-(lactic-co-glycolic acid) (PLGA) and gelatin were combined to yield a highly porous microstructure capable of cell support. Techniques were optimized to generate microspheres with a diameter of 150 - 300 µm, average pore size of 20 µm and a porosity >90%. To demonstrate the feasibility of the 3D microspheres to act as a cell delivery vehicle, we cultured iPSC-derived NSCs for up to 28 days on microspheres. To define the impact of the substrate on NSC attachment and differentiation, we compared NSC response to culture on uncoated spheres versus spheres coated with Matrigel, poly-L-ornithine, or poly-L-ornithine/laminin. After 24 hours of culture on the 3D microsphere structure, NSCs exhibited high attachment and typical NSC morphology. After 7 days, NSCs exhibited a 5-fold increase in cell number, broad microsphere distribution, and cytoskeletal processes mediating cell-cell contacts. In addition to their ability to act as a cell delivery vehicle, we functionalized the surface of the microspheres with hydroxyapatite (HA) minerals by immersion in a simulated body fluid over various time periods. To validate their multifunctional capacity, we demonstrated the model protein bovine serum albumin could be loaded into the HA crystal matrix on the porous microspheres and released in a controlled manner over 10 days. Ongoing studies are defining the differentiation and functional maturation of neural lineages from NSCs within this model, evaluating other adult-derived stem cell models, including mesenchymal stem cells, within our microsphere model, and further defining the efficacy of our composite polymer/bioceramic microsphere model as a combined cellular and drug-delivery platform for additional neurologically-targeted proteins and small molecules. We have produced a promising biomaterial for combined local drug and cellular delivery for application in pharmacological analyses, developmental modeling, and regenerative techniques for neurological models.

Abstract: Direct cell reprogramming is a rapidly growing field that has challenged traditional concepts of cellular identity. The expression of Neurogenin 2 (NGN2) results in rapid reprogramming of human pluripotent stem cells (PSCs) into functional cortical glutamatergic neurons. This combines the advantage of the highly proliferative and epigenetically malleable PSC stage with the efficiency of direct reprogramming. We have previously demonstrated that gene targeting the components of a Tet-On system into two separate safe harbour sites overcome gene silencing and results in optimised transgene expression in hiPSCs (OptiOx), and consequently yields highly homogenous cultures of pure glutamatergic neurons within less than four days. The mechanisms that mediate this remarkable cellular metamorphosis remain poorly understood. To study the transcriptional events occurring as a result of NGN2 expression, three independent biological replicates were harvested at the iPSC stage (day 0), and 6h, 12h, 24h, 36h, day 2, day 3, day 4, day 14, and day 21 post induction. Cell extracts were subsequently processed for bulk RNA sequencing. This demonstrated distinct and highly reproducible transcriptional changes across each of the individual time points. To gain a more detailed insight into the distinct cellular states, we complemented our bulk-RNA-Seq approach with single cell RNA sequencing of cells harvested at the iPSC stage (day 0), as well as 12h, 24h, day 2, day 3, day 4, day 14, and day 21 post induction. Louvain network analysis demonstrated distinct cellular states through which cells synchronously progressed with little heterogeneity until attaining a distinct neuronal phenotype. In order to differentiate direct from indirect NGN2 down-stream effectors, an inducible hiPSC cell line in which NGN2 tagged with HA was constructed and validated as outlined above. CHiP-Seq data acquired on day 2 after induction was subsequently overlaid with bulk seq data and single cell seq data. This enabled identification of direct and indirect effectors of NGN2 with regards to gene regulatory networks as well as on peripheral genes over the time course of the experiment. In conclusion, we provide a detailed analysis of transcriptional events that govern the transition of iPSCs into mature glutamatergic neurons following NGN2 expression.

Title: Neurotransmitter levels in spinal-organoids vs. rodent models during central nervous system development using capillary electrophoresis-mass spectrometry

Authors: ***S. E. MURPHY**, A. C. WEISS, K. P. RAMOS-CRUZ, C. D. KAUFMAN, H. KONG, J. V. SWEEDLER, M. U. GILLETTE;
Univ. of Illinois At Urbana Champaign, Urbana, IL

Abstract: Organoids have been used for disease modeling, drug testing, developmental studies, and transplantation. Spinal organoids are 3D aggregates of motor neurons and glia cultured from stem cells *in vitro*. The extent to which spinal organoids model spinal cords enables their utility in these studies. However, the extent to which ability of spinal organoids to accurately model neurotransmitter expression in rodent spinal cord development with regard to the profile of neurotransmitters expressed has not been studied. Therefore, the rationale behind this work is to determine how accurately spinal organoids model the cell-to-cell signaling molecule complement in rodent spinal cord explants. To accomplish this, we are growing spinal organoids and characterizing their chemical contents with mass spectrometry. More specifically, using capillary electrophoresis-electrospray ionization-mass spectrometry (CE-ESI-MS), we assay the neurotransmitters present during spinal organoid and rodent spinal cord explant development. Coupling these methods is significant, because there are no reports measuring neurotransmitters in organoids and rodent spinal cord explants using CE-ESI-MS. Here we present data showing our ability to generate spinal organoids that express neuronal and glial markers as well as qualitatively measure neurotransmitters in juvenile (P7) rodent spinal cord explants. Spinal organoids were cultured for up to 2 mo. After one mo., the spinal organoids expressed the neuronal marker NeuN and the glial marker GFAP. At 2 mo., the cells positive for GFAP displayed a star shape characteristic of astrocyte morphology. Explant samples from spinal cords of P7 rodents were collected, and neurotransmitters were extracted using an acidified methanol solution and sample homogenization by homogenizing samples. Three biological replicates were

analyzed in duplicate using a laboratory-built CE-ESI-MS. The neurotransmitters acetylcholine, γ-aminobutyric acid, glutamic acid, and aspartic acid were qualitatively measured in P7 rodent spinal cord explant samples. These results demonstrate the ability to measure neurotransmitters from rodent spinal cord explants using CE-ESI-MS. Future work aims to assess the emergence of neurotransmitters during the development of spinal organoids vs. rodent spinal cord explant development using CE-ESI-MS.

Title: Retinoid x receptoralpha mediates unesterified DHA-dependent spinogenesis and excitatory synapse formation *in vivo*

Authors: *H. CAO, M. LI, G. LI, S.-J. LI, B. WEN, X. YU;
Inst. of Neurosci., Shanghai City, China

Abstract: Neural circuit formation depends on synapse development, which is governed by coordinated interaction between extracellular cues and intracellular signaling. Nuclear receptors are ligand-activated transcription factors that play important roles in the development, homeostasis, and metabolism of the organism. They sense nonpolar regulatory molecules that diffuse across the plasma membrane, and directly transduce extracellular signals to regulate transcriptional programming. Retinoid X receptor α (*Rxra*) plays central roles in many physiological processes by forming homodimers or heterodimers with other nuclear receptors, although its role in the brain is largely unknown. As an endogenous ligand for RXRs, docosahexaenoic acid (DHA)—a brain-enriched polyunsaturated fatty acid and famous nutritional additive—has been associated with various neurological and psychiatric disorders. Here, we report that DHA and *Rxra* contribute to synapse development *in vivo* as a ligand-receptor pair. In NEX-Cre *Rxra* conditional knockout (*Rxra* cKO; *Rxra* conditionally removed from all excitatory neurons from the cerebral cortex and hippocampus) mice, we found significant reduction in dendritic spine density of layer 2/3 pyramidal neurons in both developing and adult cortices. We further showed the effect of *Rxra* in regulating dendritic spine density is

transcriptional, bidirectional and cell-autonomous. Correspondingly, we detected significant downregulation of excitatory synapse number and mEPSC frequency in *Rxra* knockout neurons. Moreover, intracerebroventricular (ICV) injection of unesterified DHA significantly upregulated spine density and synaptic transmission in control, but not in *Rxra* cKO mice. Blocking DHA release from brain phospholipids led to significant reduction in spine density, an effect rescued by unesterified DHA. Finally, we found that DHA and *Rxra* likely promote synapse development by upregulating immediate early genes (IEGs) expression. Together, these results dmonstrate that unesterified DHA promotes excitatory synapse development through *Rxra*-dependent signaling *in vivo*.

Title: Expression of chimeric GluN2 subunits in hippocampal NMDA receptors reveals mechanisms regulating the postnatal development of dendritic spines on area CA1 pyramidal neurons

Authors: *R. E. KEITH[1], M. J. KEITH[2], S. SINGH[2], S. K. PACK[4], R. BINOY[2], T. C. DUMAS[3];
[1]Interdepartmental Program in Neurosci., [2]Col. of Sci., [3]Psychology, George Mason Univ., Fairfax, VA; [4]Thomas Jefferson High Sch. for Sci. and Technol., Alexandria, VA

Abstract: During postnatal brain development, activity-dependent plasticity shapes dendritic spines; these activity-dependent changes in dendritic spines are regulated by N-methyl-D-aspartate receptors (NMDARs), a glutamate receptor at excitatory synapses. In the hippocampus, NMDARs are composed of two GluN1, and two GluN2 subunits, which can be sub classed as A, B, C, or D. At three weeks of age, there is a switch in NMDAR composition, from GluN2B-containing to GluN2A-containing and triheteromeric receptors. This switch in configuration has been associated with decreased spine density in hippocampal pyramidal cells and the emergence of spatial learning and memory.
Subunit composition affects the calcium-dependent and calcium-independent signaling properties of NMDARs significantly. Compared to NMDARs with GluN2A subunits, GluN2B-NMDARs conduct calcium for longer after activation and display affinity for CaMKII and Ras-

GRF1, while GluN2A-NMDARs interact more with Ras-GRF2 and PKA. Mice lacking GluN2B postnatally show reduced spine density and learning deficits; conversely, mice lacking GluN2A show an increase in density in dentate granule cells with no change in density in pyramidal cells. To dissociate the influences of calcium-dependent and calcium-independent signaling on dendritic spines, we created transgenic mice with the amino terminal domain (ATD) and transmembrane domains (TMDs) of GluN2A subunits coupled with the carboxy terminal domain (CTD) of GluN2B (termed ABc), and vice versa (termed BAc). We crossed these mice with mice expressing GFP in hippocampal pyramidal cells, allowing assessment of spine density through fluorescence microscopy. Slices were prepared during developmental stages just before (P17-P19) and just after (P22-P24) the switch in NMDAR composition, as well as in more mature animals (P30-P60). Spine segments were traced in hippocampal pyramidal cells by three independent investigators. The results demonstrated that, at P17-19, apical and basal dendrites showed lower spine density in ABc mice and a higher spine density in BAc mice compared to wildtype controls. At P22-24, BAc mice showed reduced spine density while ABc animals showed no change from wildtypes in the apical dendrite; the basal dendrite showed no genotype differences in density. The P30-P60 spine density results are more preliminary, but currently show reduced dendritic spine density in BAc mice compared to ABc and WTs. In summary, these results suggest that calcium-dependent and calcium-independent signaling streams act in opposing ways to regulate dendritic spines on hippocampal pyramidal neurons during postnatal development.

Title: Astrocyte expression of synapse promoting genes is developmentally regulated by neuronal and astrocyte activity

Authors: *I. FARHY-TSELNICKER, C. DOWLING, N. J. ALLEN;
Mol. Neurobio. Lab., The Salk Inst., La Jolla, CA

Abstract: Astrocytes are crucial regulators of neuronal synapse development and function. In the rodent cortex neurons are arranged in 6 layers, each with stereotyped synaptic connectivity. Cortical astrocytes produce several synapse promoting factors, however, whether they

differentially regulate formation of synapses in different layers is unknown. Furthermore, the developmental expression pattern of astrocyte synaptogenic cues, and whether expression is regulated by neuronal or astrocyte activity, is unknown. Here we use mouse visual cortex to study the development of astrocytes and astrocyte-derived synapse promoting genes including glypicans, thrombospondins and Chordin like1. Using genetic mouse models, immunohistochemistry, and in situ hybridization we quantified the developmental changes in astrocyte numbers and expression levels of synapse promoting genes within each of the 6 neuronal layers. We observed differential developmental changes in expression of astrocyte-derived synapse promoting genes, which occurred mainly between post-natal days (P) 7 and 14, a time between synapse initiation and maturation. For example, glypican 4 (gpc4) expression is strongly reduced at P14 compared to P7 only in layer 1, while glypican 6 (gpc6) expression is increased in deeper layers. Next, perturbing glutamate release from thalamic neurons by knocking out VGlut2 resulted in significant increase in gpc4 expression in layer 1 at P14 compared to wild type controls, while expression of gpc6 was decreased in deep layers, thus preventing the developmental regulation. Moreover, perturbing astrocyte activity at P14 by knocking out IP3R2 resulted in a significant decrease in gpc4 expression, but had no effect on gpc6 expression. Our findings provide insight into neuron-astrocyte interaction as it occurs at the level of the distinct cortical connections during synapse development, and constitute an important frame work for future studies of astrocyte and synapse development in the cortex.

Title: SRPX2 protects synapses from excess complement-mediated elimination during development

Authors: Q. CONG, **B. SOTEROS**, *G.-M. SIA;
Pharmacol., UT Hlth. San Antonio, San Antonio, TX

Abstract: The complement system has emerged as an important mediator of synapse elimination during brain development and disease. However, whether there are endogenous mechanisms to inhibit complement activity remain unclear. Here, we show that sushi repeat protein X-linked 2

(SRPX2) is a neuronal complement regulator that protects synapses from excessive complement-mediated elimination during development. SRPX2 binds to C1q and inhibits initiation of the complement cascade, and mice lacking SRPX2 show increased C3b deposition and microglial activation. Absence of SRPX2 also causes a specific loss of thalamocortical synapses in the somatosensory cortex due to excessive pruning, which is reversed in the C1QA-SRPX2 and C3-SRPX2 double knockout mice. In addition, SRPX2 knockout mice show increased eye-specific segregation of retinal ganglion cell inputs in the visual thalamus, which is also reversed in both the C1QA-SRPX2 and C3-SRPX2 double knockout mice. These data reveal a new molecular mechanism that restricts complement activity to specific sets of synapses during development.

Title: Layer-specific reconfiguration of cortical microcircuits by visual deprivation during the critical period

Authors: *L. YAO, M. MENG, X. GU, X. ZHANG;
State Key Lab. of Cognitive Neurosci. & Learning, Beijing Normal Univ., Beijing, China

Abstract: Abnormal sensory inputs or experience during a postnatal critical period markedly alters sensory cortical functions. However, experience-induced changes of local synaptic circuits across different cortical laminae, which underlie the sensory function alteration, are poorly understood. To address this question, we conducted extensively dual whole-cell recording in the layers 2/3 and 4 of primary visual cortex (V1) prepared from the mice that experienced monocular deprivation (MD) of visual inputs during the critical period. The results suggest that there exist distinct circuit wirings of excitatory pyramidal cells and inhibitory parvalbumin (PV)-, somatostatin (SOM)- or vasoactive intestinal peptide (VIP)-expressing interneurons within the layers 2/3 and 4. The MD experience selectively modifies the strength of certain excitatory or inhibitory synapses that targeted to distinct cell types in both two layers, but exhibiting apparent layer difference. The results also indicate that synapses of inhibitory SST and PV cells are primary targets for experience modification in the layer 2/3 and 4 local circuits, respectively. Our findings provide a systematic elucidation of layer-specific reconfiguration of visual cortical microcircuits by altered experience.

Title: Complement activation during early postnatal brain development suggests earlier onset of synaptic pruning in humans

Authors: *R. E. SAGER[1], A. K. WALKER[2], K. ROBINSON[2], M. J. WEBSTER[3], C. S. WEICKERT[2];
[1]Dept. of Neurosci., SUNY Upstate Med. Univ., Syracuse, NY; [2]Neurosci. Res. Australia, Sydney, Australia; [3]Stanley Med. Res. Inst., Rockville, MD

Abstract: Dysregulation of synaptic pruning has been theorized as a pathological cause for schizophrenia and autism. Over the past decade, synaptic pruning through the classical complement pathway has been increasingly recognized as a mechanism of regulating synapses in the developing brain. However, patterns of complement expression in the human brain are not well defined in the literature. Using the dorsolateral prefrontal cortex from post-mortem humans, we extracted RNA for targeted RT-PCR (n=48) of genes from the classical complement pathway. One of these genes, C4, is a risk factor for schizophrenia, with increased risk tied directly to increased C4 mRNA levels. Our cohort for this study (n=57) was divided into five categories representing different developmental periods: neonate, infant, toddler, school age, teenager, and young adult; ranging from age two months to 25 years. Group sizes were kept as consistent as possible, with seven to 13 cases per age group. Raw transcript levels were normalized to geomean values calculated from three housekeeper genes with no significant correlations between age, pH, post-mortem interval (PMI), or RNA integrity number (RIN). All data sets were tested for significant correlations with pH, PMI, and RIN and analyzed with ANOVA or ANCOVA accordingly. We found that the mRNA of many complement components changed significantly with age, with the typical pattern being low levels in neonates which increased and peaked in toddlers, before reducing or plateauing though school age and teenage years. Among these transcripts were the classical complement cascade initiator C1q, subunit b (C1qb mRNA, F=4.713, df=5, p=0.001), and C3, a key effector molecule that marks membranes for destruction (C3 mRNA, df=5, F=2.452, p=0.047). Subsequently, inhibition of the pathway

escalates, with inhibitors increasing significantly in toddlers (CD55 mRNA, F=7.598, df=5 p<0.001; CD59 mRNA, F=11.728, df=5, p<0.001) and reaching peak expression in schoolage (CD55 mRNA; CD46 mRNA, F=3.995, df=5, p=0.004). These data suggest an increased role for the classical complement cascade in toddlers, with no induction of complement in the teenage brain. Thus, our results suggest that complement-mediated synaptic pruning may increase during the age of onset for autism, but not that of schizophrenia.

Abstract: Electrical activity in cortical networks and their composite neurons provides the basis for understanding the information processing in single neurons and interconnected neural populations [1]. To this end, numerous studies have focused on how neurons and the networks they form, operate from an electrical perspective [2,3]. The underlying molecular activity of brain cells plays important roles where both neurons and glia are complex molecular machines, adapting their responses over short and long-time scales [4]. Recent experiments have implicated the Extracellular Matrix (ECM), including an ECM specialization called the Peri-Neuronal Network (PNN), and their molecular components in neural signaling and information processing, by virtue that it strategically occupies the synaptic cleft [5,6]. Recent studies show ECM/PNN involvement in Life-long learning and memory, synaptic remodeling and significantly, in the recall of fear memory [7,8]. Furthermore, other studies have illustrated that the expression of certain ECM/PNN molecules are directly involved in modulating the efficacy of neural transmission on multiple time scales [9]. Currently, a handful of computational studies have focused on understanding the role of how the ECM influences neural signaling [10]. How the interaction between ECM and neural activity impacts network behavior and information processing has yet to be explored from a computational perspective.

We present a new biologically inspired framework and an accompanying mathematical model that captures the nature of bidirectional neuron-ECM signaling. The framework considers the roles played by various ECM/PNN molecules through their activity-driven influence on neural transmission and impact on neural responses. Our model is computationally tractable and can be applied to study the bidirectional nature of neural-ECM signaling in different brain areas and their collective influence on both single neuron responses and network activity. Finally, we present preliminary results, using a classical spiking neural oscillator (recurrently connected excitatory and inhibitory pair of neurons), to illustrate how ECM-neural interactions impacts the behavior of a spiking neural oscillator.

Title: Investigating the effects of chondroitin sulfate on dendritic spines of pyramidal neurons

Authors: *T. TANAKA[1], A. KEREVER[1], Y. SUZUKI[1], K. KATO[1], M. TOYODA[1], F. SAITOW[2], H. SUZUKI[2], H. HIOKI[3], E. HIRASAWA[1];

Abstract: [Introduction]: Research has shown that autism spectrum disorder (ASD) occurs as a result of an imbalance between excitation and inhibition of neurons in the cerebrum. However, the underlying mechanism inducing this imbalance remains unclear. One potential player in this mechanism could be the extracellular matrix (ECM), especially chondroitin sulfate (CS) which are known to repress the formation of dendritic spines. Furthermore, the expression pattern of CS dramatically changes during the critical period in the mammalian brain development, a period in which neural plasticity is known to be enhanced. From our past research, an immunostaining pattern ("CS patch") detected by an anti-CS antibody could be an indicator of an extracellular structure that orchestrates a normal neural environment. We previously found that BTBR mice, a model mouse for ASD, lack "CS patches" in the somatosensory cortex, suggesting the possible link between this observation and ASD. In this study, we first established a method to analyze dendritic spine density and morphology on pyramidal neurons of mouse cerebrum. We then investigated the effects of "CS patches" on spine density and morphology using C57BL/6 (B6) and BTBR mice. [Materials and Methods]: Pyramidal neuron from layer 2/3 of the somatosensory cortex were injected with biocytin on 300μm acute slices. Slices were cleared and immunostained with CS56 antibody to reveal the "CS patches" and streptavidin to reveal the pyramidal neuron. The image data were processed under IMARIS for rendering and analysis. During data processing, spines were classified as mushroom, thin, stubby, or filopodia depending upon the volume, length, and width. [Results]: Comparisons of dendrites inside and outside of the "CS patches" in B6 mice showed that dendrites inside had more mushroom spines. Additionally, the head volume of mushroom spines on the dendrites inside was significantly larger compared to that of dendrites outside the "CS patches". BTBR dendrites notably showed a lower spine density than B6 dendrites. [Conclusion]: Our analysis shows clear differences in density and morphology between spines inside and outside the "CS patches" for B6 mice. Additionally, those were different between B6 and BTBR mice. These results suggest an effect of specific CS recognized by CS56 antibody on pyramidal neuron spines.

Abstract: Consolidation and remodeling of synapses during the postnatal development stage strengthens the appropriate connections and eliminates wrong or unnecessary ones. These processes known as maturation and synaptic pruning, respectively, are highly dependent on sensory activity and responsible for neuronal plasticity. The development of the nervous system in Fragile X syndrome (FXS) presents abnormalities in these processes. This genetic disorder is the leading cause of hereditary mental disability, and the major genetic cause known in Autism Spectrum Disorders (ASDs). Both pathologies exhibit defective synapses that result in behavioral and learning disorders. The production of the FMRP (fragile X mental retardation protein) is eliminated in FXS. FMRP, a protein that binds and regulates the translation mRNA, plays an important role in the elimination of immature synapses. On the other hand, the Neuroligin protein, mutated in some ASDs, helps in the formation of the synaptic cleft and the maturation of neural connections. This project explores, through the molecular technique RT-PCR and behavioral assays Negative Geotaxis test and Aversive Phototaxic Suppression test, the comportment of Neuroligin and FMR1 mRNA expression as well as memory and locomotion capacity during the process of activity dependent synaptic pruning in a wildtype strain of *Drosophila melanogaster*, reared in a control protocol with normal levels of sensorial stimulation or in a sensory-deprivation rearing protocol with restriction of light, auditory, spatial and social stimuli. We found that, in the sensory-deprivation treatment, the Nlg*1* gene (present in excitatory synapses) is down-regulated and that Nlg2 (present in inhibitory synapses) and FMR1 genes are up-regulated. Also, the locomotor activity and learning capacity of the flies are reduced in this treatment, providing evidence of the importance of sensory input during nervous system development and also as an important player in the etiology of neuronal developmental disorders.

Title: The schizophrenia-associated gene CSMD1 encodes a brain-specific complement inhibitor

Authors: M. L. BAUM[1,2,4], ***M. B. JOHNSON**[4], R. FOX[4], E. NACU[5,4], W. CROTTY[4], D. WILTON[1], S. MCCARROLL[3,4], K. EGGAN[5,4], B. A. STEVENS[1,2,4,6];

Abstract: Four threads of biological observation have recently converged onto a theory in which over-exuberant synaptic pruning contributes to the pathogenesis of schizophrenia: 1) post mortem, there is a reduced number of dendritic spines in the frontal cortex of individuals with schizophrenia, 2) the disorder has a characteristic onset in late adolescence, a critical period for normal pruning and thinning of the frontal cortex, 3) clinical high risk young people who convert to psychosis have an accelerated rate of frontal cortex thinning coincident with psychosis onset, 4) human genetics strongly implicates hyper-function of synaptic pruning machinery in disease risk - specifically, disease risk increases with brain expression and genomic copy number of complement component 4 (C4), a member of a cascade of immune molecules repurposed in the brain to promote the sculpting of circuits. To further test a pruning hypothesis of schizophrenia, we investigated whether an inhibitor of this pruning machinery could also be functionally implicated in disease risk. Schizophrenia genetics, structural biology, *in vitro* biochemistry, and gene expression suggested that the large transmembrane protein encoded by the giant gene CSMD1 (CUB and Sushi Multiple Domains 1) could be such a disease associated complement inhibitor: a) a genome-wide significant association signal localizes to *CSMD1*, b) the gene encodes a protein composed almost entirely of domains conserved in regulators of the complement cascade, i.e., CUB (Complement, Urchin-EGF, BMP) and Sushi (aka CCP or Complement Control Proteins) domains, c) protein fragments of CSMD1 can directly and indirectly inhibit the activation of C4 and C3 *in vitro*, d) CSMD1 mRNA is brain-enriched.

Despite these intriguing observations, however, little was known about the about the normal functions of CSMD1 in neural tissues. Here, we show that CSMD1 protein is highly brain-enriched, particularly in cortex, present at synapses, and is expressed predominantly by neurons. Using a human stem cell line and a mouse each genetically lacking CSMD1, we present evidence that CSMD1 regulates complement activation on neural cells *in vitro* and *in vivo*, and that loss of Csmd1 abrogates the development of a complement-and-pruning-dependent neural circuit. Together, these data corroborate CSMD1 as a brain-specific complement inhibitor and further support a pruning hypothesis of neurodevelopmental etiology for schizophrenia.

Title: Spontaneous retinal activity selectively influences the establishment of cortical inhibition prior to sensory experience

Authors: *T. J. BURBRIDGE[1,2], L. CHEADLE[3], M. E. ROBIE[2], M. E. GREENBERG[4], G. J. FISHELL[2];
[1]New York Univ., New York, NY; [2]Neurobio., [4]Dept. of Neurobio., [3]Harvard Med. Sch., Boston, MA

Abstract: Patterned, spontaneous brain activity propagates throughout sensory systems during stages of brain development that occur prior to the onset of environmentally-evoked sensory experience. While such activity is known to be important for neural development, the specific roles of these highly stereotyped, intrinsically generated patterns of activity in circuit assembly have not yet been fully characterized in large part due to a technical inability to manipulate these patterns without initiating compensatory activity *in vivo*. To interrogate the role of spontaneous activity in brain development, we focused on the visual system, in which patterned “waves” of activity driven by cholinergic signaling in the retina (retinal waves) propagate through retino-

recipient brain regions and extend to the visual cortex. To manipulate retinal waves without initiating compensatory activity, we employed a transgenic mouse in which the Beta-2 subunit of the nicotinic acetylcholine receptor is conditionally removed from roughly two-thirds of the retina, leaving retinal waves in the remaining third of the retina intact. By performing *in vivo* calcium imaging, we found that retinal wave disruption in these mice persists throughout the visual system to the primary visual cortex. Microdissection and single-cell RNA-sequencing of wave-positive and wave-negative cortical regions identified through calcium imaging revealed that two inhibitory neuron subtypes, Parvalbumin (PV) and Somatostatin (SST) neurons, are particularly sensitive to patterned activity changes at the molecular level when compared to VIP interneurons and excitatory neurons. Ontological analysis of misregulated genes in PV and SST neurons suggest possible effects on inhibitory synapse formation and neurotransmission. Consistently, we found that loss of retinal waves leads to a decrease in the density of SST synapses onto pyramidal cells. These experiments reveal cell-type-specific roles for early patterned activity in cortical circuit assembly.

Title: Integrative molecular analysis of synaptic pruning in a large psychiatric cohort of postmortem prefrontal cortex

Authors: *R. G. FOX[1], B. A. STEVENS[2,1,3,4], M. B. JOHNSON[1,2];
[1]Stanley Ctr. for Psychiatric Res., Broad Inst. of MIT and Harvard, Cambridge, MA; [2]Kirby Neurobio. Ctr., Boston Children's Hosp., Boston, MA; [3]Neurol., Harvard Med. Sch., Boston, MA; [4]Howard Hughes Med. Inst., Boston, MA

Abstract: Synaptic pruning is a normal process of synapse removal and circuit refinement that occurs throughout the developing brain. This process is mediated in part by the classical complement pathway, which opsonizes or “tags” synapses and flags them for removal. Microglia, the immune phagocytes of the CNS, recognize this tag via complement receptors and engulf the unwanted synapses. In the prefrontal and other association areas of the cortex,

synaptic pruning peaks during adolescence and continues significantly later than in primary sensory cortical regions. Studies have found reduced synapse numbers in prefrontal and association cortex of patients with schizophrenia, as well as exaggerated thinning of prefrontal grey matter, suggesting that excessive synaptic pruning may contribute to the emergence of this severe mental illness. Notably, the adolescent peak of prefrontal synaptic pruning coincides with a developmental window of vulnerability for psychiatric disorders including schizophrenia. Additionally, genome-wide association studies have identified genetic risk factors for schizophrenia that implicate the complement pathway, including complement component C4A. However, studies utilizing human postmortem brain tissue have been limited by sample availability and the low-throughput of methods for synapse analysis and quantification in brain tissue sections. We have applied higher-throughput techniques for synapse counting and analysis in human prefrontal cortex tissue sections from a large cohort of psychiatric cases and controls (n=50 Schizophrenia, n=50 Bipolar Disorder, n=50 Control). In addition to a large sample size, this cohort has the advantages of extensive prior characterization, including haplotype copy number and brain RNA expression levels of complement component 4 (C4A), as well as matching DNA, RNA, and protein lysate samples for correlative measures. Applying a variety of methods to these samples, we aim to calculate the densities of molecularly defined synaptic subtypes, quantify complement protein expression and pathway activation, characterize microglia cellular phenotypes, and correlate these new data with psychiatric diagnoses, genetic risk, and other existing measurements from this cohort.

Title: Postnatal developmental functional changes between the retinohypothalamic tract and the suprachiasmatic nucleus of the rat

Authors: *M. E. REYES-MENDEZ[1], R. A. NAVARRO-POLANCO[2], E. G. MORENO-GALINDO[2], J. F. ALAMILLA[2];

Abstract: The suprachiasmatic nucleus (SCN) is the main circadian pacemaker in mammals that synchronizes several physiological processes to the environment light through the retinohypothalamic tract (RHT). Glutamate is released by RHT terminals towards SCN neurons to activate NMDA and AMPA-kainate receptors, which induces phase shifts. Previous behavioral and functional evidence indicates that rat pups are able to synchronize to the light at postnatal day (P) 6 - P8. In this work, we aimed to study the pre- and postsynaptic changes between the unmyelinated RHT-SCN connexions during the postnatal development. We carried out electrophysiological recordings in acute coronal hypothalamic slices of rat pups from three groups of age: P3-5, P7-9 and P13-18. Miniature NMDA and AMPA-kainate excitatory postsynaptic currents (EPSCs) exhibited an increase in their amplitude along postnatal development, indicating an increment of the presynaptic quantum. Also, in both NMDA and AMPA-kainate events there were a greater frequency at P13-18, suggesting presynaptic changes in the neurotransmitter release machinery. In addition, electrically evoked AMPA-kainate and NMDA components increased with age, although the rise was larger for the former. With paired-pulse stimulation, we found modifications in the short-term synaptic plasticity from *synaptic depression* to *synaptic facilitation* during postnatal development, and also changes in the readily releasable vesicle pool and in the probability of initial release. Taken together, our results showed developmental modifications in the unmyelinated RHT-SCN synapses, implying that synchronization to light at adult ages requires functional changes similar to those of myelinated fast communication systems.

Title: Retrograde control of presynaptic development by postsynaptic calcineurin at the *drosophila* neuromuscular junction

Authors: L. LE[1], H. S. KESHISHIAN[3], ***B. A. BERKE**[2];
[2]Dept. of Biol., [1]Truman State Univ., Kirksville, MO; [3]MCDB Dept., Yale Univ., New Haven, CT

Abstract: Postsynaptic Ca can influence synaptic plasticity by activating downstream kinases and phosphatases. The activation of the Ca^{2+}/Calmodulin-dependent protein kinase II (CaMKII)

or the Ca^{2+}/Calmodulin-dependent phosphatase Calcineurin (Cn) lead to distinct effects on postsynaptic physiology. However, the retrograde transsynaptic effects of postsynaptic Ca signaling on the presynaptic terminal are less well understood. We examined this phenomenon at the glutamatergic *Drosophila* neuromuscular junction (NMJ). The postsynaptic bodywall muscles *Drosophila* larvae can be experimentally manipulated for gain or loss-of-function studies using a variety of mutations and transgenes. Moreover, the subsequent effects on the presynaptic NMJ can be readily visualized and quantified. Previous work has implicated CaMKII in the retrograde control of synaptic homeostasis, but a role for postsynaptic Cn and its complex interactions with CaMKII remain to be evaluated. Our data indicate that of the three isoforms of the Cn catalytic subunit in *Drosophila*, only Pp2B-14D (14D) influences presynaptic motoneuron growth in a retrograde fashion. Expression of RNAi transgenes against 14D increased the number of presynaptic boutons, while a constitutively-active transgene decreased bouton number. This bidirectional modulation of synaptic size was not accompanied by a change to postsynaptic glutamate receptors or retrograde BMP signaling, mechanisms known to influence presynaptic growth through retrograde, transsynaptic effects. In addition, the retrograde control of growth by 14D acted at a branch-specific level. We examined the ventral Common Exciter (vCE) motoneuron that innervates multiple ventral muscles, and transgenes affecting 14D were driven in distinct subsets of the vCE's postsynaptic targets. NMJ size was affected specifically at those branches opposite the affected muscle fibers, as compared to vCE's synapses on neighboring, non-manipulated muscles. We propose that an imbalance between postsynaptic, Ca-dependent phosphorylation (by CaMKII) and dephosophorylation (by Cn) may be a trigger for local, retrograde signaling. To directly test this, we expressed multiple transgenes in postsynaptic muscle fibers to increase CaMKII activity while simultaneously increasing the activity of Cn, and visa versa. These manipulations restored NMJ size to that of controls, suggesting that this pair of enzymes function as a toggle switch in postsynaptic muscles to influence motoneuron development at the fly NMJ.

Title: Target-dependent signaling mediates synaptic plasticity at the *drosophila* neuromuscular junction

Authors: B. A. BERKE[1], L. LE[1], ***H. S. KESHISHIAN**[2];
[1]Biol. Sci., Truman State Univ., Kirksville, MO; [2]MCDB, Yale Univ., New Haven, CT

Abstract: Neurons typically innervate multiple targets, establishing synapses with varied strengths and expressions of synaptic plasticity. We examined the molecular-genetic mechanisms that allow a single motoneuron, the ventral Common Exciter (vCE) of *Drosophila*, to establish connections with distinct morphology and synaptic strength. By driving transgenes in a subset of vCE's muscle targets, we tested whether a postsynaptic cell could independently control presynaptic neuromuscular junction (NMJ) growth and physiology at its own vCE branch. In this system, postsynaptic glutamate receptor activity stimulates the release of a BMP4/5/6 homologue, Glass bottom boat (Gbb). As larvae mature and motoneuron terminals grow, Gbb facilitates presynaptic development by activating distinct pools of an R-Smad transcription factor (pMad): one in the motoneuron nucleus and another in presynaptic boutons. pMad regulates transcription within the nucleus, but its function in boutons is not fully understood. We find that postsynaptic manipulations of glutamate receptors or Gbb within subsets of target muscles leads to local effects that are mostly specific to the manipulated muscles and correlate with the presence/absence of presynaptic pMad. Specifically, RNAi knockdown of the dGluRC or dGluRIIA glutamate receptor subunits reduced quantal release at that contact and blocked the activity-dependent addition of boutons to that vCE branch. Adjacent vCE branches on unaltered muscles showed normal synaptic function and plasticity. The RNAi knockdown also resulted in the loss of presynaptic pMAD accumulation. To directly address a role for Gbb release in local synaptic plasticity, wild-type Gbb was expressed in a subset of vCE targets within a gbb mutant, which rescued synaptic function and plasticity only within local branches. Conversely, growth and plasticity were locally suppressed by an RNAi knockdown of Gbb, with vCE branches onto unaltered muscles remaining unaffected. pMAD therefore accumulates in presynaptic boutons due to Gbb release from the corresponding postsynaptic cell. Our results suggest that presynaptic pMad directs local growth and plasticity as part of a "synaptic tagging" mechanism, while nuclear pMad stimulates presynaptic development in a more global fashion.

Title: Generation and analysis of MECP2 mutant marmosets

Authors: *N. KISHI[1,2], K. SATO[3], J. HATA[1,4], M. OKUNO[1], T. ITOU[1], J. OKAHARA[1,3], H. J. OKANO[1,4], E. SASAKI[1,3], H. OKANO[1,2];
[1]RIKEN CBS, Wako, Japan; [2]Keio Univ. Sch. of Med., Tokyo, Japan; [3]CIEA, Kawasaki, Japan; [4]Jikei Univ. Sch. of Med., Tokyo, Japan

Abstract: Our human brains are composed of structures conserved through evolution and those unique to primates. Recently-evolved brain structures involve the enlargement of the cerebral neocortex and provide essential substrates for acquisition of novel brain functions unique to primates, and eventually humans. Because of the unique structure and function of the primate brain, it is impossible to gain a full, accurate understanding of either normal human brain function or mental illness (neurological and psychiatric disorders) through rodent-based studies. Traditionally-used rats and mice only possess fundamental neuronal circuits conserved across mammalian species. Particularly, the primate prefrontal cortex is responsible for higher cognitive processes, and it contains vulnerable domains involved in some psychiatric disorders. The prefrontal cortex has no clear structural or functional homolog in rodents, which suggests advantages of using non-human primates to model human neurological and psychiatric diseases. The pathophysiology of human neurological and psychiatric diseases is not always recapitulated in genetically modified (GM) rodent models, possibly due to the differences in genome information, life span, and brain structure and functions between humans and rodents.
To overcome these issues, we are developing a technique for creating knockout marmosets using zinc finger nuclease (ZFN) and CRISPR/Cas9 technology. We created and are analyzing MECP2 mutant marmosets suitable for research on Rett syndrome. MRI imaging shows that the brain size of MECP2 +/- marmoset was smaller than wild-type ones by approximately 15% at 24 months of age, and less active than wild-type ones in the daytime. Furthermore, we also obtained MECP2-null marmosets, which have smaller brains and are less active even at early developmental stages. Those results indicate that those MECP2 mutant marmosets recapitulate symptoms of Rett syndrome.

Title: FoxG1 controlled transcription in the mouse hippocampus

Authors: *T. VOGEL, D. O'HAILIN, C. HACKER, R. VEZZALI, S. HEIDRICH;
Albert-Ludwigs-University Freiburg, Freiburg, Germany

Abstract: FoxG1 syndrome is a severe neurodevelopmental disorder characterised by microcephaly and typically associated with intellectual impairment and autistic traits. Underlying this condition are mutations in the Forkhead box G1 (FOXG1) gene. A member of the forkhead box family of transcription factors, FOXG1 is involved in forebrain and telencephalon development, but both its mechanism of transcriptional control and its role in the adult hippocampus are yet to be elucidated. Our present study first employed ChIP-seq to map the distribution of FoxG1 on the chromatin landscape in an adult FOXG1-heterozygote mouse hippocampus model and discovered both shared and field-specific enrichment in the dentate gyrus (DG) and cornu ammonis (CA) regions. Peak enrichment frequently identified putative binding sites in promoter, intronic, and intergenic regions, suggesting multiple functions for FOXG1 in transcriptional control. RNA-seq and subsequent qRT-PCR validation in our FOXG1-heterzygous mouse model revealed a panel of differentially regulated neurodevelopment-associated transcripts which had been predicted on the chromatin level. As expected, the nature of FoxG1-mediated transcriptional regulation was region-dependent in a selection of identified genes. We found using a luciferase reporter assay for overexpressed FoxG1 and a truncated form bereft of the forkhead binding domain that FoxG1 might bind directly to the chromatin at some target genes, but might also act in complex with other transcription factors. Analysis of peak sequences in our ChIP-seq dataset reveals significant enrichment for other forkhead box family members as well as basic helix-loop-helix transcription factors, suggesting a synergistic and/or antagonistic function of FoxG1 within the transcriptional machinery. Manipulating these candidate co-factors by lentiviral knockdown will yield a greater understanding of the mechanism behind FoxG1's versatility in different regions of the hippocampus. Considering the memory deficits associated with hippocampal dysfunction in FoxG1 syndrome, unravelling novel molecular mechanisms for FoxG1 could highlight promising avenues of investigation for the benefit of patients and their treatment.

Title: Antisense oligonucleotide therapy in a humanized mouse model of MECP2 duplication syndrome

Authors: *Y. SHAO[1], Y. SZTAINBERG[1], P. JAFAR-NEJAD[2], F. RIGO[3], H. ZOGHBI[1]; [1]Howard Hughes Med. Inst. - Baylor Col. O, Houston, TX; [2]Neurosci. Drug Discovery, [3]Ionis Pharmaceuticals, Carlsbad, CA

Abstract: Many intellectual disability disorders are due to copy number variations, and to date there have been no treatment options tested for this class of diseases. *MECP2* duplication syndrome (MDS) is one of the most common genomic rearrangements in males and results from duplications spanning the methyl-CpG binding protein 2 (*MECP2*) gene locus. Previously, we have shown that antisense oligonucleotide (ASO) therapy can successfully reduce MeCP2 levels in an MDS mouse model and reverse the disease-like phenotypes. However, our previous MDS mouse model carried one transgenic human allele and one mouse allele, with the latter being protected from human specific *MECP2*-ASO targeting. In humans, the two *MECP2* alleles are identical and because MeCP2 is a dosage-sensitive protein, one must ensure that the ASO is titrated to target the human allele such that MeCP2 levels are reduced from 2X to 1X. Therefore, in preparation for clinically relevant studies, we characterized the effects of a human-specific *MECP2*-ASO in a new "humanized" mouse model of MDS, that carries two human *MECP2* alleles, and no mouse endogenous allele. We found that after intracerebroventricular injection in the cerebrospinal fluid, the *MECP2*-ASO efficiently downregulates MeCP2 expression throughout the brain. Moreover, *MECP2*-ASO can dose-dependently ameliorate several behavioral deficits without any dose-limiting toxic effect or safety concern. We also characterized the pharmacodynamic effect of the *MECP2*-ASO on MeCP2 and selected MeCP2-regulated genes during the duration of the treatment. Taken together, our results demonstrate that central nervous system administration of *MECP2*-ASO is well tolerated, has beneficial effects, and support a feasible translatable approach for the treatment of MDS.

Title: Loss of MeCP2 in immature neurons leads to impaired network integration

Authors: Y. SUN, Y. GAO, J. TIDEI, J. T. HOANG, D. P. WAGNER, ***X. ZHAO**;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Rett syndrome (RTT) is a neurodevelopmental disorder caused by mutations or deletions in Methyl-CpG-binding Protein 2 (MeCP2), a brain-enriched transcriptional regulator. MeCP2 is highly expressed during neuronal maturation and its deficiency results in impaired dendritic morphogenesis and reduced dendritic spine numbers in developing neurons. However, whether MeCP2 deficiency impacts the integration of new neurons has not been directly assessed. In this study, we developed a modified rabies virus-mediated monosynaptic retrograde tracing method to interrogate presynaptic integration of MeCP2-deficent new neurons born in the adult hippocampus, a region with lifelong neurogenesis and plasticity. We found that selective deletion of MeCP2 in adult-born new neurons impaired their long-range connectivity to the cortex, whereas their connectivity within the local hippocampal circuits or with subcortical regions was not significantly affected. We further showed that knockdown of MeCP2 in primary hippocampal neurons also resulted in reduced network integration. Interestingly, (1-3) IGF-1, a small peptide under clinical trial testing for RTT, rescued neuronal integration deficits of MeCP2-deficient neurons *in vitro* but not in *vivo*. In addition, (1-3) IGF treatment corrected aberrant excitability and network synchrony of MeCP2-deficient hippocampal neurons. Our results indicate that MeCP2 is essential for immature neurons to establish appropriate network connectivity.

Dept. of Neurosci., Univ. of Torino, Turin, Italy

Abstract: The CDKL5 gene provides instructions for making a protein, a serine/threonine kinase, that is essential for normal brain development by regulating both the structural organization of dendritic spines and excitatory synapse function. CDKL5 deficiency disorder (CDD) is a rare X-linked genetic disorder that results in early-onset, difficult to control, seizures, severe intellectual disability, stereotypies, limited or absent speech, autism and sensory impairments. Clinical studies indicated that CDD patients show both visual and somatosensory deficits, as well as atypical electroencephalographic waveforms deriving from epileptic activity of the cerebral cortex. However, no anatomical, cellular or molecular evidences underlying these functional alterations are available from postmortem human brains. This lack of information severely hampers the development of effective therapeutic interventions, considering that, so far, no animal model of CDD has been able to model the epileptic seizures produced by CDKL5 mutations. It is thus imperative to explore the brain of CDD individuals to obtain any possible information about the causes of such severe epileptic activity with a level of resolution that surpasses available in-vivo examination approaches in patients. We will present both anatomical and molecular datasets from the cerebral cortex, hippocampus and cerebellum of two female CDD individuals (5 and 30 years), and age/sex-matched controls, made available by the Harvard Brain Tissue Resource Center and NIH NeuroBioBank, respectively. The analyses will assess the consequences of CDKL5 mutation on both the cyto-architecture and the structural and molecular organization of synapses in the human brain. Brain blocks from the indicated brain areas are currently processed with methods for best detection of both excitatory and inhibitory synaptic molecules and for their quantitative assessment. Immunofluorescence followed by confocal microscopy as well as western blotting analysis of synaptosomes preparation are being used to reveal both the localization and expression of synaptic molecules. Moreover, we will present data on the organization and maturation of perineuronal nets (PNNs) in CDD human cortices. PNNs are critical regulators of parvalbumin interneurons network activity that is crucially involved in seizures control. Our multilevel analysis, with inherent translational potential, will provide a high quality assessment of both CDKL5 function in the human brain and disease pathophysiology to expedite therapeutic development.

Title: Developmental population-level differences of stem cell derived excitatory networks from SHANK2 ASD patients

Authors: *K. PRADEEPAN[1], J. MARTINEZ-TRUJILLO[1], J. ELLIS[2], R. MOK[3], F. MCCREADY[3];
[1]Western Univ., London, ON, Canada; [2]Developmental & Stem Cell Biol., The Hosp. For Sick Children, Toronto, ON, Canada; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: Autism spectrum disorders (ASDs) are heterogenous group of neurodevelopmental disorders that have a strong genetic contribution to the etiology of the disease. Human genome wide association studies (GWAS) have identified numerous genetic variants across hundreds of loci that contribute to this complex genetic architecture. MECP2 and SHANK2 are two genes that have been associated with ASD in functional gene clusters that encode proteins critical to synapse homeostasis. Despite SHANK2 ASD resulting from SHANK2 haploinsufficiency in human cases, animal models have been inconsistent in displaying ASD phenotypes. Due to this inconsistency and to account for genetic background, human induced pluripotent stem cells (hIPSCs) have become employed as an alternative system to investigate complex neurodevelopmental disorders. Previous research from collaborators has shown that glutamatergic cortical neurons from hIPSCs derived from neurotypical and ASD-affected donors exhibited increases in dendritic length and complexity, synapse number, and frequency of spontaneous excitatory postsynaptic currents. Their results provide evidence for structural and functional hyperconnectivity in SHANK2 neurons of ASD patients. To explore whether these single neuron differences emerge to a differentiable population difference, multielectrode array (MEA; Axion Biosystems) technology was used. By culturing glutamatergic cortical neurons on a 12-well MEA plate across approximately 8 weeks of development, we observed how the fine spatial-temporal mapping of electrical activity around each of the electrodes in the 8-by-8 grid developed spontaneous networks and differentially developed between SHANK2 mutants and wildtype populations. To characterize this development, we used a population-level analysis to show that the network burst frequency of SHANK2 mutants exhibited a peak shift towards higher frequency along development whereas wildtype was maintained within lower frequencies.

A spike time tiling correlation was calculated between electrodes to investigate functional network connectivity, reflecting both structural and functional hyperconnectivity. Individual electrode burst characterization also analyzed to reveal how the dynamics within bursts differ between the different populations. With the rise of high-throughout recording techniques, neural activity data has grown exponentially. This population analysis has been used to take advantage of this when trying to understand how circuits between neural ensembles dynamically change in response to development due to various mutations. Additional neural data being analyzed.

Title: Characterizing mitochondria markers and activity in models of neurodevelopmental disorders

Authors: *L. A. NEAL[1], J. LARIMORE[2];
[2]Biol. Dept., [1]Agnes Scott Col., Atlanta, GA

Abstract: Mitochondria are eukaryotic organelles that execute a diverse range of functions including ATP synthesis through cellular respiration, regulation of cell metabolism, calcium buffering and regulation of programmed cell death or apoptosis. Studies have implicated mitochondrial dysfunction in neurodevelopmental disorders such as Rett Syndrome and Schizophrenia. Analysis of lymphomonocytes isolated from patients with Rett Syndrome indicate genes related to mitochondrial function are upregulated due to an increased bioenergetic need. Brains from patients with schizophrenia also demonstrate a decrease in mitochondrial activity, which may contribute to the cellular abnormalities in synaptic activity, vesicle trafficking, and neurite outgrowth. This study characterized mitochondrial markers in models of both RTT and SZ to provide novel insight into mitochondrial activity in both of these neurodevelopmental disorders.

Title: MeCP2 represses enhancers through chromosome topology-associated DNA methylation

Authors: A. W. CLEMENS, ***D. Y. WU**, G. ZHAO, H. W. GABEL;
Washington Univ. In St. Louis, St. Louis, MO

Abstract: The genomes of mammalian neurons contain uniquely high levels of non-CG DNA methylation that can be bound by the Rett syndrome protein, MeCP2, to regulate gene expression. How patterns of non-CG methylation are established in neurons and the mechanism by which this methylation works with MeCP2 to control gene expression is unclear. Here we find that genes repressed by MeCP2 are often located within megabase-scale regions of high non-CG methylation that correspond with topologically-associating domains of chromatin folding. MeCP2 represses enhancers that are found in these domains and are enriched for non-CG and CG methylation, with the strongest repression occurring for enhancers located within MeCP2-repressed genes. These alterations in enhancer activity provide a mechanism for how MeCP2 disruption in disease can lead to widespread changes in gene expression. Hence, we have found that DNA topology can shape non-CG DNA methylation across the genome to dictate MeCP2-mediated enhancer regulation in the brain. Current work in the lab is focused on experimental manipulations of mCA, DNMT3a, and enhancers, in order to test this model.

Title: Impaired hippocampal sharp-wave ripples in MeCP2 knock out mice

Authors: *N. W. JOHNSON, D. GOFFIN;
Dept. of Biol., Univ. of York, York, United Kingdom

Abstract: Methyl-CpG-binding protein 2 (MeCP2) binds to methylated cytosines where it regulates gene transcription. Mutations in the gene encoding MeCP2 are the leading cause of Rett syndrome, the second most common form of intellectual disability in females. Mice lacking MeCP2 exhibit deficits in learning and memory, synaptic connectivity and synaptic plasticity. Sharp-wave ripples (SPW-Rs) in the CA1 region of the hippocampus are important in memory formation and consolidation. We performed *in vivo* recordings using chronically implanted silicon probes to investigate whether of SPW-Rs were affected in hippocampus of MeCP2 knockout mice. We found that the loss of MeCP2 decreased the frequency and incidence of hippocampal SPW-Rs during non-REM sleep. The amplitude of SPW-Rs, however, were not affected. These changes were associated with a decrease in the firing probability of putative excitatory, but not inhibitory, neurons. These results suggest that MeCP2 is required for the proper generation of SPW-Rs. These findings may play an important role in the pathogenesis of learning and memory deficits observed in MeCP2-related neurodevelopmental disorders.

Title: Early signs of CDKL5 deficiency disorder: Atypical barrel cortex connectivity precedes autistic features in mutant mice

Authors: A. RASPANTI[1], R. PIZZO[1], ***A. GURGONE**[1], C. PERNACI[3,4], A. MARCANTONI[2], M. GIUSTETTO[1];
[1]Dept. of Neurosci., [2]Dept. of Drug Sci. and Technol., Univ. of Turin, Torino, Italy; [3]Dept. of

Neurol., [4]Dept. for BioMedical Res. (DBMR), Inselspital Univ. Hospital, Univ. of Bern, Bern, Switzerland

Abstract: Mutations of CDKL5 gene, coding for a serine/threonine kinase located on the X chromosome, are responsible for the onset of CDKL5 deficiency disorder (CDD), a rare neurodevelopmental disease with no cure. Clinical features of this pathology appear shortly after birth and include severe drug-resistant epilepsy, intellectual disability, strong sensory impairment (both in visual and somatosensory perception) characterized by a prominent hyposensitivity, in addition to autistic-like tendencies. Mounting evidence indicate that CDKL5 is a kinase involved in the formation and maturation of neurons, as well as in the organization of excitatory post-synapse. Less is known on the role of CDKL5 in the wiring and function of specific brain areas. This lack of information hampers both our understanding of CDKL5 function in the brain and the development of effective therapeutic interventions. To fill this gap, by using a multidisciplinary approach we investigate whether defects in thalamocortical (TC) connectivity, reaching the barrel cortex (BC), match the onset of sensorimotor impairments and autistic features in CDKL5 mutant mice. First, we revealed that the expression of c-Fos, a marker of neuronal activation, is robustly reduced in the BC of juvenile CDKL5 null mice at post-natal day (P) 15, indicating that an hypoactivation of the BC occurs right after the end of the critical period. The reduction of c-Fos^{+} cells is associated with atypical TC connectivity in mutant mice, as revealed by the strong decrease of vGluT2^{+} thalamic afferents conveying whiskers-mediated tactile information in layer IV of the BC. Remarkably, analysis of spontaneous firing of BC derived primary neuronal network, performed at three different in-vitro developmental stages (DIV7, DIV12 and DIV16), reveal a failure of network maturation in CDKL5 null cultures. Moreover, a battery of behavioral tests, strongly relying on whiskers function, show an atypical development of innate sensory-motor reflexes in CDKL5 null mice, including a strong impairment in the cliff avoidance test starting from P3 and detectable up to P15. Finally, when tested in the juvenile play and three-chamber sociability tests, P21 CDKL5 null mice show significative early-onset alterations of social responses. Our data disclose a novel role of CDKL5 in the early establishment and function of TC connectivity in the BC. These circuit alterations that are linked to the somatosensory and motor deficits shown by CDKL5 null mice that are likely to play a crucial role in the emergence of the autistic features associated with CDD.

Title: Early molecular and cellular deficits in 3D cerebral organoid models of Rett syndrome

Authors: *V. A. PHAM[1], C. DELEPINE[1], H. W. S. TSANG[1], N. MORSHED[2], F. WHITE[2], M. SUR[1];

Abstract: Rett Syndrome (RTT, OMIM 312750) is a pervasive, X-linked neurodevelopmental disorder that predominantly affects girls. With an incidence of 1:10 000-15 000, it is the second most common cause of severe intellectual disability in females after Down Syndrome. The vast majority of typical RTT cases is triggered by a sporadic mutation in the gene encoding methyl CpG-binding protein 2 (MeCP2). RTT is a progressive disorder, characterized by deficits that are prominently manifested by early childhood. Although most research has focused on symptomatic mice and humans, recent studies have shown that MeCP2 deficiency triggers molecular and cellular defects at very early stage of embryonic brain development. We used isogenic RTT patient-derived induced pluripotent stem cells to generate 3D human cerebral organoids to recapitulate these early developmental events and to better understand the molecular and cellular complexity that underlies RTT pathology. Previously, we showed that MeCP2 deficiency was associated with an increase in neural progenitor proliferation and concomitant decrease in neurogenesis and neuronal migration and maturation (Mellios et al., Molecular Psychiatry 2018). These data suggested that dysregulation of the AKT/ERK pathway due to MeCP2 deficiency were causal for the observed phenotype. In the current study, we have further investigated the molecular underpinnings of the deficits in neuronal migration observed in RTT organoids. Using transcriptomic, proteomic and phospho-proteomic techniques, we have interrogated the consequences of RTT MeCP2 mutations on molecular signaling pathways and found an associated increase in GSK3β-β-catenin signaling, downstream of AKT. Using fluorescent markers and immunostaining, combined with multi-photon microscopy and confocal microscopy, we find that, although the morphology and polarity of radial glial cells are mostly preserved, adhesion molecules are dysregulated and neuronal migration patterns are disturbed in RTT MeCP2 mutant organoids compared to isogenic controls. These findings confirm and further clarify the role and mechanisms of early deficits during cortical development in RTT.

Title: Targeted CRISPR/dCas9-mediated escape of CDKL5 from X-chromosome inactivation

Authors: *J. A. HALMAI[1], P. DENG[3], C. GONZALEZ[1], D. CAMERON[1], J. CARTER[1], J. WALDO[1], S. DEL CAMPO[1], F. BUCHANAN[1], D. SEGAL[3], J. NOLTA[2], K. FINK[1]; [1]Dept. of Neurol. and Stem Cell Program, [2]Stem Cell Program, UC Davis Med. Ctr., Sacramento, CA; [3]Genome Ctr., UC Davis, Davis, CA

Abstract: In the wake of genome engineering, rewriting of the epigenome has risen as a promising approach for precision medicine. This approach is even more relevant in tissues that traditionally have been more difficult to edit at the genomic level, such as neurons. Neurological diseases are a heterogeneous group of disorders caused by alterations in nervous system function and many of these disorders can be attributed to genetic factors such as chromosomal aberrations or gene mutations. The neurodevelopmental disorder *CDKL5* deficiency is caused by *de novo* mutations in the *CDKL5* gene on the X-chromosome. Due to random X-chromosome inactivation, females affected by the disorder form a mosaic of cells expressing mutant and wild type alleles. Our research is focused on methods to reactivate the healthy *CDKL5* allele on the silenced X-chromosome in human neuronal-like cell lines using CRISPR/dCas9 fused to epigenetic effector domains. Our group has been the first to identify proximal *cis* regulatory elements in the *CDKL5* core promoter for CRISPR/dCas9-mediated programmable transcription in the female neuronal-like cell line SH-SY5Y. Allele-specific qPCR and targeted RNA sequencing shows a significant increase in gene expression in stable SH-SY5Y cells treated with a VP64 trans-activator is predominantly due to superactivation of the active allele in combination with limited reactivation of the silenced allele. Epigenetic editing of the *CDKL5* core promoter using a dCas9-Tet1 fusion protein for targeted DNA demethylation results in a significant increase in reactivation of the inactive allele likely due to a significant reduction in methylated CpG diresidues as demonstrated by bisulfite sequencing. This approach can be further potentiated by a combinatorial approach of targeting VP64 and Tet1 synergistically to the same locus. In addition, our approach shows we can reduce the abundance of repressive histone marks that are normally associated with the inactive X chromatin in a manner that is confined exclusively to the reactivated escape allele. We then evaluated the level of specificity via RNA-

and ChIP-sequencing. In addition, we explored global changes in methylation status using EPIC-Chip. Further elucidating and understanding the epigenetics underlying X chromosome inactivation holds great potential for children suffering from *CDKL5* deficiency and other disorders with an X-linked dominant pattern of inheritance.

(TGen), Phoenix, AZ; [5]Translational Genomics Res. Inst. (tgen), Phoenix, AZ; [6]Ctr. for Rare Childhood Disorders, Translational Genomics Res. Inst., Phoenix, AZ

Abstract: Mutation in Methyl-CpG-Binding Protein 2 (MECP2, OMIM 300005) cause classical Rett syndrome (RTT) in females. MECP2 mutations have also been linked to severe encephalopathy in male infants, X-linked mental retardation, and other disorders such as autism spectrum disorder (ASD) and learning disabilities. RTT is characterized by neuropathological changes such as small neurons (reduced soma size), increased cell packing density, and decreased dendritic arborization. However, the mechanisms by which MECP2 mutation leads to these cellular and neurological phenotypes remain unknown. Emerging evidence also indicates that the mTOR pathway is dysfunctional in *Mecp2*-deficient mice and human embryonic stem cell-derived models of RTT. Currently IGF1, a tropical growth factor, is the only FDA approved therapy in Phase III trial for RTT. However, we do not know how IGF1 works in the Rett syndrome patients. The IGF1/PI3K pathway has been identified to regulate neuronal growth and activity through the Akt/mTOR pathway. Using murine *Mecp2* knockout (Mecp2tm1.1Bird mice) (KO) and *MeCP2 A140V* "knock-in" mutant (Mut) model we aimed to understand the connection between the IGF1 and the Akt/mTOR signaling pathway. Brain lysates from KO, Mut and wild type (WT) of six-week-old male mice were compared through RNA expression

and western blot analysis. Proteins of interest were chosen based on the IGF/Akt/mTOR network interaction. Analysis in *MeCP2 A140V* mutation identified moderate gene expression changes linked to IGF-1 pathway. Western analysis from A140V mice revealed alterations in mTOR phosphorylation including SGK1 defect compared to control mice. In *Mecp2* knock out mice, there was a significant downregulation of pS6, correlating to the reduced neuronal size seen in RTT. Interestingly, we found rescued phosphorylation of MAPK protein at both 42 and 44kDa, however without any alteration in the activation of IGFIRβ. These data suggest an intricate alteration of mTOR pathway in *Mecp2* models linked to the IGF1 pathway and in-depth understanding of this pathway in RTT may improve our ability to design better therapeutics.

Title: MeCP2-mediated miR-199a processing regulates fate specification of neural stem cells

Authors: *H. NAKASHIMA[1], K. TSUJIMURA[2], K. IRIE[3], T. IMAMURA[1], K. NAKASHIMA[1];
[1]Kyushu Univ., Fukuoka, Japan; [2]Nagoya Univ., Aichi, Japan; [3]Waseda Univ., Tokyo, Japan

Abstract: Rett syndrome (RTT) is a severe progressive neurodevelopmental disorder in females, mainly caused by mutations in the X-linked gene encoding methyl-CpG binding protein 2 (MeCP2). Although initial observations had suggested that RTT patients appear relatively normal at birth and during very early stages of development, increasing evidence suggests early developmental delays in RTT patients. Previously, we have found that MeCP2 regulates processing of specific microRNAs as a component of Drosha complex and identified miR-199a as a MeCP2 target. To understanding the role of MeCP2 in developing brain, we performed single-cell analysis of MeCP2 and miR-199a deficient hippocampus. We found that neuronal population was decreased and astrocytic population was increased in MeCP2 and miR-199a deficient hippocampus. According to these results, we hypothesized that abnormal neural stem cells (NSCs) differentiation was occurred in MeCP2 and miR-199a deficient NSCs.We examined whether MeCP2 and miR-199a is indeed implicated in the process of NSCs fate determination.

We first found that neuronal differentiation was suppressed and astrocytic differentiation was enhanced in MeCP2 and miR-199a deficient NSCs. We also observed that overexpression of miR-199a rescued abnormal differentiation of MeCP2 deficient NSCs, indicating that miR-199a acts downstream of MeCP2. Taken together, our findings suggest that MeCP2 plays an important role in fate determination of NSCs by post-transcriptionally processing of miR-199a.

Title: Atypical basic auditory processing in females with Rett syndrome could implicate effective speech comprehension

Authors: *T. BRIMA[1], S. MOLHOLM[2], E. NICHOLAS[1], A. DJUKIC[3], E. G. FREEDMAN[1], J. J. FOXE[1];
[1]Dept. of Neurosci. and The Del Monte Inst. for Neurosci., Univ. of Rochester Sch. of Med. and Dent., Rochester, NY; [2]Dept. of Pediatrics, The Cognitive Neurophysiol. Laboratory, Albert Einstein Col. of Med. & Montefiore Med. Ctr., Bronx, NY; [3]Rett Syndrome Ctr. Dept. of Neurol. Montefiore Med. Ctr. & Albert Einstein Col. of Med., Bronx, NY

Abstract: Rett Syndrome (RTT) is a non-inherited X-linked neurodevelopmental disorder accompanied by progressive loss of previously acquired intellectual, language and motor abilities. This decline renders behavioral assessment of cognitive function difficult, at best. As such, very little is known about cognitive processing, including perceptual capabilities and speech comprehension across the progressive clinical stages of RTT. High-density electrophysiological recordings allow for objective examination of sensory-perceptual and cognitive processing leading to more sensitive outcome measures against which to assess the effectiveness of disease-modifying therapeutic approaches currently in development. Here we characterize basic auditory responses in RTT using auditory evoked potentials (AEPs) in response to unpredictable changes in stimulus duration. AEPs were recorded in an auditory oddball task from 18 RTT and 27 age-matched typically developing (TD) controls (Ages: 6-22 years). This task consisted of regularly occurring standard tones (1 kHz; 100ms duration)

occasionally interrupted by deviant tones (1 kHz; 180ms). Intervals between stimuli were varied in blocks and were either 450ms, 900ms or 1800ms. This task allowed us to record large numbers of trials making it possible for detailed time frequency analysis on a trial to trial level for individual participants. Classical AEPs that changed as a function of stimulus duration were present for all presentation rates in TDs. In RTT, AEPs were strikingly atypical in morphology with reduced amplitude, pointing to impaired auditory processing. However, these AEPs changed as a function of stimulus duration suggesting preserved ability of basic auditory function to track with changes in stimulus duration. Outcomes from this study show that although participants with RTT produced AEPs to basic standard auditory stimuli that track with changes in stimulus duration, these responses reveal deficits that might impact effective speech comprehension.

Title: A novel role for the Na-K-2Cl cotransporter in metabolism

Authors: *S. OMER[1], R. KOUMANGOYE[1], E. DELPIRE[2];
[1]Vanderbilt Univ., Nashville, TN; [2]Dept. of Anesthesiol., Vanderbilt Univ. Med. Sch., Nashville, TN

Abstract: The Na-K-Cl cotransporter-1, NKCC1, plays an important role in cell volume regulation. In the developing brain, studies have shown that during the perinatal period, NKCC1 facilitates the development of seizures due to its role in maintaining elevated $[Cl^-]_i$ and promoting excitatory γ-aminobutyric acid (GABA) responses. Recently we reported the first known human mutation in SLC12A2 the gene encoding NKCC1.The 17-year old patient has a complex syndrome which includes complete gastrointestinal and bladder failure; thyroid, parathyroid, and pancreatic insufficiencies; orthostatic intolerance. The patient carries a *de novo* mutation in SLC12A2. The 11 bp deletion resulted in a *non-functional* transporter. Laboratory tests conducted on the patient's muscle biopsy showed an abnormal increase in mitochondrial DNA copy number and increased glycogen levels, indicating the possibility that the transporter may play a role cell metabolism. In addition to observing an increase in mitochondrial density,

analyzed by fluorescent activated cell sorting (FACS), the patient fibroblasts also demonstrated significantly higher mitochondrial respiration, compared to control when analyzed by mitochondrial respiration stress tests. In addition, MDCK cells transfected with EGFP-tagged mutant NKCC1 also demonstrated higher mitochondrial respiration compared to cells expressing EGFP-tagged wild-type NKCC1. To further assess the role of NKCC1 in mitochondrial respiration, control MDCK cells were subjected to 20 uM bumetanide which led to increased mitochondrial respiration, compared to DMSO vehicle. Fibroblasts extracted from $NKCC1^{DFX/+}$ and $NKCC1^{DFX/DFX}$ mice also demonstrated a significant elevation in mitochondrial respiration, compared to fibroblasts isolated from wild-type littermates. Finally, mutant fibroblasts elicited an increase in mRNA transcript levels for protein involved in the unfolded protein response (UPR) pathway. These data reveal a novel role for NKCC1 in mitochondrial respiration and ER stress.Our data demonstrate that expression of a truncated Na-K-2Cl cotransporter causes increased oxygen consumption and up-regulated expression of genes involved in UPR. These data establish for the first time that NKCC1 plays a role in mitochondrial respiration and ER stress.

Title: Propionic acid affects gene expression for mitochondria biogenesis and neuron differentiation in SH-SY5Y cell line

Authors: *S. A. KIM;
Eulji Univ., Daejeon, Korea, Republic of

Abstract: Propionic acid (PPA) shows neurotoxicity and behavioral abnormalities in several animal models. In this study, it was observed the reduction of mitochondrial potential with dose-dependent manner after PPA treatment in SH-SY5Y cells. In the electron microscopic analysis, the size of mitochondria was significantly reduced by the PPA treatment. A dose-dependent increase in mitochondrial DNA copy number and mitochondrial biogenesis related gene PGC1-α, TFAM, SIRT3 and mitochondrial COX4 were significantly increased at 5mM PPA treatment in SH-SY5Y. Transcriptome analysis were performed and the genes which were revealed more

than 2-fold difference in mRNA expression level were selected. Most of all, notch signaling related genes such as ASCL1 and LFNG were selected.

Title: SON haploinsufficiency, a cause of human intellectual disabilities, affects the neuronal migrations and dendritic spine formations in the developing mouse brain

Authors: *M. UEDA, T. MATSUKI, S. EDA, A. NAKAYAMA;
Cell. Pathology, Aichi Developmental Disability Ctr. Inst. for Developmental Res., Kasugai, Japan

Abstract: SON, an RNA splicing co-factor protein, is involved in several cellular processes including transcription and cell-cycle regulations. However, the function of SON in the central nervous system is largely unknown. Previous studies revealed that 28 individuals with intellectual disability and developmental delay had *de novo* heterozygous loss-of-function (LoF) mutations in SON gene (*SON*). Neuroimaging examinations revealed most of affected individuals had brain malformations including polymicrogyria. SON expression is reduced in some tissues derived from patients, indicating that *de novo* LoF mutations of *SON* result in a haploinsufficiency. These results suggest that appropriate SON expression is important for normal brain development. This study has been carried out in order to clarify a role of SON in the brain formation during development. To examine the effects of SON-knockdown on mammalian brain development, we prepared shRNA constructs for the knockdown of mouse SON. We electroporated the shRNA constructs into the lateral ventricles of mouse brain at embryonic day 14 (E14), to address a role of SON in neuronal migration during brain development. Interestingly, neural progenitor cells in a SON-knockdown state did not effectively migrate to upper cortical plate at E18. The impairments of neuronal migrations were rescued by overexpression of human full-length SON, which is composed of 2,455 amino acids, but not with a disease-related truncation mutant (N-terminal 704 amino acids), lacking most functional domains. To investigate whether SON plays a role in dendritogenesis, we focused on analysis of dendritic spines in the postnatal cerebral cortex. At postnatal day 60, the numbers of the dendritic spines of layer II-III neurons in a SON-knockdown state were reduced compared with those in normal state. The impaired dendritic spine formation was rescued by overexpression of human

full-length SON. These data suggest that sufficient SON protein is critical to cortical neuronal migration and dendritic spine formations during development in mouse brain.

Title: Developmental iron deficiency alters TET methylcytosine dioxygenase activity and decreases global DNA hydroxymethylation in the rat cerebellum

Authors: *A. BARKS[1], P. V. TRAN[2], M. K. GEORGIEFF[2];
[1]Neurosci., [2]Pediatrics, Univ. of Minnesota, Minneapolis, MN

Abstract: Background: Iron deficiency (ID) during neurodevelopment is associated with lasting cognitive deficits and increased risk for neuropsychiatric dysfunction in humans and rodents. In rodent models, the deficits are associated with long-term gene dysregulation in the central nervous system that lasts into adulthood. The iron-dependent mechanisms that establish and maintain this gene dysregulation are incompletely understood. 5-hydroxymethylcytosine (5hmC), or DNA hydroxymethylation, is an epigenetic modification generated by TET methylcytosine dioxygenases. TETs require iron as a cofactor for their enzymatic activity. 5hmC is uniquely abundant in the brain, and is enriched in genes critical for neurodevelopment and neuronal function.
Objective: Determine the effect of a clinically relevant level ID on TET activity, *Tet* expression and DNA hydroxymethylation in the developing rat cerebellum.
Methods: Timed pregnant Sprague-Dawley rats were fed iron deficient diet (ID; 4 mg/kg Fe) starting at gestational day (G)2 to generate iron deficient anemic (IDA) offspring. Control dams were fed iron sufficient diet (IS; 200 mg/kg Fe). At postnatal day (P)7, a subset of ID-fed litters were randomized to IS diet, generating treated IDA (TIDA) offspring. All rats were euthanized at P15 and cerebellum was collected and flash frozen. Nuclear proteins were isolated from one-half cerebellum, and TET enzymatic activity was quantified by ELISA (n=5-10/group). RNA and DNA were isolated from one-quarter cerebellum. Expression of Tet1, Tet2, and Tet3 was quantified by qPCR (n=6-8/group). Global %5hmC was quantified by ELISA (n=6-10/group).
Results: Untreated P15 IDA cerebellum had decreased TET activity compared to IS controls ($p=0.03$), accompanied by decreased global %5hmC ($p<0.001$). *Tet* expression was not reduced

in the IDA cerebellum, suggesting that the decrease in %5hmC was likely due to a decrease in iron-dependent TET enzymatic activity. Treatment with iron at P7 corrected both the TET activity and the %5hmC deficits in TIDA cerebellum by P15, suggesting a mutable iron-dependent epigenetic mechanism.
Conclusions: Our results indicate that epigenetic dysregulation during neurodevelopment, through altered TET enzymatic activity, may play a role in the lasting CNS dysfunction associated with developmental ID. While the effect of IDA on global %5hmC appears to be reversible with iron repletion within this relatively short developmental time frame, it will be important to determine whether changes in 5hmC persist at the gene-specific level, and when the critical period for reversibility with iron treatment closes.

Title: Abnormal circadian rhythms in the hypothalamus in a mouse model of early life stress

Authors: *E. FITZGERALD, M. C. HOLMES, J. P. BOARDMAN, A. J. DRAKE;
Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Preterm birth is a leading cause of intellectual disability and is a major risk factor for neurodevelopmental disorders such as schizophrenia and autism spectrum disorders, but the underlying mechanisms are not fully understood. Abnormal circadian rhythms are a core feature of many neurodevelopmental disorders. Circadian rhythms are established in early postnatal life, a time which is associated with a high burden of environmental and physiological stress for infants born preterm (e.g. handling, pain, noise, sub-optimal nutrition and co-morbidities of preterm birth). We hypothesized that exposure to early life stress alters circadian rhythms in the hypothalamus during the neonatal period. We developed a novel model of early life stress in mice with relevance to preterm infants by modifying the traditional maternal separation paradigm to include manual gentle agitation. This was carried out for 2 hours per day for 3 consecutive days (postnatal day 5-7) in C57/Bl6 mice. Control littermates were left in the home cage, which was adjacent to the area of stress induction. Pups were weighed daily and were killed by decapitation at P7. Brains were dissected and divided at the midline, with half fixed for paraffin embedding and subsequent immunohistological evaluation. The other half was dissected

and snap frozen for transcriptome profiling using 3' mRNA sequencing and qPCR validation. Stressed pups gained weight at the same rate as control pups ($p=0.347$) and there was no difference in Iba1+($p=0.211$), GFAP+ ($p=0.867$) or Olig2+ ($p=0.855$) staining in the hypothalamus. The expression of several core circadian rhythm genes was altered in the hypothalamus of stressed pups, including Per1, Cry1 and NR1D1 (all $p<0.01$). Analysis of transcription factor binding enrichment implicated abnormal NFkB signalling (Fischer score=23.255), and genes involved in NFkB signalling were also differentially expressed (e.g. MyD88 and Nsfl1c: both $p<0.05$) in the hypothalamus of stressed pups. We also found altered expression of the DNA methyltransferase DNMT1 ($P<0.05$). In conclusion, early life stress leads to alterations in the expression of core circadian regulators in the hypothalamus. The altered expression of a key enzyme involved in the maintenance of DNA methylation suggests that epigenetic dysregulation could be one mechanism underpinning the disruption of circadian genes seen in this novel model of neonatal stress associated with preterm birth.

Title: Impact of cardiopulmonary bypass on postnatal SVZ neurogenesis and cortical maturation

Authors: *C. LEONETTI[1], Z. DHARI[1], L. KOROTCOVA[1], S. LIN[3], A. V. KOROTCOV[1], J. HOWICK[1], J. LI[1], P. C. WANG[3], R. A. JONAS[2], N. ISHIBASHI[1];
[1]Ctr. for Neurosci. Res. and Children's Natl. Heart Inst., [2]Children's Natl. Heart Inst., Children's Natl. Hlth. Syst., Washington, DC; [3]Dept. of Radiology, Howard Univ., Washington, DC

Abstract: Introduction: Many children with congenital heart disease (CHD) manifest various levels of neurodevelopmental impairments following cardiac surgery with cardiopulmonary bypass (CPB). The subventricular zone (SVZ) in the postnatal/adult brain is the region where

most neural stem/progenitor cells (NSPC) originate. Recent studies suggest that the SVZ plays an important role in neocortical growth of the gyrencephalic frontal lobe (FL) during postnatal life. However the effect of CPB-induced insults on postnatal SVZ neurogenesis is poorly understood. **Methods:** 3 week-old piglets were randomly assigned to control, mild-CPB (34°C full-flow, reproduces systemic inflammation) and severe-CPB insult groups (25°C circulatory-arrest, reproduces systemic inflammation with ischemia/reperfusion injury). Brains were fixed at day 3 or week 4 postoperatively. In the SVZ, we used GFAP and Sox2 to identify NSPCs, and DCX for neuroblasts. The SVZ was subdivided into three tiers, as previously described in humans, and into ventral and dorsolateral regions. In the FL, immunohistochemistry was performed in the upper and lower layers. NeuN and Tbr1 were used for mature and maturing neurons respectively, and PV, SST and CalR for subpopulations of interneurons. MRI images were analyzed to measure gyrification index (GI), fractional anisotropy (FA), total brain and cortical grey matter volumes. **Results:** Following CPB, there was a significant reduction in NSPC proliferation, $GFAP^+$ processes length, neuroblast density, and number and occupancy of neuroblast clusters. These results suggest reduced neurogenic activity in the SVZ and disruption of neuroblast migration and their contributions to FL maturation after CPB. These changes were observed 3 days and 4 weeks after surgery in both CPB groups, indicating prolonged impairment of postnatal SVZ neurogenesis. FL analysis by MRI revealed a decrease in GI and an increase in FA along with reduced cortical grey matter and total brain volumes 4 weeks after surgery. Histological analysis revealed a significant decrease of PV and SST interneuron density only in the severe group, and $Tbr1^+$ neurons in both groups. These results suggest prolonged FL dysmaturation induced by CPB. **Conclusion**: The frontal cortex is the region responsible for many higher-order cognitive functions; our results therefore provide novel insights into cellular mechanisms underlying complex neurological impairment in the CHD population. Designing new treatment aimed at restoration of SVZ neurogenic potential is required for improving cortical growth in children with CHD.

Title: Gad1 heterozygotes subjected to prenatal stress undergo epigenetic dysregulation of genes perturbing neurodevelopment and behavioral phenotypes

Authors: T. WANG[1], A. S. SINHA[1], H. MUTOH[1], T. AKITA[1], Y. YANAGAWA[2], T. KAWAI[3], K. HATA[3], *A. FUKUDA[1];

Abstract: Exposure to prenatal stress (PS) and mutations in *Gad1*, which encodes the GABA synthesizing enzyme glutamate decarboxylase (GAD) 67, are both risk factors for psychiatric disorders. Using GAD67-GFP knock-in heterozygous (HT) mice subjected to PS from embryonic day 15.0 to 17.5, we previously reported disruption of GABAergic neurogenesis in the MGE. Postnatally, the density of parvalbumin (PV)-positive GABAergic interneurons was significantly decreased in the mPFC of HT-PS mice, which is a common trait shared by different psychiatric diseases. These results suggested that these two key genetic and environmental susceptibility factors could specifically disturb the proliferation of PV-positive neurons. By contrast, these findings were not observed in wild type offspring. In this study using a genetic risk factor (*Gad1* heterozygosity) with prenatal stress, an environmental risk factor, we evaluated effect on epigenetic programming and subsequent behavioral deficits. Our results indicated multiple genes functionally associated with neurogenesis and behavior were hyper- or hypo-methylated in HT-PS mice. Some differentially expressed genes detected by high-throughput microarray expression were strongly correlated to their altered epigenetic status as validated by real-time PCR. In addition, we examined the behavioral phenotypes and found that HT-PS mice demonstrated significant deficits in sensorimotor gating, cognitive processes, social engagement, without change in anxiety and exploratory behaviors. When assessing the function of interneurons in the mPFC of HT-PS, we found that inhibitory postsynaptic currents were altered and tonic inhibition was significantly enhanced. Finally, electrocorticogram recording showed reduction in power spectrum density at gamma-frequency range in mPFC of HT-PS mice, indicating GABAergic dysfunction could underlie the behavioral deficit. These findings may provide new insights into mechanisms of the pathogenesis of psychiatric disorders.

Title: Sex differences in corticotropin releasing factor receptor 1 expression in the brain across the lifespan

Authors: *A. LOCCI, *Y. YAN, G. RODRIGUEZ, H. DONG;
Psychiatry and Behavioral Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Corticotropin releasing factor (CRF)-mediated signal transduction represents a central neuroendocrine pathway in stress response. Emerging studies indicate that during the development, signaling through CRF1 exerts long lasting effects on the brain structure and function both in physiological conditions and following stress. However, studies on the distribution of CRF1 in the mouse brain are limited, and more comprehensive investigation of CRF1 brain distribution will enhance our understanding of the basis of stress-related neural circuitries. In humans, specific CRF1 polymorphisms have been linked to the onset of adult depression following early-life adversity. Moreover, deletion of CRFR1 results in differential effects on anxiety-like behavior in male and female mice. Overall, sex differences in expression and function of CRF and CRF1 and in response to stress may potentially contribute to the etiology of stress-related psychiatric disorders such as anxiety and depression both of which are more prevalent in women than men. Therefore, the aim of this study is to characterize CRF1 expression in the brain of C57BL/6J mice at different life stages, including postnatal day 7, 1, 6, 12 and 18 months of age, both males and females in normal condition as well as after 2-hour-restraint stress. We used western blot quantification to compare CRF1 expression in the brain sub-regions including cortex, hippocampus, amygdala and hypothalamus. Our preliminary results demonstrate that at postnatal day 7 females showed higher CRF1 expression than males in the amygdala and hypothalamus ($P<0.01$), but not in the cortex and hippocampus. Moreover, we observed a higher hippocampal and hypothalamic CRF1 expression in females compared to males at 6 months of age ($P<0.05$); in addition, CRF1 expression also showed a trend of increasing in the amygdala of females compared to males at 6 months without reaching a statistically significant effect. Finally, we found that CRF1 is more abundant in the hypothalamus and cortex of females than males at 18 months of age ($P<0.05$). We are continuing this work to confirm our preliminary findings and to determine how these differences impact on both males and females in response to acute and chronic stress. Taken together, our findings suggest that CRF1 expression in the brain sub-regions changes dynamically across the lifespan, with sex- and age-dependent manner. Sex differences in the CRF1 expression and functioning may contribute to the etiology of stress-related neuropsychiatric disorders such as depression and Alzheimer's disease which are characterized by specific gender prevalence.

Title: Dio3 deficiency alters the daily profile of serum glucocorticoids and circadian gene expression patterns in a sexually dimorphic fashion

Authors: *Z. WU, A. HERNANDEZ;
MMCRI, Scarborough, ME

Abstract: *Dio3* is an imprinted gene that inactivates thyroid hormones. Previous studies have shown that cerebro-cortical and adrenal *Dio3* is expressed in a diurnal pattern, and that DIO3 deficiency in mice lengthened the periods of daily physical activity. We aimed to examine the role of *Dio3* in the regulation of circadian rhythms. We used 3-month old Dio3KO mice and wild type (WT) littermates to determine daily variations in: (i) Physical activity in metabolic cages with or without running wheels; (ii) Serum levels of glucocorticoids; (iii) Tissue expression levels of circadian genes. Metabolic cages data from Dio3KO males showed prolonged night-time activity with running wheels, but no changes in day/night walking time and walking distances. Female Dio3KO mice showed decreases in both wheel running and pedal walking distances compared to WT controls. The normal rise in serum corticosterone at the start of the dark cycle was absent in Dio3KO females, but was not altered in Dio3KO males. DIO3 deficiency also resulted in sexually-dimorphic changes in the hypothalamic expression of circadian genes. Expression of *Clock, Per1, per2, Dbp, Rora, and Cry2* at 18:00 h was significantly decreased in male KO mice, while expression of *Per2, Dbp and Rora* at 6:00 was increased in female KO mice. *Dio2*, which increases local thyroid hormone action, showed a circadian profile in WT males but not females, with elevated expression during the dark cycle. DIO3 deficiency resulted in significantly decreased *Dio2* expression in males at 18:00 h only, and a significant increased in females at 6:00 h. In WT females, *Dio3* expression showed a 12-fold elevation at 18:00, but this was not observed in WT males, who exhibited a significant trough in *Dio3* expression at 00:00 h. DIO3 deficiency resulted in *Dio3* expression being elevated at 6:00 h in females and at 00:00 h in males. The expression of *Hairless* (*Hr*), a gene highly sensitive to thyroid hormone, was elevated in Dio3KO females at 00:00 and 6:00 h, while in males it was reduced at 18:00 h and slightly increased at 6:00 h. These results suggest that the changes in circadian activity associated with DIO3 deficiency may be mediated through thyroid hormone-dependent regulation of circadian genes and/or abnormalities in the circadian variations

of circulating glucocorticoids. Overall, our study indicates that *Dio3* and local control of thyroid hormone action contribute to the normal circadian physical activity, the regulation of the adrenal axis and the hypothalamic expression of clock genes in a sexually dimorphic manner.

Title: hIPSC-derived neurons from MEHMO syndrome patients exhibit altered dendritic morphology that is rescued by the small molecule ISRIB

Authors: *M. K. ELDER[1], S. K. YOUNG-BAIRD[2], T. E. DEVER[2], E. KLANN[1];
[1]Ctr. for Neural Sci., New York Univ., New York City, NY; [2]NICHD, NIH, Bethesda, MD

Abstract: Dysregulation of protein synthesis results in catastrophic consequences for the functioning of cells, and as such, has been linked to a wide range of human diseases. Recent studies of the rare X-linked intellectual disability disorder MEHMO syndrome has revealed underlying mutations in *EIF2S3*, which encodes the γ subunit of the heterotrimeric translation initiation factor eIF2. This subunit plays a crucial role in the translation initiation pathway, and while previous studies have determined that MEHMO-linked mutations affect the formation of the ternary initiation complex in yeast, the effect of these mutations on neuronal morphology has not been investigated.
Human induced pluripotent stem cells (hIPSCs) expressing either the MEHMO mutation eIF2γ-I465Sfs*4 C-terminal frameshift or wild-type eIF2γ were differentiated to cortical neurons using regulated neurogenin-2 expression. The complexity of the dendritic arbor was evaluated using immunofluorescent detection of MAP2, and branching complexity was measured using Sholl analysis. Although the mutation had no effect on somatic size, the number of dendrites and level of branching was significantly impaired. Intriguingly, differentiation and culturing of these cells in the presence of ISRIB, which has previously been shown to suppress phenotypes associated with *EIF2B* mutations in Vanishing White Matter disease, rescued the phenotype and restored

branching complexity to WT levels.
These findings show for the first time that the eIF2γ-I465Sfs*4 C-terminal frameshift mutation found in MEHMO syndrome results in severely impaired dendritic branching. The rescue of such striking neuronal phenotypes with ISRIB suggest that it, or a related compound, could be of benefit for treatment of individuals with MEHMO syndrome in the future.

Title: Folate receptor 1 regulates neural plate cell apical constriction during neural tube formation via interacting with CD2-associated protein

Authors: O. A. BALASHOVA, *L. N. BORODINSKY;
Shriners Hosp. for Children, Univ. of California Davis, Sacramento, CA

Abstract: Neural tube defects (NTDs) are one of the most common serious birth defects diagnosed with an incidence of ~1/1,000. Clinical studies have established that folate is a prominent environmental factor needed for appropriate neural tube closure. Our study focuses on identifying the cellular and molecular mechanisms of folate action during neural tube formation. Previously we found that knockdown of folate receptor 1 (FOLR1) impairs neural tube formation and leads to NTDs. FOLR1-deficient neural plate cells fail to apically constrict and are defective in endocytosis-mediated cadherin trafficking from apical adherens junctions. Further investigation of C-cadherin endocytosis implies that this process is ubiquitination-dependent and involves proteolytical cleavage of C-cadherin.
We carried out proteomics studies through Mass Spectrometry analysis to identify the molecular partners of FOLR1 in the prospective folate-triggered signaling pathway regulating neural plate cell apical constriction during neurulation. Proteins interacting with FOLR1 include signaling molecules, regulators of actin and microtubule dynamics and ubiquitination-related proteins. We screened among FOLR1-interacting candidates for proteins with apical localization in superficial neural plate cells and found that CD2-associated protein (CD2AP) is localized to the

apical pole of neural plate cells during apical constriction. CD2AP is a scaffolding protein that regulates cytoskeletal rearrangements and protein trafficking. In non-neural tissues CD2AP mediates ubiquitination-dependent endocytosis of transmembrane proteins through its association with the ubiquitin E3 ligase c-Cbl. Knockdown of CD2AP protein by morpholinos results in NTDs. Moreover, similarly to FOLR1 downregulation, knockdown of CD2AP perturbs neural tube formation via disruption of neural plate cell apical constriction. In addition, we found that protein ligase c-Cbl localizes along with FOLR1 and CD2AP to the apical membrane of superficial neural plate cells.
Altogether these data suggest that FOLR1 and CD2AP are involved in the same molecular pathway necessary for neural tube morphogenesis.

Title: Overexpression of neuroinflammatory gene sets in postmortem autism but not MDD cortex

Authors: *K. A. YOUNG[1], A.-V. V. NGUYEN[2], H. K. YOUNG[2], P. J. TANSEY[2], M. M. MARZIALE[2], J. A. BOURGEOIS[3];
[1]Psychiatry, CTVHCS, TAMUHSC and BSWH, Temple, TX; [3]Psychiatry, [2]BSWH and TAMUHSC, Temple, TX

Abstract: Neuroinflammatory mechanisms have been proposed to mediate behavioral deficits in neurodevelopmental disorders such as autism and in mood disorders such as major depression (MDD). We interrogated differentially expressed microarray gene (DEG) sets from the cortex to compare and contrast processes that may be impacted in MDD and autism using the gene set enrichment analysis (GSEA) platform. Autism (N=50) and MDD (N=87) cases were compared to separate groups of age and gender matched controls (Gandal et al., 2018, PMID:29439242). Both interneuron and pyramidal neuron-specific gene sets were underexpressed in autism, but only interneurons were down-regulated in MDD. Astrocyte-specific genes were highly up-regulated in autism (FDR q< 0.0001) but were not differentially expressed in MDD (NS). Gene transcripts up-regulated in rodent models of middle coronary artery occlusion and LPS-induced astrogliosis (N=199; Zamanian et al., 2012 PMID:22553043) were selectively up-regulated in autism (FDR q<0.0001) compared to MDD (NS). We noted that GFAP was among the most robustly up-regulated gliosis transcripts in autism (#3/199); this transcript was not differentially regulated in MDD cortex. Microglial transcripts were similarly overexpressed in autism, but this

gene set was significantly *down*-regulated in MDD (FDR q<0.02). Toll-like receptors, which detect pathogen and host inflammatory signals in the CNS, were overexpressed in autism (FDR q<0.005) but were not differentially regulated in MDD (NS). Although neuroinflammation has been previously implicated in autism, microglial pathology has been emphasized. The present analysis suggests that additional studies of classical reactive astrocyte responses to neuroinflammation may be warranted to better characterize apparently robust neuroinflammatory proceses in autism. In contrast, while neuroinflammation has also been proposed to play a role MDD cortical pathophysiology, the present study suggests that reactive astrogliosis, microglial proliferation and inflammatory signalling by toll-like receptors may not be prominent participants in MDD cortical pathology.

Title: Investigating mitochondrial dynamic change caused by domain-specific missense mutations in DNM1L associated with a varying degree of neurological phenotypes in patients

Authors: *K. SO[1], S. BAEK[2];
[1]Div. of Integrative Biosci. and Biotech., [2]Div. of Integrative Biosci. and Biotechnology, Dept. of Life Sci., POSTECH, Pohang, Korea, Republic of

Abstract: Mitochondrial dynamics, including mitochondrial fission and fusion, plays an essential role in neurodevelopment. *DNM1L* encodes a dynamin-related GTPase which functions in mitochondrial and peroxisomal fission. Pathogenic mutations affecting different domains of *DNM1L* are associated with a wide range of neurological phenotypes from relatively mild optic atrophy to neonatal lethality. However, the underlying molecular mechanisms of genotype-phenotype correlation is not well studied. Using induced pluripotency stem cell (iPSC)-derived neural progenitor cell (NPC), we aim to investigate the neurodevelopmental function of *DNM1L* variants. We will knock out the endogenous *DNM1L* gene via CRISPR/Cas9, overexpress the *DNM1L* variants by lentiviral delivery and observe mitochondrial dynamics change in

differentiated NPCs. Our work may help to expand the comprehension of *DNM1L*-related diseases thus to develop targeted therapy.

Title: Protective efficacy of P7C3 compounds in a mouse model for the study of perinatal depression

Authors: *R. SCHROEDER[1], L. NGUYEN[2], A. A. PIEPER[3], H. E. STEVENS[1];
[1]Univ. of Iowa, Iowa City, IA; [2]Grinnell Col., Grinnell, IA; [3]Psychiatry, Univ. Hosp., Cleveland, OH

Abstract: Depression during pregnancy is difficult to treat, as both depression and its currently available pharmacologic treatments may impair offspring embryonic neurodevelopment. Therefore, new, safe, and effective treatments for antenatal depression are needed. P7C3 compounds rescue depressive-like phenotypes in multiple animal models. Additionally, when administered to dams during gestation and nursing, no apparent negative impacts on embryonic or early postnatal development are observed. We hypothesize that P7C3 compounds will rescue maternal depressive-like behavior in an animal model for the study of stress-induced depression, while maintaining normal offspring neurodevelopment and preventing maternal neurobiological deficits. To test this, pregnant CD1 dams underwent restraint stress in 45-minute sessions 3x daily. Concurrently, P7C3 compounds or vehicle was administered via oral gavage twice daily. Outcomes were assessed after non-stressed or stress conditions either with or without P7C3 compound administration in two protocols: prolonged (starting on embryonic day (E) 5), and brief (starting on E12). In two independent cohorts, we assessed anxiety- and depressive-like behaviors in dams during pregnancy (E17) and postpartum day 7. Open field, elevated plus maze, tail suspension, and forced swim tests were used to measure chronic stress-induced behavior changes and investigate a potential rescue by P7C3 compounds. In E14 offspring

embryonic brain, we examined a known prenatal-stress induced deficit, GABAergic progenitor migration delay measuring GAD67GFP+ cell distribution in developing cortical plate. We also tested adult offspring on a battery of behavioral assays, including open field, elevated plus maze, tail suspension test, forced swim test, pre-pulse inhibition, rotarod, and context-dependent fear conditioning. We then assessed their brains for GAD67GFP+ cell distribution. Our preliminary data show that chronic stress caused behavioral changes in pregnant and postpartum dams. and Rescue experiments demonstrated that P7C3 compound administration corrected the embryonic GABAergic migration deficit induced by prenatal stress. These results support the feasibility of P7C3 compounds as a treatment for maternal antenatal depression that protects offspring neurodevelopment.

Title: SEC24D is required for collagen processing and neural development

Authors: M. POPPENS[1], ***J. T. CAIN**[1], R. LAUFMANN[1], S. DAVIS[1], C.-L. LU[2], J. KIM[2], J. WEIMER[1];
[1]Sanford Res., Sioux Falls, SD; [2]Dept. of Biomed. Sci., Iowa State Univ., Ames, IA

Abstract: Cranio-lenticulo-sutural-dysplasia (CLSD) is a disorder that manifests with craniofacial and skeletal defects as well as neural deficits. CLSD is caused by perturbations in collagen transport and secretion resulting from loss of SEC23A. SEC23A is required for COPII vesicle assembly, and more specifically assembly of COPII megavesicles for the transportation and secretion of collagen. Procollagen forms 300nm-long rigid rods, which cannot be packaged is standard 60nm COPII vesicles and require specialized COPII vesicles for packaging. Loss of SEC23A disrupts COPII-collagen megavesicle formation resulting in decreased collagen secretion and increased cellular accumulation of collagen. Recently, a patient was diagnosed with CLSD linked to a mutation in the SEC24D gene. Here we show that *Sec24d* is also necessary for the packaging, transport, and secretion of collagen in *COPII* megavesicles. Loss of *Sec24d* function results in craniofacial defects and embryonic lethality in mice. Loss of *Sec24d* in fibroblasts results in altered procollagen processing, decreased secretion of collagen, and increased accumulation of collagen in the cell.

Title: A role for mitochondrial trafficking and localization in cortical interneuron migration

Authors: *A. K. MYERS[1], G. CHO[3], J. A. GOLDEN[2];
[1]Dept. of Pathology, [2]Dept. of Pathology and Lab. Med., Brigham and Women's Hosp., Boston, MA; [3]Dept. of Pathology, Brigham and Woman's Hosp., Boston, MA

Abstract: Normal cerebral cortical development requires the orderly migration of excitatory neurons (ENs) and inhibitory neurons (INs) into defined laminae. Perturbations in EN or IN migration and final cortical positioning underlies some defects in cerebral cortex circuit formation and some forms of epilepsy. Our lab has discovered that defects to oxidative phosphorylation, a mitochondrial ATP producing pathway, disrupts early IN migration but not EN migration. Additionally, our previously published data suggest INs localize mitochondria more dynamically than ENs which could make them sensitive to defects in mitochondrial trafficking. Mitochondrial transport is mediated by the trafficking proteins Miro and Trak, with Miro recruiting Trak (Milton) proteins to link mitochondria to molecular motors, thus allowing for microtubule- and actin-dependent movement. Interestingly, mutations in MIRO1 or TRAK1 proteins are associated with epilepsy. In this study, we assessed the necessity of Miro1 in neuronal migration. Using *ex vivo* electroporation to label mitochondria in excitatory or inhibitory neuron progenitors of embryonic day (E) 14.5 mouse brains, we expressed knockdown plasmids for Miro1 to disrupt mitochondrial trafficking and assessed the impact on EN and IN migration. Our data indicate that ENs and INs have similar but distinct patterns of mitochondrial localization. Mitochondria in ENs predominately localize anterior to the cell body. In contrast, mitochondria are highly dynamic as INs migrate, moving from the rear of the cell to the leading process and back. Further, our data suggests that knockdown of Miro1 disrupts mitochondrial trafficking and specifically perturbs inhibitory neuron migration, branching dynamics, and mitochondrial localization. Currently, the connection between mitochondria localization and neuronal migration is poorly studied. Our data indicate that impaired mitochondrial localization may impact embryonic brain development, specifically neuronal migration. By elucidating the mechanisms necessary for proper mitochondrial trafficking during IN migration and the

consequences of its dysfunction, we expect to define new pathways that may lead to treatment or prevention of mitochondria-related epileptic disorders.

Title: Novel *de novo* mutations in the PP2A regulatory subunit PPP2R2B causing neurodevelopmental disorders

Authors: *P. SANDAL[1], Y. KONG[1], L. BICKNELL[2], S. STRACK[1];
[1]Pharmacol., Univ. of Iowa, Iowa City, IA; [2]Dept. of Pathology, Univ. of Otaga, Dunedin, New Zealand

Abstract: Serine/threonine protein phosphatase 2A (PP2A), is a heterotrimeric protein comprised of a conserved scaffold A subunit, catalytic C subunit, and a variable regulatory B subunit. The regulatory subunit determines PP2A substrate specificity and subcellular localization. Mutations in PPP2R2B, one of twelve regulatory subunit genes is mammals, causes spinocerebellar ataxia 12 (SCA12), a rare neurodegenerative disorder. PPP2R2B encodes neuron specific and alternatively spliced cytosolic Bβ1 and mitochondria-targeted Bβ2 splice variants. The N-terminal mitochondrial targeting sequence of Bβ2 recruits it to the outer mitochondrial membrane (OMM) and induces mitochondria fragmentation and increases susceptibility to neuronal insults. Furthermore, a mouse knockout (KO) of Bβ2 shows elongated mitochondria and neuroprotection. Recently, Hamdan et al. performed whole exome sequencing on severe to moderate intellectually disabled patients and identified a possibly damaging de novo missense mutation, Arg138Pro, in the PPP2R2B gene in one patient. The patient suffered from intellectual disability (ID), intractable seizures and autistic features. A different, as yet unpublished *de novo* missense mutation was identified in a patient from New Zealand, who presents with microcephaly, cerebellar atrophy and spastic diplegia. We generated and expressed these mutations by itself and in complex with A subunit in mammalian HEK cells and initial co-immunoprecipitation experiments indicate that these mutations do not affect holoenzyme assembly. We have previously shown that under cellular stress, Bβ2 rapidly translocates to

mitochondria to promote apoptosis. In order to understand the effect of these mutations, we studied the co-localization of these mutants in Hela cells and do not see any significant difference in mitochondrial localization between these mutants and the wildtype Bβ2. We are further investigating the effect of these mutations on mitochondrial shape and localization by expressing them in hippocampal neurons. We are also generating stable mammalian cell lines to identify cellular substrates by phospho-proteomics.

Title: Cortical GABAergic interneurons require ERK/MAPK for postnatal maturation and function

Authors: *M. HOLTER[1], N. R. FRY[2], G. R. BJORKLUND[3], J. S. MARTINEZ[1], K. NISHIMURA[5], J. NICHOLS[6], T. R. ANDERSON[7], J. NEWBERN[4];

Phoenix, Phoenix, AZ

Abstract: The canonical RAS/RAF/MEK/ERK (ERK/MAPK) pathway is a highly conserved signaling cascade, the components of which have differential expression in numerous cell types. ERK/MAPK signaling is dynamic throughout neurodevelopment and present at varying levels in neuron subtypes. Consequently, dysregulated ERK/MAPK is involved in numerous neurodevelopmental syndromes, including the RASopathies and some genetic forms of Autism Spectrum Disorder (ASD). Both gain- and loss-of-function signaling through ERK/MAPK have been observed in the RASopathies and ASD. How reduced ERK/MAPK signaling affects the development and basic function of cortical neuronal subtypes such as GABAergic interneurons has not been determined. Here, we generated quadruple transgenic mutant mice to specifically delete the principal ERK/MAPK components *Mapk3/Erk1* (*Erk1*$^{-/-}$) and *Mapk1/Erk2* (*Erk2*$^{fl/fl}$) using Slc32A1:Cre or Nkx2.1:Cre from GABAergic interneurons endogenously labeled with the Cre-dependent Ai9 reporter. We determined that ERK/MAPK is not required to establish cortical GABAergic interneuron number, but is necessary for the expression of SST, a key genetic marker of approximately 30% of all cortical interneurons. Preliminary evidence suggests altered

excitatory drive onto GABAergic interneurons in *Erk1*$^{-/-}$ *Erk2*$^{fl/fl}$ Nkx2.1:Cre mutants during the second postnatal week. To determine if these physiological abnormalities were due to altered interneuron morphology, we injected a Cre-dependent AAV2/9-CAG-GFP into the neonatal somatosensory cortex to examine interneuron dendritic complexity. Due to well established roles of ERK/MAPK in activity-dependent development, we asked whether chemogenetic stimulation of GABAergic circuitry in adulthood was sufficient to rescue interneuron phenotypes in *Erk1*$^{-/-}$ *Erk2*$^{fl/fl}$ Nkx2.1:Cre mice. Models of several genetically-defined neurodevelopmental syndromes have frequently observed changes in perineuronal net (PNN) accumulation. How normal ERK/MAPK signaling is involved in this critical process of cortical maturation is still unclear. Utilizing GABAergic-specific RIP-Seq, we have identified differentially expressed genes in *Erk1*$^{-/-}$ *Erk2*$^{fl/fl}$ Slc32A1:Cre and caMEK1 Slc32A1:Cre cortices during the first week of postnatal development. Overall, our data highlight the important roles of ERK/MAPK in the development and maturation of cortical GABAergic circuitry.

Title: Cortical growth and patterning anomalies in a mouse model for CHARGE syndrome

Authors: *A. P. A. DONOVAN[1], C. MOHAN[1], J. ELLEGOOD[2], J. P. LERCH[3], A. BASSON[1]; [1]King's Col. London, London, United Kingdom; [2]Mouse Imaging Ctr., Hosp. For Sick Children, Toronto, ON, Canada; [3]Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Dominant mutations in the gene encoding the ATP dependent chromatin remodeling factor CHD7 cause CHARGE syndrome (**C**oloboma, **H**eart defects, **A**tresia of the choanae, **R**etardation of growth, **G**enital anomalies and **E**ar defects). Individuals with CHARGE syndrome often have intellectual disability and have been reported to have deficits in executive functioning. The neurodevelopmental and neuroanatomical underpinnings of these defects are not yet known, but cortical abnormalities are linked to both intellectual disability and executive dysfunction.
To identify structural changes in the brain associated with *Chd7* haploinsufficiency in the mouse, we performed MRI studies in *Chd7*$^{+/-}$ mice. These studies identified pronounced and widespread

abnormalities in the cortex and associated structures, including within the prefrontal, visual, auditory, motor, somatosensory and cingulate cortices. To investigate the underlying mechanisms, neural progenitor proliferation and apoptosis was quantified in the developing neocortex.
A genome-wide comparison of gene expression in *Chd7*$^{+/-}$ and *Chd7*$^{+/+}$ embryonic neocortices was carried out at E12.5. Gene expression changes suggestive of abnormal anterior-posterior (A-P) cortical patterning were identified and validated using *in situ* hybridization and qPCR. Restrictions in the size of frontal/motor and expansion of visual cortical modules were also identified by *in situ* hybridisation. Additionally, at E9.5, a specific reduction in the expression of *Fgf8* in the anterior neural ridge, an important A-P cortical patterning centre, was identified by *in situ* hybridisation and validated via qPCR. Together, these studies provide insights into developmental alterations in cortical patterning and subsequent A-P cortical organisation, that could underlie abnormalities in the mature cortex and aspects of neuropsychiatric dysfunction in CHARGE syndrome patients.

Abstract: Epigenetic modifications of the genome, including DNA methylation and covalent modifications of histone proteins, are critical regulators of brain cell differentiation, maturation and synaptic plasticity. However, the causal relationships among these epigenetic modifications and their impact on neuronal function are unknown. Here, we studied the interaction between

DNA methylation and histone modifications in a conditional knockout (cKO) mouse in which Dnmt3a ablation was initiated during late gestation (around embryonic day 15). We have previously shown that Dnmt3a cKO mice lack a neuron-specific epigenetic mark, namely DNA methylation at non-CG dinucleotides (mCH). This epigenetic alteration is accompanied by differential expression of ~2000 genes. Computational analysis using Binding Analysis for Regulation of Transcription (BART) suggested that a significant number of these genes may be regulated by transcription factors and chromatin regulators associated with the Polycomb repressive complex (PRC). In addition to the loss of mCH, we found ~140,000 differentially methylated regions (DMRs) with lower mCG in the cKO. These DMRs mainly mark regions that gain methylation during normal brain development, but fail to do so in the absence of Dnmt3a. To link DNA methylation with a broader context of epigenetic regulation, we profiled histone modifications in pyramidal cells by sequencing DNA fragments extracted by chromatin immunoprecipitation (ChIP-Seq). We found that a significant fraction of DMRs gained trimethylation at lysine 27 of histone 3 (H3K27me3) in cKO animals. This chromatin modification is associated with PRC-mediated repression of gene expression. By contrast, two chromatin modifications which mark active regions, acetylation of lysine 27 (H3K27ac) and trimethylation of lysine 4 (H3K4me3), were largely unaffected by Dnmt3a ablation. These results suggest that PRC-mediated repression may compensate for the loss of mCG and/or mCH, acting as an alternative repressive mechanism when DNA methylation is disrupted. Overall, our results support a link between two epigenetic mechanisms for suppressing gene expression, which may confer robustness on this critical regulatory program.

Title: Inhibition of inflammasome activation as a potential treatment for francisella tularensis infection

Authors: *A. TENA[1], C. SPENCER[2];
[1]Biol. Sci., [2]Univ. of Texas at El Paso, El Paso, TX

Abstract: *Francisella tularensis* is a gram-negative coccobacillus bacterium that causes the zoonotic disease tularemia in humans. *Ft* is transmitted through direct contact with infected

animals, consumption of contaminated food or water, inhalation or arthropod bites. Given its possible use as a bioterror agent, *Ft* is classified as a Tier 1 select agent by the CDC. Infection by *Ft* triggers an overactive inflammatory response known as a cytokine storm that results in major tissue damage leading to death of the host before onset of adaptive immunity. This inflammation is mediated intracellularly by the activation of the multi-protein cytosolic inflammasome complexes. The inflammasomes regulate the activation of caspase-1 to produce proinflammatory cytokines interleukin-1β (IL-1β) -and IL-18. Nod-like receptor (NLR) proteins, especially NLR-family pyrin domain containing 3 (NLRP3) sense the presence of *Ft* in the cytosol and activates the inflammasomes. Previous studies report that *Ft* live vaccine strain (LVS) is sensed by NLRP3 in human macrophages and by a non-NLR protein, absent in melanoma 2 (AIM2) in mouse macrophages. NLRP3 and AIM2 form a caspase-1-activating inflammasome by engaging the caspase-1-activating adaptor protein apoptosis-associated speck-like protein containing CARD (ASC) adapter protein. ASC is crucial for production of IL-1β and plays an important role in innate immune signaling by linking the communication between pathogen recognition receptors and caspase 1 in inflammasome complexes. The purpose of this project is to prevent the formation and activation of inflammasomes. We hypothesize that disrupting the formation of the inflammasome would prevent generation of the cytokine storm and its associated tissue damage and death. Bone-marrow derived macrophages were be infected with *Ft* and treated with novel inflammasome inhibitors at varying concentrations. Treated macrophages were then be stained with α-cryopyrin (NLRP3), α-ASC, and α-AIM2 and visualized via fluorescent microscopy. Activation of the inflammasomes leads to overlapping localization of the sensor and ASC. Inflammasome disrupting compounds would prevent this overlapped localization.

Abstract: Overwhelming evidence suggests that Schizophrenia (SCZ) is a neurodevelopmental disorder with a strong genetic underpinning. Genome-wide association studies identified numerous SCZ risk genes, including rare variants of members of the *SEMAPHORIN (SEMA)* family of axon guidance molecules and their receptors the *PLEXINs (PLXNs)*. Human variants of *PLXNA2* have been identified that lead to reduced *PLXNA2* gene expression in the forebrain and increased SCZ susceptibility. The underlying biology and neural circuitry perturbed by *SEMA/PLXNA2* mutations that can cause SCZ symptoms in patients remain unknown. We previously showed that in mice global *Plxna2* deficiency (*Plxna2*$^{-/-}$) disrupts migration and proliferation of early-born dentate granule cells (GCs) as they travel from the primary neuroepithelium to the dentate gyrus (DG) primordium. In mature *Plxna2-/-* mice, the stem cell niche in the subgranular zone produces fewer neurons and DG-CA3 laminar connectivity is impaired. Behavioral studies with *Plxna2* wildtype, heterozygous and null male and female mice revealed gene-dosage and sex-specific defects. Contextual fear conditioning, but cued fear conditioning, is defective in *Plxna2-/-* mice. *Plxna2*$^{-/-}$ females show reduced sociability in the 3-chamber-approach test. *Plxna2-/-* and *Plxna2+/-* males and *Plxna2-/-* females show a striking reduction in PPI (Pre-Pulse Inhibition) of the acoustic startle response. To assess the anatomical substrate associated with *Plxna2* behavioral defects, we conditionally deleted *Plxna2* in the embryonic forebrain. Conditional mutants (cKO) show defects in DG development similar to global knock-outs. Behavioral studies with *Plxna2* cKO mice revealed defects in contextual fear conditioning, and PPI. Thus, forebrain specific depletion of *Plxna2* recapitulates anatomical and behavioral defects observed in *Plnxa2*$^{-/-}$ mice. Ongoing experiments, including neural cell type specific deletion of *Plxna2*, is expected to provide insights into the neural circuits affected by *PLXNA2* mutations. Characterization of the biochemical pathways regulated by PlxnA2 signaling may be exploited therapeutically in psychiatric disorders.

Title: Exploring the phospho-proteome of Jordan's Syndrome, an autosomal dominant neurodevelopmental disorders caused by *de novo* mutations in a protein phosphatase 2A regulatory subunit

Authors: *C. JONG, R. A. MERRILL, Y. KONG, S. STRACK;
Pharmacol. and Iowa Neurosci. Inst., Univ. of Iowa, Iowa City, IA

Abstract: Jordan's Syndrome (JS) or autosomal-dominant mental retardation 35 (MRD35) is caused by *de novo* germline mutations in the protein Ser/Thr phosphatase 2A (PP2A) regulatory subunit B'δ (PPP2R5D). Relatively common among monogenic causes of neurodevelopmental disorders, JS typically presents with intellectual disability (ID) and autism. Most JS mutations switch a negatively to a positively charged residue (glutamate to lysine) in the highly conserved acidic loop that extends from B'δ towards the active site of the PP2A catalytic subunit. We hypothesize that JS-associated mutations change PP2A substrate specificity (e.g. from positively to negatively charged phospho-peptides), which would enhance cellular signaling cascades that promote growth and proliferation. To identify cellular and biochemical phenotypes of JS causing ID, we generated stable HEK293 cell lines inducibly expressing either wild-type (WT) or mutant B'δ using a PP2A reduction model. We characterized the most common B'δ mutation in JS, E198K. The PP2A reduction cell lines were induced with doxycycline or vehicle for at least three days followed by assessment of PP2A subunit expression, cellular growth, and substrate dephosphorylation by unbiased phosphoproteomics. In our reduction model, WT and mutant B'δ were overexpressed by 3-fold, concomitant with a 3-fold loss of endogenous PP2A regulatory subunits. Quantitative global phosphoproteomic analyses of reduction and overexpression models shows that the reduction model, but not the overexpression model, defines consensus dephosphorylation motifs for B'δ-containing PP2A holoenzymes. In the reduction model, WT B'δ expression caused growth arrest within 4 days, while the E198K mutation attenuated the growth inhibitory effect of B'δ, effects that are likely associated with a change in substrates specificity. Indeed, our global phosphoproteomic analyses suggest that WT B'δ preferentially dephosphorylates substrates containing positively charged residues, while E198K-mutant B'δ dephosphorylates negatively charged residues adjacent to the phosphorylation site. Our data also suggest that the E198K mutation confers high basal activity to the PP2A holoenzyme, while WT PP2A/B'δ requires phosphorylation by PKA for full activity. In conclusion, using the PP2A reduction model, we provide preliminary evidence that *de novo* mutations in PPP2R5D blunt the growth inhibitory effect of B'δ likely by a change in PP2A substrates specificity. We speculate that altered PP2A activity in JS deregulates signaling pathways mediating cell proliferation, differentiation, and morphogenesis, which in turn leads to abnormal brain development.

Abstract: *DTNBP1* variations and decreased dysbindin-1 protein are associated with schizophrenia. Downregulated dysbindin-1 decreases copper transporters ATP7A and CTR1, required for blood brain barrier crossing of copper. To further study this relationship, the role of antipsychotic treatment, and to assess if such alterations would impact cognitive function, the current study measured behavioral indices of cognitive function in dysbindin-1 knockout (sdy) mice and their wild-type (WT) littermates with or without quetiapine treatment. Peripheral blood and exsanguinated brain copper levels were assessed, plus relevant markers of mRNA expression in cortex and hippocampus.
qRT-PCR revealed that after treatment, WTs exhibited elevated cortical transthyretin (TTR), a female-driven effect. Quetiapine-mediated cortical myelin basic protein (MBP) elevation in sdys was a female-driven effect. Hippocampal CTR1, TTR, and MBP mRNA were decreased by quetiapine regardless of genotype, but a genotype/treatment interaction was observed in WT hippocampal CTR1. Male sdys exhibited excess peripheral copper that was rescued with quetiapine treatment. Untreated male sdys expressed more hippocampal MBP than other male groups. Both hindlimb clasping severity and ledge instability were exacerbated in untreated sdy vs WT mice. Interestingly, these tasks were rescued with quetiapine in a genotype and sex-specific manner.
Cerebellar ataxia is sensitive to genotype, sex, and quetiapine interactions, as is regional genetic expression. While cerebellar ataxia was responsive to treatment, quetiapine did not alter other cognitive indices indicating that quetiapine-induced alterations are not sufficient for treatment-resistant cognitive impairments. Thus, expansion for proteomic assessment and other mechanisms underlying cognitive deficiencies are needed to develop better treatments.

Title: Toxoplasma seropositivity interacts with haplotypes of risk in schizophrenia to distinguish affected individuals from unaffected siblings

Authors: J. SEVILLANO-ORTIZ[1], C. GALLO[1], G. POLETTI-FERRARA[1], J. ARNEDO[2], I. ZWIR[2,3], M. CALVO[4], E. PADILLA[4], G. GONZALEZ ALEMAN[4], N. V. FLORENZANO[4], D. KAMIS[5], J. MOLINA[6], J. TORANZO[4,7], M. USCAMAYTA AYVAR[4,7], O. MALDONADO[7], *G. A. DE ERAUSQUIN[4];

Abstract: Chronic, non affective psychotic illness is a highly heritable neurodevelopmental disorder, which nonetheless probably requires environmental injuries to interact with predisposing genes. In a sample of individuals with well-established, chronic, neuroleptic-naive non affective psychosis, their unaffected siblings, and matched healthy controls, we used a machine learning algorithm to unbiasedly uncover candidate genes associated with risk of parkinsonism and psychosis, and identified three genes containing multiple significant SNPs (KLRG1, MYO16 and RIT2). We then inputed extended haplotypes for each and evaluated the interaction between the presence of risk haplotypes and antibody titers to known infections contributing to risk of psychosis (toxoplasma, herpes virus 1) or not related to such risk (herpes virus 2). Logistic regressions of the disease status (healthy control, unaffected sibling, proband) using as predictors the risk haplotypes of the candidate genes and the antibody titers to each of the infections were run to test the interaction. Significant GXE interactions predictive of disease

status (proband) were found for the three candidate genes and toxoplasma seropositivity, such that the latter distinguished probands from unaffected siblings when both carried haplotypes of risk. Interactions for herpes virus were less consistent. This is, to the best of our knowledge, the first demonstration of a putatively causative GXE interaction between infections known to contribute to risk and extended haplotypes of risk.

Title: Unique blockage of host RNAi machinery by the zika virus capsid in fetal NSCs and mouse model

Authors: ***J. ZENG**[1], Z. ZHAO[1], Q. LIANG[2];
[1]Physiol. & Neurosci., USC, Los Angeles, CA; [2]Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China

Abstract: Zika virus (ZIKV) is a single-stranded RNA virus of the Flaviviridae family. It rapidly spread worldwide during 2015-2016 and is causally associated with fetal microcephaly, intrauterine growth retardation, and other congenital malformations. ZIKV is reported to infect placenta and fetal brain during pregnancy, particularly targeting human neural stem and progenitor cells (NSCs). Among the flavivirus family, only ZIKV is linked to microcephaly, suggesting uniqueness of ZIKV infection compared to other members, which calls for a better understanding of the molecular drivers of ZIKV immune evasion and pathogenesis in fetal brain. In addition, host molecular targets of ZIKV proteins remain elusive, which not only limits our understanding of ZIKV infection and pathogenesis, but also impedes anti-ZIKV drug development. Since the ZIKV outbreak in 2015, we have focused on understanding the complexity of ZIKV infection and pathogenesis of microcephaly. To fully understand the roles of viral proteins during ZIKV life cycle, we established the ZIKV-host interactome in human iPSC-derived NSCs. By analyzing this ZIKV-host interactome, we found that the key microRNA processing protein DICER was the top target of ZIKV capsid protein, and DICER deficiency facilitated ZIKV infection in mouse embryonic NSCs. Dysregulation of microRNAs has been

associated with many human disease diseases, including developmental neurological disorders such as microcephaly. More importantly, DICER-dependent microRNA production is commonly used by plants, fungi and invertebrates, and remains active in mammalian stem cells to produce antiviral small RNAs from the viral genomes, which inhibits viral replication via RISC-mediated RNA interference. Mechanistically, we further identified that ZIKV capsid directly interacts with DICER and blocks its ribonuclease activity, dampening the production of both viral interfering RNAs and host microRNAs that are essential for neurogenesis. Taken together, we have constructed the first interactome based on protein-protein interaction between ZIKV viral proteins and host targets in NSCs, providing unique insights into the ZIKV-specific immune evasion mechanisms. Our findings are consistent with the notion that ZIKV infection alters host mRNA and miRNA profile in NSCs or astrocytes and provided the potential molecular mechanism to the question “Why only ZIKV is link to microcephaly in clinic among flaviviruses”.

Abstract: Intellectual disability (ID) is a genetically and clinically heterogeneous disorder, characterized by limited cognitive abilities and impaired adaptive behaviors. In recent years, exome sequencing (ES) has been instrumental in deciphering the genetic etiology of ID. Here, through ES of a large cohort of individuals with ID, we identified two bi-allelic frameshift variants in *METTL5*: c.344_345delGA (p.(Arg115Asnfs*19)) and c.571_572delAA (p.(Lys191Valfs*10)), in families of Pakistani and Yemenite origin. Both of these variants were segregating with severe ID, microcephaly and various facial dysmorphisms, in an autosomal recessive fashion. METTL5 is a member of the methyltransferase-like protein family, which encompasses proteins with a seven-beta-strand methyltransferase domain. We found *METTL5* expression in various substructures of rodent and human brains and METTL5 protein to be enriched in the nucleus and synapses of the hippocampal neurons. Functional studies of these truncating variants in transiently transfected orthologous cells and cultured hippocampal rat neurons revealed no effect on the localization of METTL5 but alter its level of expression. Our in-silico analysis and 3D modeling simulation predict disruption of METTL5 function by both variants. Finally, *mettl5* knockdown in zebrafish resulted in microcephaly, recapitulating the human phenotype. This study provides evidence that biallelic variants in *METTL5* cause ID and microcephaly in humans and highlights the essential role of METTL5 in brain development and neuronal function.

Col., Lahore, Pakistan

Abstract: Wiring of cortical circuits is carried out by coordinated developmental mechanisms of neuronal migration, dendritic arborization, axon projection, and synaptogenesis. It is estimated that mutations in over 2500 genes can underlie cortical miswiring that leads to intellectual disability, a complex group of neurodevelopmental disorders characterized by significant impairment in cognition and adaptive behaviors. Up to 50% of intellectual disability cases have genetic etiologies. Identification of the specific gene variants underlying cortical wiring pathology has provided critical insights to the molecular processes behind physiological and pathological cortical circuit development.In this study, using whole exome sequencing in a large cohort of consanguineous families, we identified a missense variant of *DCTN2* that segregates with severe intellectual disability and epilepsy in an autosomal recessive fashion. DCTN2 is one of the 23 subunits of dynactin, a regulator of the dynein motor complex. It has been studied with respect to endocytosis in non-neural cells, and has been associated with motor neuron degeneration. We investigate DCTN2 in the developing brain and find it to be broadly expressed, including in neocortex and hippocampus. Using subcellular proteomics and immunolabeling, we find DCTN2 heavily enriched in growth cones of developing cortical axons. Using *in* vivo CRISPR knockout in callosal projection neurons, we identify pervasive dysmorphic axon growth cones resulting from *Dctn2* deletion both in the developing and adult cerebral cortex. These findings indicate that disruption of *Dctn2* function results in specific abnormalities in the development of cortico-cortical circuitry, potentially underlying intellectual disability and epilepsy seen in patients.

Title: Insight from modeling of non-genetic risk factors for autism in rodents

Authors: *M. A. ESTEVEZ, A. A. SARKAR, S. BANERJEE-BASU;
Mindspec, Inc., McLean, VA

Abstract: There is a growing consensus that autism spectrum disorder (ASD) has a complex etiology, encompassing both genetic and non-genetic factors. Here we analyze animal models derived from non-genetic factors curated in AutDB, a comprehensive resource for autism research. Our dataset from March 2019 catalogues 327 rodent models derived from 92 non-genetic factors (inducers) related to ASD. We classify the inducers as evidence-based when these recapitulate etiological mechanisms with human clinical or epidemiological evidence. The etiological models take into consideration developmental time points (pre-conception, prenatal or early-life) as well as their biological role. Using a large dataset of rodent models derived from 58 evidence-based environmental factors associated with ASD, we identify several research trends: (1) the bulk of the induced models originate from etiological categories in the prenatal period reflecting the importance of maternal factors; (2) the most commonly modeled inducer in rat is the prenatal exposure of valproic acid categorized under the etiological model "Maternal intake: anticonvulsant drug", while the most commonly modeled inducer in mouse is polyinosinic:polycytidylic acid categorized under the etiological model of "Maternal immune activation"; (3) while the majority of the inducers are species-specific, a total of 11 inducers (19%) have been modeled in both mouse and rat; (4) a number of induced models based on environmental factors with uncertain links to ASD are also part of this dataset; finally (5) assessment of developmental time points of induction of environmental models of ASD indicate that there is a correlation between the emergence of ASD-specific phenotypes and the neurodevelopmental trajectory. Together, our unique and comprehensive collection of non-genetic rodent models and meta-analytical approaches provide important insights into the research trends and biological underpinnings of environmental risk factors of ASD.

Title: Effects of bacterial endotoxin LPS on the neuronal regulation of the heart, a sensory-CNS-motor nerve circuit as well as at neuromuscular junctions: Crustacean model

Authors: *M. C. MCNABB[1], C. M. SAELINGER[1], R. MCNAIR[2], S. M. BIERBOWER[2], R. L. COOPER[1];

Abstract: Eatable crustaceans are susceptible to bacterial septicemia from injury or compromised defense by bacterial strains which can possibly have detrimental effects in mammals. Since many crustaceans (i.e., crabs, lobsters, crayfish) are used for animal food and human consumption, it is of interest to understand the effects potential bacterial infections can have on their and our health. The Red Swamp crayfish (Procambarus clarkii) was used as a model crustacean to investigate the effect of direct exposure to endotoxin lipopolysaccharide (LPS) and associated peptidoglycans from gram-negative bacteria (Serratia marcescens). S. marcescens is a common strain identified to cause septicemia in mammals (500 µg/ml) and is prevalently found in nature. LPS injection into the hemolymph of crayfish revealed acute changes in heart rate and effects on survival. Direct LPS exposure on an in situ sensory-CNS-motor circuit produces a decrease in function at 500 µg/ml but has no significant effect at 100 µg/ml. At the isolated neuromuscular junction, the direct action of the LPS endotoxin (500 µg/ml) enhances evoked synaptic transmission and alters facilitation, while no effect on the occurrence of spontaneous vesicle fusion events. These direct actions on tissues appear to be independent of innate immune responses and suggests the LPS receptors on these tissues have a role in excitability of neuronal function. In addition, we embarked on examining reproducibility in the data analysis with different participants.

Title: Regulation of E/I balance by active conductances

Authors: S. SHIN, M. BRIDI, S. PARK, ***S. HUANG**;
Hussman Inst. for Autism, Baltimore, MD

Abstract: Excitation and inhibition (E/I) appear concomitantly during neural activity in vivo. Balanced excitation and inhibition is required for normal brain function while imbalanced excitation and inhibition has been linked to autism and other neurodevelopmental disorders. Restoring E/I balance could potentially be a useful strategy for the development of therapeutics in these disorders. Thus, identification of factors that regulate E/I balance in neurons is important for translational research. Here we investigated the integration of excitatory and inhibitory inputs at the induction of action potentials in realistic biophysical neuronal models, and revealed that

the relationship of excitation and inhibition is a linear function with a y-intercept. This function was further validated in actual neurons with artificial synaptic inputs and in neurons with inhibitory synaptic inputs activated by optogenetic stimulation. Moreover, we showed that voltage-dependent ion channels, which control the threshold of action potentials, can regulate the function of E/I integration. These findings provide insights into potential therapeutic targets for correcting E/I imbalance in neurodevelopment and psychiatric conditions.

Abstract: Our study suggests that interhemispheric connectivity between basolateral amygdalae (BLA) is critical for BLA activity and function. However, the exact circuit mechanism remains unclear. Here we combined optogenetics and *ex vivo* slice electrophysiology to investigate the role of contralateral BLA afferents on BLA principle neuron (PN) activities. We found that no matter there were weak or strong circuit-driven inhibitions, activation of contralateral BLA afferents potentiated PN activities and had synergistic effect when paired with cortical or thalamic input stimulation. Moreover, when using theta-burst frequency stimulation (TBS) to repetitively activate contralateral BLA afferents, the inter-BLA synaptic dynamic exhibited multiple-pulse facilitation and potentiated the cortical - BLA or thalamic - BLA synaptic potentials more in the late stimulus train. Although the relationship between plasticity changes and functional significances of different cell types remains to be investigated, our study evidences that interamygdalar connectivity potentiates the BLA PN activities and plays a critical role in regulation of amygdalar activity and function.

Title: Somatic and synaptic modulation by muscarinic cholinergic receptors at synaptic connection of inhibitory interneuron onto noradrenergic neuron in locus coeruleus

Authors: *C.-C. KUO[1], M.-Y. MIN[1], H.-W. YANG[2];
[1]Dept. Life Sci., Natl. Taiwan Univ., Taipei, Taiwan; [2]Dept. Biomed. Sci., Chung-Shan Med. Univ., Taichung, Taiwan

Abstract: Activation of muscarinic acetylcholine receptors (mAChRs) is well known to increase the excitability of noradrenergic neurons in the locus coeruleus (LC) and to result in change of electroencephalography activity in anesthetized animals. Here we test, in addition to directly targeting on NAergic neurons (LC neurons), whether activation mAChRs modulated the activity of local inhibitory interneurons (IN) and the transmission at synapses of the IN onto LC neurons. To this end, we used optogenetic method to selectively activate the IN and recorded inhibitory postsynaptic currents (IPSCs) from LC neurons. Stereotaxic Injection of adeno- associative virus (AAV) carrying double a double-floxed inverted open reading frame of enhanced yellow florescent protein and channelrhodopsin2 was made into the LC in of Vgat-cre mice, in which the promoter of vesicular GABA transporter drives expression of cre recombinase. The animals were killed 3-8 weeks after the surgery for brainstem slice preparation and whole-cell patch recording was made from LC neurons. Illuminating the slices with a single blue-light pulse (2 ms) evoked IPSCs in LC neurons. Bath application of 25 μM carbamoylcholine (CCh), a potent agonist of mAChRs, attenuated the IPSCs, which was associated with an increase in the paired-pulse ratio, showing that the effect of CCh was presynaptic. In addition, bath application of CCh also dramatically increased the firing rate of both LC neurons and the IN. The presynaptic effect of CCh on inhibiting the transmission at synapses of the IN onto LC neurons was blocked by mAChR 2 (M2R) and mAChR 4 (M4R) but not by mAChR 1 (M1R) and mAChR 3 (M3R) antagonists; in contrast, the increase in firing rate of LC neurons and the IN by CCh were abolished by M1R/M3R but not by M2R /M4R antagonists. Together, the above results show the inhibitory transmission from the local IN onto LC neuron was modulated by presynaptic M2R/M4R but not M1R/M3R. Furthermore, the activation of M1R/M3R, but not M2R/M4R increased the excitability of LC neurons and the local IN. (Grant support: MOST, Taiwan).

Title: A circuit function of asynchronous glutamate release in neocortex

Authors: *S. DENG[1], J. LI[1], J. ZHU[2], Q. HE[1], L. LI[1], Y. SHU[1];
[1]Beijing Normal Univ., Beijing, China; [2]Yale Univ., New Haven, CT

Abstract: Cortical inhibition is crucial for dynamic excitation-inhibition balance and information processing in the neocortex. The temporal control of cortical inhibition determined by distinct microcircuit motifs has been extensively studied. The underlying mechanism, however, remains unclear. In this study, we performed dual whole-cell recordings from pyramidal cells (PCs) and nearby inhibitory interneurons in layer 5 of rodent neocortical slices (Sprague Dawley rats and mice, postnatal 15-20 days). We found that PC output synapses onto Martinotti cells (MCs) have two release modes: synchronous and asynchronous release. The delayed and long-lasting asynchronous release (AR) of glutamate prolongs and desynchronizes the firing in MCs, causing prolonged and imprecise inhibition in neighboring PCs. AR is much stronger at PC-MC synapses as compared with those onto fast-spiking cells and other PCs. In addition, AR is also dependent on PC subtypes, with crossed-corticostriatal PCs producing the strongest AR as compared to corticopontine and commissural PCs. Further experiments revealed that knocking out the slow calcium sensor synaptotagmin-7 reduced both the AR event number and the AR-induced basal currents, leading to a reduction of recurrent inhibition between PCs. In conclusion, our results highlight the effect of a cell-type specific glutamate AR on the operation of microcircuits mediating the slow recurrent inhibition, an important mechanism for controlling the timing and size of cortical inhibition.

Title: Circadian rhythms of viscerosensory to brainstem signaling

Authors: *F. J. SHAFFER, B. PETERSON, J. H. PETERS, I. N. KARATSOREOS; Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Circadian rhythms synchronize physiological and behavioral responses to environmental light/dark cycles, including the maintenance of autonomic tone and reflex pathways. The nucleus of the solitary tract (NTS) receives glutamatergic afferent inputs from the viscera through the vagus nerve and is directly responsive to circulating factors and hormones. It also has dense reciprocal connections to the paraventricular nucleus (PVN) of the hypothalamus, positioning it as a key integrator of circadian rhythms and visceral status. However, rhythmicity of neural communication has never been explored in the NTS. The purpose of this study was to investigate this region of the brainstem as a key candidate for the extra-SCN rhythmic control of the autonomic nervous system. To begin, we investigated the basic components of the molecular circadian clock using quantitative PCR and *in vitro* luciferase activity as reporters of clock gene expression. We extended these results using patch-clamp electrophysiology and demonstrated the additional presence of rhythmic glutamatergic neurotransmission onto NTS neurons. Spontaneous EPSC frequency, but not amplitude or tau, oscillated throughout the day with a peak at ZT8. Current-voltage relationship analysis also revealed diurnal rhythmicity of resting ionic conductances intrinsic to NTS neurons, suggesting daily changes in excitability. These findings provide a basis for future experiments exploring how the molecular clock mechanism translates to rhythmic changes in fast neurotransmission and neural activity. This provides a framework for how disruption of circadian rhythms may lead to autonomic disorders.

Abstract: Detailed knowledge of how neurons are wired together is essential for our understanding of the human brain. What we currently know about the function of neuronal microcircuits, however, is based predominantly on rodent research. At the single-cell level, pyramidal neurons are fundamentally different between human and rodent brains: human pyramidal neurons are three times larger with a distinct dendritic structure, both in terms of complexity and distribution, contain a much higher total spine count and have larger presynaptic active zones and postsynaptic densities compared to rodent. We therefore wanted to address the question what is the impact of these human-specific properties on information processing between connected pyramidal neurons? To study synaptic communication we used non-pathological human medial temporal gyrus tissue obtained through resection surgery and compared results to mouse temporal association cortex. We performed whole-cell patch-clamp recordings from up to four pyramidal neurons simultaneously, in layers 2 and 3 of human and mouse temporal cortices. We subsequently stained recorded neurons for digital morphological reconstruction and cell-type classification. Pyramidal-to-pyramidal connections were found in both species and overall connectivity rates in human and mouse layers 2 and 3 were statistically comparable. Human pyramidal connections were, however, stronger and more reliable than in mouse; excitatory postsynaptic potential amplitude was higher, while response failure rate and coefficient of variation were lower in human compared to mouse connections. Our findings uncover the functional outcome of known human-specific structural properties of human pyramidal neurons and could underlie more efficient information transfer between human neurons.

Title: Selective formation of autapses in hippocampal subiculum pyramidal cells

Authors: W. KE, *Y. SHU;
State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China

Abstract: Autapses are special synapses formed in a single neuron, from the axon onto its own soma and dendrites. Previous studies reveal massive autaptic self-innervation in cortical GABAergic neurons. Autaptic transmission produces immediate inhibition after an action potential (AP) and increases the precision of APs in a burst. We demonstrate recently that functional autapses form in neocortical pyramidal cells (PCs), particularly those in layer V projecting to subcortical brain regions. These glutamatergic autapses generate giant postsynaptic currents that are exclusively mediated by AMPA receptors. Importantly, these autapses promote burst firing and coincidence detection. Considering that hippocampus PCs share common morphological features with neocortical PCs, we sought to examine whether hippocampal PCs also form functional autapses. In this study, we performed whole-cell recording from PCs in different regions of rodent hippocampal slices. With a bath solution containing 8 mM Sr^{2+} that could desynchronize and prolong the synaptic transmission, we detected autaptic events only in subiculum PCs, but not CA1 or CA3 PCs. These autaptic events could be blocked by the ionotropic glutamate receptor blocker, kynurenic acid. To examine whether autapses selectively form in subgroups of subiculum PCs, we injected retrograde beads to nucleus accumbens and amygdala and found that subiculum PCs projecting to the nucleus accumbens show a relatively higher probability of autaptic connections than those targeting the amygdala. PCs in the subiculum can be also subdivided into two separate groups by their firing patterns: bursting and regular spiking. We found that the bursting PCs are more likely to form autapses as compared with the regular spiking PCs. Together, our results indicate that in the hippocampus excitatory autapses selectively form in distinct subpopulations of subiculum PCs. The selective formation of autapses in bursting PCs suggest an important role of autapses in the generation of AP bursts, which may enhance functional connectivity between the subiculum and downstream brain regions.

Title: Cerebellar microcircuit regulates long-term fear memory by the STAT3-mediated excitatory-inhibitory balance

Authors: *J.-K. HAN[1], S. KIM[2];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: It has been overlooked that emotional memory processing is associated with bodily movement particularly in fear memory consolidation and retrieval. Here, we found a novel mechanism by which input-output control of Purkinje cells *via* signal transducer and activator of transcription 3 (STAT3) might modulate long-term fear memory. Transcriptome analyses showed that the expression of glutamate receptor subunits, GluA1/2, were significantly increased in the Purkinje cell-specific STAT3-deficient mice compared to controls. The results demonstrate the critical role of STAT3 as a transcriptional repressor that modulates the expression level of glutamate receptors within the dynamic range. In the sense of fear memory processing, we discovered that long-term potentiation (LTP) was reframed to long-term depression at parallel fiber to Purkinje cell synapse in the STAT3 knockout mice. On the other hand, fear-conditioned Purkinje cells induced LTP at molecular layer interneuron to Purkinje cell synapse without being affected by STAT3. Unlike the synaptic changes, cerebellar STAT3 is independent on intrinsic excitability of Purkinje cells. Interestingly, STAT3-deficient mice had an aberrant long-term memory of fear, while no motor-related behavioral phenomenon was observed. All things considered, our data strongly suggest that the disruption of excitatory-inhibitory synaptic balance mediated by STAT3 in cerebellar microcircuits causes the aberrant fear memory formation, and might lead to develop the novel therapeutics for psychiatric disorders, such as posttraumatic stress disorders.

Title: Short-term sustained hypoxia increases the evoked excitatory transmission in NTS neurons of mice

Authors: *D. ACCORSI-MENDONCA[1], B. H. MACHADO[2];
[1]Univ. São Paulo, Ribeirao Preto, Brazil; [2]Sch. Med. Ribeirao Preto, USP, Ribeirao Preto, Brazil

Abstract: In this study we evaluated the effect of short-term sustained hypoxia [(SH) 24 hours, FiO_2 0.10] on the synaptic activity in the NTS neurons from mice (C57Bl/6 mice). Brainstem slices and whole-cell patch clamp were used to study the electrophysiological properties of NTS neurons from control (CON) and SH mice. We observed that passive properties of NTS neurons of mice were not affected by SH [input resistance, CON: 0.69 ± 0.1 MΩ (n=9) vs SH: 0.74 ± 0.19 MΩ (n=8)][RMP, CON: -57.4 ± 3.3 mV (n=10) vs SH: -61 ± 3.5 mV (n=7)]. SH also produced no changes in the spontaneous excitatory transmission [sEPSC frequency, CON: 1.13 ± 0.4 Hz (n=5) vs SH: 1.88 ± 0.7 Hz (n=6); amplitude, CON: 29 ± 9 pA (n=5) vs SH: 22 ± 9 pA (n=6); half-width, CON: 2.3 ± 0.5 ms (n=5) vs SH: 2.4 ± 0.3 ms (n=6)]. In contrast, SH increased the excitatory transmission in response to afferent fibers stimulation in NTS neurons of mice; the amplitude of evoked excitatory currents was larger in NTS neurons from SH mice compared to NTS neurons from control mice [CON: -62 ± 17 pA (n=8) vs SH: -153 ± 30 pA (n=9)] with no changes in the kinetic of evoked current. We conclude that SH exposure increases the evoked glutamatergic synaptic transmission in the NTS neurons of mice.

Title: Acetylcholine promotes theta oscillations and drives increased network synchrony in parvalbumin-positive interneurons in the basolateral amygdala

Authors: *J. X. BRATSCH-PRINCE, G. C. JONES, J. W. WARREN, III, A. J. MCDONALD, D. D. MOTT;
Dept. of Pharmacology, Physiology, and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: The neurotransmitter acetylcholine (ACh) plays a central role in generating and pacing theta oscillations in the hippocampus and cortex during memory encoding and consolidation. Cholinergic activation of local inhibitory interneurons is critically important in driving these oscillations, but how ACh modulates specific inhibitory networks to promote oscillogenesis in large neuronal ensembles remains unclear. The basolateral amygdala (BLa) receives dense cholinergic innervation and is involved in emotional memories. Understanding ACh modulation of rhythmic oscillations in the BLa has important implications in emotional learning and memory consolidation. This study used brain slice electrophysiology and optogenetics to explore modulation of BLa rhythmicity by ACh. We found that endogenously released ACh caused prolonged local field potential oscillations at theta frequency in the BLa. Recordings from single pyramidal neurons revealed theta oscillations that were driven by GABAergic inhibition. Between pairs of pyramidal neurons, this ACh-induced inhibition was synchronized, pointing to involvement of an inhibitory network. Selective inhibition of parvalbumin-containing (PV) interneurons disrupted ACh-induced oscillations, suggesting these cells play a role. In agreement, we found that ACh induced and enhanced synchrony in PV interneurons. In response to focal ACh application, PV interneurons were depolarized via M3 muscarinic receptors and fired spikes at theta frequency. These spikes were synchronized between pairs of PV interneurons. Below spike threshold, activation of muscarinic receptors on PV interneurons induced theta frequency membrane potential oscillations, which were synchronous across PV cell pairs. PV interneurons in the BLa are electrically coupled. We found that muscarinic receptor activation significantly increased the strength of this electrical coupling between PV cells, suggesting a mechanism through which ACh could entrain synchronous PV network activity. Collectively, this study suggests ACh can promote rhythmicity in neuronal ensembles in the BLa by activating and enhancing synchrony in the PV interneuron network.

Title: Myelination of mouse neocortical parvalbumin interneurons: Physiology and anatomy

Authors: M. KIRALY[1], K. D. MICHEVA[2], M. M. PEREZ[3], *D. V. MADISON[4];
[1]Mol. & Cell. Physiol., Stanford Univ., Stanford, CA; [2]Molec Cell. Physiol, Stanford Univ. Sch. Med., Stanford, CA; [3]Mol. & Cell. Physiol., Stanford Univ. Sch. of Med., Stanford, CA; [4]Stanford Sch. Med., Stanford, CA

Abstract: Parvalbumin (PV+) basket interneurons participate in regulating excitatory/inhibitory balance in neural circuits, neuronal synchronization, cortical rhythm generation, and in synaptic plasticity. We have characterized the electrophysiology of synaptic connections between individual presynaptic PV+ interneurons and postsynaptic pyramidal cells in simultaneous dual whole cell recordings, with subsequent anatomical reconstructed using array tomography. Arrays were immunostained for myelin basic protein to reveal the location and extent of myelin on the axons of the previously recorded PV+ interneurons. **Results**: we have recorded numerous PV+ interneuron/pyramidal neuron pairs in acute neocortical brain slices taken from animals ranging in age from P14 days to 8 months. We measured multiple parameters of the interneuron axon including path length (between PV cell and postsynaptic pyramidal neuron), length of myelin segments, % length myelinated, number and length of nodes and internodes, axon thickness, myelin thickness, branching and the number/position of synaptic contacts onto the recorded pyramidal neuron. These anatomical measurements were correlated with the physiological measurements made during the electrophysiological recordings, namely IPSC amplitude and latency. This allowed us to make an accurate estimation of action potential conduction velocity, and to correlate the number of synapses with the amplitude of the IPSC. **Conclusion:** PV+ Interneurons from young mice are very sparsely myelinated and the axonal branching is relatively simple. Synapses are few, and the IPSC relatively small. Conduction velocity is very slow, on the order of 0.05 m/s. As the animals reach adulthood, myelination increases dramatically, axon branching becomes more complicated, and the number of synapses onto the recorded target cell increases. Conduction velocity roughly doubles. There is also a trend that the IPSC grows larger on average with age. We have also shown that we can reliably induce synaptic plasticity (“iLTD”) in these unitary PV+ to pyramidal cell synaptic connections. The combination of electrophysiology and array tomography has allowed for an unprecedented

correlation between the electrical properties of single interneurons and their detailed anatomy, including the properties of and physiological significance of their myelination.

Abstract: Although electrophysiological properties and synaptic connectivity of brain cell types have been extensively studied in the rodent brain slice preparation, the equivalent functional characterization of human brain cell types has received far less attention. The limited suite of available tools for genetic targeting and manipulation of human brain cell types has posed a formidable barrier to progress in characterizing the remarkable diversity of human neocortical cell types and their defining properties. Importantly, our recent work has demonstrated the feasibility of rapid viral genetic labeling of neurons in human *ex vivo* neocortical slice cultures derived from neurosurgical tissue specimens, thus opening up a wide range of new possibilities for human cellular neuroscience. Here we extend this work by further investigating the feasibility and potential broad applicability of viral genetic labeling in combination with cutting-edge approaches such as patch-seq and multi-patching to characterize intrinsic and synaptic properties of human neurons, respectively. We characterized the impact of short-term (<10 days *in vitro*) organotypic brain slice culture and Adeno-associated virus (AAV)-mediated viral transgene

expression on intrinsic properties and synaptic connectivity and dynamics of human neocortical neurons. Surgical tissue specimens were obtained with patient consent from both temporal and frontal neocortical brain regions, and the specimens were distal to the pathological focus and invariably not required for diagnostic purposes. We performed patch-seq analysis on >100 human neocortical interneurons labeled with a pan-GABAergic AAV vector to explore the morpho-electric-transcriptomic properties of the major interneuron classes (VIP, SST, PVALB), with comparison to acute slice interneuron patch-seq data. We also utilized multi-patch clamp recording to characterize local circuit synaptic connectivity and short-term plasticity of virus-labeled and unlabeled neurons. Both excitatory and inhibitory neurons were targeted for synaptic connectivity measurements by prospective marking with pan-glutamatergic or pan-GABAergic AAV vectors, respectively, and data were compared to the corresponding acute slice data. Our work demonstrates unprecedented novel applications of cell class-specific viral genetic labeling, together with *ex vivo* brain slice culture, to explore diverse functional properties of human brain cell types.

Title: Increased climbing fiber vesicle release and aberrant innervation in CACNA2D2 knockout mice

Authors: *K. BEESON[1], R. BEESON[3], G. WESTBROOK[4], E. SCHNELL[2];
[1]Anesthesia and Perioperative Med., [2]Portland VA Med. Ctr., Oregon Hlth. and Sci. Univ., Portland, OR; [3]Aerospace Engin., Univ. of Illinois at Urbana-Champaign, Champaign, IL; [4]Vollum Insitute at Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: The alpha2delta family of proteins (CACNA2D1-4) are auxiliary subunits of voltage-dependent calcium channels, and also drive excitatory synapse formation and maturation. Unlike the majority of neurons in the central nervous system, Purkinje cells of the cerebellum exclusively express one isoform of this protein family, alpha2delta-2 (CACNA2D2), and provide a model system to understand the roles of these proteins in excitatory synaptic function. Using whole cell electrophysiologic recordings of acutely prepared cerebellar slices from wildtype and CACNA2D2 knockout mice, we found a dramatic change in the complex spiking of Purkinje cells induced by climbing fiber (CF) activation, which was coupled with increased amplitude and decay rate of underlying synaptic currents in cells from CACNA2D2 mutants. Detailed electrophysiologic analyses, in addition to immunofluorescence, electron microscopy, and computational modeling demonstrate that the larger currents in mutant mice are due to a combination of proximally shifted CF terminals and significantly increased multivesicular release, despite a reduced probability of release at these synapses. These apparently paradoxical findings are explained by the existence of a doubling in the number of vesicle release sites in CF terminals of mutant mice. In addition, enhanced glutamate transporter function compensates for increased vesicle release by accelerating glutamate clearance from the synaptic cleft, speeding decay kinetics of the synaptic currents and maintaining normal charge transfer during CF responses. Ultimately, the altered CF-induced spiking - an important signal responsible for prediction error and motor coordination - indicates that CACNA2D2 is required for normal cerebellar network activity. Thus, these studies demonstrate multiple unexpected, yet critical, roles of CACNA2D2 in synaptic structure and function.

Abstract: The hippocampus exhibits network oscillations during which selected groups of neurons are activated (ensembles), supporting spatial memory formation and consolidation.

During this process, they receive multiple synaptic inputs at their dendrites, which integrate within the somato-dendritic compartment and generate action potentials (AP) once voltage threshold is reached at the axon initial segment which is canonically believed to be located next to the soma in pyramidal cells. However, we have recently shown that in about 50% of CA1 hippocampal pyramidal cells the axon originates from a basal dendrite (axon-carrying dendrite cells, AcD cells) rather than from the soma. AcD cells are intrinsically more excitable and the axon-carrying dendrite might constitute a privileged input channel in this subset of cells. Additionally, previous work in vitro has shown that during sharp wave-ripple complexes (SPW-R) CA1 pyramidal cells are recruited in a peculiar way: their somatic action potential initiates abruptly from baseline resembling an ectopically generated spike. It is unknown how these neurons are selected to participate in the network pattern. Here we asked whether the anatomical feature of AcD cells underlies the selective activation of CA1 pyramidal cells during SPW-R. To test our hypothesis, we performed extra- and intracellular electrophysiological recordings as well as immunofluorescent staining in acute hippocampal mouse brain slices. Interestingly, excitatory input to axon-carrying dendrites remains efficient even during the strong perisomatic inhibition that accompanies SPW-Rs and prevents other pyramidal cells from firing. Thus, only AcD cells are able to fire APs during the events. In line with our previous data, AP waveforms resemble ectopically generated spikes. Multicompartment modelling of single cells confirms that in somatic recordings of AcD cells, APs initiate abruptly from resting membrane potential when excitatory and inhibitory inputs arrive with a certain spatio-temporal configuration. Intracellular administration of picrotoxin diminished perisomatic inhibition, recruited more cells into SPW-R and shifted ectopic AP waveforms towards classical APs.
In summary, AcD cells are selectively recruited during SPW-R activity while the firing probability of other neurons is controlled by perisomatic inhibition. As a result, reducing GABAergic input can modify ensemble composition within short time. Our findings suggest that perisomatic inhibition combined with different axon origins provide a mechanism to rapidly gate and route incoming information and thus enables fast modifications of ensemble compositions.

Abstract: In the central nervous system, neurons are characterized by complex morphology, long-range projection and potentially heterogeneous presynaptic puncta. However, it is not clear how information is encoded by action potentials on the axonal arborization. We chose locus coerules (LC) neurons in zebrafish as an experimental model to address this question. By combining in vivo confocal imaging and electrophysiology recording, we found that calcium activities are reliably evoked in all axon arborizations in all brain regions during both low- and high-frequency neuronal activities. The presynaptic varicosities are heterogeneous in terms of their sizes, activity strength and frequency tuning. However, heterogeneous varicosities distribute homogeneously among the axon arborization in each brain regions, enabling equal modulation effects on all brain areas during different firing modes.

Title: The influence of cortical layer 6 on neurophysiological evoked responses and spontaneous activity within a mouse barrel column

Authors: *V. MOCANU[1], A. R. ADAMANTIDIS[2], P. A. SEGUELA[3], A. SHMUEL[1];
[1]McGill Univ., Montreal, QC, Canada; [2]Dept of Neurol., Univ. of Bern, Bern, Switzerland; [3]Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: The long term goal of our research is to decipher the role of cortical layer 6 and the way it interacts with other layers during evoked responses and spontaneous activity. Previous studies (Olsen et al., 2012; Bortone et al., 2014) excited or inhibited a subgroup of pyramidal neurons in cortical layer 6 (L6 Pyr) with high temporal, location and cell type precision, by using the GN220 transgenic mouse lineage and optogenetics. Whiskers are the main somatosensory modality of rodents. To test the effect of L6 Pyr on activity of the barrel cortex, we expressed

light-sensitive selective ion channels (opsins), introduced genetically via viral microinjections, in the L6 Pyr of the barrel cortex of 3-6 months old mice of indiscriminate gender. Then, by photostimulating at the appropriate wavelength and at power levels increasing from 0.1mW to 12.8mW, we modulated the activity of L6 Pyr during periods of either spontaneous neural activity or during a train of 2Hz piezoelectric-driven deflections of four major whiskers. We used optical imaging of intrinsic signals to guide the insertion of a laminar probe into a barrel, from which we recorded extracellular broadband electrophysiology. A layer-wise analysis of either current source density or action potentials time-courses showed that optogenetic activation of L6 Pyr suppressed stimulus-evoked responses (S-ER) in the upper cortical layers while increasing action potential activity in L6, all in a light power-dependent manner (see figure, left side). The onset and offset of the optogenetic photostimulating light engendered neurophysiological responses that became stronger and faster with increasing light power (see figure, right side). Conversely, inhibiting L6 Pyr using eArch3.0 increased the strength of incoming S-ER, to an extent where the hyperpolarization following the strongest S-ER trailed into the next stimulus cycle and diminished its S-ER. Our finding extend previous work on the inter-laminar interactions at the meso-scale to the domain of the barrel cortex.

Title: Trans-synaptically activated neurons act as temporal coders

Authors: *A. LEVI[1], S. SOMECK[1], E. STARK[2];
[1]Sagol Sch. of Neurosci., Tel Aviv Univ., Tel Aviv, Israel; [2]Dept. of Physiol. and Pharmacol., Tel Aviv Univ., Tel Aviv-Yafo, Israel

Abstract: Within a neural network, information is encoded by spiking activity of multiple synaptically-connected neurons. The mechanisms of spike generation by one cell, and of transmission between cells have been studied before, yet it remains unclear whether a neuron is an integrator or a coincidence detector.
We used extra-cellular recordings and optogenetic manipulations in neocortex and hippocampus of freely-moving mice expressing light-sensitive opsins in either pyramidal cells (PYR) or parvalbumin-immunoreactive (PV) interneurons. We used Gaussian white noise (GWN) stimulation patterns while simultaneously recording spiking activity of multiple neurons. We defined spiking reliability as the correlation between spike trains during repeated stimulation trials, where every spike is convolved with a Gaussian kernel with a specific SD. To determine the dependence of reliability on the time window, we repeated the process with SDs ranging from sub-millisecond to hundreds of ms.
We found that the reliability of directly-activated units either increased with increasing kernel SD, or exhibited a single peak in the reliability vs. SD curve. The first behavior indicates higher reliability with longer integration time, corresponding to a “rate code”; whereas the second behavior corresponds to a preferred window or a “temporal code”. In some cases, the same cell was tested with multiple stimulation intensity levels of the exact same GWN pattern. Units tended to change their behavior from temporal to rate coding with increased stimulation intensity. These findings suggest that the same cell can generate spikes via two distinct dynamical mechanics: at low input levels, specific temporal windows dominate, whereas at higher input levels, the cells behaves as a monotonous integrator of its inputs.
We monitored networks in which multiple directly-activated units exhibited putative monosynaptic connections with a single unit that was not directly-activated by the GWN input. In contrast to the mixed behavior of the directly-activated units, the vast majority of indirectly activated units exhibited a single reliability peak at an SD range of 4-8 ms. This “temporal coding” behavior was observed for multiple types of indirectly-activated units, regardless of stimulation intensity. This suggests that during trans-synaptic activation, cells tend to detect coincidence events of the spike trains of their presynaptic partners.
Thus, the present results correspond to a transition from rate code/mixed-mode mechanism of spike generation in a directly-activated neuron; to a temporal/coincidence detection mechanism of spike transfer in a synaptically-activated neuron.

Title: Computer models of mouse area M1 show avalanches for full model and subcircuits defined by layer or cell type

Authors: *D. W. DOHERTY[1], S. DURA-BERNAL[2], W. W. LYTTON[3];
[1]SUNY Downstate Med. Ctr., Brooklyn, NY; [2]Physiol. and Pharmacol., State Univ. of New York Downstate Med. Ctr., Brooklyn, NY; [3]SUNY Downstate, Brooklyn, NY

Abstract: Beggs and Plentz (2003) reported avalanches in local field potential recordings from organotypic cultures and in unit recordings from acute slices of rat somatosensory cortex with a power-law value of -1.5. Since then, a range of avalanche size distribution values has been reported from about -2.05 to -1.25.
We investigated the circuitry underlying avalanche propagation in a computer model of area M1 of cerebral cortex. This allowed us to distinguish the characteristics of avalanches along different routes defined by either layer or cell type, as well as throughout the column. The M1 model is a moderately detailed simulation of a full-depth cylindrical column of 300μm diameter, containing 10,074 neurons with about 18 million connections. Activation was with an 0.57nA intracellular square-wave current applied to all cells in a 40μm cylindrical subvolume.
Avalanche sizes from all neuron types and layers of the M1 cortical column fit the power-law value -1.80. Avalanches in the population of excitatory neurons fit -1.69 and the population of M1 inhibitory neurons fit to the power-law value -1.72 for avalanche size. Avalanche sizes in layer 2/3 fit a relatively steep -1.94 and similarly in layer 5B they fit -1.90. The power-law value became sharply less negative in layer 4 at -1.75 and in layer 5A at -1.61 and layer 6 at -1.63. Excitatory neurons appeared to form two groups. One group includes three neuron types: IT2/3 neurons carried avalanche sizes that fit power-law value of -1.64, IT5A also neurons fit -1.54 and IT6 fit -1.60. Three other excitatory neurons form the second group: IT4 neurons with avalanche sizes that fit -1.75, IT5B neurons at -1.71 and PT5B neurons at -1.76. Inhibitory neurons also formed two groups. One group had very steep power-law curves and the size of their avalanches did not get very large. This group included PV2/3 neurons with a power-law value of -2.27 and SOM6 at -2.44. The second group had somewhat less steep curves and included SOM2/3 -1.84, PV5A -1.41 (small sample), and PV5B -1.65. SOM5A, SOM5B, CT6, and PV6 neurons had low

response rates and therefore did not generate enough data to determine the shape of their avalanche size distributions.
In conclusion, several excitatory neuron types, particularly IT2/3, IT5A, and IT6, may operate at criticality in our simulated M1 cortical column. Our data also suggest that some inhibitory neurons, especially PV2/3 and SOM6, may not operate in the critical state. Avalanche size distribution is differentially expressed across different layers and different cell types in our simulated M1 cortical column.

Title: How to control a neuronal network near its critical point

Authors: D. R. CHIALVO[1], S. A. CANNAS[2], T. S. GRIGERA[3], D. A. MARTIN[1], ***D. PLENZ**[4];
[1]UNSAM, Ctr. for Complex Systems & Brain Sci., San Martin, Argentina; [2]FAMAF/UNC, Inst. de Fisica, Cordoba, Argentina; [3]Univ. Nacional de La Plata, Inst. de Física de Líquidos y Sistemas Biológicos, La Plata, Argentina; [4]Section on Critical Brain Dynamics, Natl. Inst. of Mental Health, NIH, Bethesda, MD

Abstract: It is now generally accepted that criticality endows neuronal networks with a variety of functional advantages including great flexibility, very large dynamic range, extreme sensitivity, optimal information processing via its long range correlations in space and time, large memory capacity, among the most relevant (Beggs & Plenz 2003, Chialvo, 2010). Despite the abundance of reports of *observed* criticality much less is known about the process that makes neuronal networks to *be there, i.e., how the system reaches and stays at criticality.* To shed light on the problem here we expand previous work on controlling criticality (Cannas et al., 2019) to the realm of neuronal networks. We make use of a generic property of the fluctuations near a point of instability: as the system approaches the critical point the temporal correlations of global variables became stronger. Our results show that it is sufficent to feedback the value of the autocorrelation to a network's control parameter (such as excitability) to drive an arbitrary neuronal network near its critical point. Numerically we show that the strategy is equally effective over a variety of networks architectures and selection of control parameters.

Experiments in real neuronal networks are currently conducted to identify the predicted shape of the autocorrelation function.

Title: Correlation drives computation in local cortical networks at synaptically relevant timescales

Authors: *S. P. FABER[1], N. TIMME[2], J. M. BEGGS[1], E. L. NEWMAN[3];
[1]Indiana Univ., Bloomington, IN; [2]Psychology, IUPUI, Indianapolis, IN; [3]Dept. of Psych. and Brain Sci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: How do neurons work cooperatively to support neural information processing? The amount of processing is widely presumed to be related to the amount of correlated information in the firing of upstream neurons. However, the amount of correlation that is most desirable remains disputed. High levels of correlation result in an abundance of redundant information, arguably reducing processing efficiency. Alternatively, low levels of correlation mean that inputs are often too uncoordinated to result in meaningful integration. Which of these paradigms is most relevant for cortical information processing is undetermined. Here, we sought to address which is more relevant by recording and analyzing the spiking activity, in organotypic cultures of mouse somatosensory cortex, from hundreds of neurons. For these recordings, we identified the effective functional network representing activity propagation through the cortical circuit at timescales relevant to synaptic communication. At each possible point of neural computation-the transformation of multiple inputs by a single neuron-we asked how the correlations between the inputs related to the computation performed by that neuron. Our results first revealed that the large majority of our networks operate in a low-correlation regime. Subsequently, we found strong positive correlations in the amount of correlation and computation across networks. This suggests that, at shorter timescales, increased correlation is preferable for driving computation.

When we considered interactions at extra-synaptic timescales, we found an increase in the mean correlation suggesting a transition to a high-correlation regime. Interestingly, at these longer timescales we also found increasingly negative relationships between correlation and computation. Together, these findings suggest that computation in these networks is optimized for intermediate levels of correlation, rather than simply minimal or maximal levels of correlation. We discuss this further in the context of multivariate transfer entropy, firing rate and Shannon entropy.

Abstract: The field of neuroepigenetics has grown rapidly over the past few decades and has recently implicated chromatin phenomena in the etiology of several psychiatric disorders including major depressive disorder (MDD). While it has been demonstrated that dysregulation of histone posttranslational modifications (PTMs) may be involved in the deleterious transcriptional processes that promote physiological maladaptations in MDD, the field still has only a limited understanding of the underlying mechanisms contributing to this disorder. While it is clear that serotonergic signaling in brain, or aberrations thereof, plays a critical role in the pathophysiology and treatment of MDD, new data from our laboratory suggest potential alternative mechanisms of action for monoamines-so-called histone serotonylation-whereby, for example, the presence of serotonin in the nucleus of dorsal raphe (DRN) neurons may directly mediate transcriptional responses related to various forms of serotonergic plasticity, and the subsequent mediation of mood. Our preliminary data indicate that histone serotonylation is significantly altered in both postmortem DRN tissues from MDD subjects and in chronically stressed rodents, phenomena that appear to be reversed by antidepressant treatments. Furthermore, potentiation of such alterations in a rodent model of MDD (e.g., chronic social defeat stress, CSDS) induced various molecular and circuit level adaptations throughout the

DRN. Our studies provide a causal link between these molecular changes and the persistence of depressive-like phenotypes.
While a majority of antidepressant treatments target dysfunction of serotonergic neurotransmission in brain, these drugs are only are only effective for ~1/3 of individuals with MDD. Therefore, it is important to establish novel approaches that specifically target histone PTMs in a cell-type specific manner *in vivo* to better understand their direct contributions to disease states for the development of future pharmacological interventions. Thus, we have developed novel intein-based chemical methodologies to synthesize specific histone PTMs to more directly assess a functional role for histone serotonylation in depressive-like behaviors.

Title: Identification of novel substrates of monoaminylation in brain, and their regulation by drugs of abuse

Authors: *A. F. STEWART[1], R. BASTLE[1], R. THOMPSON[3], A. LEPACK[1], Y. LYU[1], L. FARRELLY[4], H. MOLINA[5], T. MUIR[3], I. S. MAZE[2];

Abstract: Monoamines are traditionally regarded as chemical signals that act extracellularly on surface bound receptors in brain. However, recent work from our lab demonstrates that non-vesicular monoamines have a neurotransmission-independent function in nuclei of monoaminergic cells, whereby they can be transamidated onto glutamine 5 of histone 3 to act as a novel epigenetic marker relevant in pathophysiological conditions, such as substance abuse disorders (SADs). Therefore, we hypothesized that non-histone proteins may similarly be monoaminylated. To selectively isolate monoaminylated proteins in brain, we developed a novel endogenous chemical tagging method to specifically immunoprecipitate (IP) dopaminylated/noradrenylated proteins. This approach utilizes the unique chemistry of the

catechol ring to selectively add biotin tags to endogenously modified proteins. Following chronic drug self-administration in rats, immunoprecipitations coupled to mass spectrometry identified novel monoaminylated proteins, including multiple isoforms of CaMKII, with their monoaminylation states regulated by drugs of abuse. We further characterized CaMKII dopaminylation utilizing *in vitro* enzymatic assays coupled to mass spectroscopy, to identify glutamine 284/285 (depending on isoform) as selective sites of monoaminylation on CaMKII. These data represent not only a possible novel biochemical mechanism of regulation of CaMKII, but also a possible shift in our conceptualization of monoaminergic transmission: monoamines would not then simply act at surface bound receptors, but also infiltrate the post-synaptic cell and modify proteins therein.

Title: Sex-dependent roles for histone serotonylation in neurodevelopment

Authors: *J. C. CHAN, A. RAMAKRISHNAN, L. SHEN, I. MAZE;
Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Monoaminergic systems are critical for brain development, impacting cell proliferation, migration, differentiation and axonal elaboration. In particular, serotonin (5-HT) is the most widely distributed monoamine in the brain, with a dual role acting as both a neurotransmitter and trophic factor during development. For example, 5-HT can bind receptors on 5-HT terminals, negatively regulating formation of serotonergic projections to other brain regions, modulating the plasticity of these circuits. Thus, regulation of 5-HT levels during such sensitive windows of development is essential, and dysregulation of 5-HT homeostasis may contribute to increased risk of psychopathology later in life. One example is hyperserotonemia, an endophenotype consistently found in about 30% of autistic patients, where 5-HT levels are increased in whole blood but decreased in brain, resulting in the developmental hyperserotonemia hypothesis. Yet, despite substantial evidence supporting these roles of 5-HT in neurodevelopment and disease, our understanding of the cellular mechanisms by which 5-HT

dysregulation during developmental windows impacts long-term outcomes is still unclear. Recently, our lab established a novel epigenetic role for 5-HT. We have demonstrated that 5-HT is deposited on the glutamine at position 5 of the histone H3 tail (H3Q5ser) by the transglutaminase enzyme TGM2. This serotonylation reaction stabilizes the canonically transcriptionally-active lysine 4 tri-methylation (H3K4me3), resulting in the combinatorial modification H3K4me3Q5ser that correlates with permissive gene expression. Thus, we hypothesized that histone serotonylation may provide 5-HT a crucial role in chromatin regulation of neurodevelopment. We focused on the involvement of histone serotonylation in two predominant serotonergic tissues during embryogenesis: the embryonic brain and the placenta, which converts the precursor amino acid tryptophan from maternal blood to bioavailable 5-HT in the embryonic bloodstream. Using immunoblotting, we demonstrate that H3K4me3Q5ser levels differ across embryogenesis in brains and placentas of male, but not female, embryos. We also performed ChIP-seq of H3K4me3Q5ser, along with RNA-seq, in these tissues to identify the impact of sex and developmental timing on genome-wide enrichment of this mark. Ongoing experiments focus on manipulation of developmental histone serotonylation levels and long-term consequences on brain function. These studies suggest an important role for histone serotonylation in neurodevelopment that, when disrupted, may contribute to developmental origins of neuropsychiatric disorders.

Title: The effect of local translated mtIF3 on axonal pathfinding by modulating mitochondrial function

Authors: L. CHEN, L. XIANG, ***W. WANG**;
Mental Hlth. Sch., Wenzhou Med. Univ., Wenzhou, China

Abstract: As previously known, axonal pathfinding is partly regulated by local protein synthesis of specific genes within axon. The role of local translation of many cytoskeleton genes such as *actin* and *cofilin1* has been studied well. A subgroup of mRNAs, which are transcribed from the nuclear-encoded mitochondrial genes, are enriched in axon terminus, however, the contribution of local translation of these mRNAs remains obscure. In our study, we found that one of them, mitochondrial translational initial factor3(mtIF3), could be locally translated in axon. As a

consequence, the deficiency of local translation of mtIF3 disrupted ATP generation and Ca2+ buffering of mitochondrions in axon, as well as axonal outgrowth. We figured out that locally synthesized mtIF3 protein regulated protein synthesis inside mitochondrion, which in turn had an effect on mitochondrial function in axon. As expected, when we exclusively inhibited protein synthesis inside mitochondrion in axon, axonal growth and axonal pathfinding in cultured neurons was also interfered. Taken together, our findings indicate that local protein synthesis in axon may impact on axonal pathfinding in a novel manner by directly modulating mitochondrial function.

Title: Influence of histone H3Q5 histaminylation on WDR5-mediated H3K4 methylation and circadian rhythmicity

Authors: *R. M. BASTLE[1], S. ZHAO[2], A. RAMAKRISHNAN[1], R. THOMPSON[3], A. AL-KACHAK[1], S. FULTON[1], A. LEPACK[1], L. FARRELLY[1], Y. LYU[1], H. MOLINA[4], L. SHEN[1], T. MUIR[3], H. LI[2], I. MAZE[1];
[1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Tsinghua Univ., Beijing, China; [3]Princeton Univ., Princeton, NJ; [4]Rockefeller Univ., New York, NY

Abstract: Monoaminylation is a recently discovered phenomenon where intracellular, non-vesicular monoamines can be post-translationally added to glutamine (Q) residues on proteins via the tissue Transglutaminase 2 enzyme. Our laboratory has demonstrated that histone H3 is a robust substrate for monoaminylation on its fifth glutamine residue (i.e., H3Q5) within the N-terminal tail and we have uncovered roles for H3Q5 serotonylation and dopaminylation in transcriptional activation and dopaminergic neurotransmission, respectively. Given that brain histamine levels are largely rhythmic across 24 h and govern wakefulness, we sought to explore the role of H3Q5 histaminylation (i.e., H3Q5his) in regulating circadian rhythms. Upon measuring H3Q5his levels in mouse brain using site-specific antibodies, we found that H3Q5his expression is enriched in the tuberomammillary nucleus (TMN) of the hypothalamus, the source of brain histamine, and exhibits a rhythmic pattern of expression across 24 h. This expression pattern is sensitive to sleep disturbance, as delivery of zolpidem (10 mg/kg, i.p.), which rapidly

induces sleep, alters TMN H3Q5his expression. Furthermore, viral-mediated knockdown of TMN H3Q5his disrupts circadian locomotor activity in mice. To investigate the molecular mechanisms mediating these effects, we performed isothermal titration calorimetry to examine binding efficiencies of known epigenetic regulator proteins onto H3Q5his. We found that WDR5, which is involved in depositing methyl groups onto H3K4, has significantly reduced binding (~5 fold) to H3Q5his compared to unmodified H3. We found that this effect is due to the charge repulsion between the positively-charged histamine and lysine in the binding pocket of WDR5 (K259). Furthermore, using MALDI-TOF mass spectrometry we found that the presence of histamine on H3Q5 significantly decreases MLL1-mediated methyltransferase activity onto H3K4. Ongoing studies are utilizing viral vectors to manipulate the charge of WDR5 (K259) and associated H3Q5his interactions to measure its effect on circadian gene expression and behavior. These experiments promise to reveal a novel mechanism in which brain H3Q5his may influence H3K4 methylation in the context of circadian rhythms.

Title: Region specific effects of histone H3 dopaminylation in cocaine-seeking behavior

Authors: *A. LEPACK[1], S. L. FULTON[3], A. F. STEWART[1], R. M. BASTLE[2], P. J. KENNY[4], I. S. MAZE[2];
[2]Dept. of Neurosci., [1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Neurosci., Mount Sinai Icahn Sch. of Med., New York, NY; [4]Dept. of Pharmacol. and Systems Therapeut., ICAHN Sch. of Med. at Mount Sinai, New York, NY

Abstract: Substance use disorder–a persistent, relapsing illness characterized by pathological drug taking and seeking-behaviors–is hypothesized to result from a functional “rewiring” of the brain’s normal reward circuitry. Such “rewiring” is thought to be caused by long-lived changes in gene expression that promote physiological alterations implicated in addiction. Recently, we identified a role for the previously uncharacterized histone modification, H3 glutamine 5 dopaminylation (H3Q5dop), in drug-induced transcriptional plasticity. Withdrawal (WD) from

chronic cocaine self-administration (SA) in rats results in increased levels of H3Q5dop in ventral tegmental area (VTA), which correlates with a pathophysiological accumulation of intracellular dopamine (DA) during abstinence. Furthermore, by viral-mediated reduction of H3Q5dop in VTA during WD, we can attenuate cocaine-seeking behavior through reversal of gene expression patterns contributing to aberrant, cue-induced DA release. Interestingly, we also observe H3Q5dop expression in non-DAergic producing brain regions, specifically regions to which the VTA projects (e.g. prefrontal cortex [PFC] and nucleus accumbens [NAc]). Following short (24hr) WD from cocaine, we observe a robust increase in H3Q5dop in the NAc, which persists up to 30 days following abstinence from cocaine, an effect that is not seen in the PFC. In addition, viral-mediated blockade of H3Q5dop in the NAc, but not the PFC, results in decreased cocaine-seeking behaviors following prolonged WD from cocaine, suggesting a circuit-based phenomenon for H3Q5dop in regulating addictive and relapse-associated phenotypes. Taken together, these studies establish a critical neurotransmission-independent role for DA in addiction and promise to aid in our understanding as to how neurotransmission-independent DA function in brain to regulate neuronal plasticity and cocaine-mediated behaviors.

Title: Profiling cell-type specific chromatin accessibility in human OFC implicates astrocyte dysfunction in MDD

Authors: *S. L. FULTON[1], J. FULLARD[2], J. BENDL[2], A. LEPACK[3], R. M. BASTLE[5], A. AL-KACHAK[3], C. A. TAMMINGA[6], P. ROUSSOS[2], I. S. MAZE[4];
[1]Neurosci., Mount Sinai Icahn Sch. of Med., New York, NY; [2]Genomics, Mount Sinai, New York, NY; [3]Neurosci., [4]Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [5]Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [6]Univ. of Texas Southwestern Med. Ctr. at Dallas, Dallas, TX

Abstract: Major Depressive Disorder (MDD) is a chronic debilitating disease that arises from a complex interaction of genetics and environmental influences like stress, leading to persistent changes in frontolimbic gene expression and cellular function. However, the epigenetic mechanisms that transduce stress into coordinated gene expression changes are not well

understood. Chromatin accessibility profiling allows researchers to define the active repertoire of cis-regulatory elements for a given disease. We implemented FANs (*F*luorescence-*A*ctivated *N*uclear *S*orting) coupled with ATAC-seq (*A*ssay for *T*ransposase-*A*ccessible *C*hromatin-Sequencing) to investigate the cell type-specific regulatory landscape of human MDD. We identified over 200 MDD-specific open chromatin regions (OCRs), which were all in the non-neuronal cell population in postmortem orbitofrontal cortex (OFC) tissue, a region that processes reward-based decision-making and may mediate anhedonic symptoms in MDD. Gene set analyses of these genomic regions showed enrichment for astrocyte-mediated NF-Kb inflammatory response. These results converge with mounting evidence that inflammation stress can be a major contributor to MDD, though the specific role of astrocytes is not well characterized. We used transcription-factor motif discovery to identify ZBTB7A, a DNA-binding protein with recognition sequences significantly overrepresented in MDD-specific OCRs. ZBTB7A is a well-characterized chromatin remodeling factor, though its function in psychiatric disease has not been explored. Recently, ZBTB7A has been shown to orchestrate chromatin accessibility for a distinct subset of delayed induction NF-Kb target genes, raising the intriguing possibility that ZBTB7A may regulate the transduction of chronic NF-Kb stress signaling from adaptive to pathological**.** We found that ZBTB7A mRNA and protein are upregulated in human MDD OFC postmortem tissues. Zbtb7a mRNA is also significantly upregulated in OFC astrocytes of CSDS (chronic social defeat stress) susceptible mice. Using a cell-type specific sequencing approach, we found that over 60% of the upregulated astrocytic genes in stress-susceptible animals are Zbtb7a targets. Viral overexpression of Zbtb7a specifically in astrocytes in both the mouse and rat OFC increased vulnerability to developing stress-related behavioral deficits after an acute stressor, suggesting that upregulation of ZBTB7A in OFC astrocytes acts as a pathogenic driver of pro-inflammatory NF-Kb signaling in MDD through epigenetic modulation of chromatin accessibility at key downstream target genes, leading to MDD-related behavioral deficits.

Abstract: Schizophrenia (SCZ) is a severe psychiatric disorder affecting ~1% of the world's population. It is largely heritable with genetic risk reflected by a combination of highly penetrant rare mutations and common variants of small effect. Most commonly prescribed antipsychotic drugs for the treatment of SCZ share antagonist activity against dopamine receptors and primarily address the positive psychotic symptoms of the disease. Unfortunately about one third of SCZ patients do not respond to treatments, indicating that better therapeutics aimed at targeting novel candidates may prove beneficial. In addition, chromatin modifications are known to play critical roles in the mediation of many neurodevelopmental processes, and, when disturbed, may also contribute to the precipitation of psychiatric disorders, such as SCZ. While a handful of candidate-based studies have measured changes in promoter-bound histone modifications, few mechanistic studies have been carried out to explore how these modifications may affect chromatin to precipitate behavioral phenotypes associated with SCZ.
We applied an unbiased and integrative approach to evaluate the epigenetic landscape of SCZ in human induced pluripotent stem cells (hiPSC), neural progenitor cells (NPCs) and neurons from schizophrenia patients *vs.* matched controls. Using proteomics-based, label free liquid chromatography mass spectrometry (LC-MS/MS) on purified histones from these cells, we specifically identified H2A.ZK4K7K11ac and H4K5K8K12ac to be significantly increased in SCZ neurons *vs.* controls, but not in hiPSCs or NPCs from the same subjects. These results were confirmed by western blotting and LC-MS/MS in postmortem SCZ cortical brain tissues. Histone interaction assays revealed the bromodomain containing protein, BRD4 (a known acetyl "reader," particularly for H4), as a novel binder of H2A.ZK4K7K11ac, data which were further confirmed by structural and biophysical assessments. Given such links between BRD4 and H2A.Z/H4 acetyl states found to be increased in SCZ neurons, we hypothesized that inhibiting BRD4 might itself help to ameliorate, SCZ-like phenotypes (e.g., aberrant gene expression and behavior) in both hiPSC neurons and rodent models of abnormal sensory-motor gating associated with SCZ. We have found that treatments with the BRD4 inhibitor, JQ1 (which inhibits BRD4 binding to both H2A.Z and H4 acetyl signatures), partially rescues the transcriptional and behavioral deficits associated with the disease. Thus, drug treatments aimed at alleviating BRD4 interactions with its acetylated histone targets may be useful in ameliorating deficits associated with SCZ.

Abstract: Understanding the dynamic transcriptional responses of specific neural cell-types is crucial for decoding behavioral plasticity. A nuclear RNA-seq approach can help reveal how experiences affect active transcriptional states. The genetic accessibility and conserved behavioral response to alcohol seen in *Drosophila* make them a great model for investigating unresolved questions in the alcohol and addiction fields. Here we addressed how alcohol hijacks memory-encoding transcriptional processes to drive maladaptive decision-making. Flies were exposed to either repeated bouts of air, ethanol, odors, or paired ethanol-odors, and then 24 hours after treatment, nuclear RNA-seq was performed on mushroom body neurons. Differential expression analysis showed significant experience-specific changes at the transcript, and not gene, level. This suggests that alternative splicing is an important mechanism by which long-term memories are encoded, and that alcohol exposure alters this process. Intriguingly, eight particular transcripts were differentially expressed when flies formed associative memories of intoxication (ethanol-odor training). One of these candidates, *Stat92E*, has known protein-protein interactions with spliceosomal proteins, which suggests a possible means through which alcohol disrupts normal splicing. Together these findings suggest a layer of molecular plasticity through which alcohol could influence memory formation and alcohol-associated behaviors.

Title: Evaluating the role of translational efficiency in synaptogenesis in *Caenorhabditis elegans*

Authors: *K. ALIZADEH, B. D. ACKLEY;
Mol. Biosci., Univ. of Kansas, Lawrence, KS

Abstract: Nidogen is a conserved basement membrane protein required for the proper formation and organization of synapses. In *Caenorhabditis elegans*, nidogen functions to efficiently localize the presynaptic scaffold protein SYD-2/α-liprin at synaptic active zones. The synaptic phenotype in nidogen mutants is suppressed by loss-of-function in genes that encode a calcium channel (*unc-2* or *unc-36*), the calmodulin kinase (*unc-43),* or calmyrin (*calm-1*), demonstrating that calcium signaling is important in synaptic morphogenesis. Previous work identified proteins that associate with CALM-1 in a calcium-dependent fashion, including RACK-1 and multiple ribosomal proteins. Loss of function in *rack-1* results in a synaptic phenotype equivalent to the loss of nidogen, and this phenotype can be suppressed by the loss of *calm-1*. Interestingly, RACK-1 is known to be a translational inhibitor in many contexts, although whether this is how it is functioning in synaptic nidogen pathway is unclear. To test this, we are using RNAi to inactivate the ribosomal proteins isolated in our biochemical screen. The viability of RNAi in studying these genetic interactions has been validated by our previous screens. In particular, using RNAi, the *nid-1* loss-of-function phenotype was suppressed with the loss of *calm-1,* and phenocopied with the loss of *rack-1*. Furthermore, there is the question of the range of activity of RACK-1. While the role of RACK-1 in synaptic development might be through global translation inhibition, this protein could also be associated with only certain ribosomes, in which case, identifying the mRNAs associated with these ribosomes can point at new genes that are important in synaptic development. We are purifying and studying these mRNAs using immunoprecipitation and sequencing. the results from this project will shed light on the biochemistry of synapse formation and organization. This information will be important in better understanding synaptogenesis in invertebrates and vertebrates.

Title: Epigenetic control of a stress-induced increase in GluA2 AMPA receptor subunit expression

Authors: J. FAWCETT-PATEL[1], J.-Y. HWANG[2], S. ZUKIN[3], *J. LIU[1];
[1]LSU Hlth. Sci. Ctr., New Orleans, LA; [2]Creighton Univ. Sch. of Med., Omaha, NE; [3]Albert Einstein Col. of Med., Bronx, NY

Abstract: Transient stimuli can induce persistent alterations in synaptic function to modify both behavior and cognition. The cerebellum plays an important role in emotion, in part, *via* extensive projections to higher cortical regions. We have shown that a single exposure to predator odor promotes transcription of the AMPA receptor (AMPAR) subunit GluA2, thereby altering the AMPAR phenotype at synapses onto inhibitory interneurons in the molecular layer of the cerebellar cortex. Though AMPAR phenotype has been implicated in stress and anxiety susceptibility, the underlying molecular mechanisms governing such experience-dependent changes in excitatory signaling have yet to be elucidated. The transcriptional repressor REST binds to an RE1 recognition motif within the GluA2 proximal promoter where it acts via epigenetic remodeling to repress GluA2 expression. The present study was undertaken to examine the possibility that stress acts *via* a decrease in REST level/activity to increase GluA2 transcription in cerebellar interneurons. Using chromatin immunoprecipitation (ChIP) assays, we show that stress induces chromatin remodeling at the GluA2 promoter. Stress decreases REST occupancy and increases H3K9ac and H2K4me3, marks of epigenetic activation. Together, these changes induce a switch from a transcriptionally repressive to a permissive chromatin state. We show a requisite role for the histone acetyltransferase CBP/p300 in regulation of synaptic GluA2 content by stress, assessed electrophysiologically. Furthermore, we show a decrease in REST protein expression as assessed by immunofluorescence and Westerns. We previously found that the stress-induced increase in GluA2 transcription was ERK-dependent. This is significant in that ERK phosphorylates a degron motif within the REST carboxy-terminal domain, thereby promoting targeting of REST to the ubiquitin-based, proteosomal pathway for degradation. We further show that the stress-induced decrease in REST occurs in a proteasome-dependent manner. Collectively, our findings suggest that stress stimulates GluA2 transcription *via* ERK-

mediated degradation of REST, which increases excitatory synaptic efficacy onto interneurons, enhancing feed-forward inhibition in the cerebellar cortex.

Title: The translin/trax microRNA-degrading complex mediates translation-dependent synaptic plasticity in the hippocampus

Authors: *M. S. SHETTY[1,3], X. FU[4], A. J. PARK[5], T. ABEL[1,3,2], J. M. BARABAN[4];

Abstract: Enduring forms of synaptic plasticity require *de novo* protein synthesis which also involves local translation of mRNAs that have been pre-positioned near the synapses. As the microRNA system suppresses translation, the ability of plasticity-inducing stimuli to trigger rapid degradation of microRNAs could play a key role in driving *de novo* translation underlying persistent forms of synaptic plasticity. As recent studies have identified the translin/trax (TN/TX) complex as a microRNA-degrading enzyme that is enriched in brain, we are investigating the hypothesis that the TN/TX complex mediates translation-dependent forms of synaptic plasticity. In support of this, we have found that translin KO mice display defects in synaptic tagging and spatial object location memory (Park et al., 2017). However, since translin deletion also causes loss of trax protein, which has been shown to exert translin-independent cellular effects, it is unclear if the defects in synaptic plasticity or memory displayed by translin KO mice are due to loss of the TN/TX microRNA-degrading enzyme. To address this question, we have generated mice containing a point mutation in trax, E126A, that abolishes TN/TX RNase activity and are assessing if this mutation is sufficient to phenocopy the defects in synaptic plasticity and memory displayed by translin KO mice. In preliminary studies, we have confirmed that this mutation does not alter the expression of translin or trax proteins in the brain, nor their ability to co-precipitate. As a first step in assessing the impact of the trax(E126A) mutation on

hippocampal synaptic plasticity, we have evaluated its effect on “spaced 4-train” LTP, a plasticity paradigm that is translation-dependent and is impaired in translin KO mice. We have found that hippocampal slices prepared from adult trax(E126A) mice show a deficit in this form of late-LTP compared to the WT littermates. Thus, these findings strongly support the hypothesis that synaptic activation of the TN/TX microRNA-degrading enzyme mediates *de novo* translation critical for sustained LTP.

Title: Epitranscriptomic regulation of protein synthesis, learning and memory by N^6-methyladenosine(m^6A)

Authors: J. KORANDA[1], M. J. PATEL[1], J. Y. DELGADO[1], H. SHI[2], J. THOME[1], W. FU[1], L. MO[1], L. O. VAASJO[1], A. OSUMA[1], C. HE[2], ***X. ZHUANG**[1];
[1]Dept. of Neurobio., [2]Dept. of Chem., Univ. of Chicago, Chicago, IL

Abstract: *N^6*-methyladenosine (m^6A) is the most abundant mammalian internal mRNA modification. It profoundly regulates RNA splicing, transport, localization, translation and degradation, and may play a central role in the spatial and temporal control of protein synthesis. The emergence of m^6A research is largely facilitated by the discoveries of its key effector proteins: m^6A “writers” (methyltransferases, e.g. METTL14) install m^6A, “erasers” (demethylases) remove m^6A, and “readers” (e.g. YTHDF1, 2 and 3) recognize and bind to m^6A to determine the fate of the modified RNA. Different m^6A readers may mediate different downstream functional consequences of m^6A modification of mRNA.
Recent data suggest that m^6A deficiency impairs both neurodevelopment and adult central nervous system functions, and impairs learning and memory. Our earlier published studies have shown that conditional deletion of Mettl14 in striatal neurons impaired motor learning. Further studies by us found that conditional deletion of Mettl14 in striatonigral neurons, striatopallidal neurons or dopamine neurons altered dopamine signaling, responses to cocaine and dopamine-dependent learning. Finally, constitutive deletion of Ythdf1 impaired protein synthesis, altered synaptic transmission, and impaired many different forms of learning/memory.

However, because m^6A modifies thousands of transcripts and profoundly impacts many neuronal functions, it's been a challenge to systematically investigate how the dynamic regulation of the m^6A pathway may control specific protein synthesis with good spatial and temporal resolution to affect synaptic plasticity, learning and memory. We are using various genetic approaches to manipulate the effector proteins. What the targets of these effector proteins are, how the above manipulations may affect translation globally or translation of specific mRNAs, synaptic protein turnover, synaptic transmission, plasticity, dendritic spine morphology and behavior are being systematically examined.

Title: MicroRNA-134-5p inhibition rescues long-term plasticity and synaptic tagging/capture in an Aβ (1-42)- induced model of Alzheimer's disease

Authors: *N. BABY, N. KALYANI, T. DHEEN, S. SAJIKUMAR;
Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Progressive memory loss is one of the most common characteristics of Alzheimer's disease (AD), which has been shown to be caused by several factors including accumulation of amyloid β-peptide (Aβ) plaques and neurofibrillary tangles. Synaptic plasticity and associative plasticity, the cellular basis of memory, are impaired in AD. Recent studies suggest a functional relevance of microRNAs (miRNAs) in regulating plasticity changes in AD, as its differential expression was reported in many AD brain regions. However, the specific role of these miRNAs in AD has not been elucidated. We have reported earlier that Late-Long Term Potentiation (L-LTP) and its associative mechanisms such as Synaptic Tagging and Capture (STC) were impaired in Aβ (1-42)-treated AD condition. This study demonstrates that expression of miR-134-5p, a brain specific miRNA is upregulated in Aβ (1-42)-treated AD hippocampus. Interestingly, the loss-of function of miR-134-5p restored L-LTP and STC in AD. Inhibition of miR-134-5p upregulated the expression of plasticity-related proteins, CREB-1 and BDNF in AD brains which are otherwise downregulated in AD condition. The results provide the first

evidence that the miR-134-mediated post-transcriptional regulation of CREB-1 and BDNF is an important molecular mechanism underlying the plasticity deficit in AD, thus demonstrating the critical role of miR-134-5p as a potential therapeutic target for restoring plasticity in AD condition.

Title: Spatio temporal dynamics of miRNA mediated regulation of local protein synthesis

Authors: ***M. WANG**[1], T. GOLDAU[2], R. KLIMEK[2], A. HECKEL[2], E. M. SCHUMAN[1]; [1]Max Planck Inst. For Brain Res., Frankfurt, Germany; [2]Inst. of Organic Chem. and Chem. Biol., Goethe-University, Frankfurt, Germany

Abstract: Local protein synthesis is required for initiation and maintenance of some forms of synaptic plasticity. The localization of messenger RNAs (mRNAs) in neuronal processes and the spatial regulation of their translation are of particular importance. One mechanism to locally control mRNA translation is via the micro RNA (miRNA) pathway, small non-coding RNAs of 19-23nt length that inhibit translation. By binding mRNAs in a sequence-dependent manner, miRISC (miRNA-induced silencing complex) leads to the translational inactivation or degradation of the target mRNA. The brain expresses a large number of tissue-specific or -enriched miRNAs. Both miRNA and the protein complexes involved in their biogenesis and functions are found in distal dendrites, where they are also subject to regulation by neuronal activity. Little is known, however, about the spatio-temporal dynamics of miRNA function and activity in neurons. To this end, we have developed and optimized a tool to control miRNA activity in space and time - a dual-fluorophore-labeled and light-inducible anti-miR. A tracking fluorophore enables the visualization and localization of the anti-miR in real time. Following photo-activation and miRNA sequestration a second fluorophore, the hybridization-sensing fluorophore, lights up. Using the anti-miR, we are investigating the role of miR-181a, a miRNA that is highly abundant in the hippocampal neuropil, on the local regulation of its targets such as Camk2a and Gria2, two proteins critical for the function and plasticity of synapses. Following transfection into primary hippocampal neurons there is rapid movement of anti-miR molecules throughout the dendrites. In order to gain insight into the correlation between miRNA activity

and its target protein expression, we are analyzing the nascent protein synthesis of candidate miR-181a targets following photo-activation. We predict that successful hybridization of the anti-miR to miR-181a should enhance translation of the target mRNAs.

Title: The gating pore blocker 1-(2,4-xylyl)guanidinium inhibits the pacemaking of substantia nigra dopaminergic neurons

Authors: *K. JEHASSE[1], S. HARTMANN[3], L. MASSOTTE[1], B. LAKAYE[2], J. ROEPER[3], V. M. SEUTIN[1];
[1]Lab. of Neurophysiol. - GIGA Neurosciences, [2]Lab. of Mol. Regulation of Neurogenesis, Univ. of Liege, Liege, Belgium; [3]Inst. of Neurophysiol., Goethe Univ. Frankfurt, Frankfurt, Germany

Abstract: The exact ionic mechanisms of the slow and very regular pacemaking exhibited by midbrain dopaminergic (DA) neurons are still unclear. Several studies have shown that both voltage-gated Ca^{2+}, Na^{+} and HCN channels as well as voltage-independent Na^{+} channels open during the interspike interval (ISI). This happens to a varying extent depending on the region (substantia nigra, pars compacta [SNc] or ventral tegmental area [VTA]). In VTA DA neurons, TTX-sensitive sodium channels are necessary for generating the subthreshold membrane potential oscillations that drive pacemaking. In contrast, the subthreshold pacemaker currents in DA SN neurons are TTX-insensitive and less well defined. While HCN, Kv4 and Ca^{2+} channels all modulate pacemaker frequency, the nature of the essential current remains elusive. Given that Khaliq & Bean (2010) showed the net inward current during the ISI to be very small (in the range of 1-6 pA), we tested the hypothesis that alternative pores with very small unitary conductances (fS range) might underlie the « pacemaker current ». One type of unconventional "gating pore" has so far only been identified in channelopathies (Jiang et al., 2018). This tiny current through a pore related to the S4-voltage sensor is inhibited by 1-(2,4-xylyl)guanidinium (XG) (Sokolov et al., 2010). When we superfused midbrain slices with XG, the drug inhibited

the firing of both rat and mouse DA SNc neurons in a concentration-dependent manner (concentration of drug that inhibited the firing of rat DA neurons by 50% was ~250 µM). Identical results were obtained using extracellular, cell-attached and whole-cell recordings. GABAergic SNR neurons were only little affected by XG. A complete cessation of firing was obtained in most rat DA neurons with 1 mM XG and this concentration was chosen for further mechanistic studies. In current clamp, XG stopped firing without hyperpolarizing the membrane. Moreover, in the presence of XG, DA neurons were still able to fire upon injection of small depolarizing currents (10-30 pA). Evoked action potentials were very similar to those recorded during spontaneous pacemaking. Voltage-clamp recordings identified in SNc DA neurons a XG-sensitive current whose properties are consistent with a pacemaker current. We are currently studying the biophysical properties of this novel pacemaker current.

Title: Principles for making a half-center oscillator

Authors: ***H. JU**[1], A. Q. SHILNIKOV[2];
[1]Neurosci. Inst., [2]Neurosci. Institute, Dept. of Mathematics and Statistics, Georgia State Univ., Atlanta, GA

Abstract: Functional neural circuits regulate many crucial biological phenomena. It is of great interest for both experimental and computational neuroscientists to understand how neurons in a circuit connect to each other to produce certain activity patterns, especially rhythmic patterns. So far, it has been revealed that a fundamental building block of many neural circuits is the half-center oscillator (HCO), i.e., two identical neurons connected with reciprocal inhibitory synapses that alternately burst for the same duration; while one spikes, the other is quiescent. Well studied examples include the crustacean stomatogastric ganglion which generates the pyloric rhythm and the swim central pattern generator (CPG) of Melibe leonina. From the observation that the two neurons in a HCO stop bursting after the elimination of the synapse arises a long-lasting

question: how to make a HCO out of two intrinsically non-bursting neurons connected by a reciprocal inhibitory synapse?
More than twenty years ago, Wang and Rinzel identified two mechanisms, escape and release, to generate the oscillatory spiking pattern in two reciprocally inhibitory model neurons which are simplified and contain a special rebound current. However, until now, it is still unknown whether the escape and release mechanisms can be used to build a HCO from two intrinsically non-bursting realistic model neurons.
Since we have developed a general parameter continuation technique to study the electrical behaviors of neuron models with various time scales, we can now apply this technique combined with other computational force to examine the applicability of the escape and release mechanisms to forming a HCO out of two intrinsically non-bursting realistic model neurons and how parameters can control the bursting properties. Furthermore, we will investigate the mechanisms underlying the swim CPG in Dendronotus iris. Since it might be the simplest rhythm-generating CPG built upon HCO (comprised of only two pairs of HCOs) and the two neurons are intrinsic non-bursters, it is an ideal system to validate the principles of making HCOs in a real functional network oscillator.

Title: Effect of temperature on half-center oscillator networks

Authors: *E. MOROZOVA, E. MARDER;
Volen Ctr. and Biol. Dept., Brandeis Univ., Waltham, MA

Abstract: The pyloric network of the crab *Cancer borealis* maintains a robust rhythm over a wide range of temperatures. Remarkably, phase relationships of the network neurons are temperature invariant. To have a better understanding of how robustness and temperature compensation of rhythmic circuits arises from the intrinsic and synaptic properties, we used the dynamic clamp to create half-center oscillator (HCO) networks of two biological neurons by connecting them via reciprocal artificial inhibitory synapses. We studied how the intrinsic properties of neurons that constitute HCOs are affected by temperature change. HCOs were built using two gastric mill (GM) neurons, which are silent in isolation with a resting potential

between -60 and -50 mV at 8^{o}C. We measured the mean membrane potential of GM neurons and their firing rates in response to 1-10 nA current steps at 8, 12, 16 and 20^{o}C. All the neurons hyperpolarized by approximately 5mV as the temperature was raised from 8^{o}C to 20^{o}C and required more current to initiate spiking. The frequency-current curves became steeper at higher temperatures. We constructed 2-cell circuits and varied synaptic and H-current conductances from 15 to 150 nS in steps, generating maps containing different combinations of these conductances at 10^{o}C and 20^{o}C. Dynamic clamp allows us to independently implement the temperature dependence of the synapses and, thus, study the contributions of the synaptic and intrinsic conductances separately to the temperature induced changes of the circuit output. Without temperature dependence in the artificial synaptic or H-currents, we observed that despite the significant effect of temperature on intrinsic properties of neurons, HCOs comprised of these neurons remain robust over a wide range of temperatures. The maps were not substantially different between 10^{o}C and 20^{o}C. There were generally a lower number of spikes per burst at higher temperature.

Title: Targeting the GSK3 pathway with modulators of voltage-gated Na+ channels

Authors: A. SINGH, P. WADSWORTH, Z. LIU, J. ZHOU, ***F. LAEZZA**;
Univ. of Texas Med. Br. at Galveston, Galveston, TX

Abstract: Resilience and vulnerability to neuropsychiatric disorders are linked to molecular changes underlying neuronal excitability that are still poorly understood. In recent studies, we have shown that vulnerability to depression is mediated by a form of maladaptive plasticity consisting of increased firing of medium spiny neurons (MSNs) in the nucleus accumbens (NAc), a brain area associated with reward-related behaviors. In these cells we showed that maladaptive firing is mediated by phosphorylation of the intracellular C-tail of the voltage-gated Na^{+} channel Nav1.6 by glycogen-synthase kinase 3β (GSK3β) and that a GSK3β-Nav1.6^{T1936} competing peptide reverses maladaptive plasticity of MSNs in animal models of depression-like behaviors. Furthermore, in vivo genetic manipulations demonstrated that GSK3β and Nav1.6 are molecular determinants of MSN excitability and that silencing of GSK3β prevents this form of maladaptive plasticity of MSNs. Building on these results, we are now designing a series of

small molecules with improved drug-like properties that target specifically and selectively the GSK3β:Nav1.6 complex. One compound, ZL141, inhibits the formation of the GSK3β:Nav1.6 complex in cells as determined by the luciferase complementation assay and fluorescence spectroscopy, and binds to the Nav1.6 C-terminal tail as assessed by surface plasmon resonance. In addition, whole cell patch-clamp recordings in HEK293 cells stably expressing Nav1.6 showed that ZL141 rescues GSK3β-dependent modulation of Na+ currents and of Nav1.6 steady-state inactivation and long-term inactivation. We expect ZL141 and other small molecule analogues targeting the GSK3β:Nav1.6 channel complex to inhibit maladaptive firing of MSNs ultimately reducing susceptibility to depression and stress disorders. These studies lay groundwork for the development of compounds targeting the GSK3β signaling pathway by modulation of functionally relevant substrates such as Nav channels.

Abstract: Since the pioneering work of Nobel Laureate from Camilo Golgi (1843-1926) and Santiago Ramon y Cajal (1852-1934), neuroscientists have sought to classify the diverse population of neurons into specific cell types. Previous studies have shown a wide-range of diversity in morphological properties and intrinsic electrophysiological properties in mouse and human neocortical neurons (Allen Institute libraries of cell types) that can be used to classify them and better understand their role in the cortical network. However, the characterization of neuron types in non-human primate (NHP) has been less systematically studied. For this study,

we have developed an experimental pipeline combining single cell patch clamp recordings, with biocytin labeling and neuronal three-dimensional reconstruction, to generate a database of cell types for neurons of the lateral prefrontal cortex (LPFC) of macaque monkeys.
We used whole cell patch clamp recordings from slices of the LPFC of 8 macaques to study the intrinsic properties of single neurons. We used a modified version of the Allen Institute electrophysiological protocol (https://celltypes.brain-map.org/). During the recording from one cell we used biocytin injection through the recording electrode, to label the neuron. We developed immunohistochemistry staining enhancing the images using anti-biocytin – streptavidin antibodies conjugated with Alexa fluor 488. We acquired high-resolution acquisition images using a 63x objective with Zeiss Laser Scanning Microscope. We conducted the 3D reconstructions using Imaris and Neurolucida 360 software. Upon completion of the reconstructions, we extract several parameters (i.e., branch order, Sholl analysis, partition asymmetry, tortuosity, etc.) to characterize each neuron. The data were stored in a database at the Robarts Institute.
We have collected 260 neurons in 8 macaque monkeys. We have processed a total of 40 neurons for imaging and reconstruction. By combining whole cell patch clamp recordings and three-dimensional reconstruction with morphological analysis, populations of neurons with similar properties can be identified in the macaque PFC contributing to the understanding of the correlation between the functional and cortical organization of single cells in the main network.

Title: Compensation of size change coexists with sensitivity to channel deletion in a model of neuronal regulation

Authors: *S. GORUR-SHANDILYA[1], E. E. MARDER[1], T. O'LEARY[2];
[1]Brandeis Univ., Waltham, MA; [2]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Neurons can increase in size dramatically during growth, yet many kinds of neurons must also preserve their intrinsic dynamics and physiological function across several length scales. For example, neurons in the crustacean pyloric pacemaker circuit can generate similar activity patterns despite multiple-fold increases in their size and changes in morphology (Bucher *et al*. 2005). The scale invariance of neuron dynamics hints at homeostatic mechanisms that can regulate the conductance densities of multiple ion channel types in an activity-dependent manner. Using conductance-based single compartment neuron models, we asked whether a biologically plausible regulation mechanism (O'Leary *et al*. 2014) can maintain intrinsic voltage dynamics in a neuron as its surface area is varied. Despite relying only on a single sensor that measures time-averaged intracellular calcium as a proxy for activity, we found that this regulation mechanism could regulate conductance densities of ion channels, and was robust to changes in the surface area of the neuron, without having to explicitly measure cell size. By mapping changes in cell size onto perturbations in the space of conductance densities of all channels, we show that robustness to size change coexists with sensitivity to perturbations that vary the ratios of maximum conductances of different ion channel types. This difference in sensitivity can explain why ratio-preserving regulation rules that regulate ion channel densities can preserve neuron function during growth, but may also be vulnerable to perturbations like deletions or over-expressions of certain channel types. Our framework makes it possible to numerically and analytically predict which perturbations the homeostatic mechanism can compensate, and which perturbations cause pathological compensation.

Title: Extracting signatures of dendritic spikes from Neuropixels recordings

Authors: *M. FAULKNER[1], M. JAKUBOWSKA[1], N. A. STEINMETZ[2], K. D. HARRIS[1], M. CARANDINI[1], A. ROTH[1], M. HAUSSER[1];

Abstract: Dendritic spikes in apical dendrites of cortical pyramidal neurons have been proposed to play a critical role in coincidence detection and synaptic plasticity. Calcium signals have also been observed during sensory detection tasks, suggesting active dendrites may contribute to sensory processing. Dendritic calcium spikes and somatic burst activity are reciprocally causally related; backpropagation of somatic bursts above a critical frequency can generate calcium spikes which in turn can generate further somatic burst firing. We are using Neuropixels recordings of somatic and dendritic signals in awake head-fixed mice performing a behavioral task to detect active dendritic events and investigate how their properties are modulated by behavioral state.
Neuropixels probes were placed parallel to the apical dendrites of layer 5 pyramidal neurons in primary visual cortex. Recordings were obtained while mice were exposed to sparse noise visual stimuli or darkness and their forepaws rested on a wheel whose movements were recorded. By analyzing both low frequency (LFP) and high frequency signals from the Neuropixels probe, electrical signals corresponding to somatic action potentials and dendritic spikes could be identified. Following spike sorting based on signals of putatively somatic origin, the dendritic signatures of well-isolated units were examined in a spatiotemporal spike-triggered average of the extracellular potentials. Units were selected for further study if they exhibited backpropagation or had a sink corresponding to the timescale and location of expected putative dendritic calcium spikes. Through subtraction of single spike events from burst spike events, we can identify non-linear signatures that match anticipated putative calcium spiking both in duration and location. We are currently examining differences in the dendritic signatures during behavioral state by using simultaneously collected wheel movement, visual stimulus and eye pupil diameter data. These results indicate that Neuropixels recordings could be used to detect dendritic spikes in vivo, allowing simultaneous capture of dendritic and somatic spiking activity during behavior.

Title: Cholinergic modulation of responses to depolarizing current ramps in CA1 hippocampal pyramidal neurons

Authors: *C. L. COMBE[1], T. MAZAHERI[2], C. C. CANAVIER[2], S. GASPARINI[1];
[1]Neurosci. Ctr., [2]Cell Biol. and Anat., LSU Health-New Orleans, New Orleans, LA

Abstract: *In vivo* measurements of CA1 place cell firing have demonstrated that firing rates are influenced by novelty and previous exposure to the environment, resulting in modulation of firing rate responses within the place field. Although synaptic plasticity likely contributes to modulation, the intrinsic properties of CA1 pyramidal neurons, such as adaptation, also influence the firing rate. To isolate these intrinsic contributions, we injected triangular depolarizing current ramps of various durations (1-10 s) to approximate the spatially-tuned, temporally-diffuse depolarizing synaptic input received by these neurons while traversing a place field. These ramps were applied to CA1 pyramidal neurons *in vitro* (slice electrophysiology) and *in silico* (multicompartmental model).
We found that, under control conditions, CA1 neurons responded with decelerating rate responses, firing more action potentials and at higher frequencies on the ascending phase than the descending phase of the depolarizing ramps, producing clockwise f-I plots. This decelerating response was more prominent when the ramps were injected in the dendrites versus the soma, especially for shorter ramps (1-2 s), representing a faster running speed, compared to longer ramps (10 s). On the other hand, the cholinergic agonist carbachol (2 μM) caused the rate responses to accelerate during the ramp, with more action potentials fired on the descending phase of the ramps (counter-clockwise f-I plots). Computer simulations were employed to dissect the mechanisms responsible for the observed asymmetry. The model was calibrated to fit the steady-state I-V curve; a persistent Na^+ current was added in and near the soma to reproduce the tetrodotoxin-sensitive region of negative slope conductance revealed by experiments. The model suggests a prominent role for the accumulation of Na^+ channel inactivation in modulating the rate responses. The classic *h* inactivation variable accounts for the weak asymmetry of somatic ramps, but a second, slower component of inactivation is required to capture the greater asymmetry of the dendritic ramps. The slow component of inactivation is prominent for dendritic channels and increases with the distance from the soma, both in the apical trunk and in the oblique dendrites of CA1 neurons. This component is also responsible for the attenuation of spike height in our simulated dendritic recordings, consistent with the literature on these neurons. Our results suggest that modulation of intrinsic ion channels by experience and novelty-related fluctuations in cholinergic activity may contribute to the shifts observed *in vivo* in peak firing rate as the place field is traversed.

Title: Influence of cocaine on sensory processing in cortical dendrites

Authors: *S. MURPHY, L. GODENZINI, R. GUZULAITIS, D. LATERRA, A. LAWRENCE, L. PALMER;
The Florey Insitute of Neurosci., Melbourne, Australia

Abstract: Cocaine exposure causes dramatic changes to the structure and functioning of individual neurons, leading to extensive remapping of brain connectivity. These changes alter the processing of synaptic input and overall brain functioning. Despite the prevalence and known detrimental effects of cocaine use on sensory processing, the modulation of cortical activity during cocaine exposure are poorly understood and are the focus of this study. Here, somatic and dendritic activity in layer 2/3 pyramidal neuron dendrites within the somatosensory cortex was investigated using two-photon Ca^{2+} imaging and whole cell patch clamp electrophysiology. During single exposure to cocaine, Ca^{2+} activity in tuft dendrites was enhanced during both spontaneous and sensory tactile stimulation. Somatic voltage was also altered in response to cocaine, leading to dramatic changes in up- and down-states in the anaesthetized mouse. These results illustrate the cellular basis of altered sensory perception during cocaine exposure, providing invaluable insight into the effects of cocaine on cortical processing of sensory information.

Title: Biophysical scaling rules for layer 5 pyramidal neurons across species

Authors: *L. BEAULIEU-LAROCHE[1], M. M. HANSEN[1], N. BROWN[1], Z. WILLIAMS[2], M. P. FROSCH[3], S. S. CASH[4], M. T. HARNETT[1];

Abstract: The size of dendritic arbors varies greatly across species, but it remains unclear how this impacts the integrative properties of cortical neurons. Here, we compare input-output relationships and associated ion channel distributions for mouse, rat, and human layer 5B pyramidal neuron somas and dendrites. Outside-out recordings demonstrated that intermediate-sized rat neurons have uniformly higher HCN and voltage-gated potassium channel densities compared to both the smaller mouse neurons and larger human neurons. Furthermore, extrapolated total conductance across the dendritic tree increased greatly from mouse to rat, but only minimally from rat to human. Despite these prominent differences in ion channel distributions, whole-cell recordings revealed that a variety of input-output properties, such as local impedance profile, were surprisingly well conserved across species. However, other functional features, including input resistance and spike properties, were substantially more variable. Our results suggest that some highly-conserved biophysical features are crucial for maintaining optimal functional set points, while other less stable features may simply reflect neuronal size. Future experiments will assess additional mammalian species and cell types to reveal what scaling rules control the electrical properties of cortical neurons across the phylogenetic tree.

Title: Layer 5 pyramidal neuron subtypes differ in plasticity in response to conditioning with repeated action potentials

Authors: D. GUAN[1], W. J. SPAIN[2], ***R. C. FOEHRING**[1];
[1]Anat. and Neurobio., Univ. Tennessee Hlth. Sci. Ctr., Memphis, TN; [2]Physiol. & Biophysics Box 357290, Univ. of Washington Dept. of Physiol. and Biophysics, Seattle, WA

Abstract: Activity can cause long term strengthening (LTP) or weakening (LTD) of synaptic connections. Activity also induces changes in the intrinsic excitability of neurons, a process referred to as LTP-IE by Cudmore and Turrigiano (2004, *J Neurophysiol* 92: 341). They found that LTP-IE was induced in L5 Pyramidal neurons (PNs) in visual cortex by a conditioning protocol (CP): a leftward shift in the f-I curve (no change in slope) and decreased AP voltage threshold (AP_{th}) and rheobase. LTP-IE occurred in L5 PNs but not L2/3 PNs or FS interneurons. To test for cell type specificity for LTP-IE within L5 PNs, we used 3 mouse lines that express GFP (*etv1, glt*) or YFP (*thy1-h*) in subsets of L5 PNs. *Thy1-h* and *glt* PNs send projections out of the telencephalon and projections of *etv1* PNs are restricted to the telencephalon. Whole cell current clamp recordings were performed upon PNs from somatosensory (*etv1, glt*) or motor cortex (*thy1-h*) under conditions where fast synaptic transmission was blocked to ensure any changes observed were intrinsic to the cell recorded from. We tested cell excitability with a family of 500 ms DC current steps and measured rheobase, firing rate, and f-I slope. This was performed at break in and repeated every 10 minutes. After excitability became stable (1-3 repeats), we used the CP of Cudmore and Turrigiano (2004; 15 supra-threshold 5ms current injections at 40Hz, repeated at 4 s intervals for 5 min). In a control group of 8 *thy1-h* PNs (no CP), excitability remained stable for >60 min. In all *thy1-h* cells (n = 10) the CP enhanced cell excitability. At 30 minutes after the CP, f-I curves showed a parallel left shift of > 8Hz, rheobase was significantly reduced, and firing rates were significantly increased (LTP-IE). In contrast, when the same CP was applied to *glt* PNs, there were no changes in rheobase, firing rate, or f-I curves (n = 8). All *etv1* PNs showed excitability changes after the CP. In 6 of 10 *etv1* PNs there was enhanced excitability (LTP-IE): no change in rheobase, increased firing rate, and increased F-I slope. In the other 4 *etv1* PNs, the CP decreased excitability: no change in rheobase, lower firing rate, and a rightward parallel shift of f-I (no slope change). This later effect is a previously undescribed long-term depression of intrinsic excitability (LTD-IE). Further experiments systematically vary the properties of the CP (frequency, number of APs) to define how these parameters influence the direction and magnitude of plasticity. We are also investigating the ionic basis for the observed excitability changes. These data show that PN types differ in their sensitivity to conditioning and may express LTP-IE or LTD-IE.

Title: Dendritic coordination in layer 5 tuft dendrites in awake, behaving mice

Authors: *N. CERMAK[1], J. SCHILLER[2];
[1]Technion, Haifa, Israel; [2]Neurobio., Haifa, Israel

Abstract: The role of dendrites in *in vivo* biophysical behavior of neurons is unclear. Studies in brain slices have clearly shown that dendrites of pyramidal neurons can utilize active conductances to perform local, nonlinear computations. However, *in vivo* evidence of such local nonlinear computations is lacking. We used two-photon microscopy to study calcium dynamics in many separate branches of tuft dendrites (within 50um of the pia) of single layer 5 pyramidal neurons in primary motor cortex. During imaging, mice were awake and running on either a freely-moving or motorized treadmill. After experiments, we also determined the structure of the full dendritic arbor, enabling us to relate calcium imaging ROIs to specific locations on the dendritic tree. To accurately determine the structure of dendritic trees we found it was necessary to use extremely sparse labelling (10-100 neurons/mm^3). Additionally, we used an AAV carrying both mRuby2 and GcaMP6f, so that the mRuby2 signal could be used for structural determination. We found that most calcium activity was shared across many branches of dendritic tree, despite distances sometimes exceeding 500 um between imaged segments. We typically did not observe single-branch activity in the absence of other branches. Dendritic activity tended to be enriched around starts or stops of freely-initiated movement bouts, as well as the duration of forced (motorized) movement. We are currently investigating the origins of these whole-tuft activity patterns, and whether they are consistent with backpropagating action potentials. Additionally, we are continuing to investigate the effect of other behavioral paradigms on branch coordination.

Title: Conditions that maximize the dimensionality of dendritic spatial computation

Authors: L. JIN[1], ***B. W. MEL**[2];
[1]Neurosci. Grad. Program, [2]Biomed. Engin., USC, Los Angeles, CA

Abstract: Dendrites are sensitive to the spatial patterning of their synaptic inputs, which can significantly increase a neuron's processing power. The limits of a single dendrite's spatial computing capabilities are unknown, however, so we asked two questions for pyramidal neurons (PNs), the main cell type of the cerebral cortex: (1) What biophysical parameter settings maximize a dendrite's nonlinear spatial processing power? And (2), for these optimal settings, what is the maximum "dimensionality" of the dendrite's nonlinear i/o function? To answer #1, we used a detailed compartmental model of a PN and a new method to quantify a single dendrite's raw nonlinear spatial processing power. We found a dendrite's ability to distinguish spatially articulated input patterns is maximized when (1) the dendrite is ~200um in length - roughly the natural length of a PN thin dendrite - whereas shorter (100um) or longer (400um) dendrites behaved more linearly; and (2) dendritic spine neck resistance was low (<50 MOhms), which is currently a matter of controversy.
To answer #2, we developed an improved method to quantify the "dimensionality" of dendritic spatial computation, building on previous observations that a dendrite's i/o function can be modeled as an asymmetric multi-dimensional sigmoid function. We found a dendrite's responses to arbitrary spatial patterns of excitation is predicted (i) poorly by a conventional 1-D i/o function, which considers only each input's "weight" while ignoring its location; (ii) moderately well by a 3-D i/o function, which measures excitation within proximal, mid, and distal compartments; and (iii) asymptotically well with 5 spatial compartments. Thus, whereas the integrative units found in conventional artificial neural networks use 1-D (sigmoid or ReLU) activation functions, that distinguish inputs only by their synaptic weights, a PN dendrite provides a higher-dimensional nonlinear i/o function that also depends on the absolute and relative locations of its inputs. An example will illustrate where multi-dimensional activation functions may be useful in natural computing contexts.

Title: Role of GABAergic inhibitory inputs on dendritic integration for wind direction-selectivity in the insect's mechanosensory projection neurons

Authors: *H. SHIDARA, H. OGAWA;
Dept. of Biol. Sciences, Fac. of Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Individual neurons receive large number of excitatory and inhibitory synaptic inputs on their dendrites and integrate them to output the processed result as spikes to postsynaptic neurons. Many studies on mammals have shown that the relationship between dendritic location of the excitatory inputs and their contribution to final outputs. In addition, recent research revealed that the local inhibitory inputs modulate the output of the neural activity, leading the change in the sensitivity for recognition. These results indicate that the dendritic integration of synaptic inputs have a crucial role for the brain function regulating animal behavior. However, the detailed relationship between the dendritic integration in individual neurons and behaviors remains unclear because the individual neurons' function does not necessarily have a direct link to the behavior due to too complicated neural system in mammals. Thus, to reveal the relationship, we focused on the simple and well-studied neural system, the crickets' cercal sensory system to detect airflow. The crickets exhibit the wind-elicited escape behavior, of which moving orientation depends on the airflow direction. The neural processing of the stimulus direction is conducted by local circuits including the identified interneurons, the giant interneurons (GIs), within the terminal abdominal ganglion. Each GI has unique dendrites, which receive directional selective inputs from sensory afferents region-specifically. Although the inhibitory inputs also have a crucial role for forming the directional selectivity, it remains unclear where and how they contribute the integration of the sensory information on GI's dendrites. Here, to examine the integration mechanism of excitatory and inhibitory inputs in GIs, we recorded the local inputs as dendritic Ca^{2+} signal and the final outputs as spiking activity by electrophysiology, respectively. The Ca^{2+} imaging results indicated that three distinct branches of dendrites in 10-3, one of the GIs, received different direction-selective inputs. Then, to investigate the effect of region-specific inhibitory inputs, we also recorded the spiking activity and Ca^{2+} responses in 10-3 with bath application of GABA-A receptor antagonist, PTX. The PTX application enhanced the spiking responses to airflow from all direction, but the preferred angle did not even change. It means the inhibitory inputs will be involved in sharpening the

directional selectivity, but not contribute to directional preference. These results showed that the relationship between the excitatory and inhibitory inputs is important for formation of directional selectivity in 10-3.

Title: Summation of subthreshold signals at individual glutamatergic synapses on dendritic spines

Authors: C. A. CELIS[1], J.-Y. WENG[2], *D. ZECEVIC[3];
[1]Yale Univ. Sch. of Med., New Haven, CT; [2]Dept. of Cell. and Mol. Biol., Yale Univ., New Haven, CT; [3]Yale Univ. Sch. Med., New Haven, CT

Abstract: The capacity of single excitatory synapses on individual dendritic spines to influence electrical signaling of individual nerve cells is not fully understood. This question is important because nonclustered, widely distributed spines are active in vivo, as documented repeatedly (e.g. Chen, Rochefort, Sakmann and Konnerth, 2013). To investigate this question, we used a combination of electrophysiology techniques, pharmacological tools, 2-photon photolysis of caged glutamate, and voltage-sensitive dye recordings from dendritic spines in rat brain cortical slices. The goal was to analyse temporal summation of excitatory postsynaptic potentials (EPSPs) generated at individual synapses. We have shown previously, in several classes of principal cortical neurons, that optical recording with voltage-sensitive dyes has the adequate sensitivity and spatiotemporal resolution to monitor synaptic signalling in individual dendritic spines, including temporal summation of uncaging evoked responses that mimic unitary EPSPs. We found that the excitatory postsynaptic currents (EPSCs) recorded electrically from the soma as well as EPSP signals recorded optically at the site of origin (dendritic spines) do not exhibit temporal summation up to the frequencies similar to 50 Hz. This is because local EPSP signals in spines return to the baseline in 10-20 ms. Thus, at common physiological frequencies (below 50 Hz), the synaptic driving force is maintained during repetitive activation of synapses preventing synaptic saturation. In contrast, the somatic electrical recordings revealed a clear sublinear summation of EPSPs at these frequencies based on widening of the synaptic signals due to cable RC filtering in the dendrites. At higher frequency of synaptic activation (100 and 200 Hz), both

the electrical EPSC signal recorded from the soma and the local optical EPSP signal from spines exhibit temporal summation. The summating signals saturated at a range of values from 15 - 80 pA for EPSCs and from 3 - 17 mv for local EPSPs. The NMDA receptors were not activated significantly by sub-linearly summated repetitive quantal EPSPs. Here, we provide evidence that the saturation of local EPSP response in spines is not due to postsynaptic glutamate receptor saturation. Instead, the sublinear response is controlled by powerful AMPA receptor desensitization.

Title: Rapid synaptically activated calcium transients in dendritic spines using electrical stimulation and low affinity indicators

Authors: K. MIYAZAKI, *W. N. ROSS;
New York Med. Col., Valhalla, NY

Abstract: Calcium imaging from dendritic spines is an important tool for examining synaptic physiology. While there are many reports of these measurements there are still some controversies about these signals. These controversies may relate to the different sources of calcium, different methods of stimulation, and different choice of indicator. It is also possible that some differences may relate to the heterogeneity among spines on the same cell and to differences in age or species of the preparation.
To examine these questions in pyramidal neurons in rat and mouse hippocampal slices we used an apparatus where the fluorescence of the indicator was excited by a laser spot focused to a region of about 12 µm diameter around the expected synaptic region and the emitted light was detected with a sensitive RedShirtImaging CCD camera recording at 1000 Hz. Neurons were filled from patch electrodes on the soma and were stimulated in current clamp with theta-glass electrodes placed on the slice near the dendrite of interest. Following single stimuli we searched for localized, all-or-none responses in the camera field. In many cases these spots corresponded to spines projecting to the side of the dendrite; in others a clear spine was not visible, possibly because it projected vertically. Using an ROI of about 1 μm^2 centered over this spot we could detect clear calcium transients using a range of indicators including the very low affinity and weak buffering OGB-5N, which has a Kd of 20-40 µM. In most experiments we also

simultaneously detected sodium transients from co-injected SBFI using a high speed multiplexing technique (Miyazaki et al., 2019).
In most cases the synaptically activated calcium transient had a fast rise time (< 10 ms) and a fast decay time (half amplitude in ~25 ms) using 150 µM OGB-5N as the calcium indicator. Even though the recovery time was fast it was still slightly slower than the signal from a backpropagating action potential (bAP) detected on the same trial. The amplitude was similar to the amplitude of the bAP signal from the same location when detected in the proximal dendritic field. A large part of the signal was blocked by APV or CPP confirming that it was due to entry through the NMDA receptor, as previously reported by many investigators. Most of the signal was also blocked by NBQX, consistent with it being due to relief of the Mg block by the fast AMPA mediated EPSP. In many cases a small, slower calcium signal could be detected in NBQX. This signal was more visible following repetitive stimulation (three shocks at 20 ms intervals) or in experiments using higher affinity indicators.

Title: Mechanisms constraining the recruitment of perisomatic and dendritic innervating interneurons in hippocampal CA1

Authors: *E. R. NEBET, S. CHAMBERLAND, R. W. TSIEN;
Neurosci. Inst., New York Univ., New York City, NY

Abstract: Information processing in the brain requires precise coordination across individual neuronal elements. Functionally distinct GABAergic interneurons control activity propagation within neuronal circuits by targeting precise spatial domains of pyramidal cells. However, the main determinants gating the recruitment of GABAergic interneurons remain generally unknown.
We performed electrophysiological recordings in CA1 of acute hippocampal slices while stimulating CA3 Schaffer's collaterals (SC). Genetically labeled parvalbumin-positive (PV+) and somatostatin-positive (SST+) interneurons were recorded from and anatomically identified.
We find that segregation of direct (CA3) and indirect (CA1) excitatory inputs contributes to cell

type-specific recruitment of three interneuron classes. PV+ perisomatic-targeting interneurons were recruited mainly via direct excitation, leading to feedforward (FF) inhibition, while SST+ oriens-lacunosum moleculare (OLM) interneurons were exclusively recruited by indirect excitation to execute feedback (FB) inhibition. Interestingly, PV+ bistratified interneurons with axons terminating on the proximal dendrites of pyramidal neurons were excited by both direct and indirect afferents to a similar extent. Thus, these interneurons map onto pyramidal cells along a spatial continuum, defined by direct and indirect recruitment. Repetitive high-frequency SC stimulation led to cell type-specific changes in their relative contribution to inhibitory activity. Perisomatic-targeting cells decreased their firing probability during repetitive stimulation while OLM cells were initially silent but later increased their activity. Bistratified cells demonstrated an elevated firing probability, which gradually decreased. Notably, these three classes of interneurons preserved their timing of AP discharge during repetitive activity. Altogether, our data highlight the main circuit determinants gating interneuron type-specific recruitment during synaptic activity. These processes might allow GABAergic interneurons to modulate their relative contribution to the net inhibitory drive in CA1 while preserving their relative timing of activation.

Title: Investigating dendritic signals evoked by natural patterns of presynaptic activity

Authors: *X. XUE, T. LUMMEN, A. HIERLEMANN, J. BARTRAM;
Dept. of Biosystems Sci. and Engin., ETH Zurich, Basel, Switzerland

Abstract: Dendrites are complex neuronal structures specialized for receiving synaptic inputs. Moreover, dendritic properties enable synaptic inputs to interact, which gives rise to a diverse repertoire of localized input processing options. Whether a specific dendritic event is evoked by such interactions is often highly dependent on the precise input activation patterns. Despite the functional significance of these events, their study is a challenging task. For example, synaptic activation sequences generated with existing chemical or optogenetic tools may not be comparable to natural ones, while the inference of innate input activation patterns with Ca^{2+} imaging is currently hindered by the slow Ca^{2+}-indicator response.

In this *in vitro* study, we developed an approach that provides, for localized synapses, precise spiking sequences of the respective presynaptic cells, while it also allows for imaging the evoked dendritic signals. To achieve this, we performed simultaneous high-density microelectrode array (HD-MEA) recordings and Ca^{2+}/voltage imaging in primary neuronal cultures. By correlating unit activity with Ca^{2+} signals in dendritic spines we were able to associate synapses with the corresponding presynaptic cells. With this information, presynaptic activation patterns could be linked to specific dendritic events. We propose that the combination of large-scale recordings of network spiking by HD-MEAs with simultaneous imaging of dendrites is a powerful approach to examine a variety of important topics including dendrite development and synaptic plasticity.

Title: Opposing changes in dendritic-soma electrical coupling underlie ES-potentiation

Authors: *J. K. CLARK, D. V. MADISON;
Stanford Univ., Palo Alto, CA

Abstract: EPSP-Spike (ES) Potentiation occurs alongside synaptic Long-Term Potentiation (LTP) as a result of high frequency stimulation (HFS). ES-potentiation is the change in excitability that is not accounted for by changes in synaptic strength after the induction of LTP. While previous studies suggest ES-Potentiation may be influenced by GABAergic signaling; ES-Potentiation does not occur in the presence of the $GABA_A$ channel blocker Picrotoxin, the underlying mechanisms regarding the expression of ES-Potentiation remain unclear. We seek to understand these mechanisms by recording simultaneous input/output (I/O) relationships of dendritic field EPSPs, somatic EPSP fields, and resultant Population Spikes before and after the induction of LTP/ES-potentiation in area CA1 of hippocampal slices. In our current study, we show that electrical coupling between dendrite and soma is decreased by an HFS-induced increase in $GABA_B$ signaling. Such a change would be expected to decrease dendritic EPSP-spike coupling, but despite this reduction, ES-Potentiation occurs, i.e. the coupling between the EPSP and the action potential is increased. These data suggest that there are two distinct and opposing changes that occur as a result of HFS: 1) a decrease in passive dendritic-somatic electrical coupling, and 2), an increase in coupling between the somatic EPSP and action potential generation. The decrease in the first of these, dendritic-somatic coupling is mediated by

a persistent increase in post HFS $GABA_B$-mediated dendritic synaptic transmission, while the second may be related to a decrease in somatic $GABA_A$-mediated transmission. These two opposing influences may function as a homeostatic mechanism to balance the excitatory/inhibitory relationship between primary neurons and interneurons, and to exert dual control on the magnitude of ES-potentiation.

Title: Developmental changes in the activity of inhibitory neurons in Dravet syndrome

Authors: *Y. ALMOG[1], K. ANDERSON[2], M. RUBINSTEIN[1];
[1]Sackler Sch. of Med., Tel Aviv Univ., Tel Aviv, Israel; [2]Goldschleger Eye Res. Inst., Ramat Gan, Israel

Abstract: Dravet syndrome (DS) is an epileptic encephalopathy caused by mutations in the *SCN1A* gene, encoding for the voltage-gated sodium channel $Na_V1.1$. The disease starts with febrile seizures occurring around six months of age and progresses to recurrent refractory seizures with frequent episodes of status epilepticus. Toward adolescence, epilepsy improves and seizure frequency is reduced. DS mice recapitulate this disease progression. Previous electrophysiological studies in DS mice demonstrated reduced excitability in multiple types of GABAergic inhibitory interneurons at the onset of spontaneous seizures, at postnatal day (P)21. However, the neuronal changes occurring during the febrile stage and later, when epilepsy improves, are less clear. We examined the excitability of CA1 hippocampal stratum oriens interneurons (O-LM) at three age points: P14 - during the febrile stage; P21 - at the onset of spontaneous seizures; P35 - following the improvement of epilepsy. Measurements of intrinsic firing properties showed a transient reduction in excitability occurring only at the onset of spontaneous seizures (P21). In contrast, examination of synaptically-evoked excitatory post-synaptic potentials (eEPSPs) and action potentials (eAPs) revealed reduced function of inhibitory neurons at all stages. At P14, the threshold for eAPs was increased (WT: -44.76±0.38 mV, DS: -42.26±0.29 mV; n=14-17; $p<0.001$) and in agreement, so was the amplitude of the eEPSPs (WT: 11.82±0.36 mV, DS: 13.2±0.47 mV; $p<0.05$). Additionally, the eAPs' max rise slope was

decreased (WT: 272.41±6.95 mV/ms^2, DS: 241.37±8.68 mV/ms^2; p<0.01), suggesting reduced sodium conductance. At P21, in addition to increased eAP threshold and eEPSPs' amplitude, and reduced max rise slope, we also observed a marked reduction in eEPSPs' duration (half-width: WT: 26.07±2.32 ms, DS: 13.72±1.03 ms; p<0.001) and as a result, shorter latency to spike (WT: 12.11±0.41 ms, DS: 9.92±0.33 ms; p<0.001). At P35, in correlation with the improvement of epilepsy, the duration of eEPSPs was increased (half-width: WT: 21.79±1.54 ms, DS: 30.89±2.67 ms; p<0.01), along with correction of latency to spike (WT: 14.79±0.57 ms, DS: 14.29±0.51 ms; p=0.51). Nevertheless, increased eAP threshold (WT: -45.52±0.51 mV, DS: -43.44±0.53 mV; p<0.01), increased eEPSPs' amplitude (WT: 9.63±0.5 mV, DS: 12.22±0.65 mV; p<0.01) and reduced max rise slope (WT: 349.59±14.51 mV/ms^2, DS: 295.97±8.65 mV/ms^2; p<0.01) persisted. Together, the examination of synaptically-evoked activity demonstrates a close correlation between the severity of Dravet epilepsy and the level of dysfunction of inhibitory neurons.

Title: Investigating the pathogenic effects of mutation in Kv3.1 causative for progressive myoclonic epilepsy

Authors: *J. C. CARPENTER[1], J. HENEINE[1], M. SAMPEDRO CASTANEDA[1], R. MANNIKKO[1], G. LIGNANI[1], S. SCHORGE[2];
[1]UCL Inst. of Neurol., London, United Kingdom; [2]UCL Sch. of Pharm., London, United Kingdom

Abstract: Progressive myoclonic epilepsy (PME) is a rare and severe epilepsy syndrome that is caused by single gene mutations. The syndrome is characterised by the core symptoms of myoclonus (involuntary muscle jerks), epilepsy and progressive neurological dysfunction, usually in the form of dementia and ataxia. Although the genetic causes of PME have been well studied, the underlying mechanisms remain poorly understood. In particular, it is not known how mutations in several different genes, of apparently unrelated and diverse biological function, give rise to this distinct epilepsy syndrome. Recently, a recurrent, *de novo* p.Arg320His mutation in KCNC1, which encodes K_V3.1, was discovered as a novel cause of PME without dementia, since

termed ‘Myoclonic epilepsy and ataxia caused by mutation of K^+ channel’ or (MEAK). Kv3.1 is a voltage-gated potassium channel that is highly expressed in parvalbumin-positive interneurons and fast-spiking neurons of the cerebellum and is important for high frequency neuronal firing. Previous biophysical studies have found the p.Arg320His mutation in Kv3.1 to be a loss-of-function with a dominant negative effect. Until now, however, the effects of this mutant channel on neuronal function have not been investigated.
Here we used transfection and lentiviral-mediated transgene delivery to express WT and mutant Kv3.1b channels in primary cortical neuronal cultures prepared from C57BL/6 neonatal mice. We carried out whole-cell current-clamp electrophysiological recordings of transduced neurons at 32°C, at 14-16 DIV, in order to assess the impact of mutant Kv3.1b channel expression on interneuronal firing. We also performed a biophysical characterisation of mutant Kv3.1b channels in *Xenopus laevis* oocytes and two-electrode voltage-clamp recordings of oocytes expressing Kv3.1b alpha-pore mutants, in order to investigate whether the p.R320H mutation results in the introduction of pathogenic gating pore currents. Our results exclude H^+-carried gating-pore currents as a mechanism of pathogenicity and reveal alterations in firing frequency for cortical interneurons expressing Kv3.1b p.R320H mutant channels. Overall, these data contribute to a greater mechanistic understanding of MEAK with implications for other forms of PME caused by different gene mutations. Our findings are important because mechanistic insights into PME are sorely lacking, yet are essential for the development of therapeutics for these devastating diseases, for which none currently exist.

Title: Pathophysiological mechanisms and treatment options for KCNA2-related developmental and epileptic encephalopathies

Authors: *U. B. S. HEDRICH[1], H. PANNIKKAVEETTIL ASHRAF[1], H. KOCH[1], H. LERCHE[1], T. V. WUTTKE[1,2];
[1]Dept. of Neurol. and Epileptology, Hertie Inst. for Clin. Brain Res., Tuebingen, Germany;
[2]Dept. of Neurosurg., Tuebingen, Germany

Abstract: Developmental and epileptic encephalopathies (DEE) are fatal disorders characterized by epilepsy, intellectual disability and other neuropsychiatric symptoms. Available treatments are largely ineffective and the development of new treatment strategies is hampered by the lack of knowledge about the mechanisms of seizure generation. Recently, we identified *de novo* mutations in the *KCNA2* gene encoding the voltage-gated potassium channel $K_V1.2$ as a causative factor for DEE (Syrbe et al., 2015; Masnada et al., 2017). Functional studies revealed mutations with only loss-of-function (LOF) effects, only gain-of-function (GOF) effects or GOF which were diminished by additional LOF effects. The electrophysiological findings correlated with distinct phenotypic features.
To understand the pathophysiological mechanisms of different *KCNA2* mutations on the morphological and electrophysiological properties of single neurons, we used the *in utero* electroporation technique and overexpressed wildtype (WT), GOF or LOF $K_V1.2$ channels in layer 2/3 pyramidal cells. Overexpression of both WT and mutant GOF channels caused a reduction in the total length and complexity of the dendritic trees of neurons analyzed in 12-15 day old cells. Additionally, whole cell patch clamp recordings revealed a reduced firing frequency of pyramidal cells overexpressing WT or mutant GOF channels compared to control cells. In contrast, pyramidal cells expressing mutant LOF channels did not show morphological alterations, but also exhibited a hypoexcitable activity.
Since treatments are often ineffective in patients carrying *KCNA2* mutations, we investigated the effect of 4-Aminopyridine (4-AP), a specific blocker of K_V1 potassium channels, on WT and mutant channels expressing cells. Further studies are needed to gain insight if pharmacological treatment with 4-AP in intact animals can also antagonize the pathophysiological consequences of *KCNA2* mutations *in vivo*.

Title: Relationship of clinical phenotypes and functional studies in neurons in SCN8A-related disorders

Authors: *Y. LIU[1], K. M. JOHANNESEN[2], M. KOKO[1], J. SCHUBERT[1], C. HØI-HANSEN[3], M. RANNAP[1], E. GARDELLA[2], G. NIELS[4], E. BRILSTRA[5], R. S. MØLLER[2], H. LERCHE[1]; [1]Dept. of Neurol. and Epileptology, Hertie-Institute For Clin. Brain Res., Tuebingen, Germany;

[2]Inst. for Regional Hlth. Services, Odense, Denmark; [3]Dept. of Pediatrics, Copenhagen, Denmark; [4]Dept. of Pediatrics, Arnhem, Netherlands; [5]Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: SCN8A encodes the voltage-gated sodium channel Nav1.6, one of four Na^+ channels expressed in the mammalian brain, which are essential for neuronal activity and involved in several neuropsychiatric diseases. More than 100 mutations in the SCN8A gene have been found in patients with broad clinical phenotypes ranging from severe early onset epileptic encephalopathy, benign familial infantile epilepsy with movement disorders, to intellectual disability without epilepsy. To correlate the genotype with the clinical phenotype, we selected several SCN8A mutations causing distinct phenotypes and performed functional analysis in both neuroblastoma cells and primary cultured mouse hippocampal neurons. A patient carrying the p.Ile1654Asn mutation suffered from absence seizures, ataxia and was refractory to valproic acid. This mutant led to barely measurable Na^+ currents in transfected neuroblastoma cells and no neuronal firing in primary cultured neurons when endogenous channels were blocked with TTX, indicating a clear loss-of-function effect. In contrast, the p.Phe846Ser mutation, which caused severe and pharmacoresistant early onset epileptic encephalopathy (including to high dosages of phenytoin), induced a large hyperpolarizing shift of the activation curve in neuroblastoma cells and robustly increased neuronal firing in primary neurons. Interestingly, it has been described, that the p.Arg1629His mutation is associated with episodic ataxia, whereas its corresponding mutation in *SCN1A* (p.Arg1648His) causes febrile and afebrile seizures. This former mutant induced both gain-and loss-of-function biophysical changes, which led to stronger neuronal firing and broader half-width of action potentials. These results suggest distinct neuronal mechanisms for different clinical phenotypes caused by *SCN8A* mutations and the importance of studies in neurons to understand disease mechanisms and to translate these findings into treatment of *SCN8A*-related disorders.

Title: Impact of developmentally-regulated alternative splicing on functional consequences of an SCN2A mutation (R853Q) associated with epileptic encephalopathy

Authors: *S. GANGULY, C. H. THOMPSON, A. L. GEORGE, Jr.;
Pharmacol., Northwestern Univ., Chicago, IL

Abstract: Mutations in genes encoding voltage-gated sodium channels (Na_V), including *SCN2A* ($Na_V1.2$), are associated with epilepsy with a wide range of clinical severity, variable age-of-onset, and different degrees of pharmacoresponsiveness. Determining the functional properties of mutant $Na_V1.2$ channels is valuable for establishing molecular mechanisms and genotype-phenotype relationships. Because epilepsy associated with $Na_V1.2$ mutations can have its onset in early life, we hypothesized that developmentally-regulated alternative splicing of the gene may influence the functional and pharmacological consequences of mutations. Therefore, we investigated the biophysical properties of *SCN2A*-R853Q mutant channels in two developmentally-regulated splice isoforms of $Na_V1.2$, one primarily expressed during early neurodevelopment and the other expressed during adulthood. We engineered the R853Q mutation into the neonatal and adult isoforms of $Na_V1.2$ and expressed both in tsA201 cells co-transfected with human β1 and β2 auxiliary subunits. Whole-cell patch clamp was used to record from transfected cells to compare voltage- and time-dependent properties of mutant and wildtype (WT) channels. Cells transfected with the R853Q mutation exhibited a smaller current density, less steep voltage-dependence of activation, enhanced frequency-dependent channel inactivation, and altered recovery from fast inactivation. The neonatal splice variant potentiated these effects of the mutant, and caused a hyperpolarizing shift in voltage-dependence of fast inactivation. Findings concerning recovery from, and onset of, slow inactivation also show considerable differences both when comparing R853Q to WT, and between adult and neonatal splice variants. In conclusion, $Na_V1.2$ R853Q exhibits functional properties consistent with loss-of-function, the degree of which is altered when expressed in the neonatal splice isoform. We conclude that developmentally-regulated alternative splicing contributes to the severity and possibly early age-of-onset observed for *SCN2A*-associated epileptic encephalopathy, and this could affect the degree of pharmacoresponsiveness at different stages of neurodevelopment.

Title: Mechanistic consequences and stoichiometry-selectivity of mutations in α4β2 nicotinic acetylcholine receptors in ADNFLE epilepsy

Authors: *S. MAZZAFERRO, S. M. SINE;
Mayo Clin., Rochester, MN

Abstract: Some 30% of monogenic epilepsies are caused by defects in genes encoding ion channels. The monogenic epilepsy known as Autosomal Dominant Nocturnal Frontal Lobe Epilepsy (ADNFLE) is caused by mutations in the α4 or in the β2 subunits of the α4β2 nicotinic acetylcholine receptor (nAChR). The α4β2 nAChR localizes to both pre- and post-synaptic regions throughout the CNS where nerve-released ACh either excites the postsynaptic neuron or enhances release of excitatory or inhibitory neurotransmitters. ADNFLE mutations identified so far cause gain of function where sensitivity and efficacy of the α4β2 nAChR to ACh are enhanced. The α4β2 nAChR is found in two stoichiometric forms, one with three α4 and two β2 subunits, and the other with two α4 and three β2 subunits, denoted $(\alpha4)_3(\beta2)_2$ and $(\alpha4)_2(\beta2)_3$, respectively. However, whether ADNFLE mutations enhance function of both stoichiometric forms is not clear. A selective effect on one stoichiometric form would be significant because the two forms diverge dramatically in their sensitivity to ACh and to allosteric modulators. To determine whether ADNFLE mutations are stoichiometry-selective, we recorded single channel currents from α4β2 nAChRs expressed in 293 HEK cells, and distinguished the two stoichiometries based on their distinct single channel current amplitudes. For the two ADNFLE mutations investigated, we observe dramatically prolonged channel openings, indicating stabilization of the open channel state. However, stabilization of the open state is significantly greater for the $(\alpha4)_2(\beta2)_3$ than the $(\alpha4)_3(\beta2)_2$ stoichiometry. Thus combined with recent cryo-EM structures of the two stoichiometric forms, the stoichiometry selective effects on receptor activation kinetics provide important insights toward drug development for therapy of ADNFLE.

Title: Hyperexcitability of hippocampal CA1 pyramidal neurons due to Kv7 channel dysfunction in a NHE6 KO model of Christianson syndrome

Authors: *A. Y. GAO, T. JAMES, R. A. MCKINNEY;
McGill Univ., Montreal, QC, Canada

Abstract: Christianson syndrome (CS) is a rare X-linked neurodevelopmental disorder characterized by intellectual disability, epilepsy, and ataxia. Of these symptoms, seizures are one of the most significant issues impacting all known CS patients, with affected individuals experiencing multiple types (e.g. tonic-clonic, myoclonic, absence) of episodes each day. This phenotype is suggestive of an imbalance in excitatory/inhibitory (E/I) neurotransmission within their neural circuitry. CS is the result of mutations in the *SLC9A6* gene encoding the organellar Na^+/H^+ exchanger isoform 6 (NHE6), an endosomal pH regulator that is essential for endosomal trafficking. In neurons, such trafficking mechanisms allow for the transport of molecules responsible for maintaining E/I balance. Thus, we investigated whether a complete loss of NHE6 could result in excitatory neuron hyperexcitability in male NHE6 knock-out (KO) mice. We first subjected hippocampal area cornu ammonis 1 (CA1) pyramidal neurons to current injections of increasingly positive magnitude in the presence of synaptic blockers and found that while CA1 neurons from age- and sex-matched wild-type (WT) mice eventually ceased action potential (AP) firing in response to more positive current steps, KO cells instead persisted in their spiking. The data signified that KO neurons were indeed intrinsically hyperexcitable. Interestingly, other active and passive properties remained unchanged between WT and KO neurons. Speculating that this phenotype was due to a loss or dysfunction of a negative regulator of AP firing, we investigated Kv7 channels, voltage-activated, non-inactivating, outwardly-rectifying K^+ channels that mediate the M-current and are partially responsible for spike-frequency adaptation. Molecular biology and immunostaining experiments revealed that among the two highly expressed neuronal Kv7 channel subunits, Kv7.2 and Kv7.3, Kv7.2 levels remained unaffected while Kv7.3 expression and localization were perturbed in KO hippocampi. Using a Kv7-specific antagonist, XE-991, we found that Kv7-mediated currents were also reduced in KO CA1 cells. Finally, by applying a Kv7 channel agonist, retigabine, we could significantly reduce AP spiking in NHE6 KO neurons, further implying an impairment of Kv7 function. Overall, the data

suggest that in NHE6 KO hippocampal neurons, alterations in Kv7 channel function result in their intrinsic hyperexcitability. Combined with other mechanisms, this could potentially leading to E/I imbalance in overall hippocampal circuitry.

Title: Mice with adult-onset P/Q calcium channel deletion recapitulates childhood absence epilepsy

Authors: *Q. M. MIAO, J. NOEBELS;
Dept. of Neurol., Baylor Col. of Med., Houston, TX

Abstract: Inborn errors of CACNA1A-encoded P/Q type voltage-gated calcium ion channels impair synaptic transmission, producing early and lifelong lasting neurological deficits. However, whether these pediatric syndromes depend on remodeled brain networks during a developmental critical remains unclear. Here P/Q channel alpha subunits were ablated by activating an ER-cre-Cacna1a/flox model in mature brain. We show that mice with adult-onset deletion of P/Q channel alpha subunits display identical patterns of absence epilepsy, ataxia, and episodic dystonia, replicating the inborn error. These data demonstrate that P/Q channels remain critical for normal function of adult brain, and that spike-wave absence seizures, the most common form of childhood epilepsy, can be generated in the adult brain due to dysfunction of P/Q channels. Uncoupling the neuronal synchronization disease phenotype from downstream neonatal remodeling during vulnerable developmental periods holds significant promise for gene-guided precision rescue strategies at later stages of the disorder. We would further explore the mechanisms of how P/Q channels' deficiency in adult mice leads to absence seizures.

Title: Characteristics of seizure-like events during a functional lack of pannexin-1 activity

Authors: *M. S. AQUILINO[1,2], P. WHYTE-FAGUNDES[4], M. K. LUKEWICH[1,3], L. ZHANG[1], B. L. BARDAKJIAN[2], G. ZOIDL[4], P. L. CARLEN[1,3,2];

Abstract: Objective Recent evidence has highlighted a connection between Pannexin-1 (Panx-1) and modulation of neuronal excitability. This work assesses the changes in behavioral and electrophysiological markers of seizure, across three distinct models of epilepsy, with and without the functional presence of Panx-1.
Methods Four groups of C57Bl6 mice were used: Panx-1 genetic knockout, strain-matched controls, controls pretreated with Brilliant Blue-FCF, and controls pretreated with Probenecid. Animals of both sexes were subjected to either acute injection of pentylenetetrazol (PTZ), acute electrical kindling of the CA3, or *in vitro* brain slice incubation with 4-aminopyridine.
Results Panx-1 knockout or pharmacological blockade of Panx-1 suppressed the severity and incidence of seizure-like responses across all models of seizure-induction. In mice subjected to acute intraperitoneal injection of PTZ, the control group had more severe seizures compared to Panx-1 deficient mice, spending a greater proportion of time following injection in higher Racine scale stages. Panx-1 knockouts outperformed controls when subjected to a paradigm of rapid kindling, having shorter after-discharges and fewer seizure-like events. Furthermore, brain slices of Panx-1 knockouts demonstrated fewer electrographic seizures when subjected to bath incubation with 4-AP than their control counterparts. Pretreatment with Brilliant Blue-FCF or Probenecid recapitulated the knockout phenotype. Cross-frequency coupling features of layer 2/3 neocortical field potentials highlight differential patterns in the control and knockout groups, suggesting Panx-1 plays a role in maintaining certain neurophysiological rhythms.
Significance Neuronal excitability is significantly impacted by the functional absence of Panx-1. Genetic, pharmacological, or stimulation-based paradigms of targeting Panx-1 function may have a therapeutic effect in the treatment of seizures and epilepsy.

Title: Cell-type specific role of pannexin1 to distinct seizure parameters

Authors: *P. OBOT, L. VELISEK, E. SCEMES, J. VELISKOVA;
New York Med. Col., Valhalla, NY

Abstract: Epileptic seizure is not solely dependent on neuronal activity but also upon the release of excitatory mediators from glial cells. Pannexin 1 (Panx1) is a plasma membrane channel present in both neurons and glial cells that when activated releases the excitatory molecule ATP. We have previously shown that blockade or deletion of Panx1 has seizure-limiting effects using the kainic acid (KA)-induced status epilepticus (SE) model in juvenile mice. Moreover, we showed that astrocyte and neuronal Panx1 contribute distinctly to KA-induced seizures: While neuronal Panx1 accelerated seizure progression and severity, astrocyte Panx1 improved the seizure outcome. The electroencephalographic (EEG) recordings confirmed that in GFAPCre:Panx1$^{f/f}$ mice the KA-induced continuous ictal activity (SE) occurred significantly faster compared to NFH-Cre:Panx1$^{f/f}$ mice. Here we further characterized the contribution of astrocyte and neuronal Panx1 to seizures using EEG and hippocampal field potential recordings. Three-weeks old male and female Panx1$^{f/f}$, GFAP-Cre:Panx1$^{f/f}$, and NFH-Cre:Panx1$^{f/f}$ mice were injected with 30 mg/kg of KA i.p. and EEG recordings were performed using an EEG-video system (Pinnacle Technology). The temporal progression of seizures from the onset of first spike, then first ictal event to the occurrence of SE was evaluated. Acute hippocampal slices prepared from the three mouse genotypes were exposed to 1 µM KA and epileptiform discharges recorded were recorded in the interface chamber (Fine Science Tools, AxoScope 10.3). Evaluation of the severity of epileptiform activity included the total duration of overall activity, number of ictal events and the fraction of ictal activity obtained within 20-min recordings. EEG recordings revealed that GFAPCre:Panx1$^{f/f}$ had delayed onset of KA-induced first spike ($p < 0.01$) as well as first ictal event ($p < 0.05$), but these animals showed faster onset of SE compared to either Panx1$^{f/f}$ or NFH-Cre:Panx1$^{f/f}$ mice ($p< 0.05$). *In vitro* field-potential recordings showed that slices from GFAPCre:Panx1$^{f/f}$ mice spent less time in epileptiform activity ($p < 0.05$), and that the fraction of ictal activity ($p < 0.01$) and the number of ictal events was decreased ($p < 0.01$) compared to slices from NFH-Cre:Panx1$^{f/f}$ and from Panx1$^{f/f}$. Our study reveals that

neuronal Panx1 accelerates the initial phases of KA-seizures, while astrocyte Panx1 delays the last phase (SE). However, during the initial 20 min, astrocyte Panx1 exacerbates epileptiform activity. Overall, these results indicate a complex interplay between Panx1 in these two cell-types in seizures.

Title: Whole-brain seizure networks in zebrafish models of GABRA1 and GABRG2-related epilepsies

Authors: *R. E. ROSCH[1], D. BURROWS[1], E. SAMARUT[2], M. P. MEYER[1];
[1]MRC Ctr. for Neurodevelopmental Disorders, King's Col. London, London, United Kingdom;
[2]NEUROSCIENCES, CRCHUM, Montreal, QC, Canada

Abstract: Mutation in genes encoding GABA receptor subunits are a well-recognised cause of epilepsy in human patients with phenotypes ranging from familial forms of generalised epilepsies to devastating early infantile epileptic encephalopathies. Two key genes that are affected by deleterious mutations in human epilepsy patients are GABRA1 and GABRG2.Recently zebrafish have emerged as an important vertebrate model to study such genetic epilepsies *in vivo*. Even early in larval development, zebrafish carrying knock-outs of a number of human ‘epilepsy genes’ can show paroxysmal convulsions and electrophysiological markers of epilepsy seizures. Furthermore, there are now tools available that allow functional imaging of whole-brain dynamics at near single-neuron scale. Here we report whole-brain calcium imaging in larval zebrafish using light sheet and two-photon microscopy and genetically encoded calcium indicators (GCaMP6f). We record light-induced whole-brain activity in fish carrying homozygous knock-outs of either the gabra1, or the gabrg2 gene. Both fish lines show light-inducible reflex seizures, with evidence of localised neuronal hyperexcitability compared to their wild-type sibs (Figure 1 shows raw fluorescence images after light exposure and relative changes in dF/F in midbrain and hindbrain for gabrg2 knock-outs and wild type controls). Using non-negative matrix factorisation on the whole-brain calcium recording, we identify key brain

areas that are involved in the different stages of these reflex seizures and evaluate how seizures differ between the two mutant lines.The combination of genetic modification and detailed imaging of neuronal function highlight the role of zebrafish in translational epilepsy research. Our results add to the wider effort in understanding the genotype-phenotype relationship in genetic epilepsies. A better multi-scale mechanistic understanding may then be a first step towards translating novel genetic diagnoses into urgently needed new therapies.

Title: Neurosteroids modulate the *in vivo* responses to fenfluramine at the sigma-1 receptor in mice

Authors: *T. MAURICE[1], A. GAMMAITONI[2], B. S. GALER[2], P. MARTIN[2];
[1]INSERM Umr_s1198, Montpellier, France; [2]Zogenix Inc, Emeryville, CA

Abstract: Fenfluramine (N-ethyl-α-methl-3-(trifluoromethyl)-benzeneethanamine, FFA) has been shown in two randomized, double-blind, placebo-controlled clinical trials to substantially reduce the frequency of convulsive seizures in patients with Dravet syndrome, a severe, treatment-resistant epileptic encephalopathy. In addition to the well-known action of fenfluramine as a releaser of neuronal serotonin, we have recently shown that FFA contributes to its antiseizure activity by acting as a potent positive modulator of the sigma-1 receptor (S1R) in in vitro tests and in vivo behavioral responses. Here, we examined whether the modulation of S1R extends to behavioral responses seen after exposure to the neuroactive steroids dehydroepiandrosterone sulfate (DHEAS) and pregnenolone sulfate (PREGS), which are S1R agonists, while progesterone acts as a S1R antagonist. The effects of the steroids on the FFA racemate or the dextro-rotary isomer (+)-FFA were evaluated in the mouse model of dizocilpine-induced learning impairment (Maurice et al. *Brain Res.* 1994;647(1):44-56). Two behavioral tests were used: spontaneous alternation in Y-maze (spatial working memory) and passive avoidance (contextual long-term memory). FFA racemate or (+)-FFA attenuated dizocilpine-induced learning impairment in both responses, in the 0.1-1 mg/kg intraperitoneal (IP) dose range. This effect was prevented by pre-administration of the S1R antagonist NE-100 (1 mg/kg IP), confirming that both the FFA racemate and the dextro-rotary isomer (+)-FFA activated S1R in vivo. DHEAS or PREGS attenuated dizocilpine-induced learning deficits in the 5-20 mg/kg IP dose range. Coadministration of DHEAS or PREGS and FFA, particularly at the lowest active dose (5 mg/kg) together with either the FFA racemate or (+)-FFA (0.1 mg/kg) resulted in an additive or synergistic effect on behavioral responses. These observations confirmed positive modulation of FFA on S1R by showing that, in physiological conditions, the drug potentiates the action of endogenous modulators of S1R as neuroactive steroids. The latter are potent modulators of the excitatory/inhibitory balance in the brain, and this effect must be considered in the anti-epileptic action of FFA.

Title: Progesterone receptor regulation of seizures

Authors: S. SHIONO, J. WILLIAMSON, J. KAPUR, ***S. JOSHI**;
Univ. of Virginia, Charlottesville, VA

Abstract: Menstrual cycle-linked hormonal fluctuations regulate seizure frequency. We tested whether progesterone receptors (PRs) regulated progesterone withdrawal seizures and susceptibility to status epilepticus (SE).
Adult female Sprague Dawley rats that developed epilepsy following cholinergic SE were studied. Seizures were monitored via hippocampal and cortical EEG and behavior. Basal seizure frequency was monitored for two weeks and then animals were daily treated with progesterone (P, 50 mg/kg/day, ip) for a week. The effect of P withdrawal on seizure frequency was determined during the subsequent week. To block PRs, half of the animals were treated with anti-progestin RU-486 (10 mg/kg/day, P+RU) during the week of progesterone. Control animals were treated with vehicle instead of RU-486 (P+V). RU-486 and vehicle were administered 30 min before progesterone. An animal that experienced twice as many seizures during withdrawal week as during pretreatment week was considered to have catamenial seizure exacerbation. RU-486 treatment protected animals from catamenial seizures (15% P+RU-treated, n=13 vs 57% P+V-treated animals, n=14, $p<0.05$, Fisher's exact test). The weekly average seizures of animals in P+V group were 30±9 and this number increased to 57±16 during withdrawal (n=14, p=0.023, paired t-test). In contrast average weekly seizures at baseline and during withdrawal remained stable in P+RU group animals (41±16 and 43±13 respectively, p=0.37, paired t-test). Thus, progesterone withdrawal-induced seizures were suppressed wit RU-486. However, inhibitory actions of RU-486 on glucocorticoid and androgen receptors may have contaminated the effect on PRs. Hence subsequent studies were performed in animals with global deletion of PRs (KO). We first determined whether global deletion of PRs (KO) affected susceptibility to prolonged seizures of SE. PR KO and littermate WT animals experienced 4-5 day-long estrous cycles and associated hormonal fluctuations. To ensure uniform hormonal milieu, SE was induced on the day of estrus in 5 KO animals and 4 WT littermates. The latency to seizure onset was similar in the WT and KO animals (756 ± 50 s, n=4 vs 646 ± 78 s, n=5). The duration of electrographic SE also appeared to be comparable between WT (458 ± 109 min, n=4) and KO animals (381 ± 89 min, n=5). However, the power of EEG in delta to gamma frequencies ended to be lower in the KO animals tan that in the WT animals. Thus, lack of PRs may reduce the severity of SE. Studies are ongoing to confirm and extend these findings.

Title: Neuromodulatory effects of dydrogesterone against anxiety and chemically-induced seizures in male rats

Authors: A. KAUR, *P. E. ALELE;
Mbarara Univ. of Sci. & Technol., Mbarara, Uganda

Abstract: Current treatment of epilepsy, a common and debilitating neurological disorder, is hampered by serious adverse effects and the incomplete control of seizure activity by standard antiepileptic drugs (AEDs). Some AEDs have been associated with suicide-related events, major congenital malformations when used in pregnancy, an incomplete efficacy that may lead to poor patient non-adherence, and increased morbidity and mortality. Dydrogesterone (DYG), a stereoisomer of natural progesterone, has been shown to significantly increase allopregnanolone levels in the frontal lobe, hippocampus, and the hypothalamus. Presumably, increased allopregnanolone increases the inhibitory effect of gamma-aminobutyric acid (GABA) in the brain. Our goal was to determine if the presumed neuromodulatory effect of DYG would impart an antianxiety effect and protect against chemically-induced seizures in adult male rats. We administered three doses of DYG (0.2, 0.6, and 1 mg/kg body weight) for 14 days. We then used the elevated plus maze to test for effects of DYG on anxiety, followed by administration of pentylenetetrazol (PTZ), a chemical convulsant, to test for seizure latency, severity, and duration in response to the treatments. Trunk blood was collected to measure serum levels of estradiol, progesterone and testosterone. All three doses of DYG significantly reduced the time animals spent on the open arm compared to diazepam ($p<0.05$). The 0.2 mg/kg DYG dose was comparable to diazepam in increasing seizure latency ($p>0.05$), whereas the 1 mg/kg DYG dose and the saline-treatment significantly reduced the seizure latency compared to diazepam ($p<0.05$). Saline treatment, 0.6 mg, and 1 mg/kg DYG treatment significantly increased seizure duration compared to diazepam treatment ($p<0.05$). Conversely, the 0.6 mg and the 1 mg/kg DYG treatments significantly reduced the seizure severity compared to the saline-treated controls ($p<0.05$). Diazepam also significantly reduced seizure severity compared to controls ($p<0.05$). No significant alterations occurred among the DYG-treated, and control groups in the serum levels of estradiol, progesterone, and testosterone after two weeks' treatment. These data support previous findings that DYG is a potent neuromodulator against seizure activity and suggest further studies to explore its therapeutic potential as an adjunct for tonic-clonic and other seizure types.

Title: Combination of allopregnanolone and midazolam administered intramuscularly terminates tetramethylenedisulfotetramine-induced status epilepticus in mice

Authors: *D. ZOLKOWSKA, N. GARIBAY, C. W. FLAMM, M. A. ROGAWSKI;
Dept. of Neurol., Sch. of Med., Univ. of California, Davis, Sacramento, CA

Abstract: Tetramethylenedisulfotetramine (TETS) is a highly lethal neurotoxic rodenticide that acts as a noncompetitive GABA-A receptor. The National Institutes of Health considers TETS to be a high priority chemical threat agent. Severe TETS intoxication causes convulsive status epilepticus (SE) that is refractory to treatment. Benzodiazepines, the standard of care for initial treatment of SE, are often ineffective in managing SE, especially when therapy is delayed. Allopregnanolone (5α,3α-P), a neurosteroid positive modulator of synaptic and extrasynaptic GABA-A receptors, may provide a superior treatment option. According to current treatment algorithms, midazolam is expected to be the first seizure therapy that will be administered in a chemical exposure emergency. It is therefore of interest to assess the efficacy of 5α,3α-P in conjunction with this initial therapy. In the present study, we determined whether intramuscular (IM) 5α,3α-P (3 mg/kg) added to IM midazolam (MDZ, 1.8 mg/kg) was more effective than IM midazolam alone in terminating SE in mice exposed to TETS. To create a model mimicking the SE produced by TETS in humans, mice were pretreated with a single dose of riluzole (10 mg/kg, IP) and 10 min later received a lethal dose of TETS (0.2 mg/kg, IP). Riluzole does not inhibit TETS-induced SE but does protect against the rapidly lethal effects of TETS in mice, providing a model of persistent seizure activity. Behavioral seizure activity was assessed by visual observation and the latency to cessation of SE was recorded. Animals were monitored for 72 h after seizure termination and the incidence of mortality was recorded. Latency to cessation of SE was defined as the interval between the first behavioral myoclonic body twitch and termination of behavioral seizure activity. 5α,3α-P (6 mg/ml) was dissolved in a 24% Captisol in 0.9% saline. MDZ at human equivalent dose of 1.8 mg/kg (IM) was administered at 40 min after the first myoclonic twitch. Some animals received 5α,3α-P (3 mg/kg IM) together with MDZ. Addition of 5α,3α-P reduced the time to cessation of SE from 7.23 ± 1.75 min (MDZ alone) to 4.02 ± 1.18 min and increased 72 h survival from 86.6% (MDZ alone) to 100%. The addition of 5α,3α-P caused a transient increase in sedation in the majority of animals receiving the dual therapy compared with MDZ alone, but all animals fully recovered. Our results demonstrate that

addition of 5α,3α-P to standard of care MDZ more rapidly and more effectively terminates TETS-induced behavioral seizures than does MDZ alone. Importantly, 100% animals treated with the dual therapy were protected from mortality.

Title: Metyrapone reduces seizures in GAERS: Role of corticosterone

Authors: G. DEZSI[1], E. OZTURK[1], ***N. C. J. JONES**[2];
[1]Monash, Melbourne, Australia; [2]Monash Univ., Melbourne, Australia

Abstract: Introduction: Epilepsy is a common neurological disorder characterised by the occurrence of spontaneous unprovoked seizures. People with epilepsy are treated with anti-epileptic medications, and the vast majority of these drugs target ion channels. However, one third of patients with epilepsy have inadequate control of their seizures with existing medications, sparking a need to develop new therapies targeting alternative mechanisms. Here we explored whether metyrapone, an 11-b-hydroxylase inhibitor, can influence seizures in a rat model of epilepsy. Methods: We performed a series of pharmacological studies in different cohorts of rats (n>8/group). Adult epileptic GAERS (Genetic Absence Epilepsy Rats from Strasbourg) were surgically implanted with extradural recording electrodes to facilitate EEG recording and seizure quantification, and allowed to recover. Rats were connected to the EEG amplifiers, and treated with the corticosterone synthesis inhibitor metyrapone (5-100mg/kg); corticosterone (3-30mg/kg); or the neurosteroid DOC (10-50mg/kg); or their respective vehicles. Recordings persisted for 2 hours, and resulting EEG was analysed for the frequency of spike-wave discharge seizures using semi-automated software Spike-Wave finder. Drugs were delivered in random order using a repeated measures design, whereby each animal in the cohort was exposed to all doses of drug, with at least 48 hours in between treatments, and data analysis was conducted in a blinded fashion. Results: Metyrapone completely and dose-dependently suppressed spike-wave discharges in GAERS. In this study, vehicle-treated rats experienced 77+/- 8 seizures/hour whereas rats treated with 100mg/kg metyrapone experienced 8+/- 2 per hour ($P<0.0001$). In contrast, corticosterone treatment significantly enhanced seizure frequency ($P<0.01$), whereas the neurosteroid DOC did not influence seizure frequency at the doses used. Conclusions: Here we show that the 11-b-hydroxylase inhibitor metyrapone dose-dependently reduces seizures in GAERS. This is likely mediated by inhibition of corticosterone, since

exogenous corticosterone increased seizures, but the precursor DOC did not impact seizures. Metyrapone may therefore represent a new therapy for seizures with a novel mechanism of action.

Title: AAV-Cre mediated deletion of hippocampal glucocorticoid receptors reduces status epilepticus severity

Authors: *K. L. KRAUS[1,3], A. C. WULSIN[4], J. P. HERMAN[2], S. C. DANZER[3];
[2]Dept Pharmacol. and Systems Physiol., [1]Univ. of Cincinnati, Cincinnati, OH; [3]Dept Anesthesia, [4]Pediatric Neurol., Cincinnati Children's Hsptl Med. Cntr, Cincinnati, OH

Abstract: Status epilepticus (SE) is a medical emergency with a high mortality rate. Many patients are refractory to anti-convulsive therapy; even when successfully treated, patients are usually left with disabling morbidity. Histological evidence in both human and animal tissue demonstrates significant hippocampal neuron loss and synaptic rearrangements that are thought to play a role in the subsequent development of epilepsy, as well as the cognitive deficits associated with SE. We and others have shown that epileptic activity, particularly during SE, results in hyperactivation of the HPA axis. This is evidenced by elevated glucocorticoid secretion within hours of SE as well as a state of chronic glucocorticoid hypersecretion that persists for months after the initial insult (Wulsin, A.C., 2016). Furthermore, exposure to elevated glucocorticoids can increase neuronal activity and produce neuronal injury. Therefore, *we hypothesize that glucocorticoid receptor (GR) signaling contributes to SE-induced neuronal death and injury.* To assess the role of hippocampal GRs in SE, a Cre-mediated viral deletion strategy was developed to knockdown hippocampal GR expression. Adult male and female $GR^{fl/fl}$ mice on a C57BL6 background undergo bilateral intrahippocampal viral injections of either AAV9.CamkII.Cre.eGFP (AAV9-Cre-GFP; 1µL, 3e1011 vg/mL) or AAV9.CamkII.eGFP (AAV9-GFP; 1µL, 2.4e1011 vg/mL) as control. To characterize the viral spread in each mouse, a Nikon TiE inverted microscope and lumencor SpectraX light source is used for high-speed

imaging of all hippocampal sections. Imaging confirmed robust GFP-labeling of dentate granule cells throughout the rostral-caudal extent of the hippocampus with this approach. GR immunostaining of the tissue confirmed deletion of GRs in AAV9-Cre-GFP-expressing cells. Histological stains and probing for activated caspase-3 revealed no evidence of viral toxicity. In initial experiments, we induced SE by systemic administration of the mAchR agonist pilocarpine (vs. saline control) two weeks after viral infusion. Hippocampal GR knockdown increased the latency to first seizure after injection and reduced SE-induced mortality (n=14 control, n= 13 GR knockout; $p < 0.01$, t-test). These studies establish the utility of a new approach to selectively eliminate GRs from adult hippocampal neurons and demonstrate that hippocampal GR activation contributes to SE severity and mortality.

Title: Inhibition of NMDA currents in dissociated neurons derived from kindled rat hippocampus

Authors: *J. MARTINEZ-LAZCANO[1], E. G. GUEVARA[3], E. LARA-GONZALEZ[4], E. RENDON-OCHOA[4], J. BARGAS[5], C. PAZ[2];
[2]Neurophisiology, [1]INNyN, Mexico City, Mexico; [3]Inst. Nacional de Neurología y Neurocirugía, Mexico City, Mexico; [4]Neurosciences, UNAM, Mexico City, Mexico; [5]Inst. De Fisiologia Celular - Univ. Nacional Autonoma De Mexico (UNAM), Mexico DF, Mexico

Abstract: The epilepsy is characterized by sustained depolarization and rapid frequency discharges attributed to over-stimulation of N-methyl-D-aspartate (NMDAr)receptors, several studies suggest the regulation of NMDAr activity through inhibition of P-glycoprotein activity and drug-resistance protein-1 (MRP1). Our group has hypothesis that Probenecid, an inhibitor of the activity and expression of some ABC-type transporters, can modify the activity of the NMDA receptor. Whereby, our aim was evaluated the effect of probenecid on NMDA-induced currents in dissociated hippocampal cells from control and kindled rats. Material and Methods: The rats were decapitated to extract the brain and place it in a Krebs solution at 25 ° C; pH: 7.4, 300 ± 5 mOsm / l and saturated with 95% O2 and 5% CO2. Subsequently, sagittal slices of the hippocampal CA region of 300 μm thickness were obtained and enzymatic and mechanical cell dissociation was performed. The cell suspension was placed in a petri dish with solution at room temperature, after 15 min the neurons were adhered to the base of the petri-box to perform

voltage-clamp records of currents evoked by NMDA. The records were made using an electrode with resistance of 4-7 MΩ, applying a 100 μM solution of NMDA and different concentrations of probenecid (0.2, 2, and 20 mM) to the record plate and obtained with an Axopatch 200B amplifier and controlled and monitored with pClamp-8.2. Results: Probenecid produces a dose-dependent reduction in the current evoked by NMDA, in neurons derived from the hippocampus of the CA region of control rats. In the case of neurons obtained from kindled rats, our observed that the NMDA current residuals were less compared against control neurons. In neurons from kindled rats the NMDA current was reduced compared to neurons from control rats in present of 20 mM of Probenecid. Discussion and Conclusions: Probenecid inhibits currents evoked by NMDA in dissociated neurons from control rats and kindled rats.

Title: Carbamazepine and GABA have distinct effects on seizure onset dynamics

Authors: *D. N. CRISP[1], R. PARENT[2], G. G. MURPHY[3], W. C. STACEY[4];
[1]Biomed. Engin., [2]Mol. and Behavioral Neurosciences Inst., [3]MBNI/Physiology, [4]Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: Intro:
Our recent work has demonstrated that seizures can be classified according to the dynamics of their onset transitions and that these transitional dynamics can be an indicator for changes in brain state during epileptogenesis. Future research into epilepsy treatment could benefit from understanding if these dynamic classifications are linked to specific biological mechanisms. We investigated the effect different anticonvulsants have on the type of seizure onset bifurcation *in vitro* using acutely prepared mouse brain slices.
Methods:
In vitro horizontal brain slices (n = 100) containing hippocampus, amygdala, and entorhinal cortex regions were prepared and extracellular field potentials were recorded in the presence of the pro-convulsant high potassium/low magnesium (HPLM) aCSF to produce ictal-like activity. The control group (40/100) received no anticonvulsants, while the two experimental groups were treated with HPLM + 50 uM carbamazepine (30/100) or HPLM + 10 uM GABA (30/100). The

concentration of HPLM was high enough to induce seizures in all slices despite anticonvulsants. Ictal onset bifurcations from hippocampal recordings were labeled by three independent reviewers. Label validity was confirmed with both Fleiss Kappa testing and rigorous machine learning feature analysis.
Results:
Three out of four possible onset dynamics (supercritical Hopf, subcritical Hopf, and SNIC bifurcations) were present in all three experimental conditions. The control group had mostly SNIC bifurcations (23/40), followed by subcritical Hopf (12/40), then supercritical Hopf (5/40). Both experimental conditions (Carbamazepine and GABA) deviated from this distribution significantly.
Interpretation:
This result suggests that the pathway to seizure onset is modulated by the different mechanisms of the two anticonvulsants. Dynamics theory suggests that this effect occurs because the anticonvulsants modulate the preictal brain state and change the potential pathway into seizure.

Title: Antisense oligonucleotide therapy for scn2a gain-of-function epilepsies

Authors: *M. LI[1], N. JANCOVSKI[1], P. JAFAR-NAJAD[2], L. E. BURBANO[1], A. NEMIROFF[3], K. DALBY[3], S. MALJEVIC[1], C. A. REID[1], F. RIGO[2], S. PETROU[1,3];
[1]Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia; [2]Ionis Pharmaceuticals, Carlsbad, CA; [3]RogCon Biosci., Miami, FL

Abstract: OBJECTIVE: To establish the therapeutic potential of antisense oligonucleotides (ASOs) in *SCN2A* gain-of-function developmental and epileptic encephalopathy (DEE) by evaluating its efficacy in a mouse model containing a recurrent *SCN2A* variant identified in patients with early-onset DEE.
BACKGROUND: *SCN2A* encodes for a voltage-gated sodium channel and *de novo* variants are the cause of a spectrum of early-onset DEE. There is growing evidence showing early disease onset correlates with gain-of-function variants, but therapies using conventional sodium channel blockers can be complicated by low selectivity. To improve selectivity, we employed the ASO technology and identified a lead ASO that specifically downregulates mouse *Scn2a* expression.
DESIGN: Mice heterozygous for *Scn2a* R1883Q (equivalent to human *SCN2A* R1882Q) displayed spontaneous seizure as early as postnatal (P) day 1 and lethality from P13. ASO was

injected into the ventricle and efficacy was assessed by slice electrophysiology, survival, seizure counts, EEG and behavioural tests.
RESULTS: A single dose of ASO significantly extended survival, with 90.2 % of the ASO group surviving on P30, while none from control group survived. Further monitoring found 68.9 % of ASO group lived until P80. A subset of mice received second ASO injection at P25 and resulted in survival beyond P180. ASO treatment not only prolonged lifespan but also abolished behavioural seizure and EEG interictal activity. Recordings from excitatory neurons revealed increased action potential firing, which was normalized to wildtype level with ASO treatment. Performance in a battery of motor and psychosocial behavioural tests revealed alteration in anxiety-like traits that was rectified by lowering the ASO dose.
CONCLUSIONS: *Scn2a* downregulatory ASO significantly improved survival and mitigated seizure in a mouse model of *Scn2a* gain-of-function DEE. Therapeutic window can be maximised by dose titration and repeated dosing. This study demonstrates ASO is a viable therapeutic strategy for *SCN2*A gain-of-function epilepsy.

Title: Blockade of PD-1/PD-L1 suppressed epileptiform activities in both *in-vivo* and *in-vitro* seizure models

Authors: *Z. CHEN;
Fudan Univ., Shanghai, China

Abstract: PD-1 receptor and its ligand PD-L1 are important in immunotherapy particular in cancer therapy. Although PD-1/PD-L1 have been found to also exist in neurons, the function of PD-1/PD-L1 in the central never system, particularly in relation with epilepsy, is still unexplored. In this study, we studied the relationship and the influence of PD-1/PD-L1 pathway on epileptogenesis. Either pentylenetetrazole (PTZ) or cyclothezide (CTZ) induced *in vivo* and *in vitro* epilepsy model were used in this study. SHR-1210 (PD-1 antibody) and SHR-1316 (PD-L1 antibody) applied intracerebraventricular (i.c.v.) significantly inhibited PTZ (50 mg/kg. i.p.) induced seizure behavior and epileptiform like EEG activities in both rat and mice seizure model. *In vitro,* SHR-1210 and SHR-1316 also significantly inhibited CTZ induced epileptiform burst discharges in cultured hippocampal neurons. In conclusion, our results suggest that

blockade of PD-1/PD-L1 could interference with the occurrence of the burst activities suppress seizure behavior.

Title: Selective hyperactivation of JNK2 in an animal model of chronic epilepsy

Authors: F. A. CONCEPCION[1], A. N. PARIKH[2], M. N. KHAN[3], R. D. BOEHM[2], A. DHAMI[2], ***N. P. POOLOS**[1];
[1]Neurol., [3]Neurosci., [2]Univ. of Washington, Seattle, WA

Abstract: c-Jun N-terminal kinases (JNKs) are members of the mitogen-activated protein kinase (MAPK) family. Hyperactivation of JNKs by phosphorylation (pJNK) is associated with debilitating neurodegenerative diseases, including Alzheimer's and Parkinson's. In a rat model of epilepsy produced by chemoconvulsant-induced status epilepticus, we previously reported elevated pJNK levels during chronic epilepsy, and showed that pharmacological JNK inhibition reduced seizure frequency (Tai TY et al, *Neuroscience*, 2017). We also have described the time course of JNK activation during the development of epilepsy in our animal model and found that JNK hyperactivation only occurred in the chronic epilepsy phase of spontaneously recurring seizures and not during the earlier stages of epileptogenesis (Parikh AN et al., *Soc. Neurosci. Abstr*., 2017). In this current study, we sought to identify which of the JNK isoforms (JNK1, JNK2, or JNK3) contributes to the overall increased pJNK levels seen in chronic epilepsy in our animal model. After pJNK enrichment by immunoprecipitating CA1 hippocampal homogenates with an anti-pJNK antibody (Ab), the ratios of individual JNK isoforms between the chronically epilepsy rats and their naïve, age-matched controls were determined by Western blotting for the two JNK electrophoretic bands at 54 kDa and 46 kDa. Subsequent Western blotting with the anti-pJNK Ab was used to normalize protein loading between experimental and control samples. These experiments revealed a significant increase in pJNK2 levels in chronic epilepsy when compared to naïve controls (54 kDa: 142 ± 12.4%, n=8, p=0.012; 45 kDa: 114 ± 5.9%, n=8, p=0.048). No changes in phosphorylation/activation levels were observed for either JNK1 (54 kDa band: 99 ± 7.5%, n=8, p=0.883; 45 kDa band: 104 ± 4.8%, n=8, p=0.415) or brain specific

JNK3 (54 kDa band: 109 ± 17.1%, n=8, p=0.609; 45 kDa band: 106 ± 13.9%, n=8, p=0.682). However, analysis of total levels (phosphorylated and nonphosphorylated) of JNK isoforms showed no significant changes in the total expression of any JNK isoform, including JNK2. This suggests that elevated levels of pJNK2 in epilepsy arise from activation by upstream signaling pathways, not from increased protein expression of JNK2. In summary, our results show that JNK2 is selectively hyperactivated in chronic epilepsy. Given our previous observation that overall JNK inhibition reduces seizure frequency, this investigation suggests that selective JNK2 inhibition may be a potential antiepileptic strategy.

Title: P110β-selective inhibition in a PTEN-deficient mouse model for epilepsy rescues molecular and behavioral phenotypes

Authors: A. R. WHITE, D. TIWARI, M. MACLEOD, A. SNIDER, S. C. DANZER, *C. GROSS;
Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Approximately 2.2 to 3 million people in the US have been diagnosed with epilepsy, affecting all ages, races, genders, and socioeconomic groups. Studies have shown that epilepsy in about one third of patients is uncontrolled with current medications, leaving a vast need for improved therapies.
The causes of epilepsy are diverse and not always known but one prominent gene mutated in a small subpopulation of patients is Phosphatase and Tensin homolog (PTEN) [1]. PTEN has been extensively studied in cancer biology, as it is commonly mutated in a host of cancers. Phosphoinositide 3-kinases (PI3Ks) are the enzymatic counter actors of PTEN. There are three class 1A PI3K catalytic isoforms, p110α, β and δ. Inhibition of only one of these PI3K catalytic isoforms, p110β, but not p110α and δ, reduces tumor progression in prostate cancer [2]. P110β-selective inhibitors are currently being evaluated in clinical trials for PTEN-deficient cancers.

Our lab has shown that the same PI3K isoform, p110β is upregulated in the inherited intellectual disability and autism spectrum disorder (ASD) Fragile X Syndrome (FXS) and that inhibition of p110β rescues many FXS phenotypes, including audiogenic seizures, in a FXS mouse model [3,4]. This work collectively leads to the hypothesis that inhibition of p110β will reduce PI3K signaling and subsequently rescue seizure and behavioral phenotypes in neuron-specific PTEN KO mice.
In the present study, we have used the p110β-selective inhibitor GSK6A to assess both molecular and clinical phenotypes in the context of PTEN deficiency. In CamKIIα-Cre;Ptenfl/fl mice, GSK6A significantly reduces aberrant protein synthesis and cell signaling to levels comparable to littermate controls. In this mouse model, GSK6A is also able to restore nesting behavior to littermate control range. Additionally, ongoing seizure assessment suggests a decrease in seizure quantity after one week of GSK6A administration as compared to vehicle controls. Each study utilizes both female and male mice, with littermate controls, and experimenters were blinded during analysis. All molecular experiments were subjected to power analysis to guarantee rigor. Seizure assessments are ongoing in order to successfully realize analogous rigor. In summary, our results suggest that selective inhibition of the PI3K isoform p110β rescues a broad spectrum of neuronal phenotypes in PTEN-deficient mice.

Title: [E/Z] isoxylitones as JAK-STAT inhibitor: The promise of a new drug class

Authors: *S. U. SIMJEE, U. NISAR, F. SHAHEEN, A.-U.-R. RAHMAN, M. I. CHOUDHARY;
H.E.J. Res. Inst. of Chemistry, Intl. Ctr. for Chem. and Biol. Sciences, Univ. of Karachi, Karachi, Pakistan

Abstract: Purpose: Epilepsy is a neurological disorder marked by recurring seizures. Despite availability of a broad category of AEDs, over one-third of the epileptic patients do not respond

to these drugs. Thus finding new therapeutics to overcome the untreatable epilepsy is needed. Activation of Janus Kinase (JAK)/Signal Transducer and Activator of Transcription (STAT) signaling pathway has been reported to link with epilepsy and thus can be use as a target molecular pathway to interrupt the process of epileptogenesis. In the present study, we targeted the JAK/STAT pathway using [*E/Z*] isoxylitones in order to inhibit epileptogenesis following a brain insult in an animal model. The outcome of these studies could lead to new therapies that can be used to prevent or inhibit development of epilepsy. **Methods:** Pentylenetetrazole (PTZ)-induced kindling in mice was used as a model of epileptogenesis. Seizure-related behaviors were monitored following PTZ administration. JAK/STAT were analyzed in mice brain samples using RT-PCR and immunohistochemistry. **Results:** It was observed that [*E/Z*] isoxylitones, a sodium channel blocker not only halt the epileptogenesis in PTZ-kindled mice but also effectively reduces the JAK-1, JAK-3, and STAT-5a expression in cortex and hippocampus of the treated mice brain. **Conclusion:** The present data suggests that isoxylitones act at the underlying molecular mechanism to control the seizure pattern, such as the downregulation of JAK/STAT treated mice brain. These findings uncover a potential effect of the JAK/STAT pathway in epileptogenesis and may provide a new therapeutic target that can be harnessed for the prevention of epilepsy development and/or progression. At this stage we propose to examine isoxylitones to determine 1) its potency to inhibit JAK/STAT pathway and cellular toxicity in primary hippocampal neurons, 2) ability to block acute seizure- induced JAK/STAT pathway activation and off-target effects on other kinases. The expected outcome is identification of lead JAK/STAT inhibitors that can be advanced towards clinical testing for epilepsy disease modification.

Title: Targeting overexpressed TGF-β linked MAPK pathway to halt pentylenetetrazole-induced epileptogenesis in mice

Authors: *M. SHAHID[1], U. NISAR[1], F. SHAHEEN[1], M. ASKANI[1], S. U. SIMJEE[1,2];
[1]H.E.J. Res. Inst. of Chem., Intl. Ctr. For Chem. and Biol. Sci., Karachi, Pakistan; [2]Dr. Panjwani Ctr. for Mol. Med. and Drug Res., Intl. Ctr. for Chem. and Biol. Sci., Karachi, Pakistan

Abstract: Epilepsy is illustrated by persistent predisposition of the brain to generate seizures and considered as one of the most common, chronic, neurological disorder affecting around 1% of

the individuals worldwide. A growing body of advanced researches now points a link between inflammation and various epilepsy syndromes, reflecting both an inflammatory state inside the epileptic brain along with increased permeability of the blood-brain barrier, heading towards enhanced neuronal excitability. The probable contribution of TGF-β in epileptogenesis is reinforced by animal studies viewing TGF-β up-regulation as measure of inflammatory reaction in the brains of kindled animals that are exposed to status epilepticus. The main focus of this study was to investigate the potential relationship between the TGF-β associated MAPK pathway and epilepsy which will aid in confirming that up regulation of TGF-β genes might be one of the underlying cause of epilepsy. A novel anticonvulsant [E/Z] isoxylitones was used to treat epileptic seizures along with standard antiepileptic drugs (AEDs) diazepam and valproic acid in pentylenetetrazole-induced kindling model of mice. To confirm aforementioned evidences, expression levels of TGF-β, TRAF6 and JNK3 genes along with inflammatory cytokine interleukin-1β (IL-1β) were analyzed. It was observed that as compared to the PTZ-control group, there was a significant decrease in the response of seizures observed in [E/Z] isoxylitones treated group. Furthermore, expressions of these genes were significantly reduced in [E/Z] isoxylitones and standard AEDs treated groups. It is concluded that, TGF-β signaling pathway can be a potential subcellular target for reducing seizure duration and associated neuronal death in epilepsy and [E/Z] isoxylitones is an effective way to achieve this therapeutic target.

Title: Neuroprotective and anti-inflammatory effect of fingolimod (FYT720) in a rat model of epileptogenic cortical dysplasia

Authors: *F. COLCIAGHI[1], B. CIPELLETTI[1], A. CATTALINI[1], E. RINALDI[2], A. CONSONNI[2], F. BAGGI[2], C. CAGNOLI[1], R. MANTEGAZZA[2], M. DE CURTIS[1], G. S. BATTAGLIA[1];
[1]Epilepsy Unit, [2]Neuroimmunology and Neuromuscular Dis. Unit, Fondazione IRCCS Inst. Neurologico Carlo Besta, Milano, Italy

Abstract: Clinical and experimental evidence provided support that both innate and adaptive immunity may be crucial in the pathophysiology of epilepsy. The methylazoxymethanol/pilocarpine (MP) rat is a convulsive model of human cortical dysplasia (CD), the most common developmental malformation that causes refractory epilepsy. We showed that pilocarpine-induced status epilepticus (SE) and subsequent seizures (SRS) in MP rats lead to progressive cortical/hippocampal neurodegeneration and neuroinflammation (Colciaghi 2001, 2014; Nobili 2015). More recently we observed increased blood-brain-barrier (BBB) leakage, infiltration of $CD8^+$ cells and increased expression of sphingosine 1-phosphate receptors (S1Ps) in the cortex of MP rats in the course of epilepsy. Fingolimod (FYT720) the first oral disease-modifying therapy approved by FDA and EMA for relapsing-remitting multiple sclerosis, is able to cross the BBB and to bind S1P receptors expressed on CNS resident cells. Here we verified whether FYT720 could be protective for both neurons and glia and modulate seizure activity in MP rats. Rats with cortical dysgeneses were generated by prenatal injection (E15) of MAM (15 mg/kg i.p.) in pregnant rats. N=20 adult MAM rats were implanted with EEG cortical electrodes. One week later, rats received pilocarpine (270 mg/kg i.p.) for induction of the SE and SRS. N=5 MP rats that survived SE received FYT720 formulated in pellet (2 mg/kg body weight/day) for 20 days, starting from the 5^{th} day after SE. Additional n=5 MP rats received conventional pellets and were used as proper epileptic untreated controls. In both groups we performed: i) GFAP/Iba-1/CD8 IHC analysis to assess gliosis/cytotoxic T cell infiltrates ii) FluoroJade (FJ^+) assay to assess neurodegeneration iii) EEG analysis to assess seizure activity. Here we show that fingolimod exerts robust neuroprotective (↓FJ^+ cells) and anti-inflammatory (↓GFAP/Iba-1/$CD8^+$ cells) effects in the cerebral cortex and hippocampus of FYT720-MP *vs* untreated-MP rats. Although seizure analysis is currently underway, our data suggest that fingolimod could be a new therapeutic approach for the prevention of epileptogenesis in CD rat model.

Abstract: In order to determinate the anticonvulsive effect of Sparteine (Sp) through the activation or inactivation of the M2 and M4 subtype of muscarinic acetylcholine receptor (mAChR) we used male Wistar ratas (200-350 g) with cannula implantation in the right ventricle to inject drugs (i.c.v., total volumen per drug 2.5µl) . All animals were behavioral recorder using racine scale 30 min before drugs and continually during and after drugs administration until 3 h after kainic acid (AK). Control groups (n=6, per group): saline solution (SS, 0.9%, i.p.), dimethyl sulfoxide (DMSO, i.c.v.), KA (9 mg/kg, i.p.) and Sp+KA (30 mg/kg, i.p., Sp was administrated 30 minutes before KA). Experimental groups (n=6, per group): were pre-treated one hour before Sp and one and a half hour before KA administration (i.c.v.) with the antagonist of M2 AF-DX 116 (AF; 4.74µM) or M4 PD102807 (PD; 100µM) and agonist of M2 Arecaidine but-2-ynyl ester tosylate (Ar; 20nM) or M4 VU10010 (VU; 10µM). Results are showed in figure 1. Mean ± Standar Error of Mean (SEM) are showed, Kruskal-Wallis test plus Dunn´s multiple comparación test was performance, significance $p<0.05$.

Title: Effect of cerebrolysin on cognitive impairment and dendritic morphology of granular neurons in the dentate gyrus of rats with temporal lobe epilepsy

Authors: *L. A. PICHARDO-MACIAS, V. DÍAZ-VILLEGAS, I. L. FLORES-NAVARRETE, S. GUZMÁN-VELÁZQUEZ, D. A. ÁLVAREZ GARCÉS, S. R. ZAMUDIO;
Fisiología, Inst. Politécnico Nacional, CDMX, Mexico

Abstract: Temporal lobe epilepsy (TLE) is characterized by an abnormal increase and synchronization of neuronal electrical activity, which is manifested by spontaneous recurrent seizures (SRS). Studies of patients with TLE suggest that cognitive impairments are a common comorbidity frequently associated with changes in hippocampal synaptic plasticity. Cerebrolysin (CBL) is a biologically active mixture of peptides with low molecular weight and with neuroprotective and neurotrophic effects. Therefore, the objective of this study was to determine whether CBL treatment reduces the number of SRS, improves cognitive deficits (learning and spatial memory) and reduces dendritic alterations of granular dentate neurons in rats with TLE. For this purpose, male Wistar rats were divided into the following groups: a) control, b) control + CBL c) epileptic and d) epileptic + CBL. TLE was induced by systemic administration of lithium and pilocarpine, epilepsy was determined by monitoring of behavioral in video recordings. CBL (538 mg/kg) or vehicle (i.p.) were administered for 5 consecutive days per week for 3 weeks. After treatment, the Barnes maze test (BMT) was used to assess spatial navigational learning and memory. The dendritic morphology of the dentate gyrus was evaluated by the Golgi-Cox staining method. The results of this study did not support an antiepileptic effect of CBL; epileptic animals treated with this agent showed secondarily generalized seizures similar in frequency and intensity to those of epileptic animals treated with vehicle. However, we observed that CBL attenuated the dendritic deterioration caused by epilepsy, which was related to improved cognitive performance of CBL-treated animals in the BMT compared to epileptic rats. In conclusion, CBL did not show an anticonvulsant effect on secondarily generalized seizures; however, CBL can be proposed as an add-on therapy in the management of epilepsy to prevent neuronal alterations and to improve memory and learning processes.

Title: Cenobamate (YKP3089) dose-dependently reduced spike-and-wave discharges in the genetic absence epilepsy rats from Strasbourg (GAERS) animal model

Authors: *S. M. MELNICK[1], H. SHIN[2], C. ROUCARD[3], K. GLENN[1];
[1]SK Life Science, Inc., Paramus, NJ; [2]SK Biopharmaceuticals, Co., Ltd., Seongnam, Gyeonggi, Korea, Republic of; [3]Synapcell, Saint Ismier, France

Abstract: Background: The GAERS animal model shows behavioral and pharmacological features of absence seizures and the characteristic spike-and-wave discharges (SWD) on electroencephalograms (EEG). Cenobamate is a novel antiepileptic drug in development for treatment of focal (partial-onset) seizures. Its potentially unique dual mechanism of action may include 1) enhancement of fast and slow inactivation of sodium channels and inhibition of the persistent component and 2) positive allosteric modulation of $GABA_A$-mediated ion channels. This study assessed dose-dependent effects of cenobamate on SWD in the GAERS model. **Methods:** Male GAERS animals received EEG electrode implants at 3 months old. After 1-week recovery and screening EEG, rats were randomized in a crossover design to 5, 10, 20 or 30 mg/kg cenobamate, vehicle (30% PEG300), or 150 or 200 mg/kg valproate via intraperitoneal injection with 3-day washouts. EEGs were performed on freely moving rats for 20 min pre-injection (baseline) and 90 min post-injection. Blinded experts analyzed EEGs to identify SWD. Time course of number and cumulative duration of SWD were analyzed by 2-way repeated measures ANOVA, then Bonferroni-paired comparisons vs baseline, vehicle, and valproate. **Results:** Both valproate doses led to significant reductions in the number and cumulative duration of SWD vs vehicle, with peak effects in cumulative duration at 30-50 min, followed by a diminished effect to 90 min. The lowest cenobamate dose showed no significant effects on either parameter. Increasing cenobamate doses showed significant, dose-dependent reductions in the number and cumulative duration of SWD vs vehicle (**Figure**), with maximal effects at 30-50 min that were sustained to 90 min. **Conclusions:** Cenobamate induced a dose-dependent reduction in the number and cumulative duration of SWD in the GAERS model with a near maximal reduction at 30 mg/kg cenobamate. The effect of cenobamate was more prolonged than that of valproate. These data suggest that cenobamate may be effective in treating patients with absence seizures.

Title: Cannabidiol elevates the ratio of feedforward to feedback inhibition to dampen hippocampal activity propagation

Authors: *S. CHAMBERLAND[1], E. R. NEBET[1], E. C. ROSENBERG[1], O. DEVINSKY[2], R. W. TSIEN[1];
[1]Neurosci. Inst., New York Univ., New York, NY; [2]Dept. of Neurol., New York Univ., New York City, NY

Abstract: *Cannabis sativa* L. derivatives are emerging as therapeutics for some forms of epilepsy, with one formulation being FDA approved (Devinsky et al., 2017, 2018). Cannabidiol (CBD) administration to patients with certain treatment-resistant epilepsies significantly decreases the number and severity of seizures. However, the effects of CBD on neuronal activity and neuronal circuits remain obscure. We combined electrophysiology, optogenetics and single-cell anatomical tracing in acute hippocampal slices to dissect the effects of CBD at the neuronal and circuit levels. Our results show that CBD decreases the propagation of high-frequency activity from region CA3 to region CA1 region of the mouse hippocampus. This CBD action is abolished by GPR55 deletion or block of GABAergic transmission. The dampening of high-frequency activity was traced to disparate CBD effects on perisomatic-targeting parvalbumin+ (PV) and dendritic-targeting somatostatin+ (SST) interneurons (INs): enhanced feedforward recruitment of PV-INs but attenuated feedback recruitment of SST-INs. This countermodulation of PV- and SST-INs was shown to be due to alterations in the intrinsic excitability of PV- and SST-INs. Notably, the CBD-induced attenuation of high frequency spike throughput was mimicked by optogenetic drive of PV-INs, but not of SST-INs. Finally, CBD quieting of SST-INs further disinhibits PV-INs through a novel synaptic mechanism controlling the firing of PV-INs. Thus, in hippocampal CA1, increased recruitment of PV-INs suffices to dampen high-frequency activity propagation. Altogether, these mechanisms may contribute to the anti-seizure effects of CBD.

Abstract: Matrix metalloproteinases (MMPs) are synthetized by neurons and glia and delivered into the extracellular space, where they act as modulators of neuroplasticity, but also as neuroinflammatory agents. They are responsible for the degradation of cell adhesion molecules and extracellular matrix proteins through proteolytic cleavage. We have previously shown that in human as well as experimental temporal lobe epilepsy (TLE), the development of epilepsy (epileptogenesis) is associated with increased expression of MMPs. Therefore, they form a novel therapeutic drug target to treat or even prevent epilepsy. Unfortunately, currently available MMP inhibitors are not selective and cause side effects and toxicity, thus limiting their therapeutic use. The aim of the present study is to determine whether the newly-developed selective

MMP2/MMP9 inhibitor IPR-179 can modify epileptogenesis without side effects in two rodent models of TLE. The effects of IPR-179 (6 mg/day i.p.) were studied on the development of electrically-induced seizures using the rat rapid kindling model as well as on the development of spontaneous recurrent seizures using the intrahippocampal kainic acid mouse model. Furthermore, cognitive function was assessed using the novel object recognition task, spatial navigation using a labyrinth test and locomotion/anxiety using the open field test. In the rapid kindling model, rats treated with IPR-179 (n=8) showed reduced seizure severity over the course of kindling compared to vehicle-treated animals (n=8). In the intrahippocampal kainic acid mouse model, treatment with IPR-179 (n=10) resulted in reduced frequency and duration of spontaneous seizures as compared to vehicle-treated mice (n=8). Furthermore, cognitive decline was attenuated after IPR-179 treatment. Importantly, IPR-179 did not cause toxic effects or behavioral abnormalities in both animal models. These data show that IPR-179 has disease-modifying effects in two rodent models of epilepsy and attenuates seizure-induced cognitive decline. Since side effects were not observed in these experiments and increased expression of MMPs is also evident in resected brain tissue of patients with TLE, this novel MMP inhibitor deserves further investigation in clinical trials.

Title: Effect of WIN 55,212-2 administered alone in a kainic acid-induced status epilepticus model

Authors: ***M. D. BURELO**[1], C. RIOS[1], A. DIAZ-RUIZ[2], V. BARON-FLORES[1];

Abstract: Status epilepticus (SE) is a neurologic and medical emergency condition where continuous generalized seizures are manifested without full recovery of consciousness resulting in irreversible brain damage, significant disability and may be fatal. The early escalation to anesthetic agents for refractory generalized convulsive status epilepticus, to prevent neuronal injury and pharmaco-resistance associated with prolonged seizures is increasingly used, although morbidity and mortality are improved by this approach. Additional trials for new anti-epileptic drugs should be performed in order to achieve prompt recognition, early seizure termination, and simultaneous evaluation for any potentially treatable cause in the patient with SE. The aim of this study was to evaluate the effect of the synthetic cannabinoid WIN 55,212-2 (WIN) administered in a single dose during the SE induced by kainic acid to assess the control of seizures. For this, we used 12 male Wistar rats weighing 250-350g that were randomly allocated to either one of our two groups, group 1: Kainic acid (KA) + Vehicle (n = 6), Group 2: KA + WIN (3 mg/kg, ip, n = 6). Seven days before SE-induction, rats were surgically implanted with three stainless-steel electrodes into the motor cortex (MCx) of each animal. We performed the behavioral and electroencephalographic (EEG) recordings, using a video-EEG device. We ensured the exact moment of SE installation, by looking at the recordings, both behaviorally and electroencephalographically. Such signals were recorded at five different times: T1: baseline; T2: in SE; T3: 1 h; T4: 2 h and T5: 24 h after presenting SE. 10-secs epochs were selected avoiding signal artifacts and containing the epileptiform EEG activity. An automated analysis based on the fast-Fourier transformation method to estimate the total spectral power (μV^2) and the mean frequency (Hz) was applied to the EEG signals. The results showed no difference between the two groups on the intensity of the electrographic SE, but when assessing behavioral seizures during SE based on the Racine scale, we noticed WIN had a reducing effect. We are currently working on the Histology assay to complement this study to observe the severity of neuronal damage after SE.

Title: Regulation of indoleamine 2,3-dioxygenase 1 and 2 expression by microglia, relevance to acquired epilepsy

Authors: *Z. A. MACDOWELL KASWAN[1], M. HURTADO[2], A. J. STEELMAN[2], G. G. FREUND[3], R. H. MCCUSKER[2];
[1]Neurosci. Program, [2]Dept. of Animal Sci., [3]Dept. of Pathology, Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Indoleamine 2,3-dioxygenases (Ido1 and Ido2) are the first and rate-limiting enzymes for the conversion of tryptophan to kynurenine (Kyn). Kyn production, following Ido1/2 upregulation in response to inflammatory signals, promotes immunosuppression. Additionally, microglia convert Kyn into the seizure-inducing metabolite quinolinic acid. Thus, Kyn production via Ido1/2 is postulated to play a role during neuroinflammation, ictogenesis and acquired epilepsy. Intracerebral injection of C57BL/6 mice with Theiler's murine encephalomyelitis virus (TMEV) is used as a preclinical model of ictogenesis and acquired epilepsy. Infected mice have increased Ido1 and Ido2 expression by microglia and IFNγ expression within the hippocampus. Our preliminary data show that TMEV-infected Ido1 knockout mice have increased seizure incidence compared to C57BL/6 mice, while Ido2 knockout mice have reduced seizure incidence, clearly implicating opposing roles for the Ido's in ictogenesis. While it is not known how TMEV induces Ido1/2 expression *in vivo*, TMEV ssRNA and dsRNA are capable of activating toll-like receptor (TLR7) and pattern recognition receptors MDA5/RIG-1, respectively. To assess the mechanism by which TMEV induces Ido1/2, we treated microglial cells with TLR7 agonists (resiquimod and gardiquimod), MDA5/RIG-1 agonists (poly(I:C) HMW/LyoVec and poly(I:C) LMW/LyoVec) and the pro-inflammatory cytokine interferon (IFNγ). We also tested the effects of the 2-propanolol analogue VIS351 (which increases Ido-dependent tolerogenic activity) and cannabidiol (CBD, an anti-epileptic agent). Our results show that the viral mimetics do not directly enhance expression of either Ido1 or Ido2, but IFNγ strongly enhances Ido1 expression. These data indicate that the changes in Ido1 expression my microglia *in vivo* are likely indirectly mediated by IFNγ. In contrast, the tolerogenic compound VIS351 increases Ido2 expression. VIS351 also increases microglial expression of the cytokines interleukin (IL) 6 and tumor necrosis factor (TNFα). CBD did not change Ido1/2 expression, but induced expression of another enzyme capable of converting tryptophan to kynurenine, tryptophan 2,3-dioxygenase (Tdo2). CBD also induced cytokine expression (IFNγ, IL-10, IL-1β and TNFα). Taken together, these data suggest that Ido1 and Ido2 are induced in microglia, but by distinct mechanisms. Their opposing roles during acquired epilepsy strongly suggests that it is possible to attenuate seizures by independently regulating Ido1 and Ido2.

Title: Regulation of indoleamine 2,3-dioxygenase expression by dendritic cells, relevance to viral-induced seizures

Authors: M. HURTADO[1], Z. A. MACDOWELL KASWAN[2], A. J. STEELMAN[1], G. G. FREUND[3], *R. H. MCCUSKER[1];
[1]Animal Sci., [2]Neurosci., [3]Dept. of Pathology, Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Epilepsy is one of the most prevalent neurological disorders and affects about 3 million people in the United States. Approximately 50% of cases are a result of acquired epilepsy, which can be caused by a number of risk factors, including viral encephalitis and the ensuing persistent neuroinflammation. Neuroinflammation has been implicated to play a role in neurodegeneration and ictogenesis via the induction of indoleamine 2,3-dioxygenases (Ido1 and Ido2); enzymes that initiate tryptophan metabolism to kynurenine (Kyn) and Kyn metabolites of which several are ictogenic. Previous studies have demonstrated that mice infected intracerebrally with Theiler's murine encephalomyelitis virus (TMEV) have increased Ido1 and Ido2 associated with seizure incidence. We have demonstrated that Ido1 knockout mice have a higher seizure incidence compared to C57BL/6 mice, whereas Ido2 KO mice have diminished seizure incidence, indicating an opposing role for the two enzymes. Thus, Ido's involvement in ictogenesis requires further examination. Our exciting new 10x single-cell sequencing data identified dendritic cells within the TMEV-infected mouse hippocampus. These infiltrating immune cells were the major source of downstream enzymes (Kmo, Kynu and Haao) that generate ictogenic Kyn metabolites. Dendritic cell activation is implicated in seizure susceptibility as they modulate the immune response in an Ido1/2 dependent manner. Thus, we examined how treatment with immune-inducing agents affected Ido1/2 expression by dendritic cells. TMEV ssRNA and dsRNA induce inflammation by their interaction with toll-like receptor (TLR7) and pattern recognition receptors (MDA-5/RIG-1), respectively. Thus, we treated bone-marrow derived dendritic cells with interferon (IFNγ) and agents that act as viral mimetics (MDA-5/RIG-1 agonists poly(I:C) HMW/LyoVec and poly(I:C) LMW/LyoVec; TLR7 agonists resiquimod (R848) and gardiquimod (Gard)). We also investigated a 2-propanolol analogue, VIS351 with Ido-dependent tolerogenic activity. IFNγ increased Ido1 expression, an effect that was diminished by VIS351. In contrast, Ido2 expression was increased by R848 and Gard in

addition to IFNγ, but also decreased by VIS351. MDA-5/RIG-1 agonists did not alter Ido1 or Ido2 expression. Thus, Ido1 and Ido2 expression are differentially regulated by the viral mimetics. Based on differential effects of Ido1 KO and Ido2 KO on ictogenesis, it should be possible to modulate seizures by differentially modulating Ido1 and Ido2 expression.

Title: Application of CCKb receptor antagonist on the treatment of kainic acid-induced epileptic mice

Authors: *A. TAN[1], J. HE[2];
[1]City Univ. of Hong Kong, Hong Kong, Hong Kong; [2]City Univ. of Hong Kong, Hong Kong, China

Abstract: Epilepsy is a group of long-term neurological disorders characterized by seizures and it causes unconscious changes in body movement, body function and sensation awareness. Epileptic seizure affects over 50 million people worldwide and it is difficult to cure. The excitation/inhibition imbalance of neuronal network will lead to the generation of epilepsy. Most seizures involve neocortex and hippocampus, which are associated with neuronal plasticity. The entorhinal cortex is part of the medial temporal lobe or hippocampal memory system and constitutes the major gateway between the hippocampal formation and neocortex. Cholecystokinin (CCK) from the entorhinal cortex enables neural plasticity in the neocortex. In the present study, we investigated the relationship between neuroplasticity and epilepsy. Our previous studies showed that long-term potentiation (LTP) was blocked with the infusion of CCKb antagonist *in vitro*. In our experiment, we explored the treatment strategy for the kainic acid-induced epileptic mice. C57BL/6 mice with kainic acid application developed daily seizures

at a frequency of 1-8 times and at the stage of 3-5. We have adopted a new scale for seizure measurement. We calculated the seizures in twelve hours every day and evaluated the severity of seizures via the accumulative scores. The seizure scale was reduced after the one-time intraperitoneal injection of CCKb antagonist. Our results imply that the application of kainic acid in the hippocampus temporally activates the temporal lobe, possibly facilitating CCK release in the brain. With the injection of CCKb antagonist, further enhancement of the excitatory circuitry can be blocked.

Title: Characterization of the effects of a ghrelin receptor agonist on cell viability in excitotoxic conditions

Authors: *A. BUCKINX, A. DE SMET, D. DE BUNDEL, R. KOOIJMAN, I. SMOLDERS; Vrije Univ. Brussel, Brussels, Belgium

Abstract: Temporal lobe epilepsy is the most common form of pharmacoresistant epilepsy, a disease often featured by neuroinflammation, excitoxicity and neuronal loss in the hippocampus. Ghrelin receptor agonists, such as JMV-1843, have been shown to exert anticonvulsant, anti-inflammatory and neuroprotective effects, rendering these compounds highly interesting drug candidates for new therapeutic strategies for epilepsy. However, the molecular mechanisms-of-action of these agonists remain unexplored. Therefore, we aimed to study the effect of JMV-1843 on cell death, inflammation and autophagy in hippocampal cell cultures treated with excitotoxic concentrations of the neurotransmitter glutamate.
Experiments were conducted using the mHippoE14 cell line, consisting of hippocampal neurons, astrocytes and microglia, the SH-SY5Y neuronal cell line, the 1321N1 astrocytic cell line, and the BV2 microglial cell line. The specific culture medium for each cell type was refreshed every 2-4 days, and cells were kept under standard conditions (37°C, 95% O_2/ 5% CO_2). For evaluating cell viability, cells were seeded at a density of 100,000 cells/ 0.5 mL culture medium in a 24-well plate. The next day, cells were exposed to glutamate in the presence or absence of JMV-1843

and harvested 24 hours later for cell counting with trypan blue.
First, we established that the optimal glutamate concentration required to induce approximately 40% cell death in the mHippoE14 cell line after 24 hours was 20 mM, corresponding to what has been described in literature. Preliminary experiments (n=4) reveal that JMV-1843 exerts a trend towards a neuroprotective effect at the highest dose tested (1 μM). However, JMV-1843 did not completely abolish neuronal cell death induced by glutamate administration. The same dose of JMV-1843 significantly increased cell viability of astrocytes.
JMV-1843 was demonstrated to be anticonvulsant, however, how it exerts such effects at the molecular level remains up to now unknown. This study already suggests that JMV-1843 can enhance astrocyte survival in the central nervous system and it remains to be established if and how other processes such as autophagy and inflammation take part in modulation of cell survival in different types of neurons and glial cells. Although caution is required when extrapolating *in vitro* results to *in vivo* observations, these results may potentially aid in understanding the possible molecular mechanism-of-action behind JMV-1843's anticonvulsant effects.

Title: LPS induced peripheral inflammation prevents SUDEP in DBA/1 mice

Authors: *Y. P. ADHIKARI[1], X. JIN[2];
[1]STARK Neurosciences Res. Inst., Indianapolis, IN; [2]Iupui STARK Neurosci. Res. Inst., Indianapolis, IN

Abstract: Sudden Unexpected Death in Epilepsy patients (SUDEP) is the sudden and unanticipated death of a relatively healthy person with epilepsy where no structural or toxicological cause of death can be identified after post mortem analysis. SUDEP is the cause of premature death of 50% patients with chronic refractory epilepsy. Respiratory failure during seizures is regarded as an important mechanism of SUDEP. 5-HT neurotransmission is important to prevent respiratory failure during seizure. Previous studies showed that abnormal 5-HT neurotransmission is involved in the pathogenesis of SUDEP and that enhancing 5-HT neurotransmission in the brain-stem suppresses SUDEP. Although peripheral inflammation is known to enhance 5-HT neuron activation and, 5-HT synthesis and release, the effect of

peripheral inflammation on SUDEP susceptibility has not been investigated so far. We investigated the effect of LPS-induced peripheral inflammation on SUDEP susceptibility in DBA/1 mice. The DBA/1 mice exhibit tonic seizures in response to loud sound stimulation which lead to seizure induced respiratory arrest (S-IRA) and result in SUDEP. We found that intraperitoneal administration of LPS significantly reduced the incidence of S-IRA in DBA/1 mice in response to audiogenic stimulation. This protective effect peaked at 8-12 hours after LPS injection and could be attenuated by blocking TLR4 or RAGE receptors prior to LPS administration or by administration of 5-HT3 receptor antagonist -Ondansetron. The results suggest that LPS induced peripheral inflammation is effective in preventing SUDEP through the activation of TLR4/ RAGE signaling and enhancing 5-HT neurotransmission.

Title: Blocking receptor for advanced glycation end-products (RAGE) or toll like receptor 4 (TLR4) attenuates posttraumatic epileptogenesis in mice

Authors: *X. PING[1], M. S. RIPSCH[1], F. A. WHITE[2], X. JIN[3];
[1]Stark Neurosci. Res. Inst., Indianapolis, IN; [2]Anesthesia, Indiana Univ. Sch. Med., Indianapolis, IN; [3]IUPUI Stark Neurosci. Res. Inst., Indianapolis, IN

Abstract: Development of posttraumatic epilepsy occurs in a complicated neurobiological environment including on-going secondary injury caused by traumatic brain injury (TBI). Neuroinflammation is an important factor that contributes to posttraumatic epileptogenesis. However, the mechanism remains poorly understood. High mobility group box 1(HMGB1) signaling pathways have been implicated in inflammatory responses and epileptogenesis. In this study, we tested the hypothesis that blocking RAGE or TLR4 signaling pathways may prevent posttraumatic epileptogenesis in a mouse model of partial cortical isolation (undercut). Adult mice that underwent undercut surgery received daily injections of saline, RAGE antibody, or a TLR4 inhibitor TAK-242 for 1 week and were tested for seizure susceptibility in 2 weeks after injury. Undercut animals treated with RAGE antibody or TAK-242 showed significantly higher seizure threshold than saline-treated undercut mice in a pentylenetetrazol (PTZ) test.

Consistently, undercut injury in RAGE knockout mice didn't cause a reduction in seizure threshold in PTZ test, suggesting a preventative effect on posttraumatic epileptogenesis. We further used continuous video and wireless electroencephalographic (EEG) recordings to monitor spontaneous seizure activity between 2-6 weeks after undercut injury and found a significant decrease in frequency of spontaneous seizures in RAGE antibody or TAK-242 treated group (0.46 ± 0.30, 0.18 ± 0.23, and 0.09 ± 0.15 seizures/day for saline, RAGE antibody, and TAK-242 groups respectively. $p < 0.05$ in RAGE antibody and TAK-242 groups vs saline group). Histological analyses of lesioned cortical tissues showed higher neuronal densities in Nissl staining and higher densities of GAD67-immunoreactive interneurons in RAGE antibody or TAK-242 treated groups than the control undercut group. Immunostaining to GFAP and Iba-1 revealed lower densities of astrocytes and microglia in cortex of the treatment groups, suggesting reduced glia activation. These results suggest that blocking RAGE or TLR4 signaling pathways is a promising strategy for preventing posttraumatic epilepsy in TBI patients.

Abstract: Lacosamide (LCM) is an anticonvulsant drug approved as adjuvant therapy in the treatment of partial seizures with or without secondary generalization in patients 17 years of age or older. LCM acts by increasing the slow inactivation of voltage-dependent sodium channels, producing stabilization of the hyperexcitable neural membranes. The goal of this study was to evaluate the LCM effect in the pentylenotetrazole (PTZ)-induced kindling model, as well as, some biochemical parameters. Male mice CF-1 were divided into the following experimental groups: saline, saline-PTZ, diazepam-PTZ, LCM 20 mg/kg-PTZ, LCM 30 mg/kg-PTZ and LCM 40 mg/kg-PTZ. Diazepam (2mg/kg) was used as a positive control. On alternate days, animals received LCM or controls and after 30 minutes they received PTZ (50 mg/kg), totaling 11 days of treatment. After PTZ administration, animals were observed for 30 minutes regarding latency time for the first seizure (LFS) lasting more than 3 seconds and occurrence of clonic seizures.

After the last day of treatment, animals were euthanized and hippocampus, bone marrow and peripheral blood samples were collected for biochemical analyzes. ROS production, SOD and CAT activity, complexes I-III, II and II-III activity, genotoxicity (Alkaline Comet Assay), mutagenicity (Micronucleus test) and COX-2 and Bcl-2 expression (Western blotting) were performed. The seizures occurrence was analyzed by Fisher Exact test. LFS by Generalized Estimating Equations. Biochemical data were analyzed by one-way ANOVA ($P \leq 0.05$). This project was approved by the UFRGS Committee on Ethics in the Use of Animals (CEUA; N. 34134). The results demonstrated that LCM did not decrease the percentage of seizures and it did not increase the latency time for the first seizure in the kindling model. However, LCM 30 and 40 mg/kg reestablished the mitochondrial complex I-III activity. ROS production was reduced by the 3 doses of LCM and SOD also had its activity reduced. LCM did not induce chromosomal mutations and doses of 20 and 30 mg/kg prevented the genotoxic damage caused by PTZ in the hippocampus. COX-2 levels decreased in animals treated with LCM 30 and 40mg/kg and Bcl-2 levels increased with LCM 40mg/kg. Although LCM did not reduce the convulsive behavior in the kindling model, our findings provide evidence that LCM has an important neuroprotective profile on biochemical parameters associated with epilepsy.

Title: Chiral hydroxyamides as anticonvulsants

Authors: *S. E. MEZA TOLEDO, J. ESQUIVEL-VARGAS, J. A. MARTÍNEZ-RODRÍGUEZ, J. PERALTA-CRUZ, M. GONZÁLEZ-FLORES;
Biochem., Inst. Politécnico Nacional, Esc.Nac.Cien.Biol, Mexico City, Mexico

Abstract: Compound DL-3-hydroxy-3-ethyl-3-phenyl propionamide (DL-HEPP) has a broad profile of anticonvulsant activity. However, the mechanism underlying the anticonvulsant action of DL-HEPP is not known. In order to study if GABAergic mechanisms are involved in the anticonvulsant action of HEPP, we resolved its enantiomers and measured their protection against convulsant drugs acting at GABAergic system such as bicuculline, a competitive $GABA_A$ receptor antagonist, and thiosemicarbazide, a glutamate decarboxylase inhibitor. The racemate was resolved from the (+) and (-) 1-phenyelthylamine salts of the acids. The optically

active acids were then esterified and reacted with ammonia to give (+) HEPP and (-) HEPP. Optical purity of amides was greater than 99% enantiomeric excess determined by chiral high performance liquid chromatography. Pharmacologically, (+) HEPP, (-) HEPP and DL-HEPP have a similar significant anticonvulsant activity against bicuculline and thiosemicarbazide-induced seizures in mice, but the time course of the anticonvulsant activity was different. These results suggest that (+) HEPP and (-) HEPP may be acting through GABAergic mechanisms. The anticonvulsant activity of DL-HEPP and its enantiomers was greater than that of sodium valproate, an antiepileptic used in clinic. This study shows that (+) HEPP and (-) HEPP represent a new class of anticonvulsant compounds worthy of further development for potential antiepileptic therapy.

Title: Altered human oligodendrocyte heterogeneity in multiple sclerosis

Authors: *S. JAEKEL[1], E. AGIRRE[2], A. MENDANHA FALCAO[2], D. VAN BRUGGEN[2], K. WAI LEE[2], I. KNUESEL[3], D. MALHOTRA[4], C. FFRENCH-CONSTANT[5], A. WILLIAMS[5], G. CASTELO-BRANCO[2];

Abstract: Oligodendrocyte pathology is increasingly implicated in neurodegenerative diseases as oligodendrocytes both myelinate and provide metabolic support to axons. In multiple sclerosis (MS), demyelination in the central nervous system thus leads to neurodegeneration, but the severity of MS between patients is very variable. Disability does not correlate well with the extent of demyelination, which suggests that other factors contribute to this variability. One such factor may be oligodendrocyte heterogeneity. Not all oligodendrocytes are the same—those from the mouse spinal cord inherently produce longer myelin sheaths than those from the cortex, and single-cell analysis of the mouse central nervous system identified further differences. However, the extent of human oligodendrocyte heterogeneity and its possible contribution to MS pathology remain unknown. Here we performed single-nucleus RNA sequencing from white matter areas of post-mortem human brain from patients with MS and from unaffected controls. We identified

subclusters of oligodendroglia in control human white matter, some with similarities to mouse, and defined new markers for these cell states. Notably, some subclusters were underrepresented in MS tissue, whereas others were more prevalent. These differences in mature oligodendrocyte subclusters may indicate different functional states of oligodendrocytes in MS lesions. We found similar changes in normal-appearing white matter, showing that MS is a more diffuse disease than its focal demyelination suggests. Our findings of an altered oligodendroglial heterogeneity in MS may be important for understanding disease progression and developing therapeutic approaches.

Ctr., Maastricht, Netherlands

Abstract: Glutamate has been implicated in a wide range of brain pathologies and is thought to be metabolized via the astrocyte-specific enzyme glutamine synthetase (GS). We show here that oligodendrocytes, the myelinating glia of the central nervous system, also express high levels of GS in caudal regions like midbrain and spinal cord. Selective removal of oligodendrocyte GS in mice led to reduced brain glutamate and glutamine levels and impaired glutamatergic synaptic transmission without disrupting myelination. Furthermore, animals lacking oligodendrocyte GS displayed deficits in cocaine-induced locomotor sensitization, a behavior that is dependent on

glutamatergic signaling in the midbrain. Thus, oligodendrocytes support glutamatergic transmission through the actions of GS and may represent a therapeutic target for pathological conditions related to brain glutamate dysregulation.

Title: Mass spectral analysis of developmental changes in the lipid composition of myelin membranes

Authors: *E. M. TRIPLET[1], H. YOON[2], I. LANZA[3], I. A. SCARISBRICK[2];
[1]Neurosci. Program Mayo Clin. Grad. Sch. of Biomed. Sci., [2]Physical Med. and Rehabil., [3]Physiol. and Biomed. Engin., Mayo Clin., Rochester, MN

Abstract: Lipids are key structural and signaling molecules in the CNS. Lipid synthesis is required for neurite outgrowth, synaptogenesis, the formation of myelin and the establishment of salutatory conduction. Lipid composition across neurons and glia is very different and underpins their functional properties. For example, myelin membranes are enriched in cholesterol and glycerophospholipids while neurons rely heavily on sphingolipids and gangliosides for modulation of membrane protein activity and signaling. Derivatives of cholesterol—steroids—and long chain fatty acids—endocannabinoids and prostaglandins—also act as signaling and regulatory factors.
Changes in lipid metabolism contribute to a variety of CNS disorders, including Neiman-Pick and Huntington Disease, and are also associated with Alzheimers, as in the association between hypercholesterolemia and the lipid carrier protein ApoE. The recent development of highly sensitive Liquid Chromatography with tandem mass spectrometry (LC-MS-MS) assays for lipids permits us to quantify a wide variety of CNS lipids for the first time. Our long-term goal is to utilize these methods to generate a better understanding of changes in lipids across the neuron and myelin compartments developmentally and in response to injury and repair. These assays may be particularly useful to screen for factors that can improve regeneration of neuron and myelin membranes. In the current study, we compared the abundance of cholesterol, free fatty

acids, galactosylceramides, sphingolipids and sphingomyelins in the spinal cord of male mice at postnatal day 21 (P21), the peak of myelination, or in adulthood (P90). Furthermore, we made direct comparisons between the abundance of lipids extracted from the spinal cord as a whole relative to isolated myelin. Findings indicate a general enrichment in myelin-associated lipids—cholesterols, galactosylceramides, and sphingomyelin—occurs in the spinal cord through development, with concurrent decreases in free fatty acids. In contrast, the relative abundance of the predominantly neuronal sphingolipids is diminished over the same period of CNS maturation.

Title: Schwann cells transport nucleic acid-containing cargo into axons via myelin injection bodies

Authors: *W. TEO[1], P. K. STYS[2];
[1]Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada; [2]Clin. Neurosci, Univ. Calgary, Calgary, AB, Canada

Abstract: Myelination facilitates fast action potential conduction. In addition, myelinating glia are thought toprovide trophic and metabolic support to their ensheathed axons. Thus, loss of myelination not onlyadversely affects conduction but also the survival of axons, leading to axonal degeneration andneurological disability. How glial cells support axons is only beginning to be understood. Recently weproposed a chemical communication between electrically active axons and their myelin in the CNSvia a glutamatergic "axo-myelinic synapse" (Micu et al., 2016). Here we studied myelinated spinalroot axons maintained ex vivo at 35 °C from young adult mice. Exposure to sucrose to promotefusion of vesicles and release of transmitter into the periaxonal space resulted in invagination of NileRed-labeled myelin into the axon (Figure) as discrete "myelin injection bodies (MIBs)" beginningwithin 20 min of treatment. Raising axonal Ca by release of intracellular stores with caffeine, oractivation of L-type voltage gated Ca channels with Bay K8644 (both of which we hypothesize willpromote transmitter release from axon into the periaxonal space) produced a similar effect. Theinterior of most (but not all) MIBs stained positive with the membrane-permeable nucleic acid dyeSYTO40. The precise nature of this cargo is currently under investigation.CONCLUSION:

we proposed that an important mechanism by which myelinating glia can supporttheir fibers is by deliberately orchestrated deformation of the myelin sheath and injection of MIBs intothe axon. The nature of the injected cargo is not yet known, but may include nucleic acid-containingorganelles.

Title: To explore the characteristics of glial cells in pig models

Authors: ***N. YU**[1], W. ZUO[2], S. YANG[1];
[1]The Pla Gen Hosp, Beijing, China; [2]Nankai Univ., Tianjin, China

Abstract: Objective: To explore the characteristics of glial cells in pig models.
Materials and methods: Compare the different kinds of glial cells in the central and peripheral nervous systems of the large animal model——pig model(BAMA Mini pig)and small animal model——mouse model, guinea pig model and rat model.
Results:(1)Morphology: In pig model nervous system, except that the myelin ensheathing of

optic nerve or olfactory nerve is central myelin sheath, the other ten pairs of cranial nerves all have the transition area of central myelin sheath and peripheral myelin sheath, which can be called transition zone. The two ends of the transition zone are different from the complete structure of the Nodes of Ranvier, and its morphological and electrophysiological characteristics are similar to the "heminode" of the cochlear nerve through the habenular hole. In addition, the satellite cells also express the specific marker of neurons——2-phospho-D-glycerate hydrolase(NSE). The associations between Satellite cells and neurons in pig models are more similar to humans than other small animal models.(2)Nerve injury test: after short-term noise exposure of auditory nerve, it was found that no obvious damage was found in the neurons of spiral ganglion, and the satellite cells which were around the neurons were damaged and then proliferated and repaired. After compression of the trigeminal nerve, it was found that the pathological changes were mainly located in the transitional zone, but no significant abnormality was found in the rest areas.
Conclusions:(1)Except optic nerve and olfactory nerve, the other ten pairs of cranial nerve had transitional zones. The transitional zone is the transition between central myelin sheath and peripheral myelin sheath. Its structure is unstable and it is easy to appear pathological changes when it is affected by the outside world. Therefore, the neurilemmoma and neuralgia of the cranial nerve may all originate here.(2)The satellite cells which are around the ganglion neurons in the peripheral nervous system, some of which are similar to glial cells and some of which are similar to neuron cells. Therefore, these cells may not be only classified as glial cells or neuron cells. The satellite cells may differentiate earlier than glial cells in the process of stem cell differentiation. It may not only secrete neurotrophic factors, but also participate in the formation and differentiation of neurons.(3)Large animal model——pig model is more similar to human, and it is a more suitable research object than small animal model, like mouse model, guinea pig model and rat model.

Title: Specific oligodendrocyte populations have differential spatial distribution and susceptibility to injury

Authors: *E. M. FLORIDDIA[1], S. ZHANG[3], D. VAN BRUGGEN[1], J. P. GONCALVES DOS SANTOS[1], M. ALTINKOK[1], E. LLORENS-BOBADILLA[2], J. FRISÉN[2], G. CASTELO-BRANCO[1];

Abstract: Oligodendrocytes (OLs) are the myelinating cells of the central nervous system (CNS). While the OL is thought to be homogenous, we recently found twelve transcriptionally distinct OL states/subtypes in the juvenile and adult mouse CNS. The functional consequences of the OL transcriptional heterogeneity are unknown. Here, we unveil spatial preference and differential susceptibility to injury of distinct mature OLs (MOLs). Using RNAscope in situ hybridization (ISH), we observed that a specific subtype of MOLs, MOL2, is preferentially distributed in the white matter of the spinal cord. In contrast, MOL5/6 were found to be most abundant in the corpus callosum in the brain and in the dorsal horn of the spinal cord. Furthermore, we observed that these subtypes also segregate in the dorsal funiculi of the spinal cord, with MOL2 and MOL5/6 preferentially distributed at the level of the dorsal columns (sensory ascending tracts) and corticospinal tract (motor descending tracts), respectively. These spatial preferences could reflect diverse developmental origins of these MOL subtypes. However, fate mapping and single-cell RNASeq analysis indicated that the developmental origin of the OL progenitors does not influence their specification into distinct MOL subtypes. In the context of disease, we observed a significant loss of MOL2 but not MOL5/6 following spinal cord injury, suggesting that MOL2 are more susceptible to traumatic injury than MOL5/6. Altogether, our data suggest that the transcriptional heterogeneity of the OL lineage reflects functional MOL subtypes, most likely dictated by their final location and environment rather than their developmental origin.

Title: Satellite glial cells in sensory ganglia express functional TRPA1 that is sensitized in neuropathic and inflammatory pain

Authors: *S. SHIN[1], H. YU[1], Q. HOGAN[1], B. PAN[1], I.-Z. BRANDON[1], F. WANG[3], Y. CAI[4], C. L. STUCKY[2];
[1]Anesthesiol., [2]Cell Biology, Neurobio. and Anat., Med. Col. of Wisconsin, Milwaukee, WI; [3]Med. Experiment Ctr., Shaanxi Univ. of Chinese Med., Xianyang, China; [4]Xi'an Jiaotong Univ. Hlth. Sci. Ctr., Xi'an, China

Abstract: Transient Receptor Potential Ankyrin 1 (TRPA1) is well documented as an important molecule in pain hypersensitivity following inflammation and nerve injury and in many other cellular biological processes. Here, we show that TRPA1 is expressed not only by sensory neurons of the dorsal root ganglion (DRG) but also in their adjacent satellite glial cells (SGCs), as well as non-myelinating Schwann cells. TRPA1 immunoreactivity is also detected in various cutaneous structures of sensory neuronal terminals, including small and large caliber cutaneous sensory fibers and endings. The SGC-expressed TRPA1 is functional. Like DRG neurons, dissociated SGCs exhibit a robust response to the TRPA1-selective agonist allyl isothiocyanate (AITC) by an increase of intracellular Ca2+ concentration ([Ca2+]i). These responses are abolished by the TRPA1 antagonist HC-030031 and are absent in SGCs and neurons from global *Trpa1* null mice. SGCs and neurons harvested from DRGs proximal to painful tissue inflammation induced by plantar injection of complete Freund's adjuvant show greater AITC-evoked elevation of [Ca2+]i and slower recovery compared to sham controls. Similar TRPA1 sensitization occurs in both SGCs and neurons during neuropathic pain induced by spared nerve ligation. Together, these results show that functional TRPA1 is expressed by sensory ganglia SGCs, TRPA1 function in SCGs is enhanced after both peripheral inflammation and nerve injury, and suggest that TRPA1 in SGCs may contribute to inflammatory and neuropathic pain.

Title: Targeting of Neurofascin to nodes of Ranvier is regulated by a paranodal switch

Authors: *Y. ZHANG[1], S. YUEN[1], E. PELES[2], J. L. SALZER[1];
[1]Neurosicence Inst., NYU Sch. of Med., New York, NY; [2]Deptartment of Mol. Cell Biol., Rehovot, Israel

Abstract: The paranodal junctions flank mature nodes of Ranvier and provide a barrier between ion channels at the nodes and juxtaparanodes. These junctions also promote node assembly and maintenance by mechanisms that are poorly understood. Here, we examine their role in targeting of NF186, a key adhesion molecule of PNS and CNS nodes. We previously showed NF186 is targeted via its ectodomain to forming PNS (hemi)nodes by diffusion trapping whereas it is later trafficked to mature nodes by a transport-dependent mechanism mediated by its cytoplasmic segment. To address the role of the paranodes in this trafficking switch, we compared targeting of NF186 ectodomain and cytoplasmic domain constructs in wild type vs. paranode defective, i.e. Caspr-null mice. Both pathways are affected in the paranodal mutants. In the PNS of Caspr-null mice, diffusion trapping mediated by the NF186 ectodomain aberrantly persists into adulthood whereas the cytoplasmic domain/transport-dependent trafficking is impaired. In contrast, targeting of NF186 to CNS nodes does not undergo a switch - it is predominantly targeted to both forming and mature CNS nodes via its cytoplasmic domain and requires intact paranodes. FRAP analysis indicates the paranodes provide a membrane diffusion barrier that normally precludes diffusion of NF186 to nodes. Linkage of paranodal proteins to the underlying cytoskeleton likely contributes to this diffusion barrier based on analysis of 4.1B and βII spectrin expression in Caspr-null mice. Together, these results implicate the paranodes as membrane diffusion barriers that regulate trafficking to nodes and highlight differences in the assembly of PNS and CNS nodes.

Title: Oligodendrocyte progenitor cell regional and temporal heterogeneity indicate diverse functional states

Authors: *Y. KAMEN, S. O. SPITZER, S. SITNIKOV, K. A. EVANS, D. KRONENBERG-VERSTEEG, H. PIVONKOVA, S. DIETMANN, O. DE FARIA, JR, S. AGATHOU, H. O. B. GAUTIER, R. T. KARADOTTIR;
Wellcome - MRC Cambridge Stem Cell Institute, Dept. of Vet. Med., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: In the central nervous system, oligodendrocyte progenitor cells (OPCs) give rise to oligodendrocytes, which myelinate axons throughout life. Myelin is essential for rapid electrical conduction through axons and input synchronicity, and the importance of myelin is made clear in white matter disorders such as Multiple Sclerosis. Recent evidence also shows that the generation of new myelin is a mechanism underlying learning in adults. OPCs receive synaptic inputs from neurons, have voltage-gated ion channels, and neurotransmitter receptors, allowing them to sense neuronal activity, which is thought to regulate myelination and myelin regeneration. Functional expression of voltage-gated sodium channels (Na_V), voltage-gated potassium channels (K_V), AMPA/kainate receptors (AMPA/KAR), and NMDA receptors (NMDAR) is often described as a hallmark of OPCs. Using whole-cell patch-clamp in NG2-eYFP transgenic mice, we show that OPCs are first born without any voltage-gated ion channels or glutamate receptors, and gradually acquire them at different rates. In the second postnatal week, OPCs diverge between and within regions, with a greater proportion of OPCs responding to NMDA application in heavily myelinated regions, with larger current densities, while NMDAR disappear from unmyelinated regions first. Thus, unlike previously believed, OPCs are heterogeneous both temporally and between and within regions. In addition, by combining patch-clamp with flow cytometry and bulk RNAseq, we show that ion channel expression correlates with the proliferation or differentiation potential of OPCs, suggesting that this heterogeneity rather indicates different functional states. Finally, we find similar OPC states during remyelination following ethidium bromide-induced demyelinating lesions. A number of cues, such as cytokines, growth factors, or G protein-coupled receptors, are known to regulate ion channel expression, and may therefore regulate OPC state transitions both in healthy and lesioned tissue. Moreover, drugs acting on G protein-coupled receptors promote myelin repair in demyelinating lesion models. Thus, understanding both OPC functional states and state transitions may be fundamental to our understanding of myelination and myelin repair.

Abstract: Many drugs target the extracellular regions (ECRs) of cell-surface receptors. The large and alternatively-spliced ECRs of adhesion G protein-coupled receptors (aGPCRs) have key functions in diverse biological processes including neurodevelopment, embryogenesis, and tumorigenesis. However, their structures and mechanisms of action remain unclear, hampering drug development. The aGPCR Gpr126/ADGRG6 regulates Schwann cell myelination, ear canal formation, and heart development; and *GPR126* mutations cause myelination defects in human. Here, we determined the structure of the complete Gpr126 ECR and revealed five domains including a previously-unknown proteolytic domain. Strikingly, the Gpr126 ECR adopts a closed conformation that is stabilized by an alternatively spliced linker and a conserved calcium-binding site. Alternative splicing regulates ECR conformation and receptor signaling, while mutagenesis of the newly-characterized calcium-binding site abolishes Gpr126 function *in vivo*. These results demonstrate that Gpr126 ECR utilizes a multi-faceted dynamic approach to regulate receptor function and provide novel insights into ECR-targeted drug design.

Title: Dynamics of oligodendrocyte generation in multiple sclerosis

Authors: *M. YEUNG[1], M. DJELLOUL[1], E. STEINER[1], S. BERNARD[2], M. SALEHPOUR[3], G. POSSNERT[3], L. BRUNDIN[4], J. FRISÉN[1];

Neuroscience, Dept. of Neurosurg. and Neurol., Karolinska Institutet, Stockholm, Sweden

Abstract: Myelin is formed by oligodendrocytes in the central nervous system and functions to maximize the efficiency and velocity of action potentials along neuronal axons. A hallmark of multiple sclerosis is the loss of oligodendrocytes and myelin, leading to conduction deficits, and resulting in severe neurological symptoms and disability. Myelin can be regenerated (remyelination), especially early in the disease process. In animal models of MS, myelin is regenerated by newly generated oligodendrocytes, and remaining mature oligodendrocytes do not seem to contribute to this process. Given the differences in the dynamics of oligodendrocyte generation and myelination between rodents and humans from previous studies, it is not clear how well experimental animal models reflect the situation in multiple sclerosis. To address this we assessed the dynamics of oligodendrocyte generation in patients with multiple sclerosis by analyzing the content of ^{14}C derived from nuclear bomb tests during the Cold War, in genomic DNA of oligodendrocytes. We found that the generation of new oligodendrocytes in normal appearing white matter was increased several-fold in a subset of patients with aggressive multiple sclerosis, revealing the ability to substantially increase the generation of oligodendrocytes that fails in most patients. Surprisingly, oligodendrocytes in shadow plaques - thinly myelinated lesions thought to represent remyelinated areas - were old in multiple sclerosis patients. This absence of new oligodendrocytes in shadow plaques suggest that remyelination is not carried out by new but by old pre-existing oligodendrocytes, or that remyelination of lesion occurs transiently or not at all in multiple sclerosis. We reveal unexpected oligodendrocyte generation dynamics in multiple sclerosis, which highlights the heterogeneity of the disease process and should guide the use of current and the development of new therapies.

Title: Modulation of sympathetic neuronal activity in spontaneously hypertensive rats

Authors: ***M. HABURCAK**, S. SONA, N. GERARD, J. ENES, S. J. BIRREN;
Biol., Brandeis Univ., Waltham, MA

Abstract: We present data that implicate peripheral, local satellite glial cells of the superior cervical ganglion (SCG) in the modulation of sympathetic neuronal activity and investigate this regulation under pathological conditions, namely in a hypertensive animal model. Spontaneously hypertensive rats (SHRs) display increased sympathetic drive that precedes the onset of hypertension. We evaluated morphological changes within the developing ganglion, and determined the effects of satellite glial cells on intrinsic properties and excitability of SCG neurons of normotensive rats and prehypertensive SHRs during the postnatal period. Within the SCG, satellite glia enwrap individual neuronal soma during a developmental period of neuronal hypertrophy. Glial changes in SHR ganglia included expression of the glial activation marker glial fibrillary acidic protein (GFAP) in young animals, suggesting that activated glia contribute to pathological processes in prehypertensive animals. We found that satellite glia promote cholinergic neurotransmission between cultured sympathetic neurons, further suggesting that glial interactions contribute to heightened sympathetic drive preceding hypertension. In addition, these glia release neurotrophins, providing a non-target-derived alternative, local source of neurotrophic factors in the sympathetic system. These actions of satellite glial cells open new possibilities for designing new targets for manipulating sympathetic neuronal activity in hypertension. In addition to the actions of glia, SHR neurons exhibited alterations in their excitability and intrinsic properties that were dependent upon interactions with cardiomyocytes isolated from the hearts of prehypertensive animals, demonstrating that cells from both the local ganglionic environment and distant targets contribute to the regulation of the peripheral sympathetic circuit in hypertension. Taken together, our results provide a greater understanding of the complex interplay of a variety of cell types and sympathetic neuronal activity implicated in the development of cardiac dysfunction in the hypertensive model.

Authors: ***B. ZOTTER**[1], O. DAGAN[1], J. SAMANTA[2], H. BALOUI[3], J. L. SALZER[1]; [1]Neurosci. Inst. and Dept. of Neurosci. and Physiol., NYU Sch. of Med., New York, NY; [2]Sch. of Vet. Med., Univ. of Wisconsin Madison, Madison, WI; [3]Depts. of Neurosci. and Clin. Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Peripheral nerves contain a variety of cell types in addition to axons and Schwann cells (SCs) including perineurial glia (PG), endoneurial fibroblasts (EFs), and vascular components. Interactions among all of these cellular elements are important for proper nerve organization. During development, SCs express the morphogen Desert Hedgehog (Dhh), which is critical for PG development. Dhh expression continues in myelinating SCs throughout adulthood. The cellular targets of Dhh both during development and in the adult PNS are incompletely characterized. Here we used a genetic fate-mapping strategy to identify hedgehog-responsive cells in peripheral nerves. Binding of Dhh to its cognate target cells upregulates the transcription factor Gli1, which is therefore a sensitive reporter for hedgehog signaling; Gli1 is also a marker of neural stem cells as well as perivascular mesenchymal stem cells. Here, we demonstrate that PG, EFs, and pericytes in the PNS are Gli1 positive and co-express PDGFRα, a marker of mesenchymal stem cells. Knockout of Gli1 during development had no obvious effect on the perineurium but drove the majority of EFs to dramatically alter their phenotype and form minifascicles, perineurial-like cellular sheaths which divide the nerve into many small compartments. Gli1-positive EFs also give rise to minifascicles following nerve transection injury and are involved in the formation of a fibrotic tissue bridge between the cut ends of the nerve, highlighting their plasticity with injury. Taken together, these results indicate Gli1-positive EF have stem-like properties and suggest their fate during development and after nerve injury is under the control of SCs via Dhh-Gli1 signaling. Pharmacological manipulation of Dhh

signaling by specific targeting of Gli1 may be useful in regulating the EF phenotype during nerve repair and regeneration.

Title: How is the regional specificity of myelination established and maintained?

Authors: *L. O. SUN[1], S. B. MULINYAWE[1], H. Y. COLLINS[1], A. IBRAHIM[1], Q. LI[1], D. J. SIMON[2], M. TESSIER-LAVIGNE[2], B. A. BARRES[2];
[1]Neurobio., [2]Stanford Univ., Stanford, CA

Abstract: Nervous system function depends on proper myelination for insulation and critical trophic support for axons. Myelination is tightly regulated spatially and temporally, but how it is controlled molecularly remains largely unknown. Here, we identified key molecular mechanisms governing the regional and temporal specificity of central nervous system (CNS) myelination. We leveraged our whole-genome RNA sequencing datasets (Zhang et al., 2014 Journal of Neuroscience) and identified a novel oligodendrocyte(OL)-enriched transcription factor, transcription factor EB (TFEB), that is highly expressed by premyelinating OLs and is critical to mediate programmed cell death of a subset of premyelinating OLs. Genetic deletion of TFEB in OL lineage cells causes ectopic myelin formation in the cerebellar molecular layer, a non-myelinated brain region, as well as precocious myelination in many other brain areas. To determine the downstream mechanisms, we conducted unbiased RNA-Seq analysis in TFEB KO premyelinating OLs and found that TFEB induces transcriptional expression of PUMA, which encodes a pro-apoptotic factor that further activates Bax/Bak-dependent programmed cell death. Indeed, PUMA KO mice as well as Bax/Bak OL conditional KO mice completely phenocopy TFEB conditional KO animals in ectopic OL survival and aberrant myelination in vivo. Finally,

TFEB conditional KO, PUMA KO, and Bax/Bak conditional KO mice phenocopy each other in disrupted myelination timing. Our results demonstrate that OL programmed cell death mediated by the TFEB-PUMA-Bax/Bak pathway powerfully controls regional and temporal specificity of CNS myelination that allows for proper circuitry function, shedding lights on a common principle shared by neurons and glia in shaping the nervous system.

Title: Regulation of glial size by a Golgi membrane protein eas-1/GOLT1B

Authors: *A. ZHANG, D. YAN;
Mol. Genet. and Microbiology, Duke Univ., Durham, NC

Abstract: The regulation of glial growth is a fundamental biological process necessary for the proper morphogenesis and continued function of the nervous system. Not only do glia have to grow in accordance with the developing nervous system to maintain their cellular contacts, but glia such as oligodendrocytes cells continue growing postnatally to myelinate axons, a process associated with learning. However, due to the complexity of the nervous system and the broad range of cellular contexts, the underlying molecular mechanisms regulating glial growth are poorly understood.
To investigate the mechanisms involved in regulating glial size, we used *C. elegans* amphid sheath (AMsh) glia as a model owing to their simple nervous system and genetic tractability. We show that a conserved Golgi membrane protein *eas-1/GOLT1B* negatively regulates glial growth, whose function has not been characterized in animals. Using a heat shock promoter to drive *eas-1* expression, we show that the gene is required for the continued maintenance of glial size beyond the initial morphogenesis during the embryonic development. Through a suppressor screen, we found that *eas-1* inhibits a conserved ER-resident E3 ubiquitin ligase *rnf-145/RNF145*, which in turn promotes nuclear activation of *sbp-1*, the *C. elegans* homolog of the SREBPs, which are key regulators of sterol and fatty acid homeostasis, to restrict cell growth. In accordance with the role of *sbp-1* in regulating the expression of genes that catalyze the production of long chain polyunsaturated fatty acids (LC-PUFAs), we found that dietary

supplementation of eicosapentaenoic acid (EPA) but not the saturated palmitic acid in *eas-1* mutants rescued the glial size phenotype. Furthermore, our genetic analyses show that the *rnf-145- sbp-1* pathway functions in parallel with the TOR pathway while *eas-1* functions upstream of both to regulate AMsh cell growth. Together, our findings reveal a novel and potentially conserved mechanism underlying the regulation of glial size, that may aid in our understanding of how glia regulate their size given the diversity of cellular contexts.

Title: GALC is required by myelinating glia and macrophages to prevent psychosine-induced demyelination and galactosylceramide-induced neuronflammation

Authors: *M. FELTRI[1], N. WEINSTOCK[2], D. SHIN[2], N. SILVESTRI[3], H. XINYING[4], N. DUC[5], J. KOFLER[6], M. ESCOLAR[7], M. GELB[4], E. BONGARZONE[5], L. WRABETZ[2]; [2]Hunter James Kelly Res. Col. of Medicine,, Univ. of Illinois at Chicago, Chicago, IL; [6]Dept. of Pathology, [7]Dept. of Pediatrics,, Univ. of Pittsburgh Sch. of Medicine,, Pittsburgh,, PA

Abstract: Lysosomal storage disorders (LSDs) are inherited metabolic diseases caused by enzyme deficiencies [1]. Therapy for LSDs relies on cross-correction of lysosomal enzymes between cells [2,3]. In globoid cell leukodystrophy (GLD), mutations in the galactosylceramidase gene (GALC) cause toxic accumulation of a minor GALC-substrate, psychosine, that may directly induce demyelination, a neuroinflammatory “globoid” cell reaction and neurodegeneration. The cellular origin of psychosine, the role of the GALC major substrate galactosylceramide and the efficiency of GALC transfer *in vivo* are poorly understood [4 5,6]. Using a novel GLD model we show that cross-correction does not occur *in vivo* in the peripheral nervous system and that GALC-deficient Schwann cells are the source of psychosine, which

causes demyelination, but not formation of globoid cells. Infiltrating neural macrophages require GALC for myelin degradation, as ablating GALC in Schwann cells and macrophages produce a GLD-like phenotype. GALC-deficient macrophages are induced to globoid cells by galactosylceramide, suggesting a role for this major GALC substrate. Finally, nerves from GLD patients treated with hematopoietic stem cell transplantation have fewer globoid cells than untreated patients, suggesting that the effect of therapy is strongly influenced by the phagocytic function of healthy macrophages. These data reveal that GLD pathogenesis may consist of two intertwined mechanisms: psychosine-induced demyelination and secondary neuroinflammation from galactosylceramide storage in macrophages.

Title: Developmental origin of oligodendrocytes determines their function in the adult CNS

Authors: ***S. FORSTER**[1], R. J. M. FRANKLIN[1], E. M. FLORIDDIA[3], D. VAN BRUGGEN[3], G. CASTELO-BRANCO[3], S. CHENG[3], T. BUSSEY[2], B. PHILIPPS[2], E. KIM[2], C. J. HEATH[2], W. D. RICHARDSON[4], R. B. TRIPATHI[4];
[2]Behavioural and Clin. Neurosci. Inst., [1]Univ. of Cambridge, Cambridge, United Kingdom; [3]Biomedicum/C6, Karolinska Institutet, Stockholm, Sweden; [4]Univ. Col. London, London, United Kingdom

Abstract: In the mouse embryonic forebrain, oligodendrocyte progenitor cells (OPCs) are generated in consecutive waves from distinct brain regions along a spatiotemporal gradient, with ventral OPCs emerging before dorsal OPCs. Whether this developmental diversity of oligodendrocyte lineage cells is functionally important is unknown. Using a genetic strategy to ablate dorsally-derived oligodendrocyte lineage cells (OLCs), we found that the areas in which dorsally-derived OLCs normally reside in the adult CNS are now populated and myelinated by the ectopic dispersion of OLCs of ventral origin. These ectopic OLs have a distinctive gene expression profile, as well as subtle myelin abnormalities. The failure of ectopic OLs to assume the role of the original dorsally-derived cells results in behavioural deficits in the adult animal. This study thus provides evidence for the biological significance of developmental heterogeneity

within the oligodendrocyte lineage, revealing why this heterogeneity is important for homeostatic brain function.

Title: Essential role of NG2 glia in the regulation of brain innate immunity

Authors: *S.-Z. ZHANG, Y.-J. LIU, Q.-Q. WANG, Q.-Q. YANG, Y.-Q. YIN, R. CHEN, Q.-Q. SUN, Y.-J. LIU, Y.-D. LI, J.-C. HOU, J.-W. ZHOU;
Inst. of Neuroscience, CAS, Shanghai City, China

Abstract: Brain innate immunity is vital for maintaining normal brain functions. Immune homeostatic imbalances play pivotal roles in the pathogenesis of neurological diseases. However, the molecular and cellular mechanisms underlying the regulation of brain innate immunity are still largely unknown. Here, we show that neuron-glial antigen 2 (NG2) glia are required for the maintenance of immune homeostasis in the brain via transforming growth factor-β2 (TGF-β2)-TGF-β type II receptor (TGFBR2)- CX3C chemokine receptor 1 (CX3CR1) signaling, which suppresses the activation of microglia. We demonstrate that ablation of NG2 glia results in profound downregulation of the expression of microglia-specific signature genes. Mice with ablated NG2 glia display a remarkable inflammatory response in multiple brain regions following exposure to endotoxin lipopolisaccharides (LPS). The microglia become hyper-responsive to LPS stimulation in the absence of NG2 glia, which is accompanied by marked downregulation of expression of microglia enriched genes. Gain- or loss-of-function studies

show that NG2 glia-derived TGF-β2 and its receptor TGFBR2 in microglia are key regulators of the CX3CR1-modulated immune response. These findings suggest that NG2 glia play a critical role in modulation of neuroinflammation and define a new fundamental mechanism by which brain innate immune homeostasis is maintained.

Title: Phosphorylation state of ZFP24 controls oligodendrocyte differentiation

Authors: *B. ELBAZ, A. KOLARZYK, B. POPKO;
Dept. of Neurol., Univ. of Chicago, Chicago, IL

Abstract: Myelin is a multilayer lipid membrane structure that ensheaths and insulates axons. In the central nervous system (CNS), myelin is formed by oligodendrocytes. During CNS development oligodendrocyte progenitor cells terminally differentiate into mature oligodendrocytes, produce myelin and wrap axons. The differentiation of oligodendrocytes and their expression of myelin protein gene transcripts are under tight transcriptional control. Zinc finger protein ZFP24, formerly known as ZFP191, is necessary for oligodendrocyte maturation and CNS myelination. We have demonstrated that ZFP24 binds to a consensus DNA sequence in proximity to genes important for oligodendrocyte differentiation and CNS myelination, and we have shown that this binding enhances target gene expression. We have also demonstrated that ZFP24 DNA binding is controlled by phosphorylation. Phosphorylated ZFP24, which does not bind DNA, is the predominant form in oligodendrocyte progenitor cells. As these cells mature into oligodendrocytes, the non-phosphorylated, DNA-binding form accumulates. We performed a large, unbiased screen and found that ZFP24 is phosphorylated by several isoforms of Protein

Kinase C (PKC) and Calcium and Calmodulin dependent Kinase (CAMK). We also found that ZFP24 is dephosphorylated by the calcium and calmodulin dependent phosphatase Calcineurin. Using the Cuprizone model, we found that ZFP24 is important for CNS remyelination. In addition, we found that active, non-phosphorylated, ZFP24 is capable of inducing oligodendrocyte differentiation. Therefore, our studies provide potential therapeutic targets, the modulation of which might enhance the presence of the non-phosphorylated form of ZFP24 and the promotion of oligodendrocyte maturation and CNS remyelination.

Title: The role of oxidized SOD1 aggregates in aging

Authors: *K. SHAFIQ, T. GUAN, J. KONG;
Dept of Human Anat. of Cell Sci., Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Super oxide dismutase 1(SOD1) is one of the primary anti-oxidant enzymes in human body that converts the superoxide free radicals into oxygen and less toxic H_2O_2. Oxidative stress induced SOD1 aggregation is found to be a common pathology of age related neurodegenerative conditions like Amyotrophic lateral sclerosis, Parkinson's and Alzheimer's disease. Among the four cysteine residues, cysteine 111 group is unique to human SOD1 (hSOD1) which is located on the surface of the protein in a reduced state. In transgenic mice expressing mutant G93A-SOD1, we found that cysteine 111 is prone to oxidation and such modified SOD1 monomers irreversibly crosslink with each other and form intracellular aggregates. The aggregates appear to increase as early as the mice are 100 days old, and the mutation of cysteine111 group abolished such process. Aberrant accumulation of protein aggregates are prominent in aging and age-related neurodegenerative diseases. Based on these, we hypothesized that 1) oxidation of cysteine 111 leads to the formation of SOD1 aggregates which in turn accelerate the aging in the central nervous system; 2) selective clearance of aggregates can delay the aging process. To observe the progressive changes, we have tested G93A mice of different age groups ranging from 50 days to 150 days. Collected spinal cord samples were incubated with maleimide polyethyleneglycol (malPEG) which reacts to reduced thiol group of cysteine 111 residue. MalPEG-modifiable SOD1 represent the native SOD1 and shows a band shift of 5-10 KDa in western blot. We then investigated the serum samples using an oxi-sod1 ELISA assay. Samples

are first incubated with iodoacetate-agarose to pull down the native SOD1, then the supernatant is subjected to ELISA to measure the remaining oxidized SOD1. We found a significant increase of oxidative SOD1 in both spinal cord and serum in older age mice. Present findings indicate that SOD1 aggregates can be a potential biomarker of aging, and inhibiting SOD1 aggregate formation may offer avenues to reduce aging and age-related diseases.

Title: Dietary yeast restriction attenuates polyglutamine toxicity via insulin-like signaling and immune signaling in *Drosophila*

Authors: *M. SUZUKI[1,2,3], A.-M. NEUMANN[3], Y. SAITOH[3], N. FUJIKAKE[3], K. WADA[3], K. SANGO[1], Y. NAGAI[2,3];

Abstract: Aging is known to be a significant risk factor for neurodegenerative diseases, most of which share a common molecular pathogenesis involving protein misfolding and aggregation. The balance between protein and carbohydrate in diet is known to be one of the determinant for life-span in flies and mice. In *Drosophila*, dietary yeast restriction (DR) regimen produces low protein to carbohydrate ratio and delays age-associated changes and extends life-span. We explored whether DR improves misfolding protein-induced neurodegeneration. *Drosophila* models of Alzheimer's disease, polyglutamine disease or amyotrophic lateral sclerosis either expressing Aβ, MJD or TDP-43 protein, respectively, were fed a high-yeast diet (HD: 5% sucrose, 20% yeast extracts) or a low-yeast diet (LD: 5% sucrose, 5% yeast extracts). We found that LD significantly suppresses compound eye degeneration, locomotor dysfunction and shortened life-span of these model flies. Meanwhile, the diet did not affect the compound eye degeneration induced by apoptosis, suggesting that its effects are specific to misfolding protein-related neurodegeneration. DR also suppressed misfolding of these proteins as evident by reduced accumulation of MJD protein inclusions and TDP-43 protein oligomers. Next we focused on the role of insulin-like signaling, which is known to mediate the effect of DR in aging. It was showed that the beneficial effects of DR are canceled by using mutant background

of *insulin-like peptides* and *chico*, a homolog of IRS. To further explore the mechanisms we performed microarray analyses and found that immune signaling activation might be attenuated by DR. Genetic analyses demonstrated that knockdown of *Relish*, a homolog of NFκB, canceled the effect of DR both in cell-autonomous and non-cell autonomous manners. Our findings demonstrate that the DR condition suppresses neurodegeneration through affecting protein misfolding, and suggest the role of metabolic and immune signaling in the effect of the DR.

Abstract: Glycolysis is a fundamental and conserved pathway responsible for generating ATP and metabolites. We previously observed that glycolytic enzymes form clusters near the synapse in response to energy stress (induced by transient hypoxia). To better understand the dynamics of the clusters under transient hypoxia, we combined microfluidics with imaging and characterized the relocalization of the rate-limiting glycolytic enzyme, phosphofructokinase (PFK-1) in *C. elegans* neurons. We observed that PFK-1 dynamically forms clusters under transient hypoxia and diffuses in the cytoplasm under normoxia. We also identified that this glycolytic compartment exhibits liquid-like characteristics. PFK is active in its tetrameric state, and a PFK-1 mutant that is incapable of forming tetramers (PFK-1 mutant F674K) is also incapable of dynamic relocalization to synapses upon energy stress. We also observed that the CRY2 tagged PFK-1 is sufficient to induce non-CRY2 tagged PFK-1 clusters via self-association. In summary, our study suggests that PFK-1 self-interaction (tetramer formation) is necessary for its clustering near synapse and might be important for its function.

Title: Driving brain aging by disruption of muscle proteostasis: Role of ABC transporters in protein clearance and tissue aging

Authors: *M. MORI[1], M. MOUJAHIDINE[2], A. BASSETT[3], P. HAGHIGHI[2];
[1]Buck Inst. For Res. On Aging, Novato, CA; [2]Buck Inst. for Res. on Aging, Novato, CA; [3]Univ. of San Francisco, San Francisco, CA

Abstract: The decline in protein homeostasis (proteostasis) is a major hallmark of aging and is a central pathology for various diseases of age. Using genetic tools available in *Drosophila melanogaster*, we have identified a novel regulator of tissue proteostasis and demonstrate the interplay between muscle proteostasis and brain aging. We have identified a member of the ABC transporter family to be required to maintain proteostasis in various tissues including the brain. Tissue-specific knockdown of the ABC transporter is sufficient to disrupt age-dependent proteostasis in respective tissues. As the transporter is responsible for the import of amino acids and metabolites, we believe amino acid metabolism plays a key role in the maintenance of proteostasis. Furthermore, muscle-specific manipulation of the ABC transporter results in an increased inflammatory response in the brain of aged animals. Transcription levels of inflammatory stress response genes are increased with age, and disruption of muscle proteostasis further aggravates inflammation. These results indicate that brain aging can be driven by amino acid metabolism and deterioration of proteostasis in the muscle.

Title: VRK2 regulates the formation of stress granules via phosphorylation of G3BP1

Authors: *K.-W. JO, Y.-H. JEONG, K.-T. KIM;
Pohang Univ. of Sci. and Technol., Pohang, Korea, Republic of

Abstract: In mammalian cells, global translational repression occurs by the assembly of cytoplasmic messenger ribonucleoprotein (mRNP) granules called stress granules (SGs) in response to environmental stresses. The RasGAP SH3 domain binding protein 1 (G3BP1) is one of the factors of stress granule assembly and it is known to induce the formation of SGs through oligomerization. Previous reports showed that G3BP1 is phosphorylated at serine 149 (S149), which causes the interference in G3BP1 oligomerization. However, a kinase involved in the phosphorylation of G3BP1 is still yet to be revealed. Here we identified Vaccina-related kinase 2 (VRK2) directly interacts with G3BP1. Furthermore, VRK2 interacts with G3BP1 and phosphorylates at serine 149 of G3BP1, which attenuates the aggregation of SGs. Moreover the phosphorylated form of G3BP1 and VRK2 levels are consistently decreased under cell stress conditions. Notably, our work reveals a novel function of VRK2 in cellular defensive response under stress condition by regulating SG formation as an upstream kinase of G3BP1.

Title: Deletion of Caveolin 1 accelerates hippocampal senescence via reprogramming glucose metabolism

Authors: *M. WU, C. GAO, Q. DU, J. SHEN;
Sch. of Chinese Med., The Univ. of Hongkong, Hong Kong, Hong Kong

Abstract: Ageing is the biggest risk factor to neurodegenerations including Alzheimer's disease etc. Convergent lines of evidence suggest membrane/lipid rafts (MLR) is essential for development and stabilization of synapse and neural plasticity. Exploring the molecules in regulating MLR functions would offer the therapeutic targets against neurodegenerations. Caveolin-1 (Cav-1), a well-established mediator for lipid homeostasis, was documented as a target to alleviate the ageing associated neurodegeneration. Deletion of Cav-1 induced the alternative cellular glucose metabolism, which would help to explain the roles of such protein in ageing associated neurodegeneration. In our study, we found that compared with adult mice (4 months), Cav-1 protein displays the increasing expression in aged hippocampus (18 months). We employed Cav-1 knockout adult mice to investigate the glucose metabolic related biological phenomena in hippocampus. By detecting the markers of oxidative damage 4-HNE as well as glycolysis/TCA switch turnover the activity of pyruvate dehydrogenase, we found Cav-1 KO increased the byproduct of oxidative damage as well as the reprogrammed glucose metabolism, which mimic the phenomena in aged wild type mice. In addition, at age of 18 months, Cav-1 KO mice showed deficit cognitive functions and increased cell death in hippocampus. As one of the components of mitochondria-associated membrane (MAM), down regulation of Cav-1 detached the mitochondria and ER and thus cause the glucose metabolic reprogram by ROS burst, thereby induced the ageing associated neurodegeneration. As a conclusion, Cav-1 may be a potential target for anti-ageing and neurodegenerative therapy.

Title: Study of the development and aging of the brain through metabolic pathways

Authors: *K. BAI, C. J. CORTES, A. R. LA SPADA;
Dept. of Neurology, Dept. of Cell Biology, Dept. of Neurobiology, Duke Ctr. for Neu, Duke Univ., Durham, NC

Abstract: The purpose of this study is to investigate activity of metabolic pathways in mice brain models at different stages of aging. Certain pathways, such as lysosomal biogenesis and autophagy pathways, are known to decline with age. Dysfunction of these pathways lead to neurodegeneration in the brain, which can manifest as a variety of neurodegenerative diseases, such as Alzheimer's and Parkinson's disease. qPCR analysis and immunohistochemistry were performed on brain samples from mice categorized into different age groups (6 months, 14 months, and 24 months). Markers of glycolysis, chaperones, ER stress, inflammation, and autophagy pathways were selected and studied. Preliminary results from qPCR indicate that younger age groups have significantly higher transcription levels of markers of certain cellular pathways in brain cells, suggesting a decline in transcriptional activity of protein quality control and bioenergetic pathways in the aging brain. Immunohistochemistry will be a necessary next step to further explore these findings. The ultimate goal of this study is to better our understanding of brain pathways in order to find more effective therapeutic candidates for neurodegenerative diseases.

Title: Anti-obesity effects of tocotrienols and rice bran in high-fat diet-treated mice: Does obesity accelerate brain oxidation?

Authors: *K. FUKUI[1], M. SHIRAI[2], T. NINUMA[3], Y. KATO[1];
[2]Dep of Biosci. and Engin., [1]Shibaura Inst. Technol., Saitama, Japan; [3]Shibaura Insti Technol., Saitama, Japan

Abstract: The ratio of obesity is increasing in many countries and is known to increase the risk of many severe diseases. The onset and progression of these diseases are deeply correlated with oxidative damage. However, the relationship between obesity and oxidative damage has not yet elucidated. Recently, several lines of evidence have demonstrated that neurodegenerative diseases such as Alzheimer's and Parkinson's are also related to oxidative damage. On the other hands, tocotrienols (T3s) which are one kind of vitamin E, have unique functions. One beneficial effect of T3s is anti-obesity. In this study, we investigated brain antioxidant networks in high-fat (HF) diet-treated mice in the presence or absence of T3s and bran. Before start of study, we measured T3 levels in five different commercially-available non-mixed breeds of whole grain wheats, and bran. The highest T3s level was bran. Co-treatment with T3s and bran significantly inhibited bodyweight gain in HF diet-treated mice. Although, we recognized that enough volume

of T3s reached liver in T3s-treated groups, serum and cortex T3 levels and brain antioxidant enzyme activities and protein expressions did not differ among the groups. These results indicate that treatment with T3s for eight weeks had showed an anti-obesity effect in HF diet-treated mice. However, significant alterations in T3 levels were not observed in the serum and brain of mice.

Title: CYP46A1 knock-out causes age-dependent transcriptional changes in cholesterol biosynthesis within the mouse hippocampus

Authors: *L. H. ZIOLKOWSKI, H.-J. SHU, A. BENZ, S. J. MENNERICK;
Psychiatry, Washington Univ. In St. Louis, St. Louis, MO

Abstract: Brain cholesterol plays an important role in myelin composition, membrane structure and cellular physiology. Due to its inability to cross the blood-brain barrier (BBB), cholesterol is produced in the brain by local *de novo* synthesis. Subsequent removal of the labile neuronal pool of cholesterol from the brain is facilitated by cholesterol 24-hydroxylase (Ch24H), an enzyme that converts cholesterol into 24S-hydroxycholesterol (24S), which can readily pass through the BBB. 24S is an endogenous agonist of the Liver X Receptor (LXR) transcription factor, through which it regulates cholesterol homeostasis. 24S also positively modulates NMDAR function, which might also affect transcription to alter neuronal function. To investigate the transcriptional effects that result from a lack of 24S, we examined whole-body deletions of CYP46A1, the gene that encodes cholesterol 24-hydroxylase. We performed RNA-seq and qPCR on the dentate gyrus and CA1 regions of the hippocampus in knock-out mice. Interestingly, transcription was largely unaffected by CYP46A1 loss in young animals at post-natal day 45, possibly due to the high cholesterol demands in the brain after birth. Conversely, at post-natal days 100 and 365, transcription of various genes involved in cholesterol metabolism was depressed in knock-outs compared to wild-types. Gene set enrichment analysis revealed that transcription of cholesterol biosynthesis pathways were downregulated in the hippocampi of adult and aged CYP46A1 knock-out mice. LXR target genes were largely unaffected throughout all age points, with the exception of ABCA1, which was unexpectedly upregulated in CA1 at P100 and P365. Our

results confirm an earlier study that suggests that constitutive 24S loss does not alter LXR target genes in a predictable manner. Our work adds distinct developmental and sub-region effects to the transcriptional consequences of 24S deletion. It appears that excess cholesterol in the brain causes delayed downregulation of its own synthesis through an unknown mechanism, warranting further investigation.

Title: Short term caloric restriction in mice attenuates age related increases in calcium buffering of basal forebrain neurons

Authors: *E. BANG, A. FINCHER, S. NADER, D. A. MURCHISON, K. S. MONTOGOMERY, W. H. GRIFFITH;
Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Age is the greatest risk factor for acquiring Alzheimer's disease and related dementias and the resulting cognitive impairment is a major contributor to a decreased quality of life in the aging population. Extensive pharmaceutical efforts to address this problem have not produced effective treatments. Recent studies have shown the potential of dietary regimens to support healthy aging. The data presented here are part of a project to study the effects of caloric restriction (CR) on age-related cognitive decline, intracellular $^{Ca2+}$ homeostasis and synaptic transmission in the mouse basal forebrain (BF). Previously, we have shown that an age-related increase in intracellular $^{Ca2+}$ buffering in the rat BF is associated with altered spontaneous synaptic transmission and cognitive impairment. This change in buffering is prevented by post-adolescent life-long CR. Here, we investigate whether intermittent fasting (IF), a form of CR, alters age-related changes in BF physiology and behavior in a mouse model. We will use both young (3-7 mo) and aged (20-24 mo) mice and alternate day fasting/ad libitum feeding for 4-6 weeks as an IF protocol with age-matched ad lib. fed controls. Experiments are in progress to study cognitive abilities (Barnes Maze), intracellular calcium buffering and synaptic transmission. After IF, aged mice showed reduced body weight compared to aged controls (8% after last feeding day and 15% after last fasting day). IF aged mice were observed to binge on feeding day, and food intake per feeding day increased 68% compared to aged control. However, total food consumption was reduced by 25% in IF mice relative to aged controls. We assessed

intracellular $^{Ca2+}$ buffering in acutely dissociated neurons of the medial septum/diagonal band using a non-invasive method that leaves native buffers intact. Fura-2 was loaded into the neurons by the AM method and $^{Ca2+}$ transients were stimulated by increasing durations of picospritzer applied depolarizing solution (HEPES-buffered saline + 20 mM K^+). Relative buffering slopes for each cell were generated by plotting the calibrated amplitude of transients against the stimulus duration (x10). Smaller slopes indicate greater buffering. Slopes were: for young controls 67.4 ± 4.5 (n=44); aged controls 35.6 ± 4.2 (n=39); and for aged IF 50.6 ± 5.9 (n=38). Young and aged IF slopes were significantly greater ($p<0.05$) than aged control slopes, but were not different from each other. These data suggest that short-term IF can reverse the increased $^{Ca2+}$ buffering observed during aging in mouse BF.

Title: Chemogenetic activation of orexin/hypocretin neurons ameliorates aging induced changes in behavior and energy expenditure

Authors: *J. PALLAIS, Jr[1], M. STANOJLOVIC[1], V. MAVANJI[2], C. M. KOTZ[1,2];
[1]Integrative Biol. and Physiol., Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Minneapolis VA Hlth. Care Syst., Minneapolis, MN

Abstract: Aging is a complex and multifactorial process that reduces the overall quality of life, life expectancy, and ultimately leads to death. Aging is known to affect numerous physiological processes in addition to behavior. Many of the processes affected by aging are at least partially regulated by orexin neurons in the lateral hypothalamus. In this study, it was hypothesized that stimulation of orexin neurons would ameliorate the adverse effects of aging on metabolism and behavior. To test this, young and middle-aged mice were prepared with DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) in orexin neurons. DREADD targeting was achieved by stereotaxic injection of AAV vectors (AAV2-hSyn-DIO-hM3D(Gq)-mCherry) into the lateral hypothalamus, which contains the orexin field, of 5 and 12 month old orexin-cre female mice. The DREADD targeting was then confirmed by immunohistochemistry (IHC) analysis of orexin A and mCherry expression. After recovery from the procedure, the animals

were subjected to several behavioral assays that include the elevated plus maze (EPM), open field test (OFT), and the novel object recognition test (NORT). These assays were used to assess the effects of aging on general locomotion, anxiety-like behavior, and working memory. To measure spontaneous physical activity (SPA) and energy expenditure (EE), a comprehensive laboratory animal monitoring system (CLAMS) was used. The results indicate that chemogenetic activation of orexin neurons ameliorates aging-induced reductions in anxiety-like behavior in middle-aged mice ($p<0.005$) as well as increases general locomotion in both young and middle-aged mice ($p<0.05$). Chemogenetic stimulation of orexin neurons increases SPA ($p<0.01$) and EE ($p<0.005$) in middle-aged mice, restoring SPA and EE to the levels observed in young animals. These data demonstrate that orexin neurons have neuromodulation potential and can be used as potential therapeutic targets for age-related impairments in cognitive and anxiety-related behavior, and energy balance.

Title: The characterization of neuronal pexophagy *in vitro*, and in an *in vivo* model of brain aging

Authors: ***N. UZOR**, J. MORUNO MANCHON, D. MORALES-SCHEIHING, C. R. REYNOLDS, J. STEPHENSON, A. F. MACK, L. D. MCCULLOUGH, A. S. TSVETKOV; McGovern Med. Sch., Houston, TX

Abstract: Aging in the brain leads to the gradual impairment of pathways involved in organelle and protein turnover. Previous research shows that the turnover of organelles (like mitochondria) changes with age, but it is unclear if the turnover of peroxisomes, related structures that metabolize fatty acids, and both produce and break down reactive oxygen species, is explicitly affected.
To answer this question, we first investigated pexophagy - the selective autophagy of peroxisomes - in cultured primary neurons. We transfected a cohort of embryonic rat neurons with Keima-per, a fluorescent protein tagged to peroxisomes that changes its excitation and emission based on pH, and an empty plasmid. Analysis of Keima-per acidic fluorescence (an

indicator of peroxisomes that are degraded in acidic lysosomes) revealed that 1) neuronal pexophagy is basally active, and that 2) neuronal pexophagy occurs faster than neuronal mitophagy.
Pex5 is a protein necessary for pexophagy to occur, so, next, we investigated how neuronal aging affects Pex5 *in vivo*. Using Western blotting and qRT-PCR, we analyzed the whole mouse brain; with immunohistochemistry, we analyzed the cortex and hippocampus. We discovered that 1) global Pex5 protein levels are lower in the aging mouse brain compared to younger brains (n=5, young v. aged males $P<0.05$, young v. aged females $P<0.01$), that 2) *Pex5* gene expression is lowered in the aged mouse brain, particularly in the male mouse brain (n=5, young v. aged males $P<0.01$), and that 3) in preliminary IHC data, Pex5 protein levels are lowered in aged mouse neurons in both the cortex and hippocampus. From these results, we conclude that aging abnormally influences Pex5, a critical regulator of pexophagy. These findings identify pexophagy as a future target for improving homeostasis in neuronal aging.

Title: Histone methyltransferase inhibition attenuates H3K9me3 elevation and synaptic dysfunction caused by oxidative stressors

Authors: *A. IONESCU TUCKER[1], L. TONG[1], N. C. BERCHTOLD[2], K. TSEUNG[3], C. W. COTMAN[1];
[1]UC Irvine, Irvine, CA; [2]Univ. California Irvine, Irvine, CA; [3]Scripps Col., Claremont, CA

Abstract: Age is the number one risk factor for cognitive decline, and recent findings show that age-related repression of gene expression plays a role in compromising learning and memory. Our lab has previously found that a specific repressive epigenetic mark, histone 3 lysine 9 trimethylation (H3K9me3) is increased in aged mice and humans. We repressed H3K9me3's catalyzing enzyme (SUV39H1) with a selective inhibitor called ETP69, and found that it

increased hippocampal BDNF levels, hippocampal spine density and cognition in aged mice. We predicted that hippocampal H3K9me3 and coincident neuronal impairments are upregulated by age-associated stressors. Oxidative stress is a key contributor to brain aging, so we investigated if oxidative stressors, such as amyloid beta oligomers and the catalase inhibitor 3-amino-1,2,4-triazole (3AT), elevated H3K9me3 levels. We found that both amyloid beta oligomers and 3AT led to an increase in H3K9me3 without affecting cell survival in rat hippocampal neuron cultures. Amyloid beta oligomers further reduced levels of the synaptic marker PSD-95, while 3AT reduced levels of the glutamate receptor GluR1, thus impairing synaptic plasticity. Concurrent treatment with ETP69 and optimized doses of oxidative stressors attenuated synaptic impairments and H3K9me3 elevation. Our data reveal that catalase inhibition and amyloid beta oligomer treatment cause SUV39H1 dependent epigenetic changes and synaptic dysfunction which can be prevented by ETP69.

Title: Interacting, subject-specific, and accelerated aging-related features of the human choroid plexus

Authors: M. J. NEEL, B. A. JOHNSON, I. NGUYEN, N. L. VUKALOVICH, B. H. NGUYEN, Z. MUTTALIB, *E. S. MONUKI;
Pathology & Lab. Med., UC Irvine Sch. of Med., Irvine, CA

Abstract: The choroid plexus (ChP) contributes to central nervous system (CNS) homeostasis through its function as an immune cell gateway, production of cerebrospinal fluid (CSF), and blood-CSF barrier formation. Despite these functions, the ChP is a relatively understudied tissue. In particular, aging and disease-related features of the ChP, including fibrosis, oncocytic transformation, lipid vacuoles, and Biondi amyloid inclusions lack thorough characterization. Studying these features can help us understand ChP dysfunction in aging and disease and help validate disease models using stem cell-derived ChP cells. In our ChP studies, we came across a pediatric case with undiagnosed type I diabetes that presents all four features. This case contains clusters of Biondi inclusions throughout the ChP, a feature previously seen only in adults. To

study the Biondi inclusions further, we histologically studied human ChP autopsy samples from the pediatric case and from adult and Alzheimer's disease (AD) cases. We used a novel whole-mount thioflavin S staining protocol to visualize Biondi inclusions in three dimensions for blinded counting and categorization into distinct morphologies. We detected several distinct morphologies not previously described. Relative distributions appeared consistent across multiple regions from the same case, except for the pediatric case, but varied across different cases. Inclusions also appeared fragmented when present in oncocytic cells. Our results suggest that Biondi inclusions can occur in ages much younger than previously reported, possibly in relation to stressors such as those present in diabetes, and suggest that Biondi inclusions and their interactions with other features are more varied and complex than previously thought.

Title: Effect of chronic ozone exposure on object-place recognition task and dendritic spines of CA1 neurons

Authors: *P. C. BELLO-MEDINA[1], R. A. PRADO-ALCALA[2], S. L. RIVAS-ARANCIBIA[3]; [1]Dept. de Fisiologia, Facultad de Medicina-UNAM, UNAM, Mexico; [2]Inst. de Neurobiología-UNAM, Queretaro, Queretaro, Mexico; [3]Facultad De Medicina, UNAM, 04510 Mexico DF, Mexico

Abstract: Currently, the increase in the amount of atmospheric pollutants such as ozone, produces reactive oxygen species (ROS), which cause oxidative stress throughout the body, causing an increase in the number of people with respiratory and neurodegenerative diseases. The purpose of this research was to evaluate whether chronic exposure to ozone produces a deleterious effect on object-place recognition task and on density and morphology of dendritic spines in CA1 of dorsal hippocampus. Rats were exposed to ozone (0.25 ppm) or to ozone-free air for a period of 15, 30, 60, or 90 days. Once the period of exposure to ozone was over, the

animals were trained in an object-place recognition task and were sacrificed immediately afterward. The brains were stained with the Golgi-Cox technique. The chronic oxidative stress produced a deficit in learning and in the retention of the object-place recognition task. Likewise, there was a decrease in the density of dendritic spines and in mushroom spine ratio, and an increase in stubby spine ratio in the pyramidal neurons of CA1. These results suggest that environmental contaminants affect learning and memory, which could be caused by the loss of inputs in the neurons of CA1 from dorsal hippocampus. We thank to Erika Rodríguez-Martinez, Gabino Borgonio-Perez, and Andrea C. Medina for their excellent technical assistance. Title: Modulation of antioxidant response and neuroinflammation in frontal cortex of demented vs. non-demented individuals with Alzheimer's neuropathology

Authors: *A. FRACASSI[1], O. ZOLOCHEVSKA[1], S. MORENO[2], G. TAGLIALATELA[1]; [1]The Mitchell Ctr. for Neurodegenerative Diseases, Dept. of Neurol., Univ. of Texas Med. Br., Galveston, TX; [2]Science-LIME, Univ. Roma Tre, Rome, Italy

Abstract: Alzheimer's disease (AD) is characterized by progressive neurodegeneration in the cerebral cortex, histopathologically hallmarked by amyloid β (Aβ) extracellular plaques and intracellular neurofibrillary tangles, constituted by hyperphosphorylated Tau protein. Correlation between these pathological features and dementia has recently been challenged by the emergence of "Non-Demented with Alzheimer's Neuropathology" (NDAN) individuals, cognitively intact despite displaying pathological features of AD. The existence of these subjects suggests that some unknown mechanisms are triggered to resist Aβ-mediated detrimental events. Notably, Aβ accumulation affects mitochondrial redox balance, increasing oxidative stress status, which in turn is proposed as a primary culprit in AD pathogenesis. To clarify the relationship linking Aβ,

oxidative stress and cognitive impairment, we performed a comparative study on AD, NDAN and normally-aged human *post-mortem* frontal cortices. We quantitatively analyzed immunofluorescence distribution of 8-oxo-dG, as oxidative damage marker, and of SOD2, CAT, PGC1α, PPARα, as key factors in antioxidant response, as well as the expression of miRNA-485, as a PGC1α upstream regulator. Our results confirm dramatic redox imbalance, associated with impaired antioxidant defenses in AD brain. By contrast, NDAN individuals display low oxidative damage, associated with high levels of scavenging systems, possibly resulting from lack of PGC1α miRNA-485-related inhibition. Comparative analyses in neurons and astrocytes further highlighted cell-specific mechanisms to counteract redox imbalance. Furthermore, given the involvement of microglia in activating neuroinflammation and the scavenging function of activated microglia in the clearance of Aβ deposits, we addressed the expression and localization of such microglial/proinflammatory proteins (IBA1, CD68 and TREM2). Overall, our data emphasize the importance of transcriptional and post-transcriptional regulation of antioxidant response and neuroinflammation in AD. This suggests that efficient antioxidant "safety mechanism" and the modulation of neuroinflammation may prevent Aβ-mediated damage, supporting neuroprotective therapies aimed at ameliorating redox imbalance and neuroinflammation in AD patients.

Title: Clearance of senescent glial cells prevents tau-dependent pathology and cognitive decline

Authors: *T. BUSSIAN[1], D. BAKER[1,2];
[1]Biochem. and Mol. Biol., [2]Pediatric and Adolescent Med., Mayo Clin., Rochester, MN

Abstract: Cellular senescence is a state of irreversible cell-cycle arrest that is induced by a variety of intracellular and extracellular stress factors. Characterized by expression of $p16^{INK4a}$, a protein that inhibits cell cycle progression, senescent cells play a prominent role in the aging

process through their distinct, inflammatory, secretory phenotype. Indicators of senescence have been found in patients suffering from a variety of neurodegenerative diseases, but whether these cells play a role in these pathologies is unknown. Here we demonstrate a causal link between the accumulation of senescent cells and tauopathy-induced cognitive decline. Using the $MAPT^{P301S}$PS19 mouse model of tau-dependent neurodegeneration, we discovered that $p16^{INK4a}$-positive astrocytes and microglia accumulate prior to neurofibrillary tangle (NFT) deposition and neurodegenerative cognitive decline. Clearance of these cells with the INK-ATTAC transgenic mouse model prevented gliosis, hyperphosphorylation of soluble and insoluble tau, and NFT formation. Importantly, senescent cell removal also prevented the loss of neurons in the hippocampus and cortex, thereby preserving cognitive function. Pharmacological treatment with a first-generation senolytic also impacted tau aggregation. Collectively, these results indicate that cellular senescence plays a role in the initiation and progression of neurodegenerative tauopathies and suggest that these cells may provide a novel therapeutic avenue for disease treatment.

Title: Aquaporin-4 distribution correlates to increase in phosphorylated tau accumulation in sprague dawley rats fed a high fructose diet

Authors: P. WOLLER[1], *J. K. MORRIS[2];
[1]Neurosci. Program, [2]Biol., Baldwin Wallace Univ., Berea, OH

Abstract: According to the Center for Disease Control, 10% of the U.S. population has type 2 diabetes. Type 2 diabetes is a resistance to the presence of insulin in the bloodstream and occurs in adults over 45. In a person with type II diabetes, their cells utilize glucose in response to insulin in the bloodstream. Since neurons main energy source is glucose, this can have devastating effects on neurons and may result in neurodegeneration. Consumption of fructose may lead to a greater risk of diabetes. Individuals that consume fructose, convert the fructose into lipids or free fatty acids in the liver. The brain's glymphatic system is connected to major blood vessels in the brain covered by astrocytes that form a barrier between brain tissue and the blood. The aquaporin proteins are present in the astrocytic endfeet that surround the blood vessels and allow the fluid to enter and leave the brain. Inflammation and brain injury leads to a

redistribution of the aquaporin 4 channel from the endfeet to the cell bodies. Thus, disruption of the glymphatic system might lead to the accumulation of amyloid plaques. The glymphatic system is disrupted in streptozotocin (STZ) injected animal model of type II diabetes mellitus Since the STZ-model of diabetes can be toxic to animals and cause stress, we are seeking to compare this model directly to a fructose-fed rat model. Sprague Dawley rats were either fed a control diet (n=3) or a 60% fructose diet (n=2) for 12 weeks and then perfused and tissues were collected. Floating sections were stained for cresyl violet, phosphorylated Tau, or aquaporin-4 proteins and then analyzed with non-biased stereology using the Microbrightfield system on the Olympus BH2 fluorescent microscope. The area of the hippocampus was not altered between the control, STZ injected or 60% fructose-fed rats ($p > 0.5$) while the distribution of phosphorylated tau particle density increased 2.5-fold between the control and rats fed 60% fructose diet ($p<0.5$). Additionally, we identified a significant decrease ($p<0.5$) in aquaporin-4 protein distribution on blood vessels in control (3.1 +/- 0.2 positive vessels/mm2) compared to STZ induced diabetes (2.0 +/- 0.2) or fructose-fed rats (1.45 +/- 0.2). Thus, the accumulation of phosphorylated tau may be due to the decrease in the interstitial fluid clearance that may result from the redistribution of aquaporin-4 channels from the astrocytic endfeet surrounding the blood-brain barrier to the astrocytic cell bodies.

Title: Association of improved metabolic state and behavior in long-lived DGAT1-deficient mice

Authors: R. D. CARTER[1], L. LINQUEST[1], B. A. GRUETER[3], ***C. A. GRUETER**[2]; [2]Anesthesiol., [1]Vanderbilt Univ. Med. Ctr., Nashville, TN; [3]Anesthesiol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Lipids are recognized as signaling molecules that have the capacity to trigger profound physiological responses in processes of the central nervous system (CNS). Imbalances in lipid signaling networks may contribute to the pathogenesis of multiple disease states including obesity- and aged- related neuropsychiatric (stress) disorders. Evidence suggests that lipids, particularly triglycerides (TG, frequently elevated in obese and aged subjects), directly affect both energy homeostatic and reward processes by modulating hypothalamic and striatal circuits, respectively. Pathways of TG metabolism can provoke a complexity of cellular responses, depending on the metabolic state of the organism. Mice lacking the triglyceride

synthesis enzyme acyl CoA:diacylglycerol acyltransferase 1 (DGAT1) are long-lived, living 25% (mean) longer than controls, and are protected from age-related increases in body fat, tissue triglycerides, and inflammation. We hypothesized that leanness, with a concomitant improvement in the metabolic state of the organism, also protects against age-related changes in cognitive function and stress behaviors. Our findings suggest that *Dgat1*-deficient mice provide a model of leanness and extended longevity which can be utilized to enhance the understanding of the interaction between the metabolic state of an organism, cognition, and behavior.

Title: Nature-inspired hybrids as multi-target pharmacological agents: Antioxidant, neuroprotective and anti-inflammatory entanglement

Authors: F. FAGIANI[1], M. CATANZARO[2], M. M. SERAFINI[3], I. ROMANONI[2], F. BASAGNI[4], M. RACCHI[2], B. VIVIANI[3], R. MICHELA[4], S. GOVONI[2], *A. PITTALUGA[5], C. LANNI[2];
[1]Scuola Universitaria Superiore IUSS, Pavia, Italy; [2]Dept. of Drug Sci., Univ. of Pavia, Pavia, Italy; [3]Dept. of Pharmacol. and Biomolecular Sci., Univ. of Milan, Milan, Italy; [4]Dept. of Pharm. and Biotech., Univ. of Bologna, Bologna, Italy; [5]Univ. of Genova, Sch. of Med. and Pharma, Genova, Italy

Abstract: Nature offers a wide chemical diversity and provides a great source of therapeutics. By combining molecular fragments deriving from garlic and curcumin, we synthesized new nature-inspired hybrids targeting the nuclear factor (erythroid-derived 2)-like 2 (Nrf2)-pathway. Since data from literature suggest that several natural compounds exhibit antioxidant, neuroprotective and anti-inflammatory activities, we tested whether our molecules exert such effects in a view of multi-target pharmacological agents. To determine the potential interest of our hybrids as antioxidants, we investigated their protective effects against H_2O_2-induced oxidative damage and evaluated their potency in comparison to two reference molecules activating Nrf2, curcumin and dimethyl fumarate (DMF). The scavenging effect on reactive oxygen species (ROS) was evaluated by DCF-DA assay to quantify the intracellular ROS production. The expression of proteins involved in the antioxidant phase II response was examined by RT-PCR and Western Blotting (WB). To evaluate whether our molecules are capable to exert a neuroprotective action by modulating the brain-derived neurotrophic factor

(BDNF) levels, BDNF protein content was assessed by WB and its RNA expression byRT-PCR. Then, we compared the effects of our hybrids on BDNF content to curcumin, a reference molecule known to significantly increase it. Finally, to investigate the anti-inflammatory potential of our molecules, we investigated their protective effect against inflammatory response, induced by lipopolysaccharide (LPS), and compared their efficacy to curcumin. The anti-inflammatory action was determined by RT-PCR and ELISA test to assess the modulation in the expression and release of pro-inflammatory cytokines such as tumor necrosis factor-α and interleukin-8. Our results suggest that the hybrids protect against oxidative damage and affect the antioxidant response by modulating Nrf2 and its main targets. In addition, the hybrids exert antioxidant effects more actively than curcumin and DMF. Furthermore, a significant increase both in BDNF protein amount and mRNA expression was observed upon treatment with the hybrids. Moreover, the molecules significantly suppressed the LPS-induced increases in mRNA expression as well as the release of pro-inflammatory cytokines, with a higher potency compared to curcumin. Overall, our data demonstrate that our molecules exhibit antioxidant, neuroprotective and anti-inflammatory properties and provide evidence of their therapeutic potential as agents counteracting oxidative stress, neurodegeneration and inflammation by affecting the neuro-glial environment.

Title: Effects of chronic rapamycin on substantia nigra dopamine neurons in aging mouse brain

Authors: *I. PARIKH[1], M. TRZECIAK[1], M. J. BECKSTEAD[2];
[2]Aging & Metabolism, [1]Oklahoma Med. Res. Fndn., Oklahoma City, OK

Abstract: The aged population of the world is expected to more than double by 2050. Age related differences have been described in the context of neurodegeneration and cognitive decline; however, alterations that contribute to age-related motor deficits are less well understood. Dopamine neurons of the substantia nigra are necessary for the initiation of movement and are believed to decline in function with normal aging. Here we used rapamycin, a

life-extending intervention that inhibits the mammalian target of rapamycin (mTOR), to study the role of dopaminergic signaling in aging mice. We performed an electrophysiological and morphological comparison of substantia nigra dopaminergic neurons in which mTOR signaling was decreased by treatment with rapamycin. Female and male of 22 month old age mice were treated with control diet, low rapamycin (14ppm) diet, or high rapamycin (42ppm) diet for 16 weeks. Using whole cell voltage-clamp recordings, we found that low and high rapamycin treatment increased the amplitude of the HCN channel-mediated hyperpolarization-activated cation current I(h) when compared to control group. There were no obvious effects of rapamycin on spontaneous firing or pacemaking of dopamine neurons. Since mTOR also regulates neuronal growth and dendrite formation, we also conducted a detailed morphometric analysis of dopaminergic neurons by filling cells with neurobiotin and performing confocal imaging. Neurons from rapamycin-treated mice showed an increase in both soma size and neuritic branching consistent with returning to a younger phenotype. We also correlated electrophysiological and morphological measures to previously-obtained open-field locomotion in individual mice. Our findings suggests that some of the positive effects of rapamycin on healthspan could be due to the improvement of structural and functional parameters in single dopamine neurons in the substantia nigra.

Title: Sexual disparities of mitochondria-associated proteins in rat brain micro-vessels: Using tandem-mass-tags to elucidate metabolic phenotypes

Authors: S. CIKIC[1], P. K. CHANDRA[1], I. RUTKAI[1], J. C. HARMAN[2], J. J. GUIDRY[2], P. V. G. KATAKAM[1], *D. W. BUSIJA[1];

Abstract: Adverse changes in small cerebral blood vessels due to aging promote cognitive impairment, strokes, vascular dementia, and Alzheimer’s disease. The frequency and severity of these diseases, age of onset, and underlying mechanisms differ between men and women. The

mechanisms underlying cerebral micro-vessel (MV) diseases are not fully known but mitochondria in endothelium appear to play pivotal roles. In this study, we assessed the sex-dependent differential expression of mitochondria-related proteins in cerebral MVs, isolated from young male and female Sprague-Dawley rats. MVs with diameter < 70 μm were used to perform a 3-vs-3 quantitative-multiplexed experiment utilizing Tandem-Mass-Tags, coupled with Liquid Chromatography Mass Spectrometry (LC/MS). MVs were homogenized in a 1% SDS solution. Then MS sample prep was performed utilizing an offline fractionation procedure. MS data and bioinformatic analyses were performed using Thermo Fisher Proteome Discoverer version 2.2., and Panther Gene Ontology and Ingenuity Pathway Analysis, respectively. Simple Wes was used for validation of proteins of interest. Protein-Protein Enrichments/Interactions were analyzed to determine the top canonical and signaling cascades involved. Our dataset identified a total of 1,969 proteins, of which, 1,871 were quantified through the use of TMT labels. 64 proteins were found to be significantly ($p<0.05$) higher expressed in female samples compared with males. In general, males exhibited more mitochondria-destructive proteins. Overexpression of one of the pentraxins in male MVs might influences the translocation of proapoptotic proteins to the mitochondria. Increased expression of a monocarboxylate transporter and its chaperon protein in male MVs might be indicative of the inhibition of glycolysis, impaired oxidative phosphorylation, and/or reduced anaplerosis. Conversely, females expressed more mitochondrial membrane proteins, anti-oxidant enzyme proteins, and those involved in use of beta oxidation. Here we present the first comparison of brain MVs and characterize sexually dimorphic mitochondrial proteins. The top 5 canonical pathways that exhibit sex-based differences are mitochondrial dysfunction, oxidative phosphorylation, sirtuin signaling, TCA cycle, and EIF2 signaling. Our preliminary results suggest there are a considerable number of mitochondria-associated proteins enriched within MVs, many of which differ by sex. Overall, female rats appear to have more anti-inflammatory/pro-healing proteins associated with mitochondrial activity than their male counterparts.

Title: Analysis of kynurenine pathway metabolism in C6 malignant glioma cells

Authors: *G. I. VÁZQUEZ CERVANTES[1], B. PINEDA OLVERA[2], D. F. GONZALEZ ESQUIVEL[1], V. PEREZ DE LA CRUZ[1];

[1]Lab. de Neurobioquimica y Conducta, [2]Inst. Nacional De Neurologia Y Neurocirugia, Mexico City, Mexico

Abstract: The kynurenine pathway (KP) is the major route of tryptophan catabolism. The intermediary products of the KP have been described as relevant molecules of brain physiology playing important roles in neurodegenerative diseases, regulation of inflammation and immune response. Most recently, expression levels of indoleamine 2,3-dioxygenase (IDO), the rate limiting enzyme of the KP have been associated with the aggressiveness of some types of cancer including glioblastoma multiforme (GBM). GBM stands as the most frequent and the most aggressive of the primary brain tumors with a survival median ranging between 13 to 15 months despite of the conventional treatments. Immunosuppressive mechanisms exerted by GBM cells allow tumors to reach their growth rate and invasiveness. In this study we explored the KP metabolism in C6 cell line. $1^{x}10^{5}$ C6 cells and primary astrocytes were incubated with 100 µM tryptophan (Trp) or L-kynurenine (L-KYN) for 2h at 37 °C. After the incubation period kynurenic acid (KYNA), 3hydroxykynurenine (3-HK) and L-KYN levels were determined by HPLC. Astrocytes and C6 cells were not able to metabolize Trp. However, C6 cells metabolized 70% more L-KYN than astrocytes. KYNA levels were higher in astrocytes compared to C6 cells. 3-HK production was not detectable in astrocytes but was present in C6 cells. KAT II activity was higher in C6 cells vs. astrocytes. KMO expression was present in C6 cells but not in astrocytes, which correlated with the activity of KMO found in C6 cells. These data suggest that C6 cells show a KP metabolism different to the astrocytes primary culture, which can be related to alteration with the immune and metabolic reprogramming C6 cells.

Title: Effects of age on feeding response: Focus on the rostral C1 neuron and its glucoregulatory proteins

Authors: H. RAMLAN, ***H. A. DAMANHURI**;
Dept. of Biochemistry, Fac. of Med., The Natl. Univ. of Malaysia, Kuala Lumpur, Malaysia

Abstract: Older people are likely to develop the anorexia of aging. Previous research has shown rostral C1 (rC1) neurons in rostral ventrolateral medulla (RVLM) are responsible for the regulation of food intake. This study aims to determine the effect of age on the function of rostral C1 (rC1) neurons in mediating the feeding response. Male Sprague Dawley rats at 3-months (n=46) and 24-months (n=46) old were used and further divided into two subgroups; 1) treatment group with 2-deoxy-D-glucose (2DG) and 2) vehicle group. Feeding hormones such as cholecystokinin (CCK), ghrelin and leptin were analysed by enzyme-linked immunosorbent assay (ELISA). Rat brain was carefully dissected to obtain the brainstem RVLM region. Further analysis was carried out to determine the level of proteins and genes in RVLM that were associated with the feeding pathway. Protein expression of tyrosine hydroxylase (TH), phosphorylated TH at Serine40 (pSer40TH), AMP-activated protein kinase (AMPK), phosphorylated AMPK (phosphoAMPK) and neuropeptide Y Y5 receptor (NPY5R) were determined by western blot. Expression of TH, AMPK, and NPY genes were determined by real-time PCR. The localization of TH, AMPK, and NPY5R within the brainstem area were determined by the double immunofluorescence staining. This study showed that blood glucose level was elevated in young and old rats following 2DG administration. Plasma CCK-8 concentration was higher in the aged rats at basal and increased with 2DG administration in young rats, but the leptin and ghrelin showed no changes. Aging decreased AMPK-positive TH neurons. Old rats showed higher TH and lower AMPK mRNA levels. Glucoprivation decreased AMPK mRNA level in young rats and decreased TH mRNA in old rats. Aged rC1 neurons showed a higher NPY5R protein level. Following glucoprivation, rC1 neurons produced distinct molecular changes across age in which, in young rats, AMPK phosphorylation level was increased, and in old rats, TH phosphorylation level was unchanged. These findings suggest that glucose-counterregulatory responses by rC1 neurons contribute to the ability of young and old rats in coping glucoprivation. Age-induced molecular changes within rC1 neurons may attenuate the glucoprivic responses. This situation may explain the impairment of feeding response in the elderly.

Title: Treatment with exogenous adropin peptide improves age-related cognitive decline and neuronal health

Authors: *S. A. FARR[1], F. XU[2], M. L. NIEHOFF[3], R. JAYANTH[5], B. A. MERSMAN[6], A. A. BUTLER[4];
[1]Intrnl. Medicine/Geriatrics, St Louis Univ/VA Med. Ctr., St. Louis, MO; [2]Dept. of Biol., St. Louis Univ. Dept. of Biol., Saint Louis, MO; [3]Intrnl. Medicine/Geriatrics, [4]Pharmacol. and Physiol., St. Louis Univ. Sch. of Med., St. Louis, MO; [5]Biol., [6]St. Louis Univ., St. Louis, MO

Abstract: There is a clear, unmet need for developing new therapies against the neurodegenerative processes causing dementia, of which AD is the most prevalent. However, few treatment options are available for treating AD and other forms of dementia. Drugs approved for AD, and many in the development pipeline, are 'disease modifiers' that target neurotransmitters. For example, cholinesterase inhibitors (AChEI: donepezil, galantamine and rivastigmine) increase acetylcholine signaling and the N-methyl-D-aspartate-receptor antagonist memantine suppresses glutamatergic (excitatory) pathways. At best, these drugs either only produce modest improvements in cognition and daily activity or temporarily slow disease progression. They do not prevent progress of neurodegeneration and atrophy. Drugs affecting multiple target pathways may have a greater chance of producing significant delays in the progression of AD. Adropin is a natural neuropeptide that is expressed throughout the brain and high levels of expression are found in the hippocampus. We previously observed that transgenic C57/BL/6J (B6) mice over expressing adropin have delayed onset of cognitive deficits and reduced inflammation at 18 months of age compared to age matched controls. Here, we examined cognitive function of 18-month old male B6 mice administered adropin (90 nmol/kg by i.p. injection at 0900) for 4 wk. After two weeks of treatment mice were tested in T-maze, novel object recognition, activity and elevated plus maze. Aged C57/BL mice treated with adropin had improved learning and memory in T-maze ($P<0.0001$ in both acquisition and 1 week retention) and NOR with 24 hour delay ($P<0.05$), both hippocampal tasks. There were no differences in activity or anxiety between the two groups. To reveal the cellular mechanisms of adropin effects on hippocampus neurons, mouse hippocampal neurons were cultured in the absence or presence of adropin. Neurons treated with adropin exhibited a more robust neural development and network formation. In addition, acute addition of adropin to cultured neurons induced an increase in neuronal firing activity and elicited a rise in intracellular calcium. The positive effects of adropin on cognition and neural morphological development and functional network activity of hippocampal neurons indicate a positive role of adropin in learning and memory. These results suggest that adropin may be a potential drug treatment for age-related dementia.

Title: Etoposide induce mitochondrial dysfunction and cellular senescence in primary cultured rat astrocytes

Authors: *M. BANG, D. KIM, E. GONZALES, K. KWON, C. SHIN;
Konkuk Univ., Seoul, Korea, Republic of

Abstract: Brain aging is an inevitable process that is characterized by structural and functional changes and is a major risk factor for neurodegenerative diseases. Most brain aging studies are focused on neurons and less on astrocytes which are the most abundant cells in the brain and known to be in charge of various functions including the maintenance of brain physical formation, ion homeostasis, and secretion of various extracellular matrix proteins. Recent studies have reported that altered mitochondrial dynamics, defective mitophagy or mitochondrial damage led to mitochondrial dysfunction, which is linked to age-related disorders. In this study, we investigated mitochondrial dysfunction phenotypes in etoposide-induced astrocyte senescence model. Senescence-associated β-galactosidase (SA-β-gal) activity was used as a cellular senescence marker. Etoposide-treated astrocytes showed cellular senescence phenotypes including increased SA-β-gal-positive cells associated with increased nuclear size and senescence-associated secretory phenotypes (SASP) such as increased IL-6 expression. Decreased expression of cell cycle markers including phospho-H3/H3 and CDK2 were also observed as well as dysregulation of cellular functions which were observed in wound-healing, neuronal protection, and phagocytosis assays. Finally, mitochondrial dysfunction was noted through the determination of mitochondrial membrane potential using tetramethylrhodamine methyl ester (TMRM) and mitochondrial oxygen consumption rate (OCR) experiments. These data suggest that etoposide can induce cellular senescence and mitochondrial dysfunction in astrocytes which may play particular roles in brain aging and neurodegenerative conditions.

Title: A novel dynamic network imaging analysis method reveals aging-related fragmentation of cortical networks in mouse

Authors: *D. A. LLANO[1], C. MA[3], A. TAHERI[3], U. DI FABRIZIO[3], K. STEBBINGS[2], G. YUDINTSEV[2], R. V. KENYON[3], T. Y. BERGER-WOLF[3];
[1]Mol. and Integrative Physiol., [2]Neurosci. Program, Univ. of Illinois at Urbana-Champaign, Urbana, IL; [3]Computer Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Network analysis of large-scale neuroimaging data has proven to be a particularly challenging computational problem. In this study, we adapt a novel analytical tool, known as community dynamic inference method (CommDy), which was inspired by social network theory, for the study of brain imaging data from a mouse model of presbycusis. CommDy has been successfully used in other domains in biology; this report represents its first use in neuroscience. We used CommDy to investigate aging-related changes in network structure in the auditory cortex using flavoprotein autofluorescence imaging. Analysis of spontaneous activations in the auditory cortex of slices as well as in vivo images of the motor cortex taken from young and aged animals demonstrated that cortical networks in aged brains were highly fragmented compared to networks observed in young animals. Specifically, the degree of connectivity of each activated node in the aged brains was significantly lower than those seen in the young brain, and multivariate analyses of all derived network metrics showed distinct clusters of these metrics in young vs. aged brains. CommDy network metrics from slice data were then used to build a random-forests classifier based on NMDA-receptor blockade data, which successfully recapitulated the aging findings. CommDy therefore provides a new dynamic network analytical tool to study the brain and provides links between network-level and synaptic-level dysfunction in the aging brain.

Title: Assessment of central AMYR blockade in the regulation of peripheral versus central metabolism mechanisms in APP/PS1 mice

Authors: *R. R. CORRIGAN[1], J. GRIZZANTI[1], G. CASADESUS[2];
[1]Sch. of Biomed. Sci., [2]Biol. Sci., Kent State Univ., Kent, OH

Abstract: Metabolic dysregulation as in METS/T2D is a major risk factor for Alzheimer's disease development. Recent evidence highlights the potential therapeutic benefits of non-aggregating recombinant forms of the pancreatic hormone amylin in AD. However, whether these effects are mediated peripherally through the improvement of metabolic tone or centrally through direct amylin receptor (AMYR) activation is not known. Furthermore, conflicting evidence exists as to the benefits of AMYR agonism versus antagonism. To test this, APP/PS1 and wild-type littermate mice were chronically treated with amylin in the periphery under central inhibition of the amylin receptor using the AC187 antagonist delivered ICV. Here we show confirmatory data on the benefits of amylin on cognition and amyloid-beta pathology. Importantly, we also show that central delivery of AC187 impairs function and increases pathology; effects mitigated by peripheral administration of amylin. This is despite the ability of AC187 to regulate glucose tolerance; an aspect also normalized by peripheral delivery of amylin. Together our data demonstrate a potentially indirect mechanism, beyond AMYR activation, associated with therapeutic benefits of this drug while also identifying a potentially detrimental role of AMYR blockade in CNS function.

Title: The influence of sex and metabolism on the development of Alzheimer's disease

Authors: *J. GRIZZANTI[1], R. R. CORRIGAN[1], S. SERVIZI[1], G. CASADESUS SMITH[2]; [1]Sch. of Biomed. Sci., [2]Biol. Sci., Kent State Univ., Kent, OH

Abstract: One of the most prominent risk factors for the development of AD is metabolic disease, particularly type II diabetes (T2D). However, to date, how T2D leads to the AD development is unclear. In addition, sex-differences in the development of both T2D and AD make the evaluation of these underlying mechanisms more difficult. As such, we aimed to discern the temporal development of AD under diet-induced METS/T2D in both sexes and in WT and the APP/PS1 AD mouse model. Our data demonstrate a male specific vulnerability to metabolic disease in both WT and AD genotypes that mimics that observed in humans and an acceleration of the AD phenotype in females. Full transcriptome sequencing was performed on 3, 6, and 9-month-old male and female WT and APP/PS1 mice and revealed interesting differences that may reflect the basis for the sexual dimorphism in metabolic disease and AD in addition to temporal changes in the expression of genes associated with AD development. These data will be validated to provide potential novel therapeutic targets.

Abstract: Neurodegenerative diseases, such as Parkinson's disease, Multiple System Atrophy or Dementia with Lewy Bodies (LB) are characterized by accumulation of misfolded α-synuclein proteins. Cell to cell spreading of misfolded proteins may be considered as a hallmark in Prion-like diseases. Using disease-specific aggregates, extracted from patient's post-mortem brains, the PRIPRO project aimed at elucidating the cellular commonalities and specificities, as well as temporo-spatial development of each pathology. The first part of this project was dedicated to the evaluation of the toxicity of LB extracts collected from different patients (patient-specific) or different brain regions (brain structure-specific), injected stereotactically into the substantia nigra of wild-type mice. The second part of the PRIPRO project aimed at assessing the infectious nature of these pathological inclusions, using parabiotic pairing of wild-type mice. In both experiments, animals were sacrificed 4 months after stereotaxic surgery. Their brains were fixed and processed for immune-histological analysis. Similarities and differences between the pathologic triggers are evaluated in relation to: (i) the extent of the induced lesion in the nigrostriatal pathway, and (ii) the extent of synucleinopathy, focusing notably on phosphorylated-α-synuclein at Ser129. Our results suggest that Lewy Bodies collected from different brain areas do not yield the same extent of neurodegeneration, thus calling for a thorough differential characterization of the specific synuclein species present in post-mortem extracts collected from different patients and different brain regions.

Title: Sleep/wake activity in the Lewy bodies mouse model of Parkinson's disease

Authors: *G. PORRAS[1], **M. PERSILLET**[2], F. DECOEUR[3], B. DEHAY[2], A. NADJAR[3], E. BEZARD[2];

Abstract: Parkinson's disease (PD) is characterized by the loss of dopaminergic (DA) neurons of the substantia nigra pars compacta (SNc) and the presence of cytoplasmic inclusions named Lewy Bodies (LB) containing notably misfolded alpha-synuclein (α-syn). Although primarily a movement disorder, PD patients exhibit a myriad of non-motor symptoms. Sleep/wake alterations, such as rapid-eye movement (REM) sleep behavioral disorder (RBD), REM loss or increased day time sleepiness, may occur in the prodromal phase of PD. They are even considered as predictors of PD. While neurotoxin-based experimental models recapitulate both motor and non-motor symptoms, their poor face validity with regard to the neurodegenerative process make them unsuitable for investigating the likelihood of a relationship between progression of neurodegeneration, progression of the α-syn pathology and occurrence of sleep/wake issues. We here take advantage of the recently developed LB mouse model of parkinsonian degeneration to investigate the potential occurrence of sleep/wake deficits as the pathology develops. Wild-type mice were injected with LB, containing pathological α-syn, extracted from the brain of PD patients leading to a progressive loss of DA neurons (LB mice). Control mice were injected with a fraction devoid of aggregated α-syn, extracted from the same patients (NoLB mice). Mice were implanted with a device recording both cortical neuronal activity (ElectroEncephaloGraphy, EEG) and neck muscles contractions (ElectroMyoGraphy, EMG) enabling the discrimination of sleep/wake cycle stages: wake, non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Recording sessions were performed once a month for 48h over a 4-month period. Alteration of the sleep/wake cycles are detailed in both LB and NoLB mice with an emphasis put upon the changes in power band frequencies. Understanding if sleep disorders may serve experimentally as a surrogate marker of neurodegeneration or pathology progression could provide a way of early detection and lead to new therapeutic strategies to slow down its progression.

Title: High content screening of synucleinopathy in primary cortical neurons: Dissecting out the interplay between the basic synuclein pools

Authors: *W. MEISSNER, F. DE GIORGI, E. BEZARD, F. ICHAS;
Inst. of Neurodegenerative Dis., Bordeaux, France

Abstract: We set up a robust 96-well High Content Screening assay of synucleinopathy in primary cultures of cortical neurons. The initiation and spread of synucleinopathy in primary cultures of cortical neurons can be achieved by treating the latter with preformed fibrillar assemblies of recombinant synuclein (PFFs) and appreciated by immunofluorescence (IF) imaging. However, several barriers have slowed the adoption of this type of assay for screening purposes: (i) the ease and reliability of the isolation and culture protocols capable to insure long term survival (>21 DIV) of primary cortical neurons in a 96 well culture format, (ii) the batch-to-batch variability of artificial recombinant PFFs in terms of bioactivity, (iii) the relative lack of characterization of the anti-synuclein antibodies for a specific use in non-denaturing conditions such as IF imaging, and (iv) the absence of dedicated image analysis routines best serving the characterization of synucleinopathy in 2D neuronal cultures. We worked at raising specifically these 4 barriers by designing novel standard operating procedures and came up with a standardized assay system exploiting automation. The base High Content Screening assay was developped for WT mouse cortical neurons cultured in 96 well plates and challenged with specific human recombinant synuclein PFFs batches. In a first phase, the extent of synucleinopathy was quantified by imaging phosphorylated synuclein at S129. This assay was characterized by a Z' factor >0.5, and was thus successfully generalized to the other key basic synuclein pools (unstructured and alpha-helical monomeric, alpha-helical multimeric, and beta-strand oligomeric & fibrillar), as well as the study of the uptake and fate kinetics of the added PFFs. The assay was also successfully transposed to primary cortical cultures of transgenic mice and to primary cortical cultures transduced using AAV infections. In conclusion, these different assays can be routinely used to characterize the bioactivity of test-compounds.

Abstract: Aggregation of alpha-synuclein has been implicated in several neurodegenerative diseases, termed synucleinopathies, which include Parkinson's Disease (PD), Dementia with Lewy Bodies (DLB) and Multiple System Atrophy (MSA). These synucleinopathies are characterized by the deposit of alpha-synuclein aggregates in intracellular inclusions in neurons and/or glial cells. Unlike in PD and DLB, where these aggregates are located predominantly in neurons, MSA is associated with cytoplasmic inclusions of alpha-synuclein in oligodendrocytes. These glial cytoplasmic inclusions (GCIs) are the pathological hallmarks of MSA and are associated with neuroinflammation, demyelination and, ultimately, neurodegeneration. This study aimed at determining the potential to induce MSA pathology in non-human primates. To this end, we inoculated MSA-derived GCI fractions into the striatum of baboon monkeys that were terminated 2 years later. Extensive histochemical and biochemical analyses were performed on the whole brain and biological fluids to evaluate pathological markers known to be affected in MSA. We characterized the pattern of dopaminergic loss in the striatum and in the substantia nigra, the regional distribution of α-synuclein immunoreactivity in several brain structures (i.e.

within hippocampus, striatum, substantia nigra, and cortex), as well as its pathological state (i.e. S129 phosphorylation) and occurrence of intracellular inclusion formation, neuroinflammation and demyelination. Overall, we observed region-specific alterations in several brain areas related to MSA pathology. In conclusion, this study provides a potential new non-human primate model for MSA research.

Abstract: The search for diagnostic and/or progression surrogate biomarkers is of paramount importance. Skin fibroblasts retain specific environmental and aging history of patient making them a suitable model, reflecting the disease status and progression. Previous studies have studied alterations in growth, morphology and mitochondrial function in Parkinson's disease skin fibroblast. Here we measured the dry of fibroblasts from several pathologies using state-of-the-art phase microscopy.To determine the dry mass of fibroblasts obtained from apparently healthy individuals and patients, fibroblasts were obtained from biopsy of patients suffering from Parkinson's disease (genetic or sporadic cases), Huntington's disease, epilepsy, Rett syndrome, cystic fibrosis or familial adenomatous polyposis and cultured. A label-free technique, the quantitative phase microscopy using Quadriwave Lateral Shearing Interferometry, was used to allow a high-sensitivity observation of living fibroblasts and to determine their dry mass[2]. We detected changes in morphology and in dry mass according to disease-related fibroblasts.

Strikingly, we observed that Parkinson's disease fibroblasts mass was statistically very different from control fibroblasts mass.These data suggest that the variations in dry mass of skin fibroblasts may reflect molecular changes associated to a given pathological status.

Title: Genetic signature of early synucleinopathy in nigrostriatal dopamine neurons

Authors: *J. R. PATTERSON[1], C. J. KEMP[1], J. W. HOWE[1], M. F. DUFFY[1], A. C. STOLL[1], K. M. MILLER[1], J. S. BECK[1], S. E. COUNTS[1], K. C. LUK[2], C. E. SORTWELL[1]; [1]Michigan State Univ., Grand Rapids, MI; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Early phases of synucleinopathies, such as Parkinson's disease (PD), have been difficult to study as animal models often fail to recapitulate the protracted progression from inclusion formation and accumulation to neurodegeneration. The alpha-synuclein (a-syn) preformed fibril (PFF) synucleinopathy model in rats, however, exhibits distinct and predictable stages throughout the progression of the synucleinopathy. With the current parameters used in the PFF model, the number of phosphorylated a-syn (pSyn) inclusion-containing neurons in the substantia nigra pars compacta (SNpc) peaks between 1 and 2 months after injection. During this time, dopamine transporter (DAT) binding decreases in the axon terminal region of the nigrostriatal dopamine neurons (striatum) long before approximately 50% of TH-immunoreactive (TH-ir) SNpc neurons are lost by 6 months. In the present study, we leverage the pretoxic synucleinopathy stage to identify the genetic signature associated with early synucleinopathy in the SNpc.
Three-month-old male and female Fischer 344 rats received unilateral, intrastriatal injections of 16 total μg of sonicated mouse α-syn PFFs or an equal volume of vehicle (phosphate buffered saline). At 1 and 2 months post-injection, animals were perfused with saline, brains removed and flash frozen. Frozen sections (20 μm thick) from the SNpc were collected and rapidly immunolabeled for either TH or pSyn. Laser capture microdissection (LCM) was used to collect TH-ir neurons from vehicle-injected rats or pSyn-ir neurons from PFF-injected rats. Genomic

DNA was removed, total RNA isolated, and ribosomal RNA removed prior to pre-amplification and library preparation performed for RNA sequencing (RNASeq).
RNASeq results are pending and will be presented at the meeting. The goal of the sequencing is to identify novel genes and pathways associated with early synucleinopathy, preceding neurodegeneration, that may identify targets for genetic or pharmaceutical intervention to prevent or slow neurodegeneration.

Title: Longitudinal PET imaging reveals early and progressive deficits in striatal dopaminergic transmission induced by synucleinopathy

Authors: *C. E. SORTWELL[1], J. R. PATTERSON[1], C. J. KEMP[1], K. M. MILLER[1], A. C. STOLL[1], K. C. LUK[2], V. SOSSI[3];
[1]MIchigan State Univ., Grand Rapids, MI; [2]Univ. of Pennsylvania, Philaldelphia, PA; [3]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: We have previously optimized and characterized the magnitude of phosphorylated a-syn (pSyn) accumulation and nigrostriatal degeneration following intrastriatal injection of a-syn preformed fibrils (PFFs) into rats using immunohistochemical methods. Peak pSyn accumulation in the ipsilateral substantia nigra pars compacta (SNpc) occurs within 2 months with no associated loss of tyrosine hydroxylase immunoreactive (THir) SNpc neurons at this time point. Within 4 months post injection significant loss of ipsilateral THir SNpc neurons occurs (~35%) that progresses to ~50% degeneration by 6 months. In the present study we sought to examine the impact of a-syn PFF injections on dopamine transporter (DAT) binding and dopamine (DA) synthesis in the striatum using positron emission tomography (PET). Male Fischer 344 rats were injected unilaterally to the striatum with either a-syn PFFs or an equal volume of saline/site as a control condition. PET scans with both [18F] fluoro-3,4-dihydroxyphenyl-Lalanine (FDOPA: DA synthesis, storage and turnover) and 11C-methylphenidate (^{11}C-MP for DAT: DAT density)

were conducted at 2, 4 and 6 months post surgery. ^{11}C-MP PET revealed significant decreases in DAT binding in the ipsilateral striatum at 2, 4 and 6 months compared to controls. Within PFF injected rats, DAT binding reduction in the ipsilateral striatum progressed significantly over the course of 6 months. FDOPA imaging revealed progressive deficits in DA synthesis/storage in the ipsilateral striatum. DA distribution volume (EVDR - reflects DA release) was significantly reduced (suggesting an increase in DA turnover) at 2, 4 and 6 months compared to controls with reductions progressing over time. The largest magnitude of decrease was observed for DAT binding, followed by EDVR and DA synthesis/storage (~ 35%, 62% and 84% of controls at 6 months).These results provide the first *in vivo* evidence that a-syn inclusion-bearing nigrostriatal neurons undergo early axonopathy and degenerative changes in dopamine transmission prior to overt degeneration. The magnitude of FDOPA and ^{11}C-MP reductions resulting from PFF-induced synucleinopathy recapitulates the progression observed in early Parkinson's disease subjects. In addition, the relative reduction in DAT binding, DA effective distribution volume and DA synthesis and storage follows the same rank order as observed in humans, with DA synthesis being relatively preserved. This external PET validation of the progression of a-syn PFF induced nigrostriatal degeneration will facilitate preclinical assessment of novel disease-modifying therapies.

Abstract: The ideal animal model of Parkinson's disease (PD) should exhibit alpha-synuclein (a-syn) pathology, protracted degeneration of the nigrostriatal system and detectable sensorimotor impairments that result in a reproducible time course and magnitude. We have

previously optimized and characterized the magnitude of phosphorylated a-syn (pSyn) accumulation and nigrostriatal degeneration following intrastriatal injection of a-syn preformed fibrils (PFFs) into rats using immunohistochemical methods. Peak pSyn accumulation in the ipsilateral substantia nigra pars compacta (SNpc) occurs within 2 months with no associated loss of tyrosine hydroxylase immunoreactive (THir) SNpc neurons at this time point. Within 4 months post injection, significant loss of ipsilateral THir SNpc neurons occurs (~35%). By 6 months PFF-induced degeneration progresses to ~50% and is accompanied by modest deficits in contralateral forelimb use. In the present study we sought to examine the effect of increased striatal distribution and injection quantity of a-syn PFFs on sensorimotor and non-motor function related to PD. Male Fischer 344 rats were injected unilaterally in the striatum with a total of 24μg a-syn PFFs into 3 sites or an equal volume of saline as a control condition. Sensorimotor function was assessed using a battery of behavioral tests sensitive to varying degrees of SNpc neurodegeneration. Non-motor testing included assays for olfaction, emotional reactivity, and cognitive function. At 6 months post injection, PFF rats displayed significant movement and somatosensory asymmetries compared to control rats. Time to initiate a forelimb step and time to contact an adhesive stimulus on the forepaw were significantly longer for the contralateral limb compared to the ipsilateral limb. Further, hindlimb stepping in the cylinder was significantly reduced in PFF-injected rats compared to controls. Cognitive function was also affected in the PFF rats, with investigation time significantly decreased in an object recognition test. Levodopa reversibility and stereological analysis of SNpc degeneration are ongoing. Establishment of a-syn PFF surgical parameters resulting in motor and non-motor deficits will facilitate preclinical assessment of novel disease-modifying therapies.

Title: A model system in primary neurons used to identify new targets modulating seed-induced alpha-synuclein pathology using siRNA-based screening

Authors: *M. AMBJORN, N. DAMSGAARD, M. LUBAS, K. FOG;
Proteinopathy, Neurosci., H Lundbeck A/S, Valby, Denmark

Abstract: Synucleinopathies incl. Dementia with Lewy bodies and Parkinson's disease are characterized by the presence of inclusions rich in phosphorylated α-synuclein and ubiquitin (Goedert M. et al., JPD, 7 (2017) S51–S69 and Sampathu D.M. et al., Am J Pathol. 2003 Jul;163(1):91-100). Evidence suggest that pathological α-synuclein species may be released from neurons to seed aggregation in adjacent cells thereby propagating disease progression (Goedert M et al, 2017). To find new targets modulating disease progression it is important to build assays recapitulating relevant aspects of human PD pathology while retaining suitability for gene loss-of function screening. We show here that exogenous α-synuclein pre-formed fibrils (PFFs) made from recombinant human α-synuclein can "seed" primary cortical neurons from hSNCA Tg mice (F28), resulting in accumulation of endogenous detergent-insoluble α-synuclein, which is phosphorylated and partly ubiquitylated, as seen during PD. Using Accell siRNAs from Dharmacon that are passively taken up by the neurons due to a special modification, we can efficiently silence genes in the mouse neurons. By targeting hSNCA as a "proof of principle", we show that the PFF-induced α-synuclein pathology can be significantly reduced using this technique, suggesting that the assay has the potential to be used for new target identification screening. It is currently not clear which function ubiquitin add to pathological α-synuclein. One likely possibility is that it targets the pathological α-synuclein for degradation, suggesting that increasing its ubiquitylation by de-ubiquitylase (DUB) inhibition could be a feasible strategy for reducing the pool of pathological α-synuclein. Along this line, it has previously been shown that USP8 inhibition can decrease the pool of soluble α-synuclein (Alexopoulou Z. et al., PNAS, 2016 Aug 9;113(32)). We are currently using our model system to silence each of the ~100 DUBs present in the mouse genome and evaluate their loss-of function effect on pathological α-synuclein accumulation following seeding and to understand how the DUBs modulate a-synuclein ubiquitylation.

Title: Discovery of candidate therapeutics for Parkinson's disease by quantitative high throughput screening (qHTS) for compounds targeting α-synuclein expression

Authors: D. P. HUYNH[1], M. GANDELMAN[1], S. PAUL[1], W. DANSITHONG[1], E. AOYAMA[1], M. HENDERSON[2], S. KALES[2], A. ZAKHAROV[2], A. JADHAV[2], G. BANTUKALLU[2], A. SIMEONOV[2], S. PULST[1], ***D. R. SCOLES**[1];

Abstract: Objectives: To identify compounds lowering α -synuclein expression toward a therapy for Parkinson's disease. **Background:** Toxic gain of α-synuclein function is an underlying feature of Parkinson's disease (PD). We hypothesize that lowering SNCA expression will be therapeutic for PD. **Methods:** We used genome editing to place luciferase in frame after the *SNCA* gene in HEK-293, reporting SNCA expression under native expression control. We used this cell line assay to perform a quantitative high throughput screen (qHTS) to identify compounds that lower SNCA expression. Compounds were screened using a multiplexed cell viability assay to ensure target reduction in the absence of cytotoxicity. Compounds were counterscreened using a CMV-luciferase HEK-293 cell line and luciferase directly. Candidate compounds were tested for lowering SNCA expression in HEK-293 cells and PD patient derived skin cell fibroblasts using ELISA assays, western blotting, and quantitative PCR. The best lead compounds were evaluated for protecting PD fibroblasts against rotenone toxicity, and for lowering SNCA expression in PD patient induced pluripotent stem cell (iPSC) derived neurons. **Results:** Compounds from six libraries totaling 149,947 were screened at 4-11 doses each, with 24 hrs treatment. Z'-factors for all screens (by library) were >0.6. Four active lead compounds that lowered SNCA-luciferase expression with IC50 < 0.1 μM by ELISA were also protective in a rotenone toxicity assay. Of these, we placed our focus on one compound, a known inhibitor of AKT, that lowered SNCA in cultured iPSC neurons by nearly 50% following treatment with 0.1 μM for 48 hrs. **Conclusions:** This study identified an AKT inhibitor that potently lowered SNCA expression in all assays including PD relevant neurons. Further evaluation will include testing for modification of PD phenotypes in a mouse model of PD, and medicinal chemistry toward the development of a new therapeutic for PD. **Support:** Supported by a grant from the Michael J Fox Foundation and the NCATS intramural research program. Title: Insight into Parkinson's disease from yeasts: Combined impact of covalent modifications and familial mutations on α-synuclein

Authors: *Y. P. GANEV, R. THOMAS, A. ROMAN, C. MWALE, P. JONES, A. BALARAM, E. TCATURIAN, S. DEBBURMAN;
Lake Forest Col., Lake Forest, IL

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder linked to the loss of dopaminergic neurons in the midbrain. A key pathological marker of PD is the presence of Lewy bodies, which are composed of misfolded α-synuclein protein. α-Synuclein is a highly post-translationally modified protein, in healthy and diseased states. While phosphorylation and nitration of α-synuclein are well-studied as contributors to PD pathology, less is known about SUMOylation, acetylation, and glycation. Also, the combined effects of these modifications remain largely unclear, on both wildtype α-synuclein (linked with sporadic PD) and the six mutant forms (A30P, E46K, H50Q, G51D, A53T, A53E) linked with early-onset familial PD. We first evaluated the effects of blocking SUMOylation on α-synuclein in the well-established budding yeast model for PD and found that α-synuclein becomes more toxic and aggregated, losing its membrane localization. Second, we found that SUMOylation and phosphorylation counteract each other in toxicity and localization. Third, we expanded our investigation to two newly reported modifications - acetylation and glycation. We found that acetylation is protective and glycation is harmful. When we combined acetylation or glycation manipulations with SUMOylation and phosphorylation alterations on the α-synuclein level, we found that the effects of these modifications are not additive - the impacts of acetylation and glycation depends on phosphorylation status. Finally, we investigated the effects of the familial mutants in tandem with altered SUMOylation or glycation. We report two familial mutant-specific effects: G51D is surprisingly sensitive and toxic to hypo-SUMOlyation, while A53E is highly toxic to hypo-glycation. These studies show the relevance of covalent modifications in sporadic and familial PD, and their in-tandem effects that underlie toxicity mechanisms.

Title: Studying the effect of co-expression of α-synuclein and leucine rich repeat kinase 2 in modelling Parkinson's disease in *drosophila melanogaster*

Authors: *D. R. JHONSA[1], I. PADDIBHATLA[3], M. SARAF[2];
[1]Pharmacol., [2]Bombay Col. of Pharm., Mumbai, India; [3]Univ. of Hyderabad, Hyderabad, India

Abstract: Familial cases of Parkinson's disease (PD) is attributed to mutations in a number of genes of which α-synuclein (SNCA) and leucine rich repeat kinase 2 (LRRK2) are being studied extensively. Using *Drosophila* model organism these genes reported to exhibit selective loss of dopaminergic neurons and locomotor dysfunction. Point mutations in both the genes resulting in formation of aberrant proteins, changes in the level of expression of wild type genes are documented affect a number of cellular processes such as synaptic vesicle trafficking, lysosomal autophagic pathway, microtubule based transport, neurotransmitter release, inflammation and mitochondrial integrity. Therefore, study of the impact of the combined expression of SNCA and LRRK2 on neurons and glial cells using *Drosophila melanogaster* as the model system can be studied to mimic PD. Hence, we are using *Drosophila* model with GAL4/UAS expression system to express α- synuclein, leucine rich repeat kinase 2 and also their mutated forms (leucine rich repeat kinase 2 LRRK2, G2019S) in the neurons and the glia cells. We have assessed neurodegenerative phenotype by performing climbing assays and immunostaining dopaminergic neurons to observe neurodegeneration. Our data shows that expression of SNCA, LRRK2 and LRRK2 G2019S individually in a pan neuronal manner and specifically in dopaminergic neurons exhibits a premature decrease in climbing ability as compared to control flies. The study of the effect of expression of SNCA, LRRK2 and LRRK2 G2019S in glia as well as the generation of recombinant flies co-expressing SNCA and LRRK2 is on-going. By comparing the effect of individual and combined expression of SNCA and LRRK2 in all the neurons, glia and dopaminergic neurons we will be able to demonstrate whether the co-expression of SNCA and LRRK2 is able to mimic the pathophysiology of PD more effectively as compared to expression of the individual genes. This study can provide further insights into the pathophysiology of PD. The data obtained from this research investigation can contribute in the search for new therapeutic targets.

Title: Exploring anxiety-like behaviors and neurochemical changes in the line 15 alpha synuclein overexpressing Parkinson's disease model

Authors: *H. B. JANSSENS[1], L. YU[1], J. ROESER[1], A. RASSOULPOUR[1], T. CREMERS[2]; [1]Charles River Labs., South San Francisco, CA; [2]Dept. of Sci. and Engin., Univ. of Groningen, Groningen, Netherlands

Abstract: Anxiety and depression have been reported to preclude motoric symptoms in Parkinson's (PD) patients years prior to PD onset, suggesting a lengthy prodromal period with compensatory neural mechanisms. Therefore, we set out to assess anxiety-like behavior and examine the levels of aSYN and neurotransmitters [dopamine (DA), serotonin (5-HT), gamma-amino butyric acid (GABA), glutamate, acetylcholine (ACh) and tryptophan] in brain regions associated with anxiety of male B6 WT and hemizygous (TG) mice of Line 15, Tg(Thy1-SNCA)15Mjff/J (JAX) at ages 12 and 18 months.

To this end, anxiety-like behavior was assessed with the open field (OF), light-dark box (LDB), and elevated plus maze (EPM) paradigms in 12 and 18 month old male C57Bl/6 WT and Line 15 TG mice. *In vivo* microdialysis was carried out following the behavioral battery. Levels of aSYN in dialysate samples were analyzed via MSD® assays, and neurotransmitters were measured via LC MS/MS.

Motoric deficits were not observed in TG versus WT mice but a general decrease in mobility with age was noted. Interestingly, we found a lack of anxiety-like behavior in TG mice compared to WT in the EPM, OF, and LDB test. In fact, a significant increase in open arm entries were observed in Tg animals compared to age matched WT animals in the EPM. In the same animals basal aSYN levels were found to vary across brain regions at 12 months of age and were significantly higher than aSYN levels at 18 months of age. This pattern was also observed with the neurotransmitters DA, ACh and GABA, all of which were higher in younger TG animals as compared to older animals. No significant changes in 5-HT, tryptophan or glutamate were observed.

Overall, these results show that an animal model of PD that has elevated aSYN levels does not mirror the observed anxiogenic phenotype observed in patients. Interestingly, we do observe age related elevations of aSYN that may be driving elevations in DA, ACh and GABA. These neurochemical changes may also underlie the observed anxiolytic phenotype in the EPM, and other yet to be examined behaviors.

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder characterized by a loss of dopaminergic (DA) neurons from the substantia nigra pars compacta (SN) in the midbrain. A pathological hallmark of PD is the presence of cytosolic inclusions, called Lewy bodies, in surviving neurons. Lewy bodies are enriched with the presynaptic protein alpha-synuclein (aSyn). Although evidence suggests that aggregated forms of aSyn are involved in dopaminergic neuronal death, the mechanism by which aSyn forms neurotoxic aggregates in PD is not understood. Data obtained by our group and others suggest that a disruption of interactions between aSyn and phospholipid membranes leads to a shift to an 'exposed' conformation that favors aggregation of the protein at membrane surfaces. Results of biochemical and biophysical analysis have shown that the familial A53E aSyn mutant has an increased propensity to adopt an exposed membrane-bound conformation and undergo membrane-induced aggregation compared to WT aSyn. Recombinant adeno-associated viruses encoding WT aSyn, A53T, and A53E were injected into rat SN to evaluate PD behavioral and pathological endpoints. Expression of all three aSyn variants was found to cause a significant loss of TH^+ neurons and striatal terminals, as well as the formation of aSyn aggregates that stained positive for pSer129 and polyubiquitin in the SN. Current studies are focused on further characterizing aSyn aggregation in this *in vivo* model, including the spread of PD pathology to glial cells and additional brain regions. The results from these studies provide valuable insights into the molecular basis for the neurotoxicity of WT and mutant aSyn and shed light on a potential role for membrane-induced aSyn aggregation in PD

pathogenesis *in vivo,* thus setting the stage for developing therapies to prevent aSyn aggregation and slow neurodegeneration in PD.

Sciences: Office of Occup. Therapy, St. Louis Univ., Saint Louis, MO; [6]Psychogenics Inc., Paramus, NJ; [7]The Jackson Lab., Bar Harbor, ME; [8]Charles River, Ashland, OH

Abstract: Heterozygous mutations in the GBA1 gene, which encodes lysosomal glucocerebrosidase (GCase), are the most common genetic risk factor for Parkinson's disease (PD). In addition, decreased GCase activity has been reported in both genetic and sporadic cases of PD. Experimental evidence suggests a correlation between decreased GCase activity and accumulation of alpha-synuclein (aSyn). Thus, understanding the potential synergistic effect of increased aSyn and decreased GCase activity is important for understanding how alterations in GCase activity may contribute to or exacerbate PD-related pathology. To enable a better understanding of the relationship between aSyn and GCase activity, The Michael J. Fox Foundation (MJFF) has developed and characterized two mouse models allowing investigation of aSyn pathology in the context of reduced GCase activity. The first model analyzes the neurodegeneration/pathology induced through constitutive overexpression of wild type human alpha-synuclein directed by the murine Thy-1 promoter (hemizygous transgenic) in the context of the GCase activity-reducing D409V mutant form of GBA (homozygous knockin). The second model analyzes the level of nigrostriatal degeneration and synuclein pathology in the GBA D409V knockin model versus wildtype mice following stereotaxic injection of aSyn preformed fibrils into the striatum. Here, we outline and discuss the results of these model characterization efforts. Together, these models provide important platforms for understanding the mechanisms

underlying GCase and aSyn dynamics, and for evaluating therapeutics targeting this pathway/relationship.

Title: Utilizing an alpha-synuclein binding aptamer to prevent protein aggregation in an alpha-synuclein overexpressing cellular model of Parkinson's disease

Authors: K. VENTURA[1], S. BOISJOLI[2], J. CALLAHAN[2], V. HUNT[2], E. MCCONNELL[2], M. DEROSA[2], ***M. R. HOLAHAN**[1];
[1]Neurosci., [2]Chem., Carleton Univ., Ottawa, ON, Canada

Abstract: In Parkinson's disease, one hypothesis states that as misfolded native or mutant alpha-synuclein protein dimers become oligomers, they form insoluble aggregates that can trigger inflammatory, apoptotic, and other toxic signals that culminate in the death of neurons. Our goal is to examine whether a DNA aptamer targeted to bind to alpha-synuclein monomers will inhibit protein aggregation and reduce pathological outcomes such as inflammation, apoptosis and neuronal death. Aptamers are single-stranded functional nucleic acids, which form unique, 3-dimensional secondary structures that facilitate their binding with high affinity and selectivity to a cognate target. Aptamers for alpha-synuclein monomer and oligomer have been previously reported but were not selected specifically to inhibit fibril formation and have not been shown to inhibit aggregation *in vitro* or *in vivo*. We recently designed an aptamer (asyn-1) that inhibits alpha-synuclein aggregation and inhibit the formation of fibrils *in vitro*. Our recent work focused on 1) the identification of DNA aptamers that bound selectively to alpha-synuclein monomer to prevent alpha-synuclein aggregation and fibrilization and 2) the pharmacokinetic profile and biodistribution of systemic administration of the aptamer. To provide a more complete understanding of the dosing effects required for the aptamer to produce changes in alpha-synuclein biology, the effects of our asyn-1 aptamer were investigated in a transfected α-synuclein expressing SHSY-5Y cell line. We have confirmed that we are able to transfect the SHSY-5Y cells, observe phosphorylated alpha synuclein by immunostaining, and observe the

uptake of the a-syn-1 aptamer after administration either as a pretreatment, treatment at the time of transfection, or as a treatment following transfection of the virus. We are now in a position to determine whether: 1) we see reduced levels of α-synuclein protein following treatment with asyn-1; 2) asyn-1 prevents fibril formation over the long term; 3) there are any negative consequences of preventing aggregation by the aptamer such as soluble, toxic fragments that would infect other neurons. Results from these studies will be presented.

Title: Behavioral assessment of the 61SNCA mouse model of Parkinson's disease employing the NeuroCube system of movement analysis

Authors: A. EDWARDS, K. COX, K. CIRILLO, ***W. J. XU**, J. A. AVILA, S. RAMBOZ; Psychogenics Inc., Paramus, NJ

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder characterized by dopaminergic neuronal loss in the substantia nigra with accumulation of α synuclein containing Lewy bodies. A number of rodent models of PD have been created to recapitulate different aspects of the disease, among these the Line 61 animal, overexpressing the human wild-type alpha-synuclein driven by the murine Thy-1 promoter, in particular has been used extensively to model α synuclein pathology [Rockenstein et al, 2002]. While previous literature has characterized the male Line 61 mice and described a gradual disease progression, female counterparts of this model have been less well studied due to the linkage of the mutation to the X chromosome. In the present study, we performed a number of behavioral assessments in the female Line 61 including wire hang and tapered beam. We also employed a proprietary NeuroCube® assessment to evaluate quantifiable, subtle changes in patterned movement in these animals. This system records and calculates several aspects of ambulation and compares them to detect emerging movement impairments that may otherwise go unnoticed. Results suggest that a mild motor phenotype is present in the female Line 61 compared to both male Line 61 as well as WT counterparts. Implications of these findings as well as use of the NeuroCube® assessment as a tool in the evaluation of rodent models of disease are discussed.

Title: Early transcranial direct current stimulation ameliorates motor and cognitive dysfunctions in Parkinson's disease model of rats

Authors: *Y.-T. HUANG[1], X.-J. FENG[3], C.-W. KUO[1,4], T.-H. HSIEH[1,2,5];
[1]Sch. of Physical Therapy and Grad. Inst. of Rehabil. Science, Col. of Med., [2]Healthy Aging Res. Ctr., Chang Gung Univ., Taoyuan City, Taiwan; [3]M.D. Program for Rehabil. Med., Anhui Med. Univ., Hefei City, China; [4]Dept. of Life Sci., Natl. Taiwan Univ., Taipei City, Taiwan; [5]Neurosci. Res. Ctr., Chang Gung Mem. Hospital, Linkou, Taoyuan City, Taiwan

Abstract: Background: Parkinson's disease (PD) is a neurodegenerative disorder characterized by the motor and cognitive dysfunctions associated with pathological losses of the dopaminergic neurons (DA) in the substantia nigra. Non-invasive brain stimulation approach such as transcranial direct current stimulation (tDCS), has been developed for modulating cortical excitability which is considered having therapeutic potential in PD. However, the therapeutic value of such approach for PD is still unclear. Consequently, we adopted the PD rat model for elucidating the possible therapeutic effects in PD. **Methods:** A hemiparkinsonian rat model, induced by unilateral injection of 6-hydroxydopamine (6-OHDA) into the medial forebrain bundle (MFB), was applied to identify the therapeutic effects of tDCS in motor and cognitive behaviors following long-term tDCS treatment (300μ anodal tDCS, 20 min each day for 5 consecutive days per week) under awake conditions for 4 weeks. After tDCS intervention, the detailed functional behavioral tests including gait, akinesia, anxiety, depression, apomorphine-induced rotational analysis as well as DA degeneration level were assessed up to 4 weeks. **Results:** After tDCS intervention, we found that four-week tDCS intervention ameliorated motor and cognitive deficits in gait pattern, akinesia, anxiety, apomorphine-induced rotation, and depression behavior. Immunohistochemically, tyrosine hydroxylase (TH) analysis demonstrated that the dopamine neurons were significantly preserved. **Conclusions:** These results suggest that early and daily tDCS could reduce the aggravation of PD symptoms and exert the neuroprotective effect in a PD rat model. Furthermore, our result may enhance the potential use of tDCS and serve as a translational platform bridging human and animal studies in the development of therapeutic tDCS application for PD or other neurological disorders.

Hospital, Linkou, Taoyuan, Taiwan; [6]Dept. of Neurol. and Dementia Ctr., Chang Gung Mem. Hosp., Taoyuan, Taiwan

Abstract: Background: Parkinson's disease (PD) is the second most common age-related neurodegenerative disease. The pathologic hallmark of PD is the loss of nigrostriatal dopaminergic neurons, leading to functional motor and non-motor disabilities. Earlier studies have been reported that gastrointestinal symptoms occur not only in advanced PD but also in the early stage of PD. In this study, we investigated whether long-term probiotics may have the neuroprotective effects in dopaminergic nigrostriatal neurons and further alleviate the impairment of gait pattern, locomotor activity, balance and novel recognition memory in a chronic progressive PD model-the MitoPark mouse.
Method: Using a MitoPark mouse model, we utilized detailed gait analysis, beam walking, rotarod, novel object recognition and immunohistochemistry to test whether daily and long-term probiotics treatment improves motor and cognitive deficits.
Results: In results, under probiotics intervention over 16 weeks in MitoPark mice, we found that the probiotics treatment for 8-16 weeks significantly reduced motor and non-motor deficits in gait, balance and memory function. Immunohistochemically, tyrosine hydroxylase (TH)-positive neurons in the substantia nigra were significantly preserved in the probiotics treatment group at the end of probiotics treatment.
Conclusion: These results suggest that early and daily probiotics treatment exerts neuroprotection and reduces the aggravation of PD symptoms in MitoPark PD mouse model. Also, our data further highlight the potential therapeutic effects of probiotics and confirm the existence of a long-term effect of daily applications of probiotics that might be useful for further potential application of human PD subjects.

Abstract: Human embryonic stem cell (hESC)-derived ventral midbrain-patterned progenitors grafted into the dopamine-depleted adult rat brain survive long-term, mature into dopamine neurons, integrate synaptically with host neurons, and extend dopaminergic axons to fill functionally-appropriate target structures and reverse motor deficits. In the clinical setting, midbrain-patterned cells are grafted heterotopically into the striatum, rather than homotopically into the substantia nigra. To determine the factors dictating the appropriateness of graft integration into the host basal ganglia, we have compared the axonal outgrowth from and synaptic inputs to midbrain- and forebrain-patterned cells placed either in the striatum or the substantia nigra of dopamine-depleted host rats. We found that graft-derived axonal outgrowth to dopamine target regions depended on midbrain patterning of the transplanted cells, whereas the anatomical location of host cells making monosynaptic contact with graft neurons depended on the location of the transplant. Moreover, there was a significant anatomical and phenotypic overlap with regions known to regulate the function of intact midbrain dopamine neurons. These results suggested that grafts placed in the clinical location - heterotopically in the striatum - may nevertheless receive input from the brain regions in the host that project to the endogenous midbrain dopamine neurons in the substantia nigra. Conventional retrograde tracing performed concurrent to graft-initiated rabies tracing confirmed that grafts placed in the striatum in fact received synaptic input from individual neurons that maintained simultaneous collateral projections to the substantia nigra. In summary, our data shows that functionally-appropriate

subtypes of host neurons provide monosynaptic input to grafts, regardless of clinically-analogous heterotopic graft placement into the striatum.

Abstract: CNM-Au8 is a suspension of clean-surfaced, faceted nanocrystalline gold with unique nanocatalytic properties. CNM-Au8 efficiently converts the bioenergetic coenzyme nicotinamide adenine dinucleotide (NADH) to its oxidized form NAD+, resulting in elevated intracellular ATP levels, while independently lowering oxidative stress through superoxide dismutase-like catalytic activity. Multiple molecular lines of evidence point to bioenergetic failure as a significant contributor to dopaminergic neuronal death in Parkinson's Disease (PD). We therefore investigated the preclinical efficacy of CNM-Au8 to address manifestations of bioenergetic failure in *in vitro* and *in vivo* models of PD.
In rat dopaminergic neural-glial co-cultures, treatment with CNM-Au8 significantly increased total intracellular levels of NAD+. When co-cultured dopaminergic neurons were subjected to the neurotoxins MPP+ or 6-OHDA, CNM-Au8 treatment significantly preserved the neurite network and enhanced the survival of dopaminergic (DA) neurons ($p < 0.05$*). Importantly, CNM-Au8-treated DA neurons challenged with 6-OHDA resulted in the reduction of alpha-synuclein aggregates in a dose-dependent manner ($p < 0.05$*). In addition, CNM-Au8 prevented the accumulation of reactive oxygen species and prevented depletion of mitochondria observed with the application of MPP+ ($p < 0.05$*). *one-way ANOVA, CNM-Au8 vs. vehicle.
To determine the efficacy of CNM-Au8 *in vivo*, rats (N=12 per group) were administered CNM-Au8 or vehicle by gavage after unilateral lesion of the right striatum using stereotactic injection

of 6-OHDA. Animals were dosed daily with CNM-Au8 or vehicle starting on Day 1 or Day 14 post-injection. Both early (Day 1+) and late (Day 14+) treatment with CNM-Au8 showed contralateral paw placement improvement vs. vehicle control at Week 6 ($p=0.07$ and $p=0.006$ respectively, unpaired t-tests) in the vertical cylinder paw placement test. Early treatment with CNM-Au8 also reduced the number of apomorphine-induced rotations of lesioned rats at Week 6 by 42% compared to vehicle ($p=0.06$, unpaired t-test). Significantly, CNM-Au8 treatment outperformed L-Dopa/Carbidopa treatment in reduction of induced rotations in this assay.
In summary, CNM-Au8 demonstrated neuroprotective activity in *in vitro* assays and *in vivo* functional behavioral tests in the unilateral lesion model of PD. These data suggest that CNM-Au8, acting through an entirely novel catalytic mechanism resulting in an enhanced bioenergetic state, represents a promising new therapeutic strategy for PD.

Title: STN DBS reduces Lewy body-like alpha-synuclein inclusion formation triggered by intrastriatal fibril injection

Authors: ***K. M. MILLER**[1], C. J. KEMP[1], J. R. PATTERSON[1], A. C. STOLL[1], K. STEECE-COLLIER[1], K. C. LUK[2], M. R. KUBIK[1], C. E. SORTWELL[1];

Abstract: Whether deep brain stimulation (DBS) of the subthalamic nucleus (STN) is disease-modifying for Parkinson’s disease (PD) remains unclear. A hallmark of PD pathology is the progressive accumulation of alpha-synuclein (alpha-syn) inclusions (i.e.: Lewy bodies). To date,

only a single report has examined whether Lewy body pathology is impacted in PD subjects by DBS (PMID: 27911008). While no effect was observed, this study was limited by the 14-year disease duration prior to DBS, long after the establishment of Lewy body pathology. No preclinical study has examined whether STN DBS can prevent the formation of alpha-syn aggregates. The distinct alpha-syn aggregation phase in the alpha-syn pre-formed fibril (PFF) model can be leveraged to examine the impact of STN DBS on accumulation of Lewy body-like pathology. Our preliminary findings suggest that STN DBS in rats reduced the formation of alpha-syn aggregates by ≈30% ($p \leq 0.022$). In the present study we test the reproducibility of this finding. Thirty adult male rats received intrastriatal injections of alpha-syn preformed fibrils (PFFs) and were implanted with electrodes in the STN during the same surgical session. Three days later, animals were randomly assigned to receive either stimulation or no stimulation for a period of 30 days. Stereological assessment of nigral neurons possessing phosphorylated alpha-syn (pSyn), phosphorylated alpha-syn truncated adamant and reactive (pSyn*), and fibrillar alpha-syn (F2) inclusions served as the primary outcome measures. Quantification of tyrosine hydroxylase immunoreactive (THir) nigral neurons and examination of BDNF-trkB signaling (ELISA) are also being conducted. In a second cohort of animals we will evaluate whether neuroinflammation is impacted by STN DBS. Stereological assessment of ionized calcium-binding adapter molecule 1 (Iba1)-ir and major histocompatibility complex II (MHCII)-ir microglia will be the primary outcome measures. Collectively, our preliminary findings suggest that STN DBS may be disease-modifying by decreasing alpha-syn pathology.

Title: Astrocyte elevated gene-1 as an endogenous anti-apoptotic factor in nigral dopaminergic neurons *in vivo*

Authors: *E. LEEM[1], T. Y. KIM[1], U. J. JUNG[2], S. R. KIM[1,3];
[1]Sch. of Life Sciences, BK21 plus KNU Creative BioResearch Group, Kyungpook Natl. Univ., Daegu, Korea, Republic of; [2]Dept. of Food Sci. and Nutrition, Pukyong Natl. Univ., Busan, Korea, Republic of; [3]Brain Sci. and Engin. Institute, Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: We recently reported the protective role of astrocyte elevated gene-1 (AEG-1) in nigral dopaminergic (DA) neurons *in vivo*. Similar to decrease in the level of AEG-1 in the postmortem substantia nigra (SN) tissues from patients with Parkinson's disease (PD), the reduction of AEG-1 in nigral DA neurons was also observed in the 6-hydroxydopamine (6-OHDA)-treated mouse model of PD. In addition, AEG-1 upregulation using adeno-associated virus serotype 1 (AAV1) attenuated the 6-OHDA-triggered apoptotic death of nigral DA neurons in the SN of mouse brain. Furthermore, although the post-administration of AAV-AEG-1 alone after disruption of nigrostriatal DA system showed no neurorestorative effect, we observed that the maintenance of neuronal AEG-1 using AAV1 contributed to the intensification of neurorestoration such as behavioral recovery by post-treatment with a constitutively active form of ras homolog enriched in brain [Rheb(S16H)], which could induce axonal regeneration from damaged DA neurons in the 6-OHDA-treated animal model of PD. Collectively, these results demonstrated that the sustained level of AEG-1 as an important anti-apoptotic factor could potentiate the therapeutic effects of treatments, such as Rheb(S16H) administration, on the degeneration of the DA pathway that characterizes PD.

Title: Intracellular delivery of parkin protects dopaminergic neurons in brain-damaged animals

Authors: *E. CHUNG, W. NAH, Y. JUNG, J. PARK, S. SHIN, J. LEE, D. MIN, M. KWON, Y. CHOI, D. JO;
Cellivery, Seoul, Korea, Republic of

Abstract: Therapeuticmolecule systemic delivery technology (TSDT), a platform for the discovery/development of new medicinal drugs, is enabled with a new generation of hydrophobic cell-penetrating peptide (CPP), namely advanced macromolecule transduction domain (aMTD). The goal of this study is to develop aMTD-fused Parkin recombinant protein as a Parkinson's disease (PD)-modifying therapeutic agent. Parkin fused to aMTD524 shows the highest solubility, yield, homogeneity and cell-permeability of the fusion protein which is called improved cell-permeable (iCP) Parkin. As an E3 ubiquitin ligase, iCP-Parkin does not require phosphorylation of Ser-78 by PINK1, but is constitutively active regardless of conformational change of its structure. In addition, iCP-Parkin is able to be distributed into deep brain by

penetrating blood-brain barrier (BBB). iCP-Parkin has therapeutic effects in various PD animal models by utilizing its capabilities of BBB penetration and cytoprotective activity. In 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced PD mice, iCP-Parkin recovers motor function in swim (83%), wire (86%) and rota-rod (93%) tests, and thereby increase expression (74%) of tyrosine hydroxylase (TH) in dopaminergic (DA) neurons. iCP-Parkin also restores movement in pole test (80%) and TH expression (74%) in 6-hydroxydopamine (6-OHDA)-induced PD mice. Lastly, in α-Synuclein-induced PD mice, iCP-Parkin recovers the behavior defect significantly in the rota-rod test (92%) and TH expression (63%), plasma dopamine (50%), and also removes aggregated α-Synuclein (75%). Based on the data, iCP-Parkin may have a great therapeutic potential as a PD-modifying agent.

Title: Effect of chronic stimulation on the electrode tissue interface and electric field distribution of chronically implanted deep brain stimulation electrodes in the rat

Authors: *J. EVERS[1], K. SRIDHAR[1], J. LIEGEY[1], J. BRADY[2], H. JAHNS[2], M. M. LOWERY[3];
[1]Sch. of Electrical and Electronic Engin., [2]Sch. of Vet. Med., [3]Univ. Col. Dublin, Dublin, Ireland

Abstract: Changes at the electrode-tissue interface in response to implantation of chronic deep brain stimulation (DBS) electrodes including alterations in impedance, neuroinflammation and gliosis are well-established. However, the influence of stimulation on these processes has not been fully described. The aim of this study was to examine the effect of stimulation on the electrode-tissue interface of chronically implanted DBS electrodes in the rat subthalamic nucleus (STN), and to estimate the distribution of the resulting electric field in a finite element model. Bipolar concentric electrodes were implanted in the STN of 15 male Wistar rats (430g). 8 rats received DBS (130 Hz, 100 µA, 60 µs, 7 hrs/day) and 7 received no stimulation for 8 wks. Impedance spectroscopy (20 Hz - 300 kHz) was performed ≥3 times/wk. Brains were fixed by cardiac perfusion with 10% neutral buffered formalin. Astrocytes (GFAP), neurofilament and microglia (Iba-1) were labelled in 5µm sections by immunohistochemistry. Experiments were

approved (AREC 17-22) and licenced (HPRA AE18982-P122) in Ireland. The experimental impedance and histopathology data were incorporated in a3D heterogeneous finite element model based on the Waxholm Rat Atlas and the electrical field distribution around the electrode was estimated. Baseline impedance at 1 kHz was 24.5 kΩ ± 2.9 kΩ(SEM). Comparing complete 8 wk data sets (N=11) impedance at 1 kHz was significantly lower in the stimulation group than in the non-stimulation group (two-way repeated-measures ANOVA: Time and Interaction P&lt0.001, Stimulation P=0.02). An increase in astrocytes and microglia with activation was observed around tracts of stimulated electrodes compared to unstimulated electrodes. In the finite element model, the shape and magnitude of the electric field distribution for voltage-controlled stimulation were highly dependent on the electrical properties of the encapsulation tissue and electrode-tissue interface while the electrical field distribution in current-controlled stimulation was independent of these variables. In conclusion, differences in the impedance and histopathological properties of the electrode-tissue interface were observed between chronically stimulated and non- stimulated electrodes. These influenced the electrical field and thus the efficacy in activation of neural structures around the electrode in voltage-controlled stimulation.

Title: The lesion of the tail of the ventral tegmental area can compensate motor and non motor symptoms in a rat model of Parkinson’s disease

Authors: *M. BARROT[1], F. FAIVRE[1], S. DOVERO[2], S. BIDO[2], A. JOSHI[1], E. BEZARD[2], M.-J. SÁNCHEZ-CATALÁN[3];

Abstract: The death of the dopamine neurons of the nigrostriatal pathway contributes to Parkinson's disease. Both motor and non-motor symptoms, such as depression and pain, are present in this neurodegenerative disease. The tail of the ventral tegmental area or tVTA, also known as the rostromedial tegmental nucleus or RMTg, is a brain structure between mesencephalon and pons, that is mostly GABAergic and that exerts an inhibitory influence on dopamine neurons from the substantia nigra *pars compacta* (SNc). The tVTA can thus control the activity of dopamine systems and influence the functions of these systems. In this study, we assessed the consequence of removing tVTA control of dopamine systems in a model of Parkinson's disease. Behaviorally, these consequences were tested on both motor and non-motor symptoms. Male Sprague-Dawley rats with a partial and bilateral 6-hydroxydopamine (6-OHDA) lesion of the SNc had lower performance in the rotarod. We observed that this deficit was no more present after an excitotoxic co-lesion of the tVTA. Doing a larger behavioral characterization of the model, we also observed some non-motor symptoms following SNc lesion, such as lower body weight, lower mechanical and thermal nociceptive thresholds, and a decrease in sucrose preference in a 2-bottle choice paradigm. The co-lesion of the tVTA, using ibotenic acid, allowed antagonizing the body weight loss, as well as the changes in mechanical nociceptive thresholds and in anhedonia-like behavior. Together, these data further support the control exerted by the tVTA on dopamine system, and show that acting on this control may modulate the motor and non-motor symptoms secondary to a partial lesion of the substantia nigra.

Title: Driving neurons in a cell-type specific manner using electrical stimulation

Authors: *T. A. SPIX, B. R. ISETT, Y. GOKSEN, A. H. GITTIS;
Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Deep brain stimulation (DBS) is a highly effective treatment for parkinsonian motor symptoms, but its therapeutic effects decay rapidly if stimulation is discontinued. Recently, we showed that long-lasting motor rescue can be induced by optogenetic interventions that transiently dissociate the activity of two neuronal subpopulations within the external globus pallidus (GPe). Optogenetic interventions that elevated the firing rates of parvalbumin-expressing GPe neurons (PV-GPe) over those of lim-homeobox 6-expressing GPe neurons (Lhx6-GPe) produced long-lasting recovery of movement that persisted for hours beyond stimulation. To determine whether electrical stimulation can be tuned to achieve similar cell-type specific responses, we used acute brain slices to measure the physiological responses of PV-GPe and Lhx6-GPe neurons to electrical stimulation of the subthalamic nucleus (STN), the primary target for DBS. Synaptic recordings revealed that Lhx6-GPe and PV-GPe neurons receive excitatory and inhibitory synaptic inputs during stimulation, but while excitatory inputs were balanced onto both cell types, inhibitory inputs were larger onto Lhx6-GPe neurons. We hypothesized that this synaptic imbalance could be leveraged to convert non-specific electrical stimulation into a cell-type specific form of neuromodulation. Using a sparse matrix optimization strategy, we found that short, high-frequency bursts (<250ms, 100hz) were effective at elevating the firing rates of PV-GPe neurons while concurrently suppressing the firing rates of Lhx6-GPe neurons. With successive trials of short-duration, high-frequency stimulation, we further confirmed that PV neurons could be preferentially excited while Lhx6 neurons were preferentially inhibited in both dopamine-intact and dopamine-depleted animals. [MOU1] These results demonstrate that by tuning electrical stimulation parameters in the STN, it is possible to evoke cell-type-specific responses in the GPe that have previously been shown to be sufficient to induce long-lasting motor rescue. These results lay the groundwork for future translational studies of cell-type-specific neuromodulation in Parkinson's disease.

Title: Functional magnetic resonance imaging of optogenetic deep brain stimulation of the subthalamic nucleus in the hemi-parkinsonian rat

Authors: *Y. LI[1], S.-H. LEE[4], C. YU[1], T.-W. W. WANG[4], Y.-Y. I. SHIH[4], W. M. GRILL[1,2,3,5]; [1]Dept. of Biomed. Engin., [2]Dept. of Electrical and Computer Engin., [3]Dept. of Neurobio., Duke Univ., Durham, NC; [4]Ctr. for Animal MRI, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [5]Dept. of Neurosurg., Duke Univ. Sch. of Med., Durham, NC

Abstract: Deep brain stimulation (DBS) is an established therapy for the motor symptoms of Parkinson's disease (PD). Nevertheless, the underlying circuit mechanisms of DBS are still unclear, and this impedes the continued improvement of DBS therapy. To fill this gap, we scanned whole brain activity during different frequencies of DBS by combining function magnetic resonance imaging (fMRI) and optogenetic DBS. fMRI enables unbiased identification of brain regions and pathways that are responsible to the effects of DBS. Optogenetics further dissects the neural circuit by targeting specific cell types or pathways. We hypothesize that different brain regions are activated dependent on the DBS frequency, which is closely related to the therapeutic effects.

We scanned four female unilateral-6-OHDA-lesioned rats during optical-stimulation of the ipsilateral subthalamic nucleus (STN). We used an ultrafast opsin (AAV5-CaMKII-Chronos-GFP) to capture the frequency-dependent effects of therapeutic DBS. The 6-OHDA lesion and the expression of virus were validated by methamphetamine-induced circling behavior (before opto-DBS: 4.75 ± 1.29 cycles/min, during 130 Hz opto-DBS: 1.62 ± 0.44 cycles/min, n = 4) and histological examination. We obtained BOLD fMRI data using whole-brain isotropic EPI sequence in 9.4T Bruker MRI scanner (TR = 2000 ms, TE = 14 ms, matrix = 72 x 72 x 32, voxel size = 0.4 x 0.4 x 0.4 mm^3). Six repetitions of the optical-stimulation train including 10 s of stimulation and 20 s rest period block following an initial 10 s baseline period were applied on STN at different frequencies (5 Hz, 20 Hz, 75 Hz, 100 Hz, and 130 Hz; pulse width 1ms). We applied core preprocessing steps including slice timing correction, motion correction, reorientation of the brain into an in-house EPI brain template using AFNI software package. The stimulation-related activation map was estimated using a general linear model (GLM) framework.

The activation maps exhibited frequency-dependent changes in BOLD signals in ipsilateral GPe, SNr, and PTg (Pedunculotegmental nucleus) and peak changes of positive BOLD response during DBS above 100Hz ($\alpha > 0.05$ with FWE error correction, p-value < 0.05, voxel size > 40) while primary somatosensory(S1) and caudate putamen (CPu) showed negative BOLD changes during low frequency stimulation (5 and 20Hz). Our result suggests that the frequency-dependent effects of STN DBS are mediated by changes in the SNr and its downstream nuclei.

Title: The use of a macroporous biomaterial scaffold for differentiation and transplantation of dopaminergic neurons in treatment of Parkinson's disease

Authors: *A. FILIPPOVA[1], K.-H. KRAUSE[2], T. BRASCHLER[2];
[1]Pathology and Immunol., [2]Univ. of Geneva, Geneva, Switzerland

Abstract: Parkinson's disease (PD) affects an estimated 6 million people worldwide. Cell therapy aimed at replacing degenerating dopaminergic neurons with dopamine-producing cell grafts has been advancing and gaining popularity in recent decades. Transplantation of fetal mesencephalic tissue into the striatum of diseased patients has shown impovement of motor function. Recent research has focused on the transplantation of human pluripotent stem cell (hPSC)-derived grafts, as amplifyable, more ethically sound cell sources. For transplantation purposes, hPSCs are typically differentiated into neural precursor cells (NPCs) and transplanted as single cell suspention. The efficacy of the graft is then dependent on the neuronal maturation in vivo and the outcome may vary depending on the patients innate microenvoronment. Transplantation of mature dopaminergic neurons could help evaluate the functionality of the final graft and decrease the variability. However, it has so far been hindered by the fragility of neurons and neurites and their intolerance to the harsh handling procedures.
This project aims at evaluating a porous biomaterial scaffold as structural support for NPCs during maturation and transplantation. Such scaffold would allow pre-transplantation characterization of the final graft and preservation of integrity of mature neurons during surgery. We developed an adhesive surface, permitting neurites to attach and spread during differentiation. After differentiation of hPSC-derived NPCs on the scaffold, we observed an increased expression of dopamine neuron-specific markers (MSX1, LMX1A, PAX8, TH, EN1, MAP2). After passing the scaffold through an injection needle, we observed enhanced neuronal survival, decreased cell loss and preservation of neurite architecture, compared to trypsinized neurons, pre-differentiated on 2D culture plates.
Unlike the rapidly biodegradable encapsulating materials, studied for such application previously, the scaffold used here was shown to biodegrade within twelve months in vivo. Thus, upon in vivo injection we expect the scaffold to structurally support the architecture of the grafted neurons within this time. Unlike encapsulating materials, a macroporous biomaterial would allow pefusion of the scaffolds with innate neurotrophic factors and facilitate interaction

with the endogenous neuronal neural network. The in vivo experiments on the latter hypothèses are currently ongoing.
In conclusion, we anticipate that using a macroporous biomaterial would help further impove the efficacy and decrease the variability of the currently developing cell replacement techniques.

Title: Targeting the microbiome in the MPTP-lesioned mouse model of Parkinson's disease: Live biotherapeutic products (LBPs) demonstrate disease-modifying effects

Authors: S. CHETAL[1], P. RAVENSCROFT[2], A. ETTORRE[1], J. B. KOPRICH[2], ***M. P. HILL**[2], J. M. BROTCHIE[2], I. E. MULDER[1];
[1]4D Pharma Res. Ltd., Aberdeen, United Kingdom; [2]Atuka Inc., Toronto, ON, Canada

Abstract: The gut microbiome plays a vital role in host health and microbiome therapeutics have shown benefits in diseases ranging from IBD to oncology. There has been an interest in the role of the (microbiota)-gut-brain axis in Parkinson's disease (PD), supported by findings such as an altered gut microbiota composition, presence of α-synuclein in the gut, and gastrointestinal co-morbidities in PD patients. These findings have led us to investigate the development of novel, microbiome-based treatments as an appealing therapeutic strategy. 4D pharma is a clinical-stage microbiome company. Its proprietary MicroRx® discovery platform identified two live biotherapeutic products (LBPs), *Parabacteroides distasonis* MRx0005 and *Megasphaera massiliensis* MRx0029, for the treatment of PD. The ability of these two LBPs to protect against nigrostriatal dopaminergic deficits was assessed in the MPTP-lesioned mouse model of PD. Six groups (Groups 1 - 6) of animals were employed. Animals in Groups 1 and 2 were administered vehicle (PBS, *PO, QD*), while animals in Groups 3 and 4 were administered the LBPs (*PO, QD*) for 35 days (Day -14 - Day 21). Animals were administered vehicle (Group 1, 0.9% saline, *IP*) or MPTP (Groups 2 - 6, 20 mg/kg, *IP, BID*) for 5 days (Day 1 - Day 5). On Days 1 - 5, animals in Groups 5 and 6 were administered vehicle or a reference treatment, 7-nitroindazole (7-NI, 50 mg/kg, *IP*, *BID*). Animals were killed on Day 22. Striatal dopamine transporter (DAT) levels were quantified by autoradiography. Striatal dopamine (DA) and its metabolites (HVA and DOPAC) levels were quantified by LC/MS. Tyrosine hydroxylase positive (TH^+) cell number in the substantia nigra (SN) was quantified by immunohistochemistry and stereology. MPTP administration produced deficits in dopaminergic function such that in vehicle/MPTP administered mice, compared to vehicle/vehicle, the number of TH^+ SN dopaminergic neurons

was reduced by 46%, striatal DA was reduced by 77%, striatal DA turnover was increased by 154% and striatal DAT was reduced by 83% (all P<0.001). 7-NI protected against MPTP-induced losses in striatal dopamine (75% increase *cf.* vehicle/MPTP; P<0.001), striatal DAT (111% increase *cf.* vehicle/MPTP; P<0.001) and TH^+ nigral cell number (56% increase cf. vehicle/MPTP; P<0.001). MRx0029 protected against MPTP-induced loss in nigral TH^+ cell numbers (65% increase *cf.* vehicle/ MPTP; P<0.01), while MRx0005 protected against the loss of striatal DA and DOPAC to a similar degree as 7-NI. In conclusion, the LBPs MRx0029 and MRx0005 had a disease-modifying effect in the MPTP model. Further investigation is needed to fully elucidate their potential in the treatment of PD.

Title: Does high frequency stimulation affect astrocytes in a model of Parkinson's disease?

Authors: *A. CAMPOS[1], D. S. KIKUCHI[2], A. F. N. PASCHOA[1], M. A. KUROKI[1], B. LASSÈGUE[2], E. T. FONOFF[3], K. K. GRIENDLING[2], C. HAMANI[4], M. S. HERNANDES[2], R. L. PAGANO[1];

Abstract: Introduction: Despite its broad therapeutic application in the management of debilitating neurological symptoms, the underlying mechanisms of high-frequency stimulation (HFS), as used in deep brain stimulation (DBS), remain largely unknown. Recent reports suggest, reactive astrocytes, which can oscillate between pro-inflammatory (A1 subtype) or neuroprotective/anti-inflammatory (A2 subtype) phenotypes, may play a role in the development and progression of neurological diseases. Given the clinical importance of HFS, we investigated the effects of DBS/HFS on astrocyte subtype in an animal model of Parkinson’s disease and

cultured astrocytes. **Methods:** Male Wistar rats were injected with 6-hydroxydopamine (6-OHDA) or saline in the left striatum. Animals were implanted or not with stainless steel electrodes in the left subthalamic nucleus (STN). Seven days after the surgery, animals were evaluated using the apomorphine-induced rotation and the bar tests. On the 8th day, animals were divided into four groups: saline, 6-OHDA, 6-OHDA + DBS OFF and 6-OHDA + DBS ON. DBS ON animals were stimulated 2 hours a day for 5 days (130 Hz, 60 µs, 0.1 mA). After the last stimulation, animals were submitted to the bar test again. On the 12th day following 6-OHDA injection, GFAP immunostaining and cytokine expression (IL-1β, IL-6, IL-10 and IFN-γ) were evaluated in the globus pallidus (GP). For *in vitro* experiments, cultured astrocytes were stimulated with HFS for 6 h, and exposed to TNFα during the last hour (for IL-6 and MCP1 expression) or the last 15 min (for NFκ-B activation by IkB-α degradation and p65 nuclear translocation) of stimulation. *In vitro* conditions were as follows: no TNFα, TNFα + HFS OFF and TNFα + HFS ON. **Results:** The DBS-treated animals presented less immobility in the bar test, suggesting an improvement of motor deficit. Six-OHDA-induced increase in GFAP was modestly but significantly reduced by DBS in GP. DBS decreased IL-1β, IL-10 and IFN-γ expression in the GP. In our *in vitro* model, MCP1 expression and NFκB activation were decreased by HFS in astrocytes. **Conclusion:** Both 6-OHDA and TNFα administration induces inflammation characterized by an increase of cytokines. Here we suggest that DBS/HFS decreases 6-OHDA/TNFα - induced astrocyte classical A1 activation. This would reduce M1 microglia attraction by inhibiting MCP1 and attenuate the INF-γ/IL-10 imbalance. These findings contribute to our understanding of the role of astrocyte signaling in HFS. They suggest that DBS can reduce neuroinflammation and thereby improve neurodegenerative disorders.

Title: Inhibition of phosphodiesterase 10A upregulates gene expression in the striatum

Authors: F. PADOVAN-NETO, G. KUREK, R. BONATE, S. PATTERSON, F. ALTWAL, A. WEST, *H. STEINER;
Chicago Med. School/RFUMS, North Chicago, IL

Abstract: The effects of dopamine (DA) in striatal projection neurons are mediated by cyclic nucleotides (e.g., cAMP). Phosphodiesterases (PDEs) catalyze cyclic nucleotides and thus potently control cyclic nucleotide signaling. Cyclic nucleotide levels are dysregulated in animal models of Parkinson's disease (PD), especially during L-DOPA-induced dyskinesias (LIDs). Recent studies show that inhibitors of PDE10A, a phosphodiesterase highly expressed in the striatum, can attenuate LIDs in animal models, suggesting the utility of PDE inhibitors for modifying abnormal cyclic nucleotide signaling and reducing dyskinesias in PD. We used a PD model, rats with unilateral 6-OHDA lesions treated with L-DOPA (5 mg/kg + benserazide, 12.5 mg/kg; 3 weeks), to investigate the impact of the selective PDE10A inhibitor TP-10 (3.2 mg/kg, which attenuates LIDs) on cyclic nucleotide signaling, as indicated by cAMP-dependent gene regulation in the striatum. Effects on the expression of PDE10A itself and the "activity" markers dynorphin (DYN, direct pathway) and enkephalin (ENK, indirect pathway) were assessed by in situ hybridization histochemistry. These treatments had a minor impact on PDE10A expression: The 6-OHDA lesion modestly decreased PDE10A mRNA levels throughout the striatum, an effect that was attenuated by L-DOPA and somewhat enhanced by L-DOPA+TP-10 treatment. As shown before, DA depletion alone decreased DYN expression and increased ENK expression, while L-DOPA considerably increased DYN expression and slightly further enhanced ENK expression. The L-DOPA+TP-10 combination modestly further increased DYN and ENK expression in the DA-depleted striatum, but dramatically elevated DYN and ENK expression in the intact striatum. This increase was most robust in the sensorimotor striatum and was directly related to the level of PDE10A expression in different striatal regions, suggesting local drug action. L-DOPA-induced alterations in cyclic nucleotide signaling and gene regulation in striatal neurons are implicated in LIDs. Our results show that the PDE10A inhibitor TP-10, in a dose that attenuates LIDs, increases gene expression in both striatal output pathways. These molecular changes may contribute to the beneficial effects of PDE10A inhibitors in the treatment of LIDs.

Title: Therapeutic effects of cortical electrical stimulation on Parkinsonian rats

Authors: *K. CHI-WEI[1], C.-Y. PAN[1], Y.-Z. HUANG[2], T.-H. HSIEH[3];
[1]Natl. Taiwan Univ., Taipei, Taiwan; [2]Chang Gung Mem. Hosp., Taoyuan, Taiwan; [3]Sch. of

Physical Therapy and Grad. Inst. of Rehabil. Science, Col. of Med., Chang Gung Univ., Taoyuan, Taiwan

Abstract: Background: Parkinson's disease (PD) is one of the prevalent neurodegenerative disorder. The pathologic hallmark of the disease results from degeneration of the dopaminergic neurons (DA) in the substantia nigra (SN), several motor disturbances. Cortical electrical stimulation (CES) has been developed for modulating cortical excitability via plasticity-like mechanism and is considered having therapeutic potentials in PD. However, the therapeutic value of such approach for PD is still unclear. Accordingly, we adopted the PD rat model for elucidating the possible therapeutic effects of CES. **Methods:** A hemiparkinsonian rat model, induced by unilateral injection of 6-hydroxydopamine (6-OHDA) into the medial forebrain bundle (MFB), was applied to investigate the therapeutic roles of CES in motor functions following long-term CES treatment for 4 weeks. After CES intervention, the detailed functional behavioral tests including gait, bar test, open field, and apomorphine-induced rotational analysis as well as DA degeneration level were assessed up to 4 weeks. **Results:** After CES treatment, we found that 4 weeks of CES intervention ameliorates the motor deficits in gait pattern, akinesia, locomotor activity, and apomorphine-induced rotation. Immunohistochemistry, tyrosine hydroxylase (TH) staining analysis demonstrated that the dopamine neurons were significantly preserved. **Conclusions:** This study documents the efficacy of CES in preventing motor and dopaminergic system abnormalities in rat model of PD. This long-term CES treatment model may serve as a bridge between animal and PD human studies. Future preclinical studies are still needed to further identify the underlying mechanisms, leading to improve CES protocols and therapies in human.

Title: Characterization of 4L/PS-NA mice for different biomarkers to model Gaucher disease

Authors: S. FLUNKERT[1], S. SCHMIDT[2], T. LOEFFLER[1], V. NIEDERKOFLER[1], J. NEDDENS[1], M. POSCH[1], E. AUER[1], J. KEHR[2], *B. HUTTER-PAIER[1];

Abstract: Introduction: Gaucher disease is the most common lysosomal storage disease. The neuronal disease variant is characterized by protein accumulations in the brain and associated neurological manifestations. It is autosomal recessively inherited and modeled by 4L/PS-NA mice that express low levels of prosaposin and saposins, as well as a functionally impaired β-glucosidase (GCase) with a homozygous point mutation at V394L.
To use this model for compound tests against Gaucher disease a detailed characterization of these mice is needed. Thus, we analyzed the 4L/PS-NA mice for GCase activity, glucosylsphingosine (GlcSph) and glucosylceramide (GlcCer) levels as well as Neurofilament light chain (NF-L) levels and neuroinflammation over age.
Method: The GCase activity was analyzed using a commercially available GCase activity assay. GlcSph and GlcCer were extracted from brain homogenates by liquid-liquid extraction and the levels of GlcSph and GlcCer in the extracts were measured by ultrahigh-performance liquid chromatography coupled to tandem mass spectrometry. To explore Neurofilament light chain levels, the NF-Light® ELISA by UmanDiagnostics was used. For measurement of neuroinflammatory processes, in particular activated microglia and astrocytosis, immunofluorescent labeling on brain sections was performed.
Results: Analyses of enzyme activity show reduced GCase levels in 4L/PS-NA and also control mice compared to C57Bl/6 mice due to the mutation in GBA. The additional reduction of prosaposin and saposins leads to progressively increasing substrate concentrations in 4L/PS-NA mouse brains compared to control animals. Furthermore, 4L/PS-NA mice show strongly increased NF-L and neuroinflammation levels.
Conclusion/ Summary: 4L/PS-NA mice mimic the most prominent features of Gaucher disease suggesting that they are a good model to study the chronic neuronopathic type 3 Gaucher disease in humans.

Title: Using multimodal serotonergic drugs as adjunct treatments for Parkinsons's disease

Authors: *F. ALTWAL, A. RITGER, N. FALCAO VOELKNER, J. DHARGALKAR, R. MALIK, V. OLIVERA, A. WEST;
Rosalind Franklin Univ., North Chicago, IL

Abstract: Parkinson's disease (PD) is a devastating neurodegenerative disorder affecting over one million Americans. The gold standard treatment for PD is levodopa (L-DOPA), which is effective for increasing dopamine (DA) tone and improving motor dysfunction, but unfortunately produces debilitating motor side-effects termed L-DOPA-induced dyskinesias (LIDs). Recent studies in dyskinetic parkinsonian models have implicated serotonergic raphe-striatal terminals in the uptake and conversion of L-DOPA to DA, as well as the non-physiological release of DA and serotonin (5-HT) which may underlie the pathophysiological mechanisms of LIDs. Indeed, the utility of co-treatments with either selective 5-HT reuptake inhibitors (SSRIs) which block the 5-HT transporter (SERT), or selective 5-$HT_{1A/B}$ receptor (5-$HT_{1A/Br}$) ligands which stimulate 5-HT autoreceptors to potentially suppress DA release from 5-HT terminals, has been assessed in pre-clinical models and clinical trials. Many of the drugs tested were found to reduce LIDs, but unfortunately also reduced the prokinetic effects of L-DOPA. The goal of the current study was to identify a multimodal 5-HT drug which can act to attenuate the expression and severity of LIDs, without interfering with the antiparkinsonian efficacy of L-DOPA.
Vilazodone is of interest in this regard as it is known to exhibit a potent SSRI-like action, along with 5-HT_{1Ar} partial agonism property. Unilateral 6-OHDA-lesioned rats modeling PD were treated with either vehicle and L-DOPA (5.0 mg/kg), vilazodone (10.0 mg/kg) and L-DOPA, or escitalopram (12.5 mg/kg) and L-DOPA. Rats were treated for 5 consecutive days/week, for 2 weeks. On the second day of each week, stepping tests were performed prior to drug administration, and 60 minutes post L-DOPA treatment, to assess forelimb akinesia. Behavioral assessment of LIDs was performed (30-180 min) at the end of each week. Vilazodone pretreatment (30 min) significantly reduced LIDs in 6-OHDA lesioned rats, but had no effects on forelimb akinesia or L-DOPA-induced prokinetic effects. Escitalopram pretreatment also induced a significant reduction in total LIDs score but interfered with the therapeutic efficacy of L-DOPA. Electrophysiological studies were conducted to assess the impact of these treatments on corticostriatal transmission and striatal neuronal activity. The current results indicate that together with L-DOPA, multimodal 5-HT drugs such as vilazodone may be an efficacious co-therapies for reducing side-effects such as hyperkinesia (LIDs) in PD patients, potentially allowing for more flexibility in L-DOPA dose ranges and protracted chronic treatment.

Title: Anti-inflammatory properties of vagus nerve stimulation provide therapeutic potential for a Parkinson's disease model

Authors: *A. Q. FARRAND[1], L. APONTE-COFRESI[1], R. VERNER[2], R. M. MCGUIRE[2], H. A. BOGER[1];
[1]Neurosci. and Ctr. on Aging, Med. Univ. of South Carolina, Charleston, SC; [2]Neuromodulation division, LivaNova PLC, Houston, TX

Abstract: Vagus nerve stimulation (VNS) is known to have anti-inflammatory properties such as reduced pro-inflammatory cytokine production and reduced activation of glia and macrophages both in the periphery and in the central nervous system, thus providing a wide range of potential clinical indications for VNS. Chronic neuroinflammation is one of the mechanisms that contributes to cell damage in neurodegenerative diseases such as Alzheimer's and Parkinson's diseases. Recent studies from our lab have shown that in a double lesion (DSP-4/6-OHDA) rat model of Parkinson's disease two daily sessions of VNS for a 10-day period are sufficient to reduce neuroinflammation in the substantia nigra and locus coeruleus, thereby leading to improved neuronal health and reduced motor deficits. However, the ideal stimulation paradigm for this Parkinson's disease model remains to be determined. Therefore, the current work employs several sets of VNS parameters in this DSP-4/6-OHDA Parkinson's disease model to better characterize the relevant waveform features for this therapy. These parameters were chosen based on the hypothesis that pulse frequency and patterning can differentially regulate afferent and efferent vagal circuits. Our results indicate that higher stimulation frequencies provide greater benefits for motor function and neuronal health as measured by tyrosine hydroxylase expression in the substantia nigra and locus coeruleus, as well as reduced intrasomal α-synuclein accumulation in neurons of the substantia nigra. Studies are ongoing in the lab to assess neuroinflammation in these brain regions and levels of pro-inflammatory cytokines, acetylcholine, and norepinephrine in serum and in the central nervous system. These changes will indicate which pathways are activated by specific sets of VNS parameters, therefore helping to characterize each stimulation paradigm and determine which paradigm provides the greatest therapeutic potential for Parkinson's disease.

Title: Microbiota-targeted therapies delay age-dependent Parkinson's disease progression

Authors: *S. M. GARCIA, W. ZHOU, D. INGUITO, C. R. FREED;
Dept. of Med., Univ. of Colorado Anschutz Med. campus, Aurora, CO

Abstract: Current therapies for Parkinson's disease (PD) temporarily improve motor function but cannot impact disease progression. We have shown that oral butyrate treatments attenuate alpha-synuclein (aSyn) pathology in the brain and improve motor and cognitive deficits in an age-dependent transgenic (Tg) mouse model of PD. However, there are obstacles associated with oral butyrate treatments such as high volume dosing and drug cost. **Objective:** To bypass these obstacles, we have designed microbiota-targeted dietary inventions to increase endogenous butyrate production in the gut. Because butyrate has multiple neuroprotective and homeostatic functions in the brain and gut, our goal was to delay CNS and ENS pathological hallmarks of PD in mice. **Methods:** To determine if our microbiota-targeted interventions delay age-dependent CNS pathological hallmarks, 12-month Thy1-Y39C *SNCA* Tg mice were separated into treatment groups (n=6) based on rotarod performance and were treated with either sodium chloride (control), oral sodium butyrate (positive control), 10% prebiotic diet, or 10% synbiotic diet for 3-months. Disease progression was determined by behavioral and aSyn neuropathology outcomes. Rotarod and Morris water maze scores assessed motor and spatial learning abilities. To assess if our microbiota-targeted interventions improve pre-motor constipation and associated ENS aSyn aggregation, 1-month PAC-A53T *SNCA* Tg mice (n=18-20) were fed a 3% oat hull control diet, control diet + oral sodium butyrate, control + probiotic diet, 20% prebiotic diet, 10% prebiotic diet, or 10% synbiotic diet for 11-months. Whole gut transit time (WGTT), fecal output/ 1-hour, fecal water content, and rotarod performance was evaluated every 3-months until 12-months. Fecal and colonic samples were collected before and after treatment to assess microbial composition for both studies. **Results:** 15-month Thy1-Y39C *SNCA* Tg mice treated with sodium butyrate, 10% prebiotic, and 10% synbiotic all show improved motor function compared to controls, but only the synbiotic treatment could reduce brain aSyn oligomerization as well as sodium butyrate. PAC-A53T *SNCA* Tg mice treated with 10% prebiotic and 10%

synbiotic diets have shorter WGTTs and increased fecal water content compared to controls as early as 3-months of age. **Conclusions:** Microbiota-targeted therapies that upregulate butyrate production in the gut improve pre-motor ENS deficits and delay disease progression in advanced stages of PD in Tg mice. Possible modes inducing the therapeutic effects observed may be due to increased circulating butyrate or modified gut-brain axis signaling.

Title: Calorie restriction: Efficacy of a lifestyle strategy to mitigate aging-related Parkinsonism when initiated in the latter half of the lifespan and nigrostriatal mechanisms

Authors: *E. A. KASANGA[1], P. KELLEY[4], K. VENABLE[5], J. TERREBONNE[4], M. CANTU[2], D. INGRAM[4], M. F. SALVATORE[3];
[1]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX; [3]Inst. for Healthy Aging, [2]Univ. of North Texas Hlth. Sci. Ctr., Ft Worth, TX; [5]CBS, [4]Pennington Biomed. Res. Ctr., Baton Rouge, LA

Abstract: Up to 50% of the elderly may suffer from locomotor impairments similar to those in Parkinson's disease. These impairments greatly compromise the ability to perform daily life activities, and portend to loss of independent living, frailty, and mortality. Engagement of lifestyle strategies in middle or advanced middle age could prove beneficial to reduce risk of aging-related parkinsonism. We previously reported that initiation of caloric restriction (CR) in middle-aged rats can reduce aging-related parkinsonism without a commensurate increase in striatal dopamine (DA) content or tyrosine hydroxylase expression. Here, we evaluated if CR could prevent aging-related motor decline when initiated well into the latter half of the rat lifespan, and well after motor decline occurs, to answer to whether there is an aging-related limit of CR efficacy. 18-month old male Brown-Norway/Fischer rats maintained on a lifelong *ad libitum* (AL) diet were grouped into CR and AL groups. CR was gradually introduced to 30% by 3 weeks after study initiation and maintained for 6 months with open-field locomotor assessments of movement frequency and speed conducted every 6 weeks. A significant and sustained decline in movement frequency was observed in the AL group from 12 weeks after initiation of the study. To the contrary, CR prevented this aging-related decline, with increased movement frequency in the CR group compared to the AL group at 12 and 24 weeks and speed at 18 weeks after CR initiation. We also observed that rats with lower baseline locomotor activity

responded better to CR intervention with less decline from baseline. This preservation of motor function was associated with an increase in dopamine D1 receptor expression in the substantia nigra, but not striatum. Striatal DA content and tyrosine hydroxylase expression were also unaffected by CR. In summary, CR may be an effective lifestyle strategy to reduce aging-related parkinsonism, even when initiated well into the latter half of the lifespan and after motor decline begins in the lifespan. These results also add to the body of work that increases in striatal DA biosynthesis may not be necessary for preservation of motor function. Targeting nigral DA neurotransmission may represent an avenue to mitigate motor impairment in individuals wherein CR or other lifestyle interventions would be contraindicated.

Abstract: Sub-anesthetic ketamine infusions are an effective therapy for the treatment of depression and pain states. We have demonstrated a therapeutic effect of sub-anesthetic ketamine in Parkinson’s disease (PD) patient case studies with L-DOPA-induced dyskinesia (LID; Sherman et al. 2016). In a preclinical model, we have reported that established LID, measured by abnormal involuntary movements (AIMs) in this model, are reduced by a 10-hr low-dose ketamine infusion paradigm (Bartlett et al. 2016), and showed since that ketamine can suppress development of LID as well, mediated by activation of mTOR, a known regulator of neuroplasticity. To further elucidate the underlying mechanism male Sprague-Dawley rats were unilaterally injected with 6-hydroxydopamine to create a PD model. In a first cohort (n = 10/group), PD rats were primed with daily injections of L-DOPA for 14 days, and treated on days 0 and 7 with either vehicle, ketamine, or ketamine plus the tropomyosin receptor kinase B

(TrkB) antagonist, ANA-12, to block signaling via brain-derived neurotrophic factor (BDNF). On day 14, ketamine treated rats showed a 50% reduction in their AIMs scores compared to vehicle ($p < 0.01$; one-way ANOVAs, Tukey *post-hoc* tests). However, this sustained effect of ketamine was blocked in rats co-treated with ANA-12 ($p < 0.05$). Dendritic spines in the striatum were then analyzed after a Golgi stain. Ketamine prevented the two-fold increase in multi-synaptic mushroom spines on the lesioned side seen in vehicle-injected rats ($p < 0.0001$). In the ketamine plus ANA-12 group ketamine's effect on mushroom spines was blocked ($p < 0.0001$). To test possible involvement of microglia in spine removal, we repeated the suppression of development of LID in a second cohort (n = 6-10). We again observed that LID AIMs were reduced at day 14 with ketamine treatment ($p < 0.05$ vs. vehicle), and investigated inflammatory markers and microglial morphology. Striatal concentrations of the pro-inflammatory IL6 were not altered by the PD-lesion, but ketamine had a significant effect to increase IL6 concentrations (2way ANOVA: lesion: $F(1,16) = 3.44$, $p = 0.08$, treatment: $F(1,16) = 10.38$, $p = 0.005$). Microglia were de-ramified in the striatum and substantia nigra of the lesioned hemisphere, but morphology was not changed with ketamine treatment at this time point, 7 days after the last ketamine treatment. In conclusion, the sustained anti-dyskinetic effect of ketamine is inhibited by blocking BDNF-signaling and involves changes in striatal spine density and a change in an inflammatory cytokine. This data provides further preclinical evidence to support repurposing of ketamine to treat PD patients suffering from LID.

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disease affecting approximately 1 million people in the United States, and there is no curative treatment for this disease. PD is characterized by severe loss of dopaminergic neurons in the substantia nigra and dopamine depletion in striatum resulting in a debilitating motor function. While the molecular mechanisms that regulate the progression of the PD are not fully elucidated, there is evidence to suggest that accumulation of DNA damage, particularly DNA double-strand breaks (DSBs), contribute to the progression of the dopaminergic neurodegeneration. The present study was undertaken to examine whether DSBs accumulation contributes to the nigrostriatal neurodegeneration in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) mouse model of PD. To test our hypothesis that DSBs accumulation has a pathogenic role in PD, we have treated primary mesencephalic neuron/glia cultures with 1-methyl-4-phenylpyridinium (MPP^+) (10 μM) for 48 h. We observed increased and sustained DSBs as assessed by γ-H2A.X (Ser139) and 53BP1 immunoreactivity, and degeneration of tyrosine hydroxylase-positive neurons when compare to control neuron/glia cultures. Next, we demonstrate that wild-type mice treated with MPTP display increased expression of γ-H2A.X (Ser139) and 53BP1 along with increased NLRP3-inflammasome as measured by immunohistochemistry and Western blot. Tyrosine hydroxylase labelling showed that DSBs and inflammatory markers were associated with significant increases in dopaminergic neuronal loss in MPTP-treated mice. Interestingly, increased dopaminergic neuronal loss was markedly reduced by treatment with a specific and selective NLRP3 inhibitor. In conclusion, our results provide the evidence that accumulation of DSBs in the brain causes increased neuroinflammation and contributes to dopaminergic neurodegeneration in Parkinsonian mice. Thus, targeting the DSBs-associated neuronal death pathway might offer a novel approach to prevent or slow down PD progression.

Abstract: Pituitary adenylate cyclase activating polypeptide (PACAP) is an endogenous neuropeptide that agonizes PAC1, VPAC1, and VPAC2 receptors. PACAP is neuroprotective after injection into the striatum in a model of Parkinson's disease (PD), and it inhibits neuronal apoptosis, suggesting that it could be a drug candidate to treat PD. However, native PACAP exhibits poor pharmacokinetics, is rapidly degraded and has low bioavailability. Glycosylation of peptides was shown to improve peptide stability, enhance (or retain) the original biological activities, and modulate the ability of the peptides to cross the blood-brain barrier (BBB). We have designed and synthesized several PACAP glycopeptides with various serine glycosides at the C-terminus as well as added amino acid substitutions to enhance stability. These glycopeptides were tested for their ability to stimulate cAMP production *in vitro* using individual CHO cell lines expressing PAC1, VPAC1, and VPAC2. The $PACAP_{1-27}$ glycosides (lactoside among others) maintained receptor agonism with modest selectivity between the PAC1 and VPAC1/2 isoforms. These results were confirmed using a high throughput calcium imaging assay (FLIPR), which showed that $PACAP_{1-27}$ and the serine glucoside ($PACAP_{1-27}$S-Glc) showed equivalent activation of the PAC1 receptor. *In vitro* half-lives in 25% serum matrix: native PACAP=13.9 min, $PACAP_{1-27}$S-Glc=28.6 min, while $PACAP_{1-27}$S-Lac stays above 50% of initial concentration over 60 min. *In vitro* half-life of native PACAP in water: 2.8 min; shorter than all glycosylated derivatives in a CSF matrix. All glycosylated peptides studied were stable over 60 min in a CSF or 180 min in water. *In vivo* CSF data using 'shotgun microdialysis' coupled with $LC\text{-}MS^3$ (n=1, 15 mg/kg, *i.v.*) shows $PACAP_{1-27}$S-Lac is able to penetrate the BBB. Native PACAP at 15 mg/kg showed ~7 μM estimated CSF concentration, $PACAP_{1-27}$S-Lac showed ~24 μM estimated CSF concentration, while serum concentration of glycosylated peptides reached 20~120 μM at 5 mg/kg. To test for *in vivo* activity of the lead glycopeptide, we began a study using a mild progressive unilateral 6-hydroxydopamine (6-OHDA) rat PD model (n=16/group). In the treatment group rats were injected (*i.p.*) with 15 mg/kg of $PACAP_{1-27}$S-Lac both 6-hrs prior and 48-hrs post 6-OHDA injection. At 2 weeks post-6-OHDA a trend of reduced amphetamine-induced rotations is seen (2-tail t-test, $p = 0.09$). The study is ongoing, and after conclusion of behavioral analysis, unbiased stereology of dopaminergic neurons in the substantia nigra will be conducted (n=8/group), and striatal dopamine content will be measured (n=8/group) to evaluate the extent of any neuroprotection.

Abstract: Currently there are no therapies to slow the dopaminergic cell loss occurring in the substantia nigra pars compacta (SN) of Parkinson's disease (PD) patients. Previously, we identified vascular endothelial growth factor B (VEGF-B) as a potential therapeutic candidate due to its upregulation in the dopaminergic cells of a rat midbrain culture when challenged by rotenone. We have also published on VEGF-B's neuroprotective effects both *in vitro* and *in vivo*. Exogenous VEGF-B is neuroprotective against rotenone in the same rat midbrain culture system as above. It is also neuroprotective in a progressive unilateral 6-hydroxydopamine (6-OHDA) rat model of PD when injected in the striatum prior to the toxin. We now add information from a genetic PD model, PTEN-induced putative kinase 1 (PINK1) knockout (KO) rats. This study adds a new cohort and expands on previously reported pilot data showing that unilateral injections of an adeno-associated virus expressing human VEGF-B (AAV2/1-hVEGF-B) into the SN and striatum of 5 month old PINK1 (KO) rats reduced motor impairment in the tapered balance beam (TBB) task. In this PD model, cumulative footslips were reduced during monthly TBB sessions post-injection (months 6-12) in the contralateral hindlimb of the PINK1 KO rats compared to PINK1 KO rats treated with VEGF-B (One-way ANOVAs; *$p<0.05$; n=9-13). After completing behavioral testing, at 12 months of age, brain tissue was harvested or perfused for either dopamine (DA) content and mechanistic studies or unbiased stereology, respectively. Through the addition of more animals, we have further demonstrated that VEGF-B-over-expression increases DA content in the striatum, analyzed via HPLC-EC, by 30% in the injected hemisphere compared to the non-injected hemisphere (One-way ANOVAs; *$p<0.05$; n=4-7). To determine if VEGF-B's effects on motor function and striatal DA content is neuroprotective or due to a functional improvement in the surviving DA neurons we are currently analyzing, via

unbiased stereology, DA neurons in the SN after co-staining for tyrosine hydroxylase and the neuronal marker, NeuN. In an effort to further characterize the potential mechanisms of VEGF-B's therapeutic effects, we have completed a new pilot analysis showing a trend of elevated phosphorylation levels of striatal mTOR (mean ratio ipsilateral/contralateral of P-mTOR/mTOR ± SEM) in the injected hemisphere, as measured with a multiplex ELISA (Kruskall-Wallis rank test, Dunn *post-hoc* test; $^{\#}p=0.09$; n=3-5). We are also adding to the prior pilot study that showed striatal upregulation of pigment epithelium-derived factor, a known inhibitor of apoptosis (ELISA), after VEGF-B over-expression.

Title: Differences of cognition and brain white matter between cART-treated HIV-infected patients with low and high CD4 nadir

Authors: *Y. YOSHIHARA[1], T. KATO[2], D. WATANABE[3], T. SHIRASAKA[3], T. MURAI[2]; [1]Human Brain Res. Center, Kyoto Univ., Kyoto, Japan; [2]Dept. of Psychiatry, Kyoto Univ., Kyoto, Japan; [3]AIDS Med. Center, Natl. Hosp. Organization Osaka Natl. Hosp., Osaka, Japan

Abstract: The introduction of combination antiretroviral therapy (cART) lead to improve immune recovery in patients with HIV. Despite viral suppression with cART, the frequency of HIV-associated neurocognitive disorders (HAND) remains high. On the biological background of HAND, there is an impaired brain white matter integrity in the patients. Diffusion tensor imaging (DTI) is a noninvasive imaging modality that can assess white matter microstructure, and tract-based spatial statistics (TBSS) can analyze the whole-brain white matter tract. On the other hand, low CD4 T-cell counts has been associated with HAND. In the present study, using DTI and TBSS, we examined the differences of cognitive dysfunction and white matter impairment between 3 groups: fifteen HIV-infected patients with low CD4 nadir (cell count <150), 16 HIV-infected patients with high CD4 nadir (cell count ≥150), and 33 age- and handedness- matched healthy controls. In addition, we examined the correlation between the white matter impairment and cognitive dysfunction in the HIV-infected patients with low CD4 nadir. All HIV-infected patients had achieved viral suppression after cART. The participants

underwent the neuropsychological tests including seven cognitive domains and DTI scan on 1.5T MRI in the National Hospital Organization Osaka National Hospital. We assessed group differences of fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD) from DTI data. The patients with low CD4 nadir had significantly lower performance of executive functions, motor skills, processing speed, and sensory-perceptual domains compared to other two groups. TBSS on the patients with low CD4 nadir showed the significant increased MD, AD, and RD in the widespread areas involving the bilateral cerebral hemispheric, cerebellar, and brain stem white matter compared to other two groups, while no differences were detected in FA. There were no significant differences of FA, MD, AD, and RD in the brain between the patients with high CD4 nadir and controls. In the patients with low CD4 nadir, there was a significant negative correlation between sensory-perceptual function scores and AD and RD in the right inferior longitudinal fasciculus. In conclusion, there were differences of cognition and white matter between cART-treated HIV-infected patients with low and high CD4 nadir. MD, AD, and RD of DTI were sensitive to detect the white matter impairment in HAND.

Title: Combined antiretroviral therapy induces hyperactivity of medial prefrontal cortex pyramidal neurons mediated by over-activation of voltage-gated Ca^{2+} channels

Authors: *L. CHEN, L. AL-HARTHI, X.-T. HU;
Dept. of Microbial Pathogens and Immunity, Rush Univ. Med. Ctr., Chicago, IL

Abstract: Combined antiretroviral therapy (cART) suppresses HIV replication, improves immune function, and prolongs life of HIV^+ individuals. Despite cART, the prevalence of HIV-associated neurocognitive disorders (HAND) occurs in ~50% of HIV^+ patients. Previous studies indicate that many antiretroviral medicines (ARVs) induce neurotoxicity in the peripheral and central nervous system; but the mechanism by which cART (or individual ARVs) induces

neurotoxicity is unknown. It is also unknown if such side effects of cART exacerbate HIV-induced neurotoxicity in the medial prefrontal cortex (mPFC), which could contribute to the underlying mechanism of HAND. Our previous study shows that lamivudine (a.k.a. 3TC, a nucleoside reverse transcriptase inhibitor, NRTI) *in vitro* induces a significant increase in firing and voltage-gated Ca^{2+} channel (VGCC) activity among mPFC pyramidal neurons. It is unknown whether such dysregulation could be induced by chronic cART. Here we assessed acute (*in vitro*) and chronic (*in vivo*) effects of Triumeq on the activity of mPFC neurons in rat brain slices using whole-cell patch-clamp recording. Triumeq is a first-line cART regimen for treating HIV/AIDS, which is formulated by three ARVs: abacavir (ABC, a NRTI), dolutegravir (DTG, an integrase inhibitor), and 3TC (a NRTI). We found that, at a concentration similar to which detected in the cerebrospinal fluid (CSF) of HIV^+ patients on this cART, acute Triumeq *in vitro* did not affect firing; but at 10x or 100x (fold) concentrations, it significantly increased firing of mPFC neurons. Chronic treatment of Triumeq *in vivo* (s.c., with equivalent dosages of humans) for 4 weeks (but not 2 weeks, wk) also significantly increased firing; and that was associated with enhanced Ca^{2+} influx *via* VGCCs. Further assessment using individual ARVs showed that 4wk treatments of ABC, DTG, or 3TC *in vivo* did not affect firing of these neurons. These results demonstrate that chronic Triumeq treatment induces hyperactivity of mPFC neurons by enhancing Ca^{2+} influx *via* over-activated VGCCs; and combined chronic treatment of ARVs *in vivo* could enhance the side effects of them. Collectively, these novel findings suggest that the side effects of chronic cART may exacerbate HIV-induced neurotoxicity in the mPFC.

Title: Genetically diverse mouse strains exhibit variable central nervous system lesions in response to viral infection

Authors: *K. S. LAWLEY[1], R. R. RECH[2], K. AMSTALDEN[1], D. THREADGILL[3], C. J. WELSH[1], C. BRINKMEYER-LANGFORD[1];

Abstract: Neurological diseases such as epilepsy, Parkinson's disease, multiple sclerosis, and amyotrophic lateral sclerosis may be partly driven by a preceding viral infection for some

patients. Interestingly, the severity and prevalence of neurological diseases and symptomologies vary greatly across individuals, even in response to the same virus. Theiler's murine encephalomyelitis virus (TMEV) provides a valuable model to understand how a single viral agent can elicit variable neurological outcomes. In mice, TMEV infection causes diverse neurological conditions, depending on the strain of the infected mouse. This suggests that the genetic background of the host influences the type and severity of the neurological disease. Although TMEV responses have been well studied in inbred mouse strains such as C57BL6 and SJL, these models fail to capture the diversity of human infection outcomes. However, the genetically heterogeneous Collaborative Cross (CC) mouse resource is designed to represent the genetic diversity observed in the human population. To further our understanding of how individual genetic backgrounds impact neurological damage in response to viral infection, we histologically characterized the central nervous system tissues of TMEV-infected mice from different CC strains. Here, we demonstrate that the CC strains exhibit variable central nervous system (CNS) lesions in response to TMEV infection, depending on the mouse strain. This suggests that the genetic diversity intrinsic to the CC strains contributes to histological differences in lesion extent and location in the CNS after viral infection, which can represent virally influenced neurological diseases in humans.

Title: Mechanisms regulating amyloid precursor protein secretases in HIV-induced neurotoxicity

Authors: *C. LOPEZ-LLOREDA[1], C. AKAY-ESPINOZA[2], K. L. JORDAN-SCIUTTO[2]; [1]Neurosci., Univ. of Pennsylvania, Philadelphia, PA; [2]Pathology, Sch. of Dent. Med. Univ. of Pennsylvania, Philadelphia, PA

Abstract: Aging is increasingly appreciated as a contributor to HIV-associated neurocognitive disorders (HAND) since antiretroviral therapy has increased the life expectancy of patients. Extracellular plaques composed of amyloid-beta (Aβ) are observed in aging-related neurodegenerative disorders, including HAND. Aβ is produced by cleavage of amyloid precursor protein (APP) by the secretase BACE1. However, this is precluded by cleavage of APP by the non-amyloidogenic secretase ADAM10. Increased BACE1 protein levels have been observed in

models of HAND. Additionally, excitotoxicity has been shown to decrease levels of ADAM10 in neurons. This would suggest there is a shift in APP secretases that could contribute to HIV-mediated neurotoxicity. In Alzheimer's Disease, BACE1 upregulation is mediated by the unfolded protein response kinase PERK. For the non-amyloidogenic pathway, sirtuin-1 (SIRT1), which is implicated in aging, has been shown to regulate ADAM10 levels. This suggests that APP processing is potentially dysregulated by changes in the protein levels of APP secretases BACE1 and ADAM10 in response to these mechanisms. To characterize APP processing in the context of an HIV insult, monocyte-derived macrophages were infected with HIV and supernatants were collected. Primary rat cortical neurons were then treated with HIV-infected macrophage supernatants (HIV/MDMs) or NMDA with or without 1 hour PERK inhibitor pre-treatment. Additionally, HIV/MDM or NMDA were co-treated with PERK activator (PA). Western blotting and MAP2 staining were performed to determine protein levels and neurotoxicity levels, respectively. NMDA treatment led to an increase in BACE1 levels, which seemed to be exacerbated when co-treating with NMDA and PA. Both HIV/MDMs and NMDA treatments led to a decrease in ADAM10 levels when compared with untreated cultures. Similarly to BACE1, HIV/MDM and NMDA-mediated decreases of ADAM10 were exacerbated by PA treatment. HIV/MDMs also decreased levels of SIRT1, pointing to a possible mechanism of ADAM10 regulation. In assessing the role of PERK in toxicity, HIV/MDM and NMDA-mediated toxicity seemed to be slightly attenuated by PERK inhibition and exacerbated by PERK activation. These results would suggest that there is reduction in non-amyloidogenic processing of APP that may be contributing to HIV-related neurotoxicity which is worsened by activation of the PERK pathway. Future studies will delve into this process by examining the specific mechanism of ADAM10 down-regulation, the role of ADAM10 in mediating toxicity, and by assessing products of APP cleavage in our model such as Aβ and soluble APP-α.

Biochem., [7]Sch. of Pharm., [8]Clementino Fraga Filho Univ. Hosp., [9]Pharm. Sch., Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Neurological complications have been reported in adult patients infected by Zika virus (ZIKV). We aimed to determine if ZIKV replicates in human and mice adult brain tissue and its possible effects on cognition. Ex-vivo human adult cortical tissue were infected with 10^7 plaque-forming units (PFU) of a ZIKV strain isolated from a Brazilian patient, or the corresponding volume of virus-free C6/36 cells conditioned medium (mock). ZIKV mRNA in tissue and infectious particles released to medium increased in a time-dependent manner, demonstrating that ZIKV successfully replicates in adult human mature neural tissue. To study the consequences of ZIKV infection in the adult brain, we performed intracerebroventricular injections of ZIKV (10^5 PFU) in adult male Swiss mice. Brain infusion of ZIKV reduced body weight without increasing mortality when compared to mock-infused mice. Increasing viral RNA levels were found in ZIKV- infected mice brain, peaking at 6 days post-infection (dpi). Viral mRNA was higher in the hippocampus and frontal cortex when compared to others brain regions. We found increased Iba-1 (microglial) positive cells and decreased synaptic puncta levels and plasticity in the hippocampus of infected-mice. Brain TNF-α and complement system proteins, C3 and C1q, mRNA levels were markedly increased at 6 dpi. Moreover, we found increased levels of CD4+, CD8+ and macrophages cells in ZIKV-infected mice brain. Iba-1/synaptophysin colocalization was higher in infected mice, suggesting microglial synaptic engulfing. Using the novel object recognition task, memory impairment was detected as early as 1 dpi, persisting for up to 30 dpi. Remarkably, blockade of TNF-α, C3 or C1q signaling, or even microglial activation prevented synapse and memory impairment in ZIKV- infected mice. TNF-α signaling blockage reduced microgliosis but microglial activation blockage did not decrease ZIKV-induced TNF-α mRNA upregulation. Results suggest that ZIKV induces synapse dysfunction and memory impairment via a TNF-α/microglia/complement axis. Our findings establish a mechanism by which ZIKV affects the adult brain and point out to the need of evaluating memory/cognitive deficits as a potential comorbidity in ZIKV-infected adults. All procedures were approved by local ethical committee (Brazilian Ministry of Health #0069.0.197.000-05, Federal University of Rio de Janeiro #043/2016 and #126/18).

Title: Prevention of HIV-1 Tat and cocaine neurotoxicity by inhibiting DEAD Box RNA Helicase 3

Authors: *B. C. CUI[1], M. AKSENOVA[1], J. SYBRANDT[2], V. SIKIRZHYTSKI[1], H. JI[1], D. A. ODHIAMBO[3], M. D. LUCIUS[1], J. R. TURNER[4], E. BROUDE[1], E. PEÑA[1], S. B. LIZARRAGA[1], J. ZHU[1], I. SAFRO[2], M. WYATT[1], M. SHTUTMAN[1];

Abstract: HIV-1 Associated Neurocognitive Disorder (HAND) is a clinically devastating yet common complication of HIV infection. The persistence of the virus in the central nervous system leads to viral protein release, most famously Tat, from the infected cells, which causes cumulative neuronal toxicity. Substance abuse in HIV infected patients greatly exacerbates the severity of such neuronal damage. Unfortunately, there is no viable or approved therapy for HAND despite the projected increase in the prevalence of HAND due to a rapidly aging HIV-positive population.
To find potential targets for anti-HAND therapy, our team has developed an AI-based literature mining algorithm. Through evaluation and prioritization of the highest scoring genes that are computationally associated with HAND, we uncovered Dead Box RNA Helicase 3 (DDX3). Moreover, a small molecule inhibitor of DDX3 helicase activity, RK-33, is readily available as an anti-cancer agent that selectively kills tumors without any observed systemic toxicity in the tested animal models.
We show that RK-33 rescues rat and mouse cortical cultures from the combined neurotoxicity of HIV Tat protein and cocaine. The results of RNA-seq and transcriptome analysis of the treated cultures reveal that the majority of Tat-activated transcripts are microglia specific genes, and that

RK-33 blocks their activations. These genes include major microglial markers and regulators of microglia activation, such as CSF1R and CSF3R. Treatment with RK-33 inhibits Tat and cocaine-dependent increase in the number and size of the microglia cells in cortical cultures. The elevated production of IL-1alpha and beta, IL-6 and TNF-alpha proinflammatory cytokines is also inhibited by RK-33 treatment. However, a further analysis of Tat and cocaine-dependent transcriptome suggests that RK-33 also affects astrocytes where it inhibits Tat-dependent activation of NF-kappa B signaling pathway. This necessitates a deeper look into complex interplay of microglia and astrocytes.
Taken together, these findings suggest that DDX3 is important to glial activation triggered by the combined insults of Tat and cocaine, and that pharmacological inhibition of DDX3 may have the potential to treat not only HAND, but also other neurodegenerative diseases with pathological activation of glial cells.

Title: Clinicoserological spectrum and potential viral factors in biofluids of a consecutive series of patients with limbic encephalitis

Authors: *A. REIMERS[1], A. M. EIS-HÜBINGER[2], A. J. BECKER[3], C. E. ELGER[4];
[1]Inst. For Neuropathology, Bonn, Germany; [2]Inst. of Virology, Bonn, Germany; [3]Inst. for Neuropathology, Bonn, Germany; [4]Clin. for Epileptology, Bonn, Germany

Abstract: Limbic encephalitis (LE) is increasingly recognized as a pathogenetic factor of temporal lobe epilepsy (TLE). Auto-antibodies (ABs) targeting neuronal surface structures, GAD65 as well as onconeuronal ABs play a role in LE. However, by far not all LE patients have

ABs in sera or cerebrospinal fluid (CSF) samples. Based on human herpesvirus 6 (HHV-6) DNA detection in brain tissue from patients with TLE, an association of persistent viral infection with TLE has been discussed. Furthermore, individual studies reported increased HHV-6 DNA in patients with clinical signs of previous inflammatory brain reaction including febrile seizures or meningoencephalitis as predisposing factors for TLE. The interval between new onset of seizures in adult patients and the diagnosis of LE varies considerably. We have carried out a systematic analysis on the distinct auto-AB status in sera / CSF samples of patients with short-term (n=175 individuals; seizure onset ≤ 24 months) versus long-term (n=70 individuals; seizure onset ≥ 96 months) intervals between the first onset of seizures and the clinical diagnosis of LE. Informed written consent was present from all patients. The detection rate of auto-ABs differed significantly between both groups (n=22 in short-term versus n=5 in long-term interval patients); GAD65 and LGI1 were significantly more frequently detected (α=0.01) in the short-term than in the long-term interval group. We will also report on potential differences between both groups of patients under study including semiological, imaging, further serological as well as neuropsychiatric factors and the detection of viral nucleic acids including HHV-6 and neurotrophic RNA-viruses. In summary, data of a very large consecutive cohort of biofluids in LE patients stratified according to the time interval to diagnosis will be presented and may provide new insights for therapy stratification.

Title: Estrogen receptor signaling in macrophages suppresses HIV-associated neurotoxic activity

Authors: *K. S. WILLIAMS[1], H. NIEVES[2], J. HAROWITZ[3], L. M. VANCE[1], A. MURRELL[1], A. FOURTE[1], K. JORDAN-SCIUTTO[3];

Abstract: Macrophages and microglia (M/M) play pivotal roles in the pathogenesis of HIV-associated neurocognitive disorders. The ensuing inflammatory M/M activation causes neuronal damage. Studies utilizing exogenous anti-inflammatory and antioxidants to mitigate disease progression have been unsuccessful; however, targeting endogenous pathways, such as estrogen signaling may be advantageous. 17β-estradiol, the most active form of estrogen, activates estrogen receptor GPER and has been reported to inhibit HIV infection in primary macrophages and peripheral blood mononuclear cells and protect neurons against HIV proteins, gp120 and tat. The literature has also suggested that Secoisolariciresinol diglucoside (SDG), a flaxseed lignin, may interact with estrogen receptors. In previous data, we have found that SDG may suppress macrophage induced neurotoxicity and viral replication during neurotoxicity. Therefore, we hypothesize that high 17β-estradiol and SDG may be neuroprotective during HIV infection and other inflammatory stimuli in an estrogen receptor dependent manner. To understand this, we stimulated or infected macrophages with HIV_{JAGO}, respectively, in the presence and absence of increasing doses of 17β-estradiol or SDG. Whole cell and cytoplasmic lysates, mRNA and conditioned medium were collected at various time points. We found that 17β-estradiol and SDG suppressed neurotoxin production and viral replication from HIV infected macrophages in an estrogen receptor dependent manner. Given these studies, estrogen signaling may reduce oxidative stress and inflammation seen during neuroinflammatory disorders, such as HIV-associated neurocognitive disorders.

Title: A promising diagnostic and prognostic biomarker for HAND: Prepulse inhibition

Authors: *K. A. MCLAURIN, R. M. BOOZE, C. F. MACTUTUS;
Psychology, Univ. of South Carolina, Columbia, SC

Abstract: In 2007, the nosology for HIV-1 associated neurocognitive disorders (HAND) was updated to a primarily neurocognitive disorder. However, currently available diagnostic tools

lack the sensitivity and specificity needed for an accurate diagnosis for HAND. Scientists and clinicians, therefore, have been on a quest for an innovative biomarker to diagnose (i.e., diagnostic biomarker) and/or predict (i.e., prognostic biomarker) the progression of HAND in the post combination antiretroviral therapy (cART) era. The translational prepulse inhibition (PPI) experimental paradigm is commonly utilized for the assessment of temporal processing, a construct analogous to speed of information processing, and which has been implicated as a potential elemental dimension of HAND. The potential utility of PPI as a diagnostic and/or prognostic biomarker for HAND was examined using intact male and female F344/N HIV-1 transgenic (Tg; *N*=20 litters) and control rats (*N*=17 litters). First, discriminant function analyses (DFA) and receiver operator characteristic (ROC) curves, complementary statistical techniques, were utilized to assess the utility of PPI as a diagnostic biomarker. In the HIV-1 Tg rat, PPI accurately diagnostics the presence of the HIV-1 transgene, relative to control animals, with both high sensitivity (i.e., 89.3-100%) and high specificity (i.e., 79.5-94.1%); results which generalize across experimental paradigms, the functional lifespan, sensory modalities, and biological sex. Second, regression analyses were conducted to examine the potential utility of PPI as a prognostic biomarker. Early alterations in PPI (i.e., Postnatal Day 30 and 60) accurately predict later neurocognitive impairments in higher-order cognitive domains, including sustained attention, flexibility, and inhibition, with regression coefficients (i.e., *r*) greater than 0.8. Thus, PPI heralds an opportunity for the development of a brief, non-invasive diagnostic and prognostic biomarker for milder forms of NCI in the post-cART era. Title: Rat model of prenatal Zika virus infection and associated neural and behavioral consequences in the offspring

Authors: *M. L. SHERER[1], P. KHANAL[1], R. PATEL[1], M. PARCELLS[2], J. M. SCHWARZ[1]; [1]Psychological and Brain Sci., [2]Dept. of Animal and Food Sci., Univ. of Delaware, Newark, DE

Abstract: Zika virus (ZIKV), a mosquito-borne flavivirus, has been associated with microcephaly and other neurological disorders in infants born to infected mothers. Despite being declared an international emergency by the World Health Organization, comparatively very little is known about the pathogenesis, mechanisms, or behavioral consequences of maternal ZIKV infection in the offspring. Our lab is interested in developing a working animal model to answer

some of these questions. Here, we use a rat model of prenatal ZIKV infection to measure the level of infectivity, as well as the rate of viral clearance in both the mother and her pups. We examine various aspects of brain development in pups, including cortical thickness, microglia morphology, apoptosis, and neurogenesis. Further, we use this model to investigate the impact of prenatal ZIKV infection on hippocampal and non-hippocampal dependent learning as well as motor learning in the juvenile and adult offspring. Given that pregnancy is associated with significant immunomodulation, we are also interested in the role that pregnancy has on the impact of ZIKV infection, therefore we compare viral infectivity between both pregnant and non-pregnant female rats. In this study, we show that prenatal ZIKV infection results in an increase in cell death and reduces hippocampal and cortical volumes in the neonatal rat brain. For the first time, we demonstrate the efficacy and validity of a rat model for maternal ZIKV infection with vertical transmission to the fetus. This model will allow us to 1) better understand the mechanisms underlying ZIKV infection and transmission to the fetus, 2) determine the impact of ZIKV infection on the developing male and female fetal brain, and 3) measure behavioral deficits and investigate potential sex differences associated with fetal ZIKV infection later in life.

Title: Herpetic lesions in encephalitis are fully reversed by Aciclovir: A case report

Authors: *A. D. CUNHA[1], A. O. CUNHA[2];
[1]Infectious Dis., Hosp. Unimed, Ribeirão Preto, Brazil; [2]Dept. of Physiol., Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: Herpetic encephalitis is the most common sporadic viral encephalitis among adults worldwide. Here, we report a case of 63-year old male patient that was admitted to the hospital with abnormal behavior and epileptic seizures. Some days before admission, the patient searched for a health facility reporting peaks of fever, dysuria and lumbar pain. He was oriented to take ciprofloxacin (every 12 hours). Upon admission, the patient had Glasgow 12, ocular aperture of 3, motor responses of 5, verbal responses of 4, confused and disoriented. Video-EEG

examination revealed moderated symmetric disorganization in basal activity due to a diffuse increase in slow theta waves. Also, rare acute type epileptiform discharges were observed in the left front-temporal region. Cephaloraquidian liquor presented a slight increase in glucose (116 mg/dl) and a high increase in protein (89.4 g/dl), together with IgG immunoglobulins for *Herpes* types 1 and 2 and for *Varicela zoster*. Magnetic resonance showed many supratentorial intraparenquimal lesions that were diffusely spread in the cortex and many subcortical structures. The patient was kept in the intensive care unit were ciprofloxacin was replaced by ceftriaxone (2 g, every 12 hours), acyclovir (10 mg/kg) and phenytoin (250 mg, e.v.). One week after admission, all medications were stopped. Eleven days after admission, the patient recovered completely and was discharged from the hospital. Magnetic resonance was repeated after three weeks and all the lesions had disappeared. Since we did not find changes in cephaloraquidian liquor that would suggest bacterial infections, we hypothesized that the patient had an inflammatory response due to a viral infection and apparently, that was the case. We conclude that acyclovir is an effective drug to rapidly treat herpetic encephalitis since it can fully reverse inflammatory lesions, behavioral impairment and seizures induced by these viruses.

Title: A proposed mechanism for selective vulnerability in the brain of the HIV-1 transgenic rat

Authors: *F. J. DENARO, M. WORTHINGTON;
Biol., Morgan State Univ., Baltimore, MD

Abstract: Since the introduction of the HIV-1 Transgenic rat (HIV-1TGR) (1) over 100 papers have been published using this model in HIV/AIDS studies. Experience with this model has demonstrated its effectiveness particularly for the study of HIV comorbidities. In humans, HIV associated comorbidities exist even with the use of very effective antiviral therapy. It is believed that the cells of viral reservoirs continue to secrete viral proteins even with treatment. Because this model produces chronic levels of HIV proteins (in particular Gp-120) it has a number of similarities to patients that are on antiviral therapy. One interesting observation in the HIV-1TGR is the selective vulnerability of differ cell types. A body of growing evidence on the cellular pathology in the HIV-1TGR has been reported and it reflects what is seen in the patient.

The observation of selective cell vulnerability is even more marked in the brain. Our early observations revealed abnormalities to the motor system. This led to examination of the Basal ganglia and the Substantia nigra. Further studies have also revealed behavioral and motor problems consistent with our earlier observations of the neuropathology. In the present study, we investigate the distribution of the HIV receptors CXCR4 and CCR5 which can bind to GP-120. There is marked homology between the rat receptors and the human receptors. Therefore, the presence of these receptors on specific cell types can provide a rationale for the observed selective vulnerability. The consequence of GP-120 binding to the receptors could lead to negative downstream effects of cell functions. The CXCR5 receptor have been previously mapped in the rat brain. In the present study we also identify the receptors and are correlating the receptors with the pathology The expression of CCR5 is a bit different. It is expressed during embryotic development but only in low levels in the adult. But in instances of inflammation this receptor is upregulated. The different characterizes of these two receptors offers a hypothesis for the development of increased pathology over time. Initially CXCR5 contributes to cell death and dysfunction, this could result in an immune response. The immune response is followed by upregulation of CCR5 with increased GP120 binding and increased pathology. Therefor the identification of HIV receptors in the HIV-1TGR offer a mechanistic rationale for the development of the neuropathology and its apparent increase over time. 1. Title: *Toxoplasma gondii* interactions and electrophysiology differences in the central nervous system

Authors: *O. A. MENDEZ[1], A. A. KOSHY[2];
[1]Neurosci., [2]Immunobiology, Neurol., Univ. of Arizona, Tucson, AZ

Abstract: *Toxoplasma gondii* is a neurotropic intracellular parasite that causes a life-long latent infection in the brain. *T. gondii's* asymptomatic persistence in the central nervous system (CNS) is unusual, leading some investigators to postulate that this chronic infection might change CNS physiology. To date, these studies have been limited to understanding global neurotransmitter changes, as no mechanism existed to interrogate the single infected neuron *in vivo*. We developed a novel mouse model that allows us to permanently mark and track CNS host cells that have been injected with parasite effector proteins, parasite proteins that are secreted into host cells and manipulate host cell signaling. As the marking of these cells depends only on the injection of a *T. gondii* protein and does not require active infection, we can identify injected host cells, even if these cells do not harbor parasites. Using this system, we have previously shown that in the CNS, *T. gondii* primarily injects neurons, which we call *T. gondii*-injected neurons (TINs). Using a custom MATLAB-based mapping program, we have found that TINs are not homogenously distributed throughout the brain but instead are primarily found in the cortex and striatum. In addition, we have found that TINs co-localize with Ctip2, a medium spiny neuron marker. Given these findings (localization in the striatum and co-localization with Ctip2), we sought to define TINs physiology in the dorsal striatum because the majority of the neurons in this area are medium spiny neurons, allowing us to leverage the well-defined electrophysiology of these cells. Using *ex vivo* slices, we have found that dorsal striatum bystander neurons, neurons near a TIN but not injected with parasite protein, show only minor changes in the passive electrophysiology properties compared to dorsal striatum neurons from uninfected mice. Conversely, the passive electrical properties of TINs are vastly abnormal, including depolarized resting membrane potentials and the need for increased current injection to induce firing. These data suggest that, *in vivo*, interacting with *T. gondii* changes neuron firing properties. Current studies are aimed at determining the mechanism leading to these drastic electrophysiological changes in TINs, including apoptotic labeling and establishing an *in vitro* system that mimics these *in vivo* findings.

Title: Morphine modulation of endolysosomal iron stores leads to FHC upregulation and dendritic spine deficits in cortical neurons

Authors: *E. IROLLO[1], B. NASH[1], E. E. RIGGS[1], P. HALCROW[2], G. DATTA[2], J. D. GEIGER[2], O. MEUCCI[1];
[1]Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Biomed. Sci., Univ. of North Dakota Sch. of Med. and Hlth. Sci., Grand Forks, ND

Abstract: Opioid abuse continues to be a severe public health problem and is prevalent among HIV+ individuals. Several studies demonstrated that drug use/abuse may accelerate HIV infection and worsen HIV-associated neurocognitive disorders (HAND). Synaptodendritic injury is correlated with neurocognitive decline and thought to be an underlying mechanism of HAND. However, the mechanism by which opioids contribute to HAND is unclear. We have previously shown that morphine decreases dendritic spine density of cortical neurons *in vitro* and *in vivo,* which requires upregulation of ferritin heavy chain (FHC), a novel negative regulator of the dendritic spine promoting CXCL12/CXCR4 chemokine axis. Here, we investigated the mechanism of morphine-mediated FHC upregulation and how various types of dendritic spines are affected using primary cortical neurons and ~4-week old Holtzman rats of either sex. In primary neurons, 24 hour morphine exposure dose-dependently increased FHC levels, and decreased the density of mushroom and thin dendritic spines. Both outcomes were blocked by inhibiting μ-opioid receptor activation with CTAP, or Gαi-protein signaling with pertussis toxin. Layer 2/3 medial prefrontal cortex neurons in morphine-treated rats also showed increased FHC levels, and decreased density of mushroom and thin dendritic spines. In primary neurons, morphine did not alter FHC transcript expression. As iron also post-transcriptionally regulates FHC, we next examined if iron was involved downstream of morphine. Both FHC and FLC (ferritin light chain), which assemble to form the ferritin iron storage complex, were upregulated by iron loading and morphine. Interestingly, morphine upregulated FHC faster than iron loading, suggesting that morphine mobilizes iron from an intracellular store. Indeed, morphine simultaneously decreased endolysosomal iron content and increased cytosolic iron levels prior to FHC upregulation. Further, chelation of endolysosomal iron with DFO blocked morphine-mediated FHC upregulation and dendritic spine deficits, whereas extracellular iron chelation with DTPA had no effect on this pathway. These studies reveal a novel interaction between opioid receptor signaling and neuronal iron metabolism that may contribute to synaptodendritic damage in opioid-using patients with HAND and in other neurodegenerative disorders with reported dysregulation of iron.

Title: Examining the contribution of excitatory and inhibitory neurons to CXCR4-induced dendritic spine changes using a lentiviral CRISPRi approach

Authors: *J. LUCHETTA, R. BRANDIMARTI, E. IROLLO, C.-T. HO, O. MEUCCI;
Dept. of Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The chemokine CXCL12 and its main signaling receptor, CXCR4, play essential roles in the CNS. CXCR4 is expressed in inhibitory neurons during development as it is key to their proper migration; however, expression of CXCR4 in the adult brain seems to be widespread. Our previous *in vivo* and *in vitro* studies have shown that the CXCL12/CXCR4 axis positively regulates dendritic spine density in mature cortical neurons. This effect is mediated by activation of the Rac1/PAK pathway and ensuing actin stabilization. Our findings also show that thin spines, a highly dynamic type of spines implicated in synaptic plasticity, are predominantly affected by the chemokine - *in vitro* as well as *in vivo*. In line with this, CXCL12 stimulation of the CXCR4/Rac1/PAK pathway rescued both dendritic and cognitive deficits in a rat transgenic model of HIV-associated cognitive decline, which is primarily caused by synaptodendritic loss. However, it is presently unclear whether CXCL12 regulates spines by acting directly on excitatory neurons or via inhibitory circuits. This study aims to determine whether CXCR4 signaling on either or both of these neuronal sub-types drives the rescue of dendritic spines. To this end, we generated several lentiviral CXCR4-CRISPRi constructs and tested them in primary cortical neurons from E17 Holtzman rats of either sex, with the intent of selectively silencing CXCR4 in inhibitory or excitatory neurons. First, we determined that the proportion of excitatory to inhibitory neurons in our cortical cultures was similar to previously published studies by immunocytochemical staining against GABA, vGAT, and vGLUT. We also confirmed CXCR4 expression in excitatory and inhibitory cultured neurons. Next, we designed two inducible CRISPRi constructs that use GFP as a reporter for dCas9 expression, and distinct small guide RNAs targeting the CXCR4 promoter near exon 1. To confine CXCR4 silencing to specific neuronal subpopulations, we generated constructs that replaced the tetracyclin-inducible system for dCas9 with excitatory neuron-specific CaMKIIα promoter, or inhibitory neuron-specific mDlx enhancer regulatory elements. We demonstrated that transduction of DIV 21 neurons using the mDlx construct restricted dCas9 to a sub-population of cells. These constructs will be used

for future work examining excitatory and inhibitory CXCR4 contributions to dendritic spine density and ultimately, cognitive performance in animal models of HIV-associated neurocognitive disorders. Additionally, these studies represent an important step toward the identification of network-level effects of CXCR4 signaling in cortical neurons.

Title: HIV-Tat protein expression modulates cognitive performance through induction of a hyperglutamatergic state in the brain

Authors: *T. J. CIRINO, H. M. STACY, S. O. EANS, S. W. HARDEN, C. J. FRAZIER, J. P. MCLAUGHLIN;
Pharmacodynamics, Univ. of Florida, Gainesville, FL

Abstract: Despite improving treatment, the prevalence of HIV Associated Neurocognitive Disorder (HAND) in HIV-positive patients has grown paradoxically worse. We hypothesize that brain exposure to HIV-1 Tat protein alters glutamatergic signaling to promote HAND symptomology. Using the GT-tg bigenic (iTat) mouse model, where brain-selective Tat expression is controlled by activation of a doxycycline (Dox) promotor, we correlated the effects of CNS-expression of HIV-Tat protein on glutamatergic signaling in brain circuits of the prefrontal cortex and hippocampus to Tat's effect on executive function and spatial learning and memory. In preliminary studies, exposure to the HIV-Tat protein significantly decreased rheobase and action potential threshold and increased excitability (in response to injected current) of layer 2/3 pyramidal neurons in the mPFC. These data reveal effects of Tat that may underlie enhanced performance of Dox treated iTat mice in an attentional set shifting assay. In contrast, HIV-Tat protein exposure increased rheobase as observed in hippocampal CA1 pyramidal cells. This effect was associated with reduced firing under low to moderate loads, although maximum firing rate was not significantly affected. These data reveal effects of Tat that may underlie impaired performance of Dox treated iTat mice as observed in a spatial memory task. Pretreatment with the glutaminase inhibitor JHU-083 prevented Tat-associated spatial learning and memory impairment supporting the link between cognitive impairment and a Tat-

induced hyperglutamatergic state. Ongoing efforts are evaluating spontaneous excitatory and spontaneous inhibitory post-synaptic currents (sEPSC/sIPSCs) in both regions after Tat protein exposure, and also evoking glutamate release in order to measure the NMDA / AMPA ratio. Additional preliminary data suggests the NR2B antagonist, ifenprodil , attenuates Tat-protein induced deficits in spatial learning and memory. Overall, these data suggest that expression of HIV-1 Tat protein in the CNS has brain region specific effects on cellular physiology and glutamatergic signaling that may underlie differential effects on behavior, specifically, improving cognitive flexibility associated with enhanced cortical function, while impairing performance in spatial learning and memory tasks associated with dysregulated hippocampal excitability. Characterizing the biological means by which HIV infection may mediate HAND symptomology in the absence of a full viral infection, may provide useful information for clinical intervention, in the current treatment era.

Title: Methamphetamine impairs IgG1-mediated phagocytosis and killing of cryptococcus neoformans by macrophage and microglia cell lines *in vitro*

Authors: *L. ASLANYAN[1], H. LEE[2], V. EKHAR[2], L. R. MARTINEZ[3], R. L. RAMOS[2]; [1]Biomed. Sci., [2]NYIT Col. of Osteo. Med., Old Westbury, NY; [3]Biol. Sci. - Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX

Abstract: The prevalence of methamphetamine (METH) use is estimated at ~35 million people worldwide, with over 10 million users in the United States. Chronic METH abuse and dependence predispose the users to participate in risky behaviors that may result in the acquisition of HIV and AIDS-related infections. METH compromises phagocyte effector functions, which might have deleterious consequences on infection control. In this study, we investigated the role of METH in phagocytosis and antigen processing by J774.16 macrophage- and NR-9460 microglia-like cells in the presence of a specific IgG1 to *C. neoformans* capsular polysaccharide. METH inhibits antibody-mediated phagocytosis of cryptococci by macrophages and microglia, likely due to reduced expression of membrane-bound Fcγ receptors. METH interferes with phagocytic cells' phagosomal maturation, resulting in impaired fungal control.

Phagocytic cell reduction in nitric oxide production during interactions with cryptococci was associated with decreased levels of tumor necrosis factor alpha (TNF-α) and lowered expression of Fcγ receptors. Importantly, pharmacological levels of METH in human blood and organs are cytotoxic to ~20% of the phagocytes. Our findings suggest that METH abrogates immune cellular and molecular functions and may be deadly to phagocytic cells, which may result in increased susceptibility of users to acquire infectious diseases.

Abstract: HIV continues to be one of the most prevalent yet treatable chronic viral infections in the world. While advancements in treatment have increased rates of survival in HIV+ individuals, secondary pathologies such as HIV-associated neurocognitive disorder occur in chronically infected persons due to HIV persistence in the CNS. Other literature also suggests that, when taken orally over decades, antiretroviral (ARV) drugs such as dolutegravir (DTG) induce peripheral neuropathies and neurodegeneration. We are currently in the preliminary stages of developing and testing ARV drug delivery using nanoparticles. Polymeric nanoparticle (NP) ARV drug encapsulations have been shown to decrease drug cytotoxicity, extend release time, and increase the efficacy of drug delivery as compared to oral administrations. Our work focuses on the design of poly-lactic-co-glycolic acid (PLGA) NP encapsulations of DTG conjugated to human holo-transferrin (hhTf), a receptor agonist known to enhance transcellular transport through endothelial cells at the BBB. *In vitro* cell viability assays were used to evaluate the cytotoxicity of NP fabrications compared to drug solution. DTG at varying concentrations (10µg/mL to 0.001µg/mL) was delivered to endothelial and CNS cells in solution or encapsulated NPs (hhTf-PLGA-DTG-NP) for 24, 48, and 96h. Cell viability assays showed

statistically significant differences in cytotoxicity of hhTf-PLGA-DTG-NP versus DTG solution applications at most DTG concentrations. Mean % viability in endothelial HCMEC/D3 cells treated with hhTf-PLGA-DTG-NP showed enhanced viability of 33% at 24h, 58% at 48h, and 39% at 96h at 1ug/mL DTG. Astrocyte viability increased by 35% at 24h, 76% at 48h, and 56% at 96h at 1ug/mL DTG. Microglia cell viability increased at 24 and 48h by 79% and 100% respectively, though by 18% increase at 96h. SH-SY5Y neuronal viability increased by 15% at 24h, 36% at 48h, and 13% at 96h. Immunocytochemistry of primary rat astrocytes, cortical neurons, HCMEC/D3s, and microglial cells exposed to hhTf-PLGA encapsulations tagged with Alexafluor 594 were performed. NP uptake was demonstrated as early as 15 minutes in all cell types. Additionally, hhTf-PLGA-NP-Alexafluor 594 were applied to HCMEC/D3 cells to investigate colocalization of hhTf-NPs to transferrin receptor via immunofluorescent labeling using confocal microscopy. Our data suggest that receptor-ligand colocalization may be occurring as early as 15 minutes in HCMEC/D3s. These results collectively indicate that our NPs may be translocated to the endothelial cells of the blood-brain barrier and improve the cytotoxic effects of DTG to CNS cells.

Title: Latent infection of herpes simplex virus type 1 augments anxiety-like behavior in BALB/c mice (*mus musculus*)

Authors: *I. K. HOUGH[1], M. M. OLESH[2], G. D. GRIFFIN[3];
[1]Biol., [3]Departments of Biol. and Psychology, [2]Hope Col., Holland, MI

Abstract: Nearly 70% of the US population has been infected with HSV-1. Epidemiological research has shown that being seropositive for HSV-1 is associated with a decrease in working memory-related tasks. To test if HSV-1 causes changes in behavior, this work used BALB/c mice to test the hypothesis that HSV-1 infections decreased performance of tasks involving working memory. Male and female BALB/C mice (infected at 6 weeks of age) were tested approximately 238 days post infection (dpi) after being inoculated with 10^5 plaque forming units of the F-strain of HSV-1. Next, mice were evaluated on the open field test and the nestlet test. The infected male mice took longer to enter the center of the field than their uninfected

counterparts ($p<0.05$), while there was no difference for the female mice. For the nestlet test, male mice shredded more than the uninfected male mice ($p<0.05$). These results indicate that HSV-1 increases the expression of anxiety-like behaviors, particularly in male mice. Future work will focus on utilizing tests for anxiety like behaviors and increasing the sample size of BALB/C mice for both males and females.

Title: Aging with HIV infection - Markers for risk of impairment: A comparison with Parkinson’s disease

Authors: *E. M. MULLER-OEHRING[1,2], R. FAMA[1], J.-Y. HONG[2], K. L. POSTON[3], H. BRONTE-STEWART[3], E. V. SULLIVAN[1], A. PFEFFERBAUM[2], T. SCHULTE[2,4]; [1]Stanford Univ. Abstract: Effective treatment with antiretroviral therapy (ART) has prolonged the life expectancies of individuals infected with human immunodeficiency virus (HIV) to be comparable to those in the general population. Despite ART and viral suppression, HIV-associated neurocognitive disorder (HAND) occurs frequently. Aging HIV individuals may be at risk for additional motor impairment similar to that in Parkinson's disease (PD), given that both diseases affect corticostriatal pathways subserving motor function. To determine cognitive and motor impairment profiles, 42 older HIV individuals, 41 PD individuals, and 37 age-matched healthy controls (HC) underwent neuropsychological testing including oral information processing speed (IP), executive functions (EF), verbal memory (VM), visuospatial skills (VS), and fine finger motor abilities (MOT). Participants were also rated on the Unified Parkinson’s Disease Rating Scale (UPDRS) for Parkinsonian motor signs and underwent MRI for brain

morphological measures. Composite scores for each category were calculated, Z-transformed, and corrected for age and education based on HC. Impairment was defined as -1.5 SD below HC (mean=0, SD=1) for each functional domain. In HIV 32% were impaired on IP, 39% on EF, 36% on VM, 39% on VS, and 15% on MOT domain scores. PD were tested on dopaminergic medication to reduce the impact of motor disturbances on test scores. In PD 22% were impaired on IP, 10% on EF, 27% on VM, 29% on VS, and 24% on MOT domain scores. In HIV, IP impairment was associated with impairment in all other cognitive and motor domains, whereas in PD it was only related to EF and VM. The subset of HIV individuals with MOT impairment also showed more parkinsonian signs, and as part of the UPDRS reported significantly more daytime sleepiness and disturbed nighttime sleep. In PD, MOT impairment (on meds) was mainly associated with UPDRS clinical motor scores (on and off meds), smaller putamen volumes, and VS impairment. Also, UPDRS-III motor scores off-dopaminergic medication were higher in PD patients with poorer nighttime sleep (rho=.33, p=.02) and more fatigue (rho=.36, p=.01). Together these results highlight that impairment in oral IP speed can serve as a marker for an increased risk of neurocognitive impairment in HIV. Considering that sleep disturbances occur in PD, and often start prior to motor signs, our finding suggests that disturbed sleep and increased daytime sleepiness may render HIV-infected individuals vulnerable to experiencing motor functional decline and developing parkinsonism. **Support:** AA023165, AA017347, AA017168, NS075097, AG047366, Michael J Fox foundation for Parkinson's research

Title: Impact of HSV1 on an *in vitro* model of traumatic brain injury

Authors: *N. WEIGLE[1], C. DA SILVA[1], K. RUSSELL[1], G. D. GRIFFIN[2];
[2]Departments of Biol. and Psychology, [1]Hope Col., Holland, MI

Abstract: Infection of Herpes Simplex Virus Type I (HSV-1) has been associated with the exacerbation of neurodegenerative pathologies. More specifically, *in vitro* and *in vivo* studies have revealed that HSV-1 can augment levels of the phosphorylated form of tau, a modified

cytoskeletal protein that is enriched in neurofibrillary tangles and forms of dementia such as Alzheimer's disease. HSV-1 is a neurotropic virus that establishes and maintains latency in sensory neurons. Physiological and emotional stressors have been shown to reactivate the virus from this latent stage and spread to the central nervous system. In an *in vitro* model of Vero cells, our data has shown increased levels of hyperphosphorylated tau as a result of HSV-1 infection. Ongoing analysis is being performed to further understand the impact of HSV-1 infection on the phosphorylation of tau in rat hippocampal neurons.

Title: Examining metabolic stress and inflammation in a murine model of HIV-associated PCNSL

Authors: S. ANDHAVARAPU[1], J. BRYANT[2], *D. PATEL[1], A. KATURI[1], H. DAVIS[2], A. HEREDIA[2], T. K. MAKAR[1];

Abstract: Background: HIV-associated primary central nervous system lymphoma (PCNSL) is a malignant diffuse large B-cell lymphoma that occurs in 3-5 % of HIV patients. Studies using animal models are critical to better understanding HIV-associated PCNSL pathogenesis and to investigate potential therapeutic strategies. Symptoms of HIV PCNSL include loss of cognitive function such as memory loss. Because the hippocampus plays a crucial role in cognitive ability, we analyzed cellular and metabolic changes in the hippocampus of the HIV-1-associated PCNSL mouse model.
Methods: The transgenic mouse line TgN (pNL43d14)26Lab (Tg26) was generated by deleting 3kb sequences of gag and pol genes from the 7.4kb HIV proviral transgene. The colony developing lymphoma was generated by cross breeding heterozygous Tg26 mice with skin lesions. 25% of HIV Tg26 mice spontaneously developed lymphoma in the CNS, whereas 75% of the mice developed systemic lymphomas. Cells from the systemic lymphomas were injected intravenously into a new set of Tg26 mice, where 2% of mice developed PCNSL. Paraffin sections of brain tissue from 3 types of mice were prepared: Wild type (WT), Tg26, and Tg26 + PCNSL. Immunohistochemical staining and brightfield microscopy were used to observe the

expression of CD45, GFAP, NFκB, TNF-α, SIRT1, and PGC1-α. ImageJ was used for histological quantifications, and Prism software was used for statistical analysis.
Results: CD45, GFAP, NFκB, TNF-α, and SIRT1 were all were significantly elevated in the hippocampal regions of the Tg26 mice and further upregulated in the Tg26 + PCNSL mice in comparison to the WT. PGC1-α was downregulated in the Tg26 mice but upregulated in the Tg26 + PCNSL mice in comparison to WT.
Conclusion: Increased GFAP signifies that there is increased glial activation in the hippocampal regions of Tg26 mice with PCNSL. Glial cell activation breaks the integrity of the blood-brain-barrier, resulting in enhanced cellular infiltration as seen with CD45 levels. NFκB is implicated with various signaling pathways in the cell including TNF-α and SIRT1, a regulator of PGC1-α. While future research will help to elucidate the interplay between these proteins, we show that there is a link between the inflammatory response and metabolic changes in the disease pathology, suggesting that targeting NFkB and SIRT1 may present a novel therapeutic approach for HIV-associated PCNSL.

Title: HIV-1 Tat interacts with selective estrogen receptor modulators to influence morphine-conditioned place preference

Authors: *A. N. QRAREYA, S. MOHAMMED, F. MAHDI, J. J. PARIS;
Bimolecular Sci., The Univ. of Mississippi, University, MS

Abstract: Opioid abuse is a common route of transmission for human immunodeficiency virus (HIV), involved in 13.8% of new infections among women and 8.3% of new infections among men. We have found that the HIV-1 regulatory protein, trans-activator of transcription (Tat), can potentiate the rewarding properties of cocaine or morphine in male mice. Tat also potentiates cocaine reward in female mice and these effects are estrous cycle-dependent. But how Tat interacts with sex steroid targets to influence opioid reward is not well-understood. We hypothesized that estradiol would potentiate Tat-mediated opioid reward and that these effects would be differentially modulated by estrogen receptor α (ERα)- and β (ERβ)-acting selective

estrogen receptor modulators (SERMs). Ovariectomized Tat-transgenic mice were treated with vehicle, a physiological regimen of estradiol (0.09 mg/kg, QOD for 12 d), the ERα-selective SERM, propylpyrazole triol (PPT; 0.09 mg/kg, QOD for 12 d), or the ERβ-selective SERM, diarylpropionitrile (DPN; 0.09 mg/kg, QOD for 12 d) and assessed for morphine reward in an unbiased conditioned place preference (CPP) paradigm. Complementary *in vitro* studies were performed on primary C57BL/6HNsd mixed glial cells that were treated with vehicle, Tat (100 nM), morphine (500 nM), estradiol, PPT, and/or DPN (0.01-10 nM) and assessed for reactive oxygen species (ROS) formation via CM-H_2DCFDA assay. All mice demonstrated morphine-CPP and induction of Tat alone did not influence this effect. However, the combination of Tat and estradiol significantly increased morphine-reward. The ERβ-selective SERM, DPN, did not influence basal morphine-CPP; however, the ERα-selective SERM, PPT, attenuated morphine-CPP in both Tat-transgenic mice and their wildtype counterparts. In primary mixed glia, Tat significantly increased the formation of ROS (~10-15% above baseline) and physiological concentrations of estradiol (0.01-1 nM) significantly attenuated this effect with or without morphine co-exposure. Of interest, the highest estradiol concentration (10 nM) significantly interacted with morphine to increase ROS production (~20% above baseline), irrespective of Tat. Similarly, DPN or PPT attenuated Tat-mediated ROS; however, these effects were notably greater with PPT. Like estradiol, both DPN and PPT significantly interacted with morphine to increase ROS, but the effects occurred at lower concentration for DPN (1 nM) and to greater effect (~30% above baseline) than PPT (at 10 nM, ~11% above baseline). Thus, estrogen receptors may serve as important targets for Tat/opioid interactions.

Title: HIV-1 Tat protein and oxycodone dysregulate adrenal and gonadal endocrine axes and promote affective and cognitive dysfunction in mice

Authors: *S. MOHAMMED[1], A. N. QRAREYA[2], F. MAHDI[2], J. J. PARIS[2];
[1]BioMolecular Sci., Univ. of Mississippi, Oxford, MS; [2]BioMolecular Sci., Univ. of Mississippi, University, MS

Abstract: Human immunodeficiency virus (HIV) is associated with co-morbid affective and neurocognitive disorders that afflict ~50% of infected individuals. One factor that may contribute to neuropathology is the HIV regulatory protein, trans-activator of transcription (Tat), which promotes neuroinflammation and neurotoxicity that can be exacerbated by opioids. We and others have observed steroid hormones, such as estradiol and/or progesterone, to attenuate Tat-mediated neurotoxicity in cell culture; however, their interactions with opioids and their protective effects in a whole-animal model are unknown. We hypothesized that doxycycline-inducible expression of Tat in transgenic mice would interact with the opioid, oxycodone, to induce psychomotor, anxiety-like, and depression-like behavior and to dysregulate adrenal and gonadal steroid hormones. When administered acutely, oxycodone (3 mg/kg) increased psychomotor behavior in an open field and induction of HIV-1 Tat protein significantly potentiated these effects. Tat expression also potentiated the anxiolytic-like effects of oxycodone, increasing entries into the center of the open field, but only among females in the diestrous phase of the estrous cycle. Tat increased depression-like behavior among proestrous, but not diestrous, females. When administered repeatedly, oxycodone (3 mg/kg, QD for 5d) interacted with Tat protein to decrease cognitive performance in a novel object recognition test among all mice with the exception of proestrous control mice. These data suggest that induction of Tat potentiates psychomotor and anxiety-like effects of acute oxycodone and either Tat induction or repeated oxycodone perturb cognitive performance. Manipulations also influenced adrenal and gonadal endocrine status in a cycle-dependent manner. Tat or oxycodone increased circulating corticosterone in all mice acutely and repeated administration produced greater elevations. Tat increased circulating estradiol and progesterone among diestrous mice and decreased estradiol among proestrous mice. Oxycodone increased estradiol and progesterone among diestrous mice when administered acutely, but only elevated estradiol when administered repeatedly. Thus, neuroendocrine function may be an important target for HIV-1 Tat/opioid interactions.

Title: High content analysis of the neuropathogenesis of SIV infection in the presence of dopamine

Authors: *H. S. JOHNSON[1], K. RUNNER[2], H. S. FOX[3], P. J. GASKILL[2];
[2]Pharmacol. and Physiol., [1]Drexel Univ. Col. of Med., Philadelphia, PA; [3]Pharmacol. and Exp Neuroscie, Univ. of NE Med. Cente, Omaha, NE

Abstract: Globally, around 37 million people are infected with HIV, despite advancements in antiretroviral therapy. HIV enters the central nervous system (CNS) rapidly after initial infection, resulting in a variety of neurological effects collectively known as NeuroHIV. These effects are thought to result, at least partially, from infection of CNS macrophages, the primary targets for HIV in the brain. NeuroHIV is altered by drug abuse, a common comorbidity in the HIV-infected population. While different types of drugs have distinct mechanisms of action, all drugs of abuse increase dopamine. Our research shows increased dopamine both enhances HIV infection and increases production of inflammatory mediators in macrophages. To better understand the impact of increased dopamine in HIV neuropathogenesis, Rhesus macaques were inoculated with SIV in the presence or absence of selegiline, which increases CNS dopamine, and sacrificed after 2 weeks to analyze early changes in brain tissue. CNS tissues were processed and analyzed by both immunofluorescent staining and HPLC to determine how regional changes in CNS dopamine influence the progress of NeuroHIV. In dopamine-rich regions such as the caudate, nuclear localization of the transcription factor NF-κB was increased in macrophages. This suggests that dopamine may enhance inflammation by increasing the release of NF-κB regulated cytokines, such as IL-6 and IL-1β, and correlates with our published data in primary human macrophages. We are currently examining the amount of infection in these regions to determine whether elevated dopamine increases SIV infection in macrophages. These data suggest an interaction between dopamine and SIV enhancing the development of NeuroHIV, a hypothesis supported by previous *in vitro* studies. Understanding the relationship between CNS dopamine and HIV infection will help us to define the impact of substance abuse on HIV neuropathogenesis, leading to more effective treatments for NeuroHIV in drug abusers.

Title: Dopamine-mediated conformational changes in CCR5 in HIV infection of myeloid cells

Authors: *S. MATT[1], Y. RONG[1], M. O'CONNOR[2], N. RADIO[3], P. J. GASKILL[1];
[1]Pharmacol. and Physiol., [2]Div. of Infectious Dis. and HIV Med., Drexel Univ. Col. of Med., Philadelphia, PA; [3]ThermoFisher Scientific Cell. Imaging and Analysis, Carlsbad, CA

Abstract: Although combination antiretroviral therapy (cART) has greatly reduced HIV-related mortality, there are still 37 million people worldwide infected with HIV. Even with cART, infected cells within the central nervous system (CNS) can produce new virus and release neurotoxic factors that may contribute to NeuroHIV. In addition, drug abuse is disproportionately prevalent within the HIV-infected population, and may exacerbate the pathology associated with NeuroHIV. Aberrant regulation of dopamine, which is elevated by the use of all illicit drugs, can also play a role in HIV progression. Our lab has previously shown that dopamine can increase HIV entry in human monocyte-derived macrophages (MDM), suggesting that drug-induced increases in CNS dopamine could accelerate the spread of infection, but the precise mechanism is unknown. One possible mechanism is dopamine-mediated changes in CCR5, the primary co-receptor used by HIV to enter myeloid cells. CCR5 can adopt many conformations, specifically in the second extracellular loop and N-terminal regions, to differentially regulate the accessibility or binding affinity to HIV, which can alter efficiency of HIV entry. Conformationally distinct CCR5 subpopulations also show different affinities with lipid rafts, which could also influence the HIV entry process. Our results demonstrate that dopamine increases the relative abundance of different CCR5 conformations on the MDM surface, and we are currently examining whether these changes also occur in microglia. We are also determining whether these dopamine-induced changes in specific CCR5 epitopes impact HIV entry. Further, our data show that CCR5 conformations differentially colocalize with lipid rafts, although this does not seem to be influenced by dopamine. A detailed understanding of dopamine-mediated changes in CCR5 will be critical to effectively tailor cART regimens that may be more beneficial in HIV+ individuals who abuse drugs. These data will support future projects targeting specific CCR5 conformations for use as novel HIV inhibitors in at risk populations, as these may be more effective in preventing HIV entry. Ultimately, our findings could also have broader implications for how dopamine can shift protein conformations in relation to other disease states.

Title: Role of dopamine in the modulation of macrophage-mediated inflammation: Implications for NeuroHIV and drug abuse

Authors: *P. J. GASKILL, R. A. NOLAN, K. RUNNER, Y. RONG;
Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Drug abuse is an important comorbidity in HIV infection, affecting 10 - 20% of HIV infected individuals. Abuse of drugs exacerbates peripheral HIV infection and has been linked to the development of NeuroHIV, as HIV-infected drug abusers have a higher risk of neurocognitive impairment. These effects are seen with all types of drugs of abuse, suggesting a common mechanism by which drug abuse impacts NeuroHIV. One mechanism common to all drugs of abuse is an increase extracellular dopamine in the CNS. Research shows correlations between dopaminergic dysfunction and HIV infection of the CNS, suggesting that inflammation induced by elevated dopamine could enhance the development of HIV-associated neuropathology. However, the precise mechanism(s) by which elevated dopamine could exacerbate the progress of HAND remain unclear. As the primary targets for and responders to HIV in the CNS are myeloid lineage cells, the effects of dopamine on these cells may be a key connection between dopaminergic changes and HIV-associated neuroinflammation.Our data show that dopamine treatment of human macrophages promotes an inflammatory phenotype in these cells by inducing production of the inflammatory mediators IL-1β, IL-6, IL-18, CCL2, CXCL8, CXCL9, and CXCL10. Further, dopamine-mediated modulation of specific cytokines is correlated with macrophage expression of dopamine-receptor transcripts, particularly DRD5, which we show to be expressed at significantly higher levels than other dopamine-receptor subtypes. Mechanistically, these effects may be induced by dopamine-mediated activation of inflammatory pathways, as our data show dopamine activates the NF-κB pathway. This results in increased expression of NF-κB modulated genes including NLRP3 and IL-1βthat prime the NLRP3 inflammasome complex. Thus, elevated CNS dopamine in the context of HIV and/or drug abuse may potentiate neuroinflammation via the NF-κB pathway. These changes may also influence the development or maintenance of addiction in these individuals. Overall, these data will provide more understanding of the role of dopamine in the development of NeuroHIV, and may suggest new molecules or pathways that can be useful as therapeutic targets for HIV-infected drug abusers.

Title: Dopamine modulates HIV entry into macrophages via G_q-dependent signaling mechanisms

Authors: *E. NICKOLOFF-BYBEL[1], P. MACKIE[4], K. RUNNER[2], R. NOLAN[3], S. MATT[5], H. KHOSHBOUEI[4], P. J. GASKILL[3];

Abstract: Despite the use of combined anti-retroviral therapy (cART), many individuals with HIV still experience neurocognitive decline and neuropathology. Significant neurologic dysfunction is seen in dopaminergic regions of the CNS, suggesting that dopamine may play a role in the development of NeuroHIV. Our lab has shown that dopamine can increase HIV entry and replication in primary human macrophages, the primary cell type infected in the CNS. However, mechanisms by which dopamine mediates these effects remains unclear. Previously, we demonstrated that activation of both D1-like and D2-like receptors increases viral entry into macrophages, suggesting these receptors may act through a common mechanism to enhance the entry process. Our current data support this hypothesis, showing dopamine stimulates calcium release in human macrophages, and inhibition of this calcium flux prevents dopamine-mediated increases in viral entry. This suggests that dopamine's effects on viral entry is modulated by signaling through a non-canonical dopamine signaling pathway, in which activation of either dopamine receptor subtype leads to IP_3-mediated calcium release and PKC activation. Our data demonstrate the activity of this pathway in human macrophages, showing that dopamine stimulates calcium release and PKC phosphorylation in these cells. The dopamine-mediated increases in both calcium release and PKC phosphorylation were inhibited by treatment with a G_q inhibitor. Additionally, our data show that dopamine receptor activation did not increase cAMP production, suggesting that canonical dopamine signaling is not occurring in these cells. Together, these data indicate dopamine mediates its effects on viral entry into macrophages via a non-canonical signaling pathway. Moreover, these data suggest dopamine may signal through different mechanisms depending on cell type, highlighting a need to re-examine the way we think of the canonical dopamine signaling paradigm. Recent studies indicate dopamine can act as a critical mediator of the neuroimmune axis, and therefore it is critical to understand how dopamine acts in distinct cell types. Future studies will further define these dopamine signaling pathways, both in the context of HIV infection and under non-pathological conditions.

Title: ERp29 a PDI family molecular chaperone: A potential target for host factor altering connexin 43 mediated gap junction intercellular communication in mouse astrocytes

Authors: *A. BOSE[1], D. THOMAS[1], P. MUKHERJEE[1], M. MAULIK[1], M. KOVAL[2], J. DAS SARMA[1];

[2]Departments of Med. and Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: In the central nervous system (CNS), gap-junctions (GJs) directly connect the cytoplasm between neighbouring cells creating a “panglial syncytium”, critical for metabolic coupling and brain homeostasis. It has been recognised for several years that certain RNA and tumor viruses decrease gap-junctional intercellular communication (GJIC) among infected cells. Recently, we showed in a mouse model of demyelination that Mouse Hepatitis Virus (MHV) infection disrupts Connexin43 (Cx43)-containing GJs predominantly expressed by astrocytes. Specifically, MHV infection repressed Cx43 trafficking to cell surface by a microtubule-dependent mechanism during the acute phase of inflammation following infection. However, the mechanism of depletion of Cx43 at the cell surface as well as its reduced expression at mRNA and total protein level is not well understood. We hypothesize that MHV induces ER stress that amplifies the unfolded protein response leading to defects in Cx43 processing and gap-junction channel formation. Consistent with inducing ER stress, MHV infection upregulated GRP78 (Bip) in a dose-dependent manner in primary astrocytes and DBT astrocytoma cells (N=3). Furthermore, MHV infection down-regulated ERp29, an ER resident PDI family protein known to promote Cx43 assembly and trafficking to the plasma membrane, thus enhancing GJIC. Stable transfection of exogenous ERp29 in DBT cells, that endogenously express internalised Cx43 and mimic retention of Cx43 in the intracellular compartment of infected astrocytes, rescued the trafficking of Cx43 to cell surface. Supporting this observation, treatment of infected primary astrocytes or DBT cells with 4-phenylbutyrate (4-PBA) that is known to upregulate native ERp29 expression, facilitated Cx43 trafficking to the cell surface and re-established GJIC.

Further studies showed increasing exogenous ERp29 expression decreased viral infectivity, fusogenicity and replication both in DBT cells and primary astrocytes. Our findings describe a previously unidentified, viral-induced ER stress pathway involving ERp29 as a potential target to restore proper trafficking of Cx43 and re-establish GJIC in the CNS. It will be interesting to explore the regulatory role of ERp29 and ERp29 rescued Cx43 mediated GJIC in mounting antiviral host response.

Title: Astrocyte derived HIV evolution in humanized mice

Authors: *H. J. BARBIAN, V. LUTGEN, L. AL-HARTHI;
Rush Univ. Med. Ctr., Chicago, IL

Abstract: HIV infects the brain during acute infection and persists in the CNS despite suppressive antiretroviral therapy. While ample data demonstrates HIV genetic compartmentalization between the CNS and the periphery, it is unclear if HIV undergoes significant evolution within the CNS and whether CNS egress contributes to peripheral HIV quasispecies. We previously developed a humanized mouse model where HIV infected human fetal astrocytes were xenotransplanted into NSG mice and reconstituted with human PBMCs. Using this model, we demonstrated that astrocytes, the predominant brain cell type, support replication competent HIV which can egress from the CNS to peripheral organs (spleen, lymph node). In this study, we assessed genomic changes in HIV that egressed from astrocytes. Using single genome amplification and direct sequencing, the gold standard for HIV quasispecies characterization, we show that virus had evolved, with 24% of spleen sequences showing mutations from the original viral inoculum. The mutated genomes showed random diversification, APOBEC mutations, Poisson distribution, star-like phylogeny, and time to most recent common ancestor analysis correctly identified the duration of infection (95% CI=27-61 days, actual=33 days), suggesting that viral evolution in this model fits the mathematical model of acute HIV-1 diversification in humans. Thus, astrocyte-derived HIV evolves and mimics the viral evolution observed in early peripheral infection and can contribute to peripheral genetic diversity. Ongoing studies are assessing HIV evolution within astrocytes over time.

Title: Hypoxia-ischemia during a neonatal sensitive period reduces purkinje neuron dendritic complexity only in males

Authors: *S. E. ARAMBULA[1], A. R. R. LEITE[2], M. PEREZ-POUCHOULEN[1], M. M. MCCARTHY[1];
[1]Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Morphology, Univ. Estadual Paulista - UNESP, Botucatu, Brazil

Abstract: Neonatal hypoxia-ischemia (HI; concurrent oxygen/blood deprivation) is a major health issue with few effective therapies. HI-related brain injuries occur in approximately 2 out of 1,000 term births and are the leading cause of mortality and disabilities in children. Notably, male infants are at a greater risk for HI and exhibit more extreme deficits than females. Although clinical evidence indicates that neonatal HI impacts the cerebellum, this region has been largely ignored in preclinical models. Cerebellar development is unique as it is one of the first brain structures to differentiate yet one of the last to fully mature; making it particularly vulnerable to developmental injury. Our lab has previously identified the second postnatal week in the rat as a sensitive period of cerebellar development that is dysregulated by inflammatory insults. This period coincides with a time of increased risk for perinatal HI (e.g. birth in human infants). Collectively, these data suggest that neonatal HI could impair cerebellar development by stunting Purkinje neuron complexity. To examine the effect of neonatal HI on Purkinje neurons we used a modified version of the Rice-Vannucci model representative of HI brain injury in the term infant. On postnatal day 1 (P1), Sprague-Dawley rat pups received bilateral intracerebroventricular injections of an AAV that expressed eGFP driven by the CB7 promoter to label Purkinje neurons. On P10, animals underwent unilateral ligation of the internal carotid artery followed by hypoxia (8% oxygen for 1hr). Age-matched, sham-operated animals served as controls for all experiments. Cerebellar vermes were collected on P17, processed for confocal microscopy and Sholl analysis of Purkinje neurons was used to quantify branching characteristics of Purkinje cells. In males, neonatal HI significantly ($P < 0.01$) reduced Purkinje dendritic arbor complexity, such that the dendritic tree branched less frequently. Intriguingly, there was a slight but significant ($P < 0.05$) increase in female dendritic branching, suggesting either that repair

mechanisms are initiated earlier in females or that females are protected from HI. Thus, optimal windows for intervention might differ between the sexes. Additional studies are underway to determine the impact of neonatal HI on other cerebellar cell types, including microglia, and astrocytes. This research fills a knowledge gap by defining the impact of HI on the cerebellum and may lead to novel insights on how sex regulates vulnerability to brain injury.

Title: Impact of hypoxic ischemic brain injury on astrocytes in the developing cerebellum

Authors: *A. R. R. LEITE[1], S. E. ARAMBULA[2], M. M. MCCARTHY[3];
[1]Morphology, Univ. Estadual Paulista - UNESP, Botucatu, Brazil; [2]Pharmacol., [3]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Neonatal hypoxia ischemia (HI) is the major cause of brain injury in the term infant and occurs when the newborn brain doesn't receive enough oxygen due to blood loss or other complications during delivery. The cerebellum is one of the first brain structures to differentiate and one of the last to mature, making it more vulnerable to perturbations occurring during development. While clinical data shows that neonatal HI impacts the cerebellum, this brain region has largely been overlooked in experimental research. To model HI in the term infant, male and female Sprague Dawley rat pups were subjected to a unilateral internal carotid artery ligation, followed by exposure to 8% oxygen air for 60 min on postnatal day (PN) 10. Control animals for all experiments were sham-operated. On PN17, animals were euthanized and cerebellar vermis were dissected, sagittally sectioned on a cryostat, and processed for immunohistochemistry. Astrocytes are dynamic cells that maintain brain homeostasis and provide structural, metabolic and trophic support to neurons. Moreover, impairment in astrocyte function during brain injury can influence neuronal survival and recent studies have shown that growth factors produced by astrocytes can be critical in regenerating trauma-damaged brain tissues. To examine the impact of HI on cerebellar astrocytes, glial fibrillary acidic protein (GFAP) immunoreactivity was evaluated. Initial analyses using ImageJ indicate that HI does not affect the number or density of cerebellar astrocytes in either males or females one week after HI

brain injury. Further studies are underway to determine how HI affects Purkinje cells and granule cells of the cerebellar vermis.

Title: Oligodendrocyte differentiation is regulated by Sirt2 in white matter after neonatal hypoxia

Authors: *B. JABLONSKA[1], L.-J. CHEW[1], M. REIBER[1], K. KUSCH[2], K. .-A. NAVE[2], V. GALLO[1];
[1]Children's Natl. Med. Ctr., Washington, DC; [2]Dept. of Neurogenetics, Max Planck Inst. for Exptl. Medicine,, Göttingen, Germany

Abstract: Diffuse white matter injury (DWMI) is a major form of brain injury, which results in chronic neurological and behavioral disabilities in prematurely born infants, including a broad spectrum of cognitive and learning disabilities until young adulthood. Using a mouse model of neonatal hypoxia, we previously demonstrated that hypoxia delayed oligodendrocyte (OL) maturation in white matter by decreasing FoxO1 induced $p27^{Kip1}$ levels. Since Sirt2 is implicated in OL maturation, we determined whether neonatal hypoxia altered Sirt2 expression and function in white matter. Hypoxia reduced Sirt2 expression and the number of $Sirt2^+$ cells in white matter along with the number of $Sirt2^+CC1^+$ and $Sirt2^+Olig2^+$ cells. Since Sirt2 siRNA treatment of cultured OLs reduced percentages of $Olig2^+$, $GalC^+$, and $O4^+$ cells, it is likely that hypoxia-induced decrease in Sirt2 prevents OL differentiation. To investigate the role of Sirt2 in OL differentiation after hypoxia, we performed loss- and gain-of-function experiments in $Sirt2^{fl/fl}PDGFR^{cre}$ and $Sirt2^{Stop}PDGFR^{cre}$ mice, in which Sirt2 was ablated or overexpressed in PDGFR-expressing oligodendrocyte progenitor cells, respectively, after tamoxifen injection at P12. The percentage of $CC1^+$ and $Olig2^+$ cells expressing Sirt2 decreased in white matter of $Sirt2^{fl/fl}PDGFR^{cre}$ mice after normoxia and hypoxia, while the opposite effect was observed in $Sirt2^{Stop}PDGFR^{cre}$ mice. In normoxic $Sirt2^{fl/fl}PDGFR^{cre}$ mice, the total number of $CC1^+$ OLs was reduced, as compared to WT mice, whereas Sirt2 overexpression elevated the number of mature OLs. Under hypoxic conditions, the absence of Sirt2 further reduced OL in white matter, whereas Sirt2 overexpression elevated the percentage of $CC1^+$ and $Olig2^+$ cells. Molecular

analysis revealed that Sirt2 formed complexes with FoxO1 and FoxO3a transcription factors in white matter. The Sirt2/FoxO1 complex and deacetylated FoxO1 were reduced by hypoxia. Instead, hypoxia enhanced formation of the Sirt2/FoxO3a complex, but also reduced deacetylated FoxO3a levels. Since FoxO1 and FoxO3a deacetylation are required for transcriptional activity, these changes induced by hypoxia suggest that reduced Sirt2-mediated deacetylation of FoxO1 and FoxO3a underlie reduced $p27^{Kip1}$ expression in injured white matter. Our findings demonstrate that i) Sirt2 promotes OLs differentiation under normoxic and hypoxic conditions, ii) Sirt2 overexpression partially rescues the effect of hypoxia on OL maturation in white matter iii) the functional involvement of Sirt2 may provide a link between cell cycle inhibitors and delayed OL maturation in hypoxia-induced white matter damage.

Title: Effects of transient receptor potential cation channel 5 inhibition on global cerebral ischemia-induced neuronal death

Authors: *B. KANG, B. CHOI, A. KHO, S. LEE, D. HONG, J. JEONG, D. KANG, M. PARK, S. SUH;
Hallym Univ., Chuncheon, Korea, Republic of

Abstract: Increased zinc accumulation in the brain plays a critical role in neuronal death in brain diseases such as ischemia, traumatic brain injury, epileptic seizure and hypoglycemia. During such conditions, vesicular zinc is pre-synaptically released into the synaptic cleft and translocated to the cytoplasm via various cation channels. It causes the production of reactive oxygen species (ROS) and neuronal death. Transient receptor potential cation channel 5 (TRPC5) is a receptor-activated non-selective cation channel. NU6027is known as an inhibitor of TRPC5, which regulate the homeostasis of metal ions. In this study, we tested that whether blocking TRPC5 by using NU6027 shows neuroprotective effects and zinc accumulation following global cerebral ischemia (GCI) in mice. We used C57BL/6J mice (aged 2-3 months)

and performed a GCI model that occluded the bilateral common carotid artery (BCCA) for 30 minutes. NU6027 (1 mg/kg, *i.p.)* was immediately injected and mice sacrificed after 24 hours. Neuronal death, zinc accumulation and oxidative stress were confirmed by Fluoro-Jade B (FJB), N-(6-methoxy-8-quinolyl)-para-toluenesulfonamide (TSQ) and 4HNE staining in the brain hippocampal region. The present study found that GCI induced by BCCA occlusion increased considerably neuronal death, zinc accumulation and oxidative stress. But, administration of NU6027 decreased the number of degenerating neurons, zinc accumulation and oxidative stress in the subiculum, CA1, CA3 and dentate gyrus after GCI, via downregulation of TRPC5 channels. Therefore, this study suggests that NU6027, a TRPC5 inhibitor, may have therapeutic potential for prevention of GCI-induced neuronal death, zinc accumulation and oxidative stress.

Ctr., Muenchen, Germany; [3]Translational Stroke Res., Inst. for Stroke and Dementia Research, Univ. of Munich Med. Ctr., Munich, Germany; [4]Cluster for Systems Neurol., Munich, Germany

Abstract: Stroke induces neuronal deafferentation leading to remote anatomical and functional changes (diaschisis) via mechanisms not yet fully understood. The aim of the current study was to characterize the long-term effect of a cortical infarct on contralesional cortical reorganization

and dendritic dynamics and to correlate these changes to sensorimotor behavior and neural activity. To achieve these aims we performed the following experiments: We (i) characterized the consequences of cortical stroke and deafferentation of neurons of origin in the contralesional cortex using anterograde and retrograde viral labeling up to two months after cerebral ischemia. (ii) determined the ipsilesional *versus* contralesional relative expression of GABA and Glutamate synaptic transmission markers. (iii) investigated dendritic spine turnover in the contralesional hemisphere by repetitive 2-photon *in vivo* imaging, in correlation with behavioral analysis using an optimized long term survival mouse model depicting large stroke and sustained sensorimotor deficit. (iv) mapped the contralesional neural activity by functional hyperemia using laser speckle imaging. Two months after stroke, we found significant contralesional cortical thinning (-11%; $p<0.001$) in absence of substantial cell loss or neuronal body shrinkage but a decrease of neuropil fraction (-14%). In parallel with changes in relative excitatory/inhibitory balance between both hemispheres, we also observed decreased contralesional spine density in apical dendrites of transcallosal neurons (-35%). The longitudinal analysis in the contralesional cortex revealed that deafferented neurons displayed dynamic dendritic spine turnover favoring spine replacement. However, their density decreased over the course of stroke recovery which plateaued after 3 weeks (40% residual deficit). This structural reorganization is accompanied by reduced functional hyperemia (-33%) in the homotopic contralateral region of the lesion and a shift of the remaining blood flow response to neighboring tissue further implicating changes in neural activity and synaptic transmission in the contralesional cortex. Our data revealed stroke-induced transhemispheric diaschisis mediated by deafferentation of transcallosal neurons. Impacted transcallosal neurons remodel their dendritic spines and trigger contralesional cortex structural and functional reorganization. Currently, we investigate whether this process can be modulated in order to counteract sustained functional impairments in the chronic phase after ischemic stroke.

Title: Effect of NSMase-2 inhibitor on extracellular vesicle release and injury after neonatal stroke

Authors: *M. LECUYER, P. PATHIPATI, J. FAUSTINO, Z. VEXLER;
Neurol., UCSF, San Francisco, CA

Abstract: Perinatal arterial stroke (occurs between the 20th gestation week to 28th day of life) leads to long-lasting cerebral disabilities. Although the inflammatory damage is a major brain injury component in the early postnatal period, microglia could limit injury after neonatal stroke (Faustino et al, J Neurosci 2011). These immune cells are central to the crosstalk between brains' cells. Release of extracellular vesicles (EV) is a largely unexplored mechanism of communication. Neutral Sphingomyelinase 2 (N-SMase2) is a plasma membrane enzyme which mediates EV release.
Aim: To understand the role and the underlying mechanisms of N-SMase2 dependent release and signaling of microglia-derived EV.
To investigate the contribution of N-SMase2 in injury after neonatal stroke, we have chosen to downregulate the gene Smpd3 (Sphingomyelin phosphodiesterase 3), which encodes N-SMase2, using a KO-CRISPR/dcas9. Control or KO-CRISPR/dcas9 was injected intracerebral at postnatal day 7 (P7) and enzyme activity examined daily between P9-P12. Transient middle cerebral artery occlusion (tMCAO) was performed at P9. In treated and non-treated pups enzymatic N-SMase2 activity and cell origin expression were examined by immunofluorescence (IF) and histological outcomes determined 72h after reperfusion. Microglia was isolated from injured/uninjured cortex by magneto-isolation. Released microglia derived EV (MEV) were characterized using Nanosight. MEV protein expression was determined by Western. Results: We observed a developmental increase of N-SMase-2 activity in naïve brain from P10 to P12 ($p<0.016$) and a significant decrease in KO-CRISPR/dcas9-treated mice compared to Control-CRISPR/dcas9 at P12 ($p<0.0062$). tMCAO reduced significantly N-SMase-2 activity in injured regions ($p<0.0043$). Based on IF, N-SMase-2 expression was markedly reduced in neurons within injured regions. Injury volume was significantly reduced by down regulation of Smpd3 ($p<0.0029$). Decreased N-SMase2 activity in Control mice correlated with reduced Glut-1 coverage, an effect in part prevented by KO-CRISPR/dcas9 pre-treatment, and neuro-protection. Microglia isolated and plated 24h after tMCAO proliferated and increase release of MEV. Uptake of MEV differs in microglia from injury region. Conclusion: Downregulation of N-SMase2 protects neonatal brain from stroke, in part due to vasculature preservation. MEV uptake by microglia from injured cortex is increased. In fine, these results will provide a better understanding of the implication of this novel cell-cell communication on severity of neonatal stroke.

Title: The anti-oxidant, n-acetyl-l-cysteine attenuates hippocampal neurodegeneration after global cerebral ischemia via inhibition of transient receptor potential melastatin 2

Authors: *D. HONG[1], B. CHOI[1], A. KHO[1], S. LEE[1], J. JEONG[1], B. KANG[1], D. KANG[1], M. PARK[1], K.-H. PARK[2], S. SUH[1];
[1]Physiol., Hallym University, Col. of Med., Chuncheon, Korea, Republic of; [2]Div. of Cardiovasc. Dis., Hallym Univ. Med. Ctr., Anyang, Korea, Republic of

Abstract: A variety of cerebral ischemia induced neurodegenerative mechanisms have been verified and demonstrated such as calcium/zinc influx into cytoplasm, reactive oxygen species (ROS) production and ionic imbalance. Our lab has suggested that excessive zinc influx into neurons after the ischemic condition can be deleterious. During ischemic conditions after stroke or heart attack, vesicular zinc can be released into the synaptic cleft, and then translocated into the cytoplasm via various cation channels. Transient receptor potential melastatins (TRPMs) are non-selective cation channels. These channels have various subunits, one of them, TRPM2 was highly distributed in the central nervous system and it has high sensitivity to oxidative damage. Several previous studies have shown that TRPM2 channel activation attributes to neuroinflammation and neurodegeneration cascades. Therefore, in the present study we verified whether anti-oxidant such as N-acetyl-l-cysteine (NAC) treatment has neuroprotection via regulation of TRPM2 after global cerebral ischemia (GCI). Also, we hypothesized that if we block zinc influx with a TRPM2 channel blocker, ischemia-induced neuronal death can be prevented. To demonstrate our hypothesis, we used a GCI animal disease model. It was induced by common carotid artery occlusion and an isoelectric period set for seven minutes. In the present study, we delivered NAC (150mg/kg) into the intraperitoneal space daily administration for 3 days and 7 days. GCI-induced cell degeneration was estimated by Fluoro-Jade B (FJB); oxidative damage by lipid peroxidation was measured by 4-hydroxy-2-nonenal (4HNE); glial activation was assessed by ionized calcium-binding adapter molecule 1 (Iba-1) and glial fibrillary acidic protein (GFAP); zinc accumulation was detected by N-(6-methoxy-8-quinolyl)-para-toluensulfonamide (TSQ); and TRPM2 channel regulation was assayed by TRPM2 staining. As a result, NAC reduced GCI-induced cell damage cascades, such as hippocampal degenerating neurons, lipid peroxidation, microglia & astroglia activation, free zinc accumulation, as well as

TRPM2 over-activation. Consequently, TRPM2 channel may be a therapeutic target to prevent ischemia-induced neuronal death.

Title: The newly-found AMP-activated protein kinase (AMPK) inhibitors reduce hypoglycemia-induced hippocampal neuronal death

Authors: *A. KHO[1], B. CHOI[1], S. LEE[1], D. HONG[1], J. JEONG[1], B. KANG[1], D. KANG[2], M. PARK[1], S. SUH[1];

Abstract: Severe hypoglycemia (below 35mg/dL) is common in patients who are continuously treated with drugs such as insulin in order to control their blood glucose level. The worst outcomes of hypoglycemia can include unconsciousness, seizure or even death. To treat hypoglycemia, glucose reperfusion, performed to recover low blood glucose level in hypoglycemic state is required, but also acts as a secondary injury, causing aggravated neuronal cell death. Severe and prolonged hypoglycemia causes oxidative stress via NMDA excitotoxicity, inflammation, blood-brain barrier disruption, mitochondrial dysfunction and zinc release. AMP-activated protein kinases (AMPK) is a sensor of AMP: ATP ratio and generally plays a role in cellular energy homeostasis under a normal condition. However, under pathological conditions such as stroke and Huntington's disease, AMPK is found to be abnormally activated. This leads to aberrant neuronal nitric oxide synthase activity which produces peroxynitrite, the strongest oxidizing agent, and exacerbates lactate accumulation, which inhibits the ability of neurons to use lactate as an energy source, contributing to neuronal death. Also, in a previous study, AMPK causes zinc-induced neuronal death via the liver kinases B1 (LKB1)-dependent induction of a pro-apoptotic Bcl-2 homology domain 3-only protein (Bim). AMPK consists of three subunits, α subunits (α1 and α2), β subunits (β1 and β2) and γ subunits (γ1, γ2 and γ3). The α subunit is responsible for the catalytic kinase activity, with α2

acting as the dominant catalytic subunit in neurons. This study was therefore conducted to confirm whether the inhibition of AMPKα2 prevents neuronal cell death, including oxidative stress, zinc toxicity, inflammation and blood-brain barrier (BBB) disruption after hypoglycemia and glucose reperfusion. To evaluate this, we used an insulin-induced hypoglycemia animal model and injected AMPK α2 inhibitors (2G11 and 1H10, respectively 20μg/kg and 5μg/kg, *i.v.*, 1time) immediately after hypoglycemia. When administered as intravenous injections after insult, 2G11 and 1H10 significantly reduced hippocampal neuronal cell death. Therefore, the present study suggests that inhibitors of AMPK could be promising drug development candidates to treat hypoglycemia. Title: Gamma knife irradiation induced blood-brain barrier disruption and activation of glial cells in mice

Authors: *B. HE[1], X. WANG[4], P. YU[1], J. JIANG[1], W.-J. LIN[2], Y. TANG[3];
[1]Dept. of Neurology, Sun Yat-Sen Mem. Hospital, Sun Yat-Sen Univ., Guangzhou, China; [2]Dept. of Neurology, Sun Yat-Sen Mem. Hospital, Sun Yat-Sen Univ., Guangzhou city, Guangdong province, China; [3]Dept. of Neurology, Sun Yat-Sen Mem. Hospital, Sun Yat-Sen Univ., Guangdong, China; [4]Dept. of Oncology, The First Affiliated Hosp. of Guangdong Pharmaceut. Univ., Guangzhou, China

Abstract: Background: Gamma knife radiosurgery is a clinically and cost effective treatment for malignant brain tumors,especially for most brain metastases. However, patients may suffer from side effects including encephaledema, delayed cerebral infarction, or cognitive dysfunction. The underlying mechanism remains unclear. Blood-brain barrier (BBB) is likely to be the first to bear the brunt. In this study, we investigated the pathological impact of gamma knife irradiation on blood-brain barrier integrity and the neuroinflammatory response in the mouse model.
Materials and Methods: C57BL/6 and BALB/c mice were irradiated with Leksell Gamma Knife with 55Gy at the 50% isodose delivered to left hippocampal area. The appearance and size of brain lesion were evaluated by 7T MRI at different time points post radiation. Cerebral blood

perfusion of mice which haven't developed lesion in the brain were evaluated by arterial spin-labeling MRI (ASL-MRI). Two-photon microscopy, Evans blue dye, and immunofluorescence staining of fibrinogen were employed to measure BBB permeability. The morphology and number of glial cells were measured and quantified using immunofluorescence staining and ImageJ analysis.**Results:** Our data showed that before the development of brain lesion, the irradiated mice displayed cortical hypoperfusion detected by ASL-MRI . Four weeks after irradiation, the cerebral lesion can be clearly seen by MRI imaging and verified by two-photon microscopy imaging with low molecular weight fluorescent dye. Increase in Evans blue dye extravasation and fibrinogen leakage into the brain in irradiated mice also suggested disruption of BBB. In addition, immunofluorescence staining of Iba1, CD68, and S100βshowed significant increase in activated microglial and astrocytes, especially around the necrotic vessels at the ipsilateral side of the irradiated brains, suggesting the disruption of BBB may further lead to activation of glial cells.**Conclusions:** Gamma knife irradiation mouse models successfully induced disruption of blood-brain barrier and the activation of glial cells surrounding necrotic area.

Title: Blood brain barrier is disrupted in intraventricular hemorrhage in extremely low preterm infants

Authors: *A. DEL POZO SANZ, Sr, M. VILLA, C. VARGAS, M. MARTINEZ, L. SILVA, J. MARTINEZ-ORGADO, A. GUTIÉRREZ-RODRÍGUEZ;
Hosp. Clinico San Carlos, Madrid, Spain

Abstract: Intraventricular Hemorrhage (IVH) is a frequent condition in extremely low birthweight preterm newborns (ELBW), representing a major risk factor for Cerebral Palsy (CP) with no current treatment. Furthermore, in these patients Blood Brain Barrier (BBB) is disrupted and leukocytes translocation and microglia activation are observed. At present, these data have been observed in other IVH neonatal models, but never in a ELBW model. We aim to determine if IVH brain damage and BBB disruption/hyperpermeability in a ELBW rat model are associated.
IVH brain damage was induced in newborn Wistar rats (1 day-old: P1). At P6, BBB disruption and brain damage was assessed by: Biochemistry [Neuroinflammation: Toll like receptor 4

(TLR-4); Oxidative stress: inducible Nitric Oxidase (iNOS); BBB hyperpermeability: Major Facilitator Superfamily Domain Containing 2a (MFSD2a); BBB disruption: Intercellular Adhesion Molecule 1 (ICAM-1)]; Spectroscopy [Excitotoxicity (Glut/NAA) and Cell metabolism (Lac/NAA)]; Flow cytometry [Total and M1/M2 ratio of microglia / macrophages activated population] studies. Non-IVH group was treated as control.
In IVH group, Biochemical analysis shows an increase of BBB permeability and damage, oxidative stress and neuroinflammation. Moreover, Spectroscopy studies revealed higher levels of excitotoxicity and cell metabolism. Flow cytometry studies revealed an increase of total microglia / macrophages population with a pro-inflammatory phenotype. N per group = 5. These results are observed in the table below.
Our findings provide BBB disfunction in our model is related with the brain damage. Furthermore, BBB could be a possible therapeutic target to prevent CP secondary to IVH in ELBW.

Title: Targeted protective role of azithromycin in a neonatal mouse model for periventricular leukomalacia (PVL)

Authors: *K. R. AYASOLLA[1], N. ZAGHLOUL[2], M. AHMED[2];
[1]Feinstein Inst. For Med. Res., Manhasset, NY; [2]Neonatology Division/ Dept. of Pediatrics, Banner - Diamond Children's Med. Ctr. ; The Univ. of Arizona Col. of Med., Tucson, AZ

Abstract.Abstract1:

Background: PVL is the most common cause of cerebral palsy in premature infants. Inflammation and microglial involvement has a role in its pathogenesis. In this study, we propose that azithromycin administration reduces the inflammatory process leading to decreased brain injury induced by Hypoxia-ischemia (HI) and with better outcome.

Objective: To examine the neuroprotective function of azithromycin as a new therapeutic approach in neonate mouse model of PVL.

Design/Methods: PVL neonate mouse model was established by temporary bilateral carotid ligation at P5, followed by hypoxia exposure with O2 concentration of 8% for 20 min. Three neonate groups were studied. Room Air Control (RA control), hypoxia Ischemia (HI) + saline injection and (HI) + azithromycin injection. Two doses of Azithromycin were injected IP at a dose of 20mg/kg at P5 (2 hours after HI insult) and at P6. At defined time points following HI, brain inflammatory cytokine markers , immunostaining for various neuronal markers, such as (neurons: NeuN; astrocytes: GFAP; for microglia: Iba1,CD68,arginase 1; oligodendrocyte: CNPase; apoptosis:caspase 3) and western blots for phospho stress kinases such as pAKT, pp38, pSAPK, pERK, pCREB and pP65 were performed. MicroRNA profile panel was studied using a custom designed microarray plate.

Results: Azithromycin treated pups showed minimal paresis and co-ordination deficits as compared to saline treated HI group, which had severe insult. Histopathology showed ventriculomegally, neuronal necrosis and apoptosis in saline treated HI group which was ameliorated in azithromycin treated HI group. There was a significant decrease in IL 12p70, IL6, KC GRO in the azithromycin treated HI vs. saline treated HI. Quantitative immunostaining showed significantly less injury in HI azithromycin treated (more NeuN, olig 2, CNPase and less expression of GFAP, caspase 3) associated with a shift towards an M2 microglial phenotype (increased arginase 1 and decreased in CD68), vs. the saline treated group. There was

a significant decrease in pAKT, pP38, pSAPK, pERK, pCREB and pP65 in the HI azithromycin treated vs. saline treated pup brains. MicroRNA, analysis showed a unique and innovative role of azithromycin in attenuating specific microRNA expression among HI treated group.

Conclusion(s): Azithromycin treatment showed significant reduction in PVL. It shifts microglial inflammation towards an M2 phenotype. Overall it significantly reduces the inflammatory milieu by decreasing pro-inflammatory cytokine release and NF-KB activity and has an innovative role by ameliorating specific microRNA expression which was previously were linked to brain hypoxia and neuro-inflammation.

Title: Effects of cerebrolysin on hippocampal neuronal death and neurogenesis after pilocarpine-induced seizure

Authors: *D. KANG[1], B. CHOI[1], A. KHO[1], S. LEE[1], J. JEONG[1], D. HONG[1], B. KANG[1], M. PARK[1], H. CHOI[2], H. SONG[2], S. SUH[1];

Abstract: Epileptic seizure occurs due to the presence of excessive, uncontrolled neuronal activity in the brain. If severe seizure continues, it leads to oxidative stress, zinc release, neuronal death, and cognitive impairment in the brain. Cerebrolysin is a porcine brain peptide that is a unique neurotropic and neuroprotective agent that not only exhibits neurotrophic factor action like to Nerve Growth Factor (NGF) but also can pass the Blood Brain Barrier (BBB), unlike NGF. Cerebrolysin has been reported to increase neuroprotective effects and neurogenesis in head trauma, ischemia, and other CNS diseases. However, the effect of cerebrolysin on seizure was not known. Therefore, this study purposes to investigate the effect of cerebrolysin on neuronal death and neurogenesis in the hippocampus after seizure. To confirm the effect of cerebrolysin, we used a pilocarpine-induced seizure animal model. Lithium chloride (127mg/kg) is injected intraperitoneally 19 hours before pilocarpine injection, scopolamine (2mg/kg) is injected intraperitoneally 30 minutes before pilocarpine injection. After 30 minutes, pilocarpine (25mg/kg) is injected intraperitoneally, seizure was induced for 2 hours. After 2 hours from the seizure induction time point, diazepam (25mg/kg) was injected to finish the induction of the seizure and then cerebrolysin (2.5ml/kg, i.p, once per day for 7 days) was immediately injected. After 1 week, we perfused seizure-induced animals by 0.9% saline and 4% paraformaldehyde and harvest brains. We performed Neuronal Nuclei (NeuN) staining to evaluate any protective effects of cerebrolysin on seizure-induced neuronal death in the hippocampus. Also, we performed bromodeoxyuridine (BrdU) staining to monitor neurogenesis. Here we found that cerebrolysin decreased hippocampal neuronal death. Cell proliferation, which confirmed active neurogenesis, was increased compared to the vehicle treated group after seizure. Therefore, the present study suggests that administration of cerebrolysin can be useful as a therapy to prevent neuronal death and restore cellular function after seizure. Keywords: Epileptic Seizure, Pilocarpine, Cerebrolysin, Neuronal death, Neurogenesis

Title: Therapeutic effects of carvacrol in hippocampal neuronal death after pilocarpine-induced seizure

Authors: *J. JEONG[1], B. CHOI[1], A. KHO[1], S. LEE[1], D. HONG[1], D. KANG[1], B. KANG[1], M. PARK[1], H. CHOI[2], H. SONG[2], S. SUH[1];

Abstract: Temporal lobe epilepsy (TLE) is one of the most devastating and common neurological illnesses experienced by young people across the world and is one of the principal causes of cognitive impairment. The underlying cause of epilepsy has not yet been elucidated, but many symptoms arise after brain injury such as stroke and head trauma. Neuronal death after seizure occurs has already been well described. When the brain is injured, free zinc is released from stores in the extracellular membrane into the intracellular space and accumulates. When zinc enters into the intracellular space, zinc is separated from zinc-binding proteins and accumulates as the free zinc form. Our lab has demonstrated that neuronal death after seizure is initiated by excessive accumulation of zinc. Transient receptor potential melastatin 7 (TRPM7) channel is known to be an ion channel to promote calcium entry into the cell. It is also known as a channel that specifically participates in the transport of zinc. Carvacrol is an essential oil extracted from *Origanum vulgare*, which acts as a TRPM7 channel inhibitor. It has been reported that there is a protective effect on neuronal death after brain injury such as ischemia or traumatic brain injury. So, we hypothesized that carvacrol, which inhibits the TRPM7 channel, may have neuroprotective effects by reducing excessive accumulation of vesicular free zinc after seizure. TLE was induced by lithium-pilocarpine in male rats. We injected lithium chloride (125mg/kg, i.p.) 19 hour before administration of pilocarpine. And we injected scopolamine (2mg/kg, i.p.) 30 minutes before pilocarpine. We injected pilocarpine (25mg/kg, i.p.) and performed behavioral testing based on the Racine stage. We injected carvacrol (50mg/kg/day, i.p.) for 3 days after seizure. To confirm the histological evaluation, we proceeded with immunohistochemistry staining. To detect degenerating neurons, oxidative injury, microglia activation and TRPM7

channel activation, we performed Fluoro-Jade B, 4HNE, Iba1, and TPRM7 staining, respectively. We also performed TSQ staining to determine the level of vesicular free zinc. As a result, degenerating neurons, oxidative injury, microglia activation, TRPM7 channel activation, and vesicular free zinc levels were reduced in the carvacrol group after seizure. Therefore, we suggest that carvacrol has neuroprotective effects by inhibiting the TRPM7 channel and thus reduces the abnormally elevated free zinc accumulation after seizure and has potentially therapeutic effects. Keywords: epilepsy; pilocarpine; carvacrol; TRPM7 channel; zinc; neuronal death.

Title: Temporal change of zinc transporters after pilocarpine-induced seizure

Authors: *S. LEE[1], B. CHOI[1], A. KHO[1], J. JEONG[1], D. HONG[1], D. KANG[1], B. KANG[1], M. PARK[1], H. SONG[2], H. CHOI[2], S. SUH[1];

Abstract: Epileptic seizure is caused by abnormal excitation of the brain and the excessive release of excitatory neurotransmitters. Seizure can destroy neuronal circuits, leading memory loss or cognitive impairment in severe cases. In previous studies, seizure caused oxidative stress, blood-brain barrier disruption, immune cell infiltration and excessive zinc release, leading to neuronal death. Zinc acts in a bidirectional manner. Under normal physiological conditions, zinc (Zn^{2+}) regulates neuronal excitation by blocking the NMDA receptor or other glutamate receptors. However, in pathological conditions such as seizure, zinc homeostasis is disrupted and zinc is excessively released into synaptic craft. This causes the accumulation of zinc in the post synaptic neuron and then acts as to promote excitotoxicity in neurons, leading to neuronal death. Zinc transporters (ZnTs) are a type of membrane transport protein that regulates intracellular and extracellular zinc concentration. ZnT1 is expressed in the plasma membrane of neurons and glia,

which transports zinc from intracellular space to extracellular space. ZnT3 is expressed in the vesicle membrane in neurons, which is necessary for the re-uptake of zinc from the cytosol. After seizure, zinc has profound effects on neuronal death in a short period of time, but it is unclear how it causes cell death. Therefore, it is very important to study on the expression of ZnT1 and ZnT3 and the consequent change in zinc accumulation in the hippocampus after seizure. For the study, we used the pilocarpine-seizure model. Seizure was induced by pilocarpine (25 mg/kg i.p.) injection. Each group was sacrificed at 0 (without diazepam), 6, 12 and 24 hours after seizures induction. To check the expression of ZnT1, ZnT3, and the degree of the neuronal death at each time, we conducted Fluoro-Jade B (FJB) and ZnT1, ZnT3 staining in the hippocampus after seizure. In FJB staining, neuronal death was increased over time and showed the most cell death at 24 hours. In the case of ZnT1 staining, expression was increased up to 12 hours, then to a maximum of 12 hours and decreased significantly from 24 hours. ZnT3 staining also increased as ZnT1 does. These data suggest that the change of zinc transporters (ZnT1 and ZnT3) and zinc level in the presynaptic terminals and hippocampal neurons are related to seizure-induced cell death and it will help to understand how these changes affect oxidative injury, inflammation, blood-brain barrier and neuronal cell death after seizure.

Title: Management of AED resistant epilepsy in children

Authors: *O. V. GLOBA[1], L. KUZENKOVA[1], E. SOROKINA[2], V. PINELIS[2], K. SAVOST'YANOV[2];
[1]Neurol., [2]Lab. of Basic Sci., Scientific Ctr. of Children's Hlth., Moscow, Russian Federation

Abstract: Childhood epilepsies a heterogeneous group of disorders and syndromes with different anthology, prognosis and treatment. The purpose of study was to recognize the possible reason of failed of AED treatment and to find the way to overcome it.Methods: 96 patients with different forms of epilepsy aged from 3 months to 16 years not the candidate for surgical treatment have been studied. The long duration EEG, high resolution MRI, biochemical, immunoassay, genetic investigations were performed to these childrenResults: In these children different metabolic epilepsies , epilepsies in neurodegeneration diseases, genetical epilepsies were found. Among them- respiratory chain disorders confirmed by mtDNA sequences, glutaric

acuduria type1, propionic acuduria, methylmalonic acuduria,Gaucher type3, glycogenosis type9, ceroud lipofuscinosis tip 2 and type 6, genetic epilepsies with mutation in genes SCN1A, SCN8A, GRIN2A, KCNMA1, SRPX2, duplication 15g11.2g13.3. The evaluation of autoantibodies to NMDA NR2a and AMPA GluR1 revealed the high level even in 4-7 times in children with metabolic epilepsies in compare with others and shows the deterioration in receptors function. In children with metabolic disorders and energy metabolism disorders we use the specific diet, supplements (L-carnitine, vitamins,coenzyme Q10, enzyme replacement or substrate reduction therapy and so on, avoid valproic acid, use phenytoin inpatients with SCN8A mutation . We use hormones as well. These treatments led to reduction in seizures frequency or to seizure remission in some cases with improvement in quality of life of patients.Conclusions: the recognition and diagnostic of underlying etiologies of intractable seizures improve the treatment management in many cases.

Title: EEG transient discharges decomposed using independent component analysis and wavelet transform

Authors: *M. VILLANUEVA, P. GAST;
Alpha Theta Ctr., San Diego, CA

Abstract: In scalp-recorded EEG measurement, transient discharges (TDs) are found among clinical populations with identifiable morphology: A sharp wave whose amplitude is 2 -3 times higher than the average background followed by a slow wave which disrupts the EEG from one to several seconds. However, due to the rare and unpredictable nature of these transients, these discharges have been referred to only anecdotally; quantitative investigation has been missing. To overcome this limitation, we conducted a longitudinal study with one participant from whom 19-ch EEG data with TDs located mainly in the left temporal area collected 23 times over 4 years (total 198 min long). The TDs were annotated by two clinical experts. Since these events are rare within a (typically) 10-minute eyes open EEG recording, we annotated each record. We extracted the transients within a 3 second envelope (1.5 before and after the event), then concatenated all the epochs into one data. In analyzing the EEG data, independent component analysis (ICA) was performed on the extended record. Equivalent current dipoles were fitted to each independent component (IC). The ICs from all the recordings were then clustered by their

dipole locations. For each IC clusters, event-related spectral perturbation (ERSP) was computed to perform time-frequency decomposition. The result revealed that the mean occurrence frequency of the TD occurred 2.75 counts per minute (SD 1.54, Range 0.80-6.19). Interestingly, the distribution of the occurrence frequency is skewed to the right as median value being 2.20, indicating that there were more times TDs were infrequent than the mean value. In fact, though based on preliminary observation due to (still) the limited number of data sets, the TD occurrence frequency distribution showed two peaks, one around 1.6 and the other around 3.2. These data suggest that the occurrence frequency of TD is non-normally distributed, indicating presence of a mode whose principle require further investigation. EEG analysis revealed that TD's time-frequency characteristics to be increased power of 12-15 Hz followed by an increase in power in the 4-8 Hz range, confirming the sharp / followed by slow wave morphology. Furthermore, a regression analysis across time points revealed that the effect of 70 neurofeedback training sessions over 4 years turned out to be non-significant. In conclusion, we provided for the first time the distribution characteristics of TD from the longitudinally collected data, and we have underpinned its ICA-decomposed time-frequency characteristics. The EEG result will be useful for building a classifier to detect rare TDs in automatized solutions.

Abstract: INTRODUCTION: Connectivity analysis can be used to identify the seizure onset zone (SOZ) in electrocorticographic (ECoG) recordings from patients undergoing epilepsy surgery. In previous studies, the dynamic of the connectivity was not considered and the average connectivity over specific time intervals was used to distinguish SOZ and non-SOZ electrodes. We proposed a dynamical connectivity analysis and investigated whether this analysis can

accurately discriminate between the SOZ and non-SOZ electrodes. **METHODS:** We retrospectively analyzed 19 seizures in six patients (4 males; aged 19-40 years), who underwent a Phase II epilepsy surgery evaluation with subdural electrodes. All patients were seizure-free after a minimum 6-month follow-up. Resections were tailored individually based on visual inspection of the ECoG ictal onset in all patients. After preprocessing of ECoG data, dynamical connectivity between subdural electrodes was calculated using Granger causality in a moving window of 10 s with 9 s overlap. We selected two groups of electrodes for our analysis: 1) visually detected electrodes (VDE) as SOZ by epileptologists; and 2) non-resected electrodes (NRE) in seizure-free patients after surgery, presumably electrodes outside of the SOZ. Then we calculated the mean of the intra- and inter-group connectivity for VDE and NRE electrodes. We used a bootstrap resampling approach for the statistical test in this study. **RESULTS:** We found a time interval in all seizures of all patients that the intra-group connectivity of VDEs (VDE→VDE) was significantly larger ($P < 0.05$) than that intra-group NREs (NRE→NRE) or inter-groups (NRE→VDE) connectivity. We also observed that the increase of the VDE→VDE connectivity may occur a short time before or after the seizure onset time (SOT) identified by epileptologists. Since visual identification of the SOT by an epileptologist depends on his/her own personal experience and judgment, this SOT may not be accurate and have a few seconds offset compared to the real seizure onset. **CONCLUSIONS:** Our results show that the dynamical connectivity analysis based on the Granger causality may be able to identify electrodes within the SOZ, and this approach may be used as a complement to the conventional approach of visually identifying the SOZ.

Med., Bronx, NY

Abstract: Background: EpiBioS4Rx aims to identify new therapies to prevent post-traumatic epilepsy (PTE) following traumatic brain injury (TBI). The EpiBioS4Rx project 2 has created a multicenter preclinical therapy screening platform which includes pharmacokinetic (PK) and pharmacodynamic (PD) studies early in the preclinical screening process to determine brain penetration and optimize treatment delivery. As part of these studies, the PK and brain uptake are characterized in naïve animals and in a lateral fluid percussion injury (LFPI) rat model of TBI. **Objective**: To characterize and compare the PK and brain uptake of kineret (IL-1ra, interleukin receptor antagonist), deferiprone (iron chelator), and Z944 (T-calcium channel blocker). These drugs encompass a range of physiochemical properties (for example, molecular weight, lipophilicity) and mechanisms of action. **Methods:** Male 11- week old Sprague Dawley rats were used as either naïve controls or following LFPI induction at the left parietal region, using a 5mm craniotomy and injury parameters optimized to induce severe TBI with a mortality of ~30%. Rats received either a bolus injection (intraperitoneal or subcutaneous), which in LFPI rats was given immediately after injury. Blood was collected from the lateral tail vein at specified timepoints bracketing 0 and 24 hours after the bolus. Parietal cortical samples were collected at similar timepoints. Deferiprone, and Z944 concentrations in plasma and brain were measured using validated HPLC-MS/MS methods. Human IL-1ra was measured using an enzyme-linked immunosorbent assay. Non-compartmental analysis and compartmental PK modeling was completed. **Results:** All drugs exhibited relatively rapid absorption with maximum drug concentrations achieved at 0.5hr for deferiprone and Z944 and 1 hr for kineret. Elimination half-lives ranged from 1-5 hrs with kineret exhibiting the slowest elimination. Z944 exhibited good brain uptake with brain-to-plasma ratios of ~0.8. Kineret has very poor brain penetration with brain-to-plasma ratios <0.001. While drug exposures were similar in the naïve and injured animals, the drug concentrations in the left (injured) cortex were greater than right in LFPI rats. **Conclusions:** The diverse physiochemical properties of the drugs screened resulted in a range of absorption, elimination, and brain penetrations. Obtaining PK information early in the screening allows us to better identify optimal compounds and assist with formulation development and dosing protocols. We can also develop PK/PD models to simulate the effect of drugs on efficacy and safety measurements, guiding optimal treatment protocols in EpiBioS4Rx.

Title: Regulation of behavior sensitization to cocaine administration in NAMPT heterozygous mice

Authors: Q. JIANG, M. NSUMU, L.-Q. ZHANG, ***X.-P. CHU**;
Univ. of Missouri Kansas City, Kansas City, MO

Abstract: Nicotinamide phosphoribosyltransferase (NAMPT), a rate-limiting enzyme in nicotinamide adenine dinucleotide (NAD) biosynthesis in mammals, converts nicotinamide into nicotinamide mononucleotide. NAMPT reveals a critical role in NAD biology, metabolism, aging, inflammation, obesity, liver injury, diabetes, stroke, cancer, and addiction. In this study, we explore the putative role of NAMPT in the regulation of behavioral sensitivity to the psychostimulant cocaine by utilizing NAMPT heterozygous (+/-) mice. Acute cocaine injection at a dose of 20 mg/kg induced an increase in locomotor activities in wild-type (WT) mice. However, cocaine induced a significantly enhanced motor response at this dosage in NAMPT (+/-) mice. In a chronic cocaine administration model (20 mg/kg, once daily for 5 days), a challenge injection of cocaine (20 mg/kg, after 2-week withdrawal) caused a profound behavioral sensitization in the cocaine-pretreated WT mice. This behavioral sensitization to challenge cocaine was also displayed and increased in NAMPT (+/-) mice. Our results demonstrate the important role of NAMPT in the modulation of behavioral sensitization to cocaine. Targeting NAMPT gene might be a therapeutic strategy against cocaine addiction.

Title: Effects of Sox11 on optic nerve regeneration and retinal ganglion cell survival

Authors: *M. NAHMOU[1], K.-C. CHANG[1], M. BIAN[1], A. MADAAN[1], X. XIA[1], Q. WANG[1], L. LIU[1], C. SUN[1], C. KNASEL[1], J. GALVAO[1], B. TANASA[1], Y. HU[3], J. L. GOLDBERG[2]; [1]Ophthalmology, [2]Byers Eye Institute--Ophthalmology, Stanford Univ., Palo Alto, CA; [3]Dept. of Ophthalmology, Stanford Univ. Sch. of Med., Palo Alto, CA

Abstract: Purpose: What are the molecular mechanisms regulating retinal ganglion cell (RGC) survival and optic nerve (ON) regeneration? Failure of RGCs to survive and regenerate after injury or in disease is a leading cause of irreversible blindness worldwide. Previously, transcription factor Sox11 was described to promote regeneration but lead to cell death of a subset of RGCs. In parallel we found that Sox11 desumoylation promotes its nuclear import and efficacy in promoting RGC differentiation from retinal progenitor cells. Here, we study the effects of Sox11 and a non-sumoylatable mutant $Sox11^{K91A}$ on RGC survival and axon growth in vitro and after optic nerve trauma in vivo. **Methods:** We examined the effect of Sox11 and $Sox11^{K91A}$ *in vitro* in primary RGCs isolated from postnatal day 2 mice and transduced with AAV2 viral vectors, examining neurite outgrowth through tracing of axons (n=40-80 cells per group and three independent experiments) and gene expression through bulk RNA sequencing (N=2). To compare the effect of Sox11 and $Sox11^{K91A}$ *in vivo*, we intravitreally injected AAV2-Sox11 and -$Sox11^{K91A}$ into adult mice two weeks before ON crush. Cholera Toxin Subunit B conjugated with Alexa-555 was injected intravitreally at day 12, 2 days before euthanasia, to label regenerating axons. ON regeneration and RGC survival were assayed by measuring CTB-labeled axons in cryosectioned optic nerves and counting RBPMS+ cells in flat-mounted retinas (N=6-8 per group). Data were analyzed by ANOVA with Tukey's test with *P* value of <0.05 considered statistically significant. This research was conducted in compliance with the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research. **Results:** *In vitro*, both Sox11 and $Sox11^{K91A}$ attenuated neurite outgrowth and survival to a comparable extent, compared to AAV-treated controls. *In vivo*, both Sox11 and $Sox11^{K91A}$ enhanced ON regeneration and attenuate cell survival, with a stronger effect on both observed with $Sox11^{K91A}$. RNA sequencing data identified 28 and 11 genes differentially down- and upregulated between Sox11 and $Sox11^{K91A}$-treated RGCs, respectively. **Conclusion:** These data confirm that Sox11 is involved in RGC axon growth and survival. *In vivo*, blocking sumoylation of K91 residue enhances effects of the wild type protein. Further analysis of the downstream-affected genes may reveal how Sox11 oppositely regulates RGC survival and growth, as opposed to more classical "pro-growth/pro-survival" signaling pathways.

Title: Respirator use protects against welding-associated changes in white matter microstructure

Authors: *E. RECHTMAN[1], P. CURTIN[1], L. ONYEBEKE[1], D. PAPAZAHARIAS[1], D. HAZELTINE[1], E. DE WATER[1], M. VENKATESH[1], R. LUCCHINI[1], D. GAUGHAN[1], C. TANG[2], M. HORTON[1];
[1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Dept Radiology & Psychiatry, Mt. Sinai Sch. of Med., New York, NY

Abstract: Welding has been associated with structural and functional brain changes and increased rates of neurobehavioral problems. Respirator use has been shown to protect against respiratory morbidity among welders. Little is known regarding the efficacy of respirators to protect welders from the neurotoxicity of welding fumes. In this preliminary study, we used diffusion tensor imaging (DTI) to investigate the association between welding and white matter (WM) abnormalities and determine the effectiveness of respirator use for protecting workers WM microstructure. We hypothesized that associations between fractional anisotropy (FA) and welding fume exposure would be detected as weak contributions from multiple brain regions, and that the use of a respirator would mitigate these effects.
We enrolled 19 welders from labor unions in the New York City area. All welders completed questionnaires to assess occupational and health histories. All subjects completed a DTI acquisition on a 3T Siemens scanner. DTI data was preprocessed using FSL pipeline and a three-tiered analytical strategy was applied: (1) voxel-wise whole brain group comparisons of FA values between respirator users and non-users across the whole WM skeleton, (2) multiple linear models to test for associations between mean FA in 48 regions defined by the ICBM-DTI-81 atlas and respirator usage, and (3) partial least squares discriminant analysis (PLS-DA) to model the divergence of WM microstructures in respirator users compared to non-users. All three approaches showed associations between respirator usage and WM microstructure in numerous regions of the brain with consistency across approaches. Welders who reported not using a respirator showed decreased FA primarily in the superior longitudinal fasciculus, the uncinate fasciculus and the superior cerebellar peduncle compared to workers who used a respirator. To our knowledge, this study is the first to explore the association between respirator usage and WM microstructure. Our findings indicate that multiple WM microstructure tracts are associated with exposure to welding fume. These tracts are part of the neural network enabling both motor and

neurocognitive processes which may explain the heterogeneity of symptoms reported in welders. These findings have implications for occupational safety regulations and policies.

Title: AAV gene therapy approach for the treatment of Dravet syndrome

Authors: *J. F. ANTINAO DIAZ[1], J. R. COUNSELL[2], S. SCHORGE[3], M. BERTI[1], J. DAVIDGE[4], S. N. WADDINGTON[1], R. KARDA[1];
[1]UCL Inst. for Women's Hlth., London, United Kingdom; [2]NIHR Great Ormond Street Hosp. Biomed. Res. Ctr., London, United Kingdom; [3]UCL Sch. of Pharm., London, United Kingdom; [4]UCL Translational Res. Office, London, United Kingdom

Abstract: Background: Dravet Syndrome (DS) is a genetic childhood epilepsy. Over 80% of the cases are caused by a mutation in the *SCN1A* gene; leading to happloinsufiency of the ion channel $Na_V1.1$. DS has an incidence rate of 1:20,000 to 40,000 live births and patients suffer from fever-sensitive, refractory and generalized seizures and cognitive impairment, which begin at around six months of age. Patients can fall into status epilepticus, which can result in premature death. This disease remains untreatable by either medical or surgical means. Using adeno-associated vectors (AAV) to treat DS presents several challenges: difficulties in propagating wild-type *SCN1A* plasmids in competent cells restrict DNA production and the large transgene (6 Kb) limits incorporation into AAV vectors. Methods: We have designed a bipartite AAV system, in which *SCN1A* is split into two complementary halves between domains 2 and 3, one of which has been codon-optimized. Each construct is driven by a human synapsin promoter. Additionally, we incorporated red and green fluorescent proteins (RFP & GFP) to the first and second halves, respectively. A control carrying only GFP was also produced. A mouse model of DS is used for *in vivo* validation. Results: We confirmed expression of channel protein by western blot in cells co-transfected with both plasmid constructs. AAV8-GFP control vector was delivered via neonatal bilateral intracerebroventricular injection into WT mice, showing widespread brain expression. Knockout Dravet mice received either both treatment vectors

(without fluorescent proteins; n=7) or control AAV8-GFP (n=3) via intracerebroventricular injection in a randomised, blinded study; no difference in survival was found. Follow on electrophysiology suggest functional channels may not be produced.Conclusion: This is the first use of a dual AAV system to restore Nav1.1 expression, as detected by western blot. Optimisation of injection and of the constructs may be carried out to improve expression.

Title: Large-scale modulation of motor cortical activity using epidural cerebellar stimulation

Authors: *T. GULATI, P. LAM, J. LEUNG;
Biomed. Sciences, Neurol., Cedars Sinai Med. Ctr., Los Angeles, CA

Abstract: Several neuromodulatory startegies have shown promise in post-stroke motor recovery. These include non-invasive approaches such as repetitive transcranial magnetic stimulation (rTMS), direct current stimulation (tDCS), as well as implantable approaches such as vagal nerve stimulation (VNS), and epidural cortical stimulation (ECS). These studies indicate that- infarct location, integrity of corticospinal tracts, as well as extent of cortical excitability achieved – all are important factors in responsivity to stimulation. Recent work by Andre Machado and colleagues has shown that deep brain stimulation (DBS) of dentato-thalamocortical (DTC) pathway augments post-stroke motor rehabilitation. This pathway originating from deep cerebellar nucleus has a dense projection to several cortical and subcortical areas, and has a capacity to induce widespread cortical modulation. Furthermore, in an ischemic cortical stroke, there is decreased afferent cerebellar input from cortex due to disruption in cerebropontocerebellar tract. This in turn leads to weakened excitatory output to cortex from the cerebellum via the DTN pathway, and makes it particularly attractive for augmentation through neuromodulation. Apart from DBS, even epidural cerebellar stimulation has been shown to modulate cortical excitability as measured through motor evoked potentials (MEPs). While these studies have provided important insight into capacity of cerebellar stimulation to modulate cortical dynamics, it remains incompletely understood as to how cerebellar stimulation affects the ongoing neural activity in the motor cortex.

We have conducted acute experiments in anesthetized rodents to assess how epidural cerebellar stimulation can affect large-scale neural activity in primary motor cortex. We find that 30 minutes of 100 - 150 μA DC stimulation can increase spontaneous firing rates ('positive' modulation) in ~33% of recorded cells while ~12% cells reduced their firing rates ('negative' modulation). These changes were long-lasting (i.e. greater than the typical observation period of 1-2 hours). Our work shows that DC stimulation over cerebellum can result in both long-lasting increases and decreases in neural firing rates. We hope that a better understanding of these phenomena can help optimize neuromodulation to enhance recovery after brain injuries – such as stroke.

Title: Early inflammation serves as a common pathway to the development of diffuse white matter abnormality (DWMA) in very preterm infants

Authors: *N. A. PARIKH[1], **J. KLINE**[1], L. HE[1], H. LI[1], P. V. S. ILLAPANI[1], M. A. KLEBANOFF[2];
[1]Cincinnati Children's Hosp., Cincinnati, OH; [2]Nationwide Children's Hosp., Columbus, OH

Abstract: Background: More than 50% of very preterm (VPT) infants exhibit DWMA (aka diffuse excessive high signal intensity) on T2w MRI at term-equivalent age. We previously identified severe retinopathy of prematurity (ROP) and surgery for necrotizing enterocolitis/spontaneous intestinal perforation as risk factors for DWMA in a single-center study.
Objective: Examine antecedent clinical factors of DWMA in a cohort of VPT infants. We hypothesize that inflammation-initiating illnesses are independent risk factors of DWMA development.
Methods: We prospectively enrolled 110 VPT infants (<32 weeks gestational age) from 4 Columbus, Ohio regional NICUs. Infants were imaged on a 3T Siemens Skyra scanner with a high-resolution (1 mm^3) structural MRI protocol at term. We objectively segmented DWMA

regions using our previously-published automated algorithm. We excluded infants with severe brain injury (N=11) or significant motion artifacts (N=1). Clinical variables with $p<0.10$ in bivariable analyses were entered into multivariable linear regression models to evaluate their association with DWMA volume by ordering them temporally (i.e., antenatal first, intrapartum next, postnatal last) and not displacing significant associations ($p<0.05$) by later occurring antecedents.

Results: Several inflammation initiating-illnesses were significantly different between infants with (>75th percentile) and without severe DWMA, including severe ROP, severe bronchopulmonary dysplasia, sepsis, and need for major surgery. In multivariable analyses, severe ROP ($P<0.001$) and severe bronchopulmonary dysplasia ($P=0.006$) remained independent risk factors, while 17-OH progesterone ($P<0.001$) therapy was protective of later DWMA development (Table 1).

Conclusion: We identified several antenatal and neonatal clinical factors that implicate inflammation as a common pathway to DWMA development. These findings enhance our understanding of DWMA pathogenesis and suggest inflammation-associated DWMA as an intermediate biomarker for targeted neuroprotective interventions in high-risk VPT infants.

Table 1. Multivariable linear regression model coefficients of clinical antecedents associated with DWMA volume, objectively-defined on structural MRI at term.

Clinical Antecedent	**Coefficient (95% CI)**	**P**
Maternal 17-OH Progesterone therapy	0.27 (0.14, 0.52)	<0.001
Severe retinopathy of prematurity	7.04 (2.42, 20.49)	<0.001
Severe bronchopulmonary dysplasia	2.73 (1.35, 5.52)	0.006
Gestational age at birth	1.11 (0.97, 1.26)	0.126

Title: Cortical maturational features are altered in very preterm infants at term equivalent age and predict cognitive and language ability at 2-years corrected age

Authors: *J. KLINE, P. V. S. ILLAPANI, L. HE, M. ALTAYE, N. PARIKH;
Cincinnati Children's Hosp., Cincinnati, OH

Abstract: Background: Very preterm infants (VPT;<32 weeks gestational age) are at high risk for neurodevelopmental impairments, including cognitive and language delays. However, there are few validated biomarkers of these impairments at term-equivalent age. Cortical features, including surface area and inner cortical curvature, are altered by preterm birth. These changes may be early developmental biomarkers, but their prognostic ability has not been evaluated.
Objectives: 1) To quantify differences in cortical features on term-equivalent age MRI between a VPT and a full-term cohort. 2) To evaluate the ability of cortical features in the VPT cohort to predict Bayley-III cognitive and language scores at 2-years corrected age.
Methods: We enrolled 110 VPT and 51 full-term infants from 4 level-III NICUs. Structural MRI was performed at term, and Bayley-III language and cognitive testing was performed at 2-years corrected age in the VPT cohort. We quantified group differences in cortical features at term. In the VPT group, we examined the correlation of cortical surface area and curvature with Bayley scores and created multivariable regression models that predicted these scores.
Results: The VPT group had significantly decreased cortical surface area and increased white matter curvature. Their Bayley scores were positively correlated with surface area and negatively correlated with curvature. In multivariable regression, cortical features explained more than one-third of the variance in Bayley scores.
Conclusions: Increased cortical curvature is a new prognostic biomarker that, when combined with cortical surface area, can predict cognitive and language development in VPT infants. Early prediction of domain-specific impairments could facilitate intervention when neuroplasticity is maximal.
Figure 1. Pearson correlation of Bayley cognitive score (top row) and Bayley language score (bottom row) with surface area (left column) and curvature (right column) in the VPT cohort. Correlation strength is shown on a representative subject brain for regions significant at $p < 0.05$.

Title: Pain and sensory features in adults with cerebral palsy

Authors: *E. M. CHIN[1], C. LENZ[2], J. JOHNSON[1], X. YE[2], E. STASHINKO[1], C. CAMPBELL[3], A. HOON[1], S. ROBINSON[2];
[1]Kennedy Krieger Inst., Baltimore, MD; [2]Neurosurg., [3]Psychiatry and Behavioral Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: *OBJECTIVE:* Chronic pain and sensory dysfunction are each known to be prevalent in adults with cerebral palsy (CP). However, cortical and primary sensory sensitivity have not been compared, and pain mechanisms in this population are not clear. The aim of this prospective observational study is to define phenotypes of pain and sensory abnormalities in individuals with CP.
METHODS: Early exploratory analysis includes 11 adult subjects with cerebral palsy (Gross Motor Functional Classification Status (GMFCS) I-V) able to self-report and 8 adult volunteers without neurologic or developmental diagnoses. Subjects reported pain interference, intensity, and quality using PROMIS short forms and the PainDETECT neuropathic screening questionnaire. A structured physical examination included quantitative measures of mechanical sensory detection (Von Frey monofilaments) and cortical somatosensory discrimination (JVP dome threshold), qualitative evaluation of pinprick and thermal sensitivity, and an attention screen (digits forward/reversed). Between-group comparisons used a ranksum test, and univariate variance analyses tested F-statistics of linear regressions against a constant model.
RESULTS: Individuals with CP reported significantly ($p<0.05$) greater pain intensity, pain interference, neuropathic qualities, and nociceptive qualities than typical controls. Median between-group difference in pain interference ($\Delta T=8.6$) was approximately two times the previously-published minimally important difference. Individuals with CP had less mechanical (n.s.) and cortical sensory ($p<0.05$) sensitivity.
Motor functioning (GMFCS level) was a poor predictor of pain interference, pain intensity, and neuropathic and nociceptive qualities (R^2_{adj} all <0.05; p all >0.10). Preserved attention functioning may be associated with less neuropathic qualities (R^2_{adj} 0.26; $p=0.09$) and less overall pain intensity (R^2_{adj} 0.16, $p>0.1$).
Anecdotally, individuals with positive PainDETECT neuropathic screens (n=2) had qualitative alterations in cool and pinprick sensation. A third individual with cool/pinprick sensory alterations but preserved attention reported minimal neuropathic pain.
CONCLUSIONS: Neuropathic and nociceptive pain as well as cortical sensory deficits appear to be common in individuals with CP. A subset of individuals with CP have phenotypes suggestive of central pain. Identification of pain-relevant sensory features may be detectable with a quick bedside screening exam. Further exploration of the role of cognitive characteristics in pain in CP is needed.

Title: Congenital malformations in newborns and their relationship with toxic factors during the pregnant stage

Authors: *G. CHÁVEZ-MÉNDEZ[1], J. ARIAS-RICO[2], O. A. JARAMILLO-MORALES[2], R. M. GUEVARA-CABRERA[2], R. C. JIMENEZ-SANCHEZ[2], R. M. BALTAZAR_TELLEZ[2]; [1]Univ. Autonoma del Estado de Hidalgo, Pachuca de Soto, Mexico; [2]Univ. Autonoma del Estado de Hidalgo, Pachuca, Mexico

Abstract: Introduction. Congenital malformations are structural abnormalities in development acquired during pregnancy. To this day, the OMS states that some 276,000 newborns die within 4 weeks of light each year because of congenital anomalies. Associated factors include: poor pregnancy control, acute infectious diseases, multiparity, tobacco and medications, which cause high incidence in child morbidity and mortality with serious sequelae. The so-called neural tube defects (NTD), which group a series of anomalies located in the Central Nervous System, have been considered as the most frequent congenital malformations and with the most serious sequelae, they maintain a global incidence of 1 to 10 per each 1000 newborns, The objective of this study is to identify the relationship of toxins in the incidence of congenital malformations in newborns at a second level hospital in Hidalgo, Mexico. Materials and Methods. Observational, analytical study of cases and controls, retrospective, cross-sectional. The population consisted of 22 newborns, of whom 11 newborns were classified as congenital malformations (cases) and 11 healthy newborns (control). The SPSS version 21 program was used to analyze the data, using descriptive statistics to determine simple, absolute and relative frequencies of the malformations and their distribution. For the analysis of cases and controls, the risk for congenital malformations with OR was calculated (Odds Ratio) with a 95% confidence interval, statistical significance was considered when $p < 0.05$. Result and Discussion. It was observed that the children of mothers exposed to toxins have 17 times more risk for congenital malformations than women not exposed, this risk being statistically significant (OR = 17.5, 95% CI, 1.5-19.1, p = 0.01). In Spain they have reported an OR for congenital defects and toxic exposure (OR = 1.84 IC 95%, 1.15-2.96, p = 0.007) although only 13.6% of malformations were presented in the Central Nervous System compared to ML Martínez Frías I report only two cases in Spain (2017). Conclusion. malformations are multifactorial in origin, prevention is mostly feasible, early diagnosis prevents further sequelae, determining the risk factors for screening and early diagnosis is important as part of preventive strategies.

Title: Impaired PLA2g6 protects against age-induced vascular stiffening and contributes to preservation of compliant vasculature

Authors: H. PAINTER, K. LAHODA, A. HIJAZI, *J. W. SHIM;
Biomed. Engin. Program, Marshall Univ., Huntington, WV

Abstract: Impairment of phospholipase A2 group 6 (PLA2g6)-dependent calcium (Ca^{2+}) entry in vascular smooth muscle cell (SMC) has been found to protect against age-induced arterial stiffening, but the mechanism and the role of vascular compliance in hydrocephalus are not well understood. Here we tested the hypothesis that impaired PLA2g6 gene could be a previously unknown contributor of preserving compliant vasculature in the brain, thereby, protective against cerebrovascular diseases. Aortic stiffness was assessed in vivo using ultrasound and compared to age-, diet-, and gender-matched (male) mice with constitutive knockout (KO: n=5 to 21) and/or SMC-specific deletion of PLA2g6 (n=3 to 4). Ventricular size of these animals was examined using histological serial sectioning (n=3). Gene expressions of PLA2g6, elastin, and specificity protein 1 (Sp1) were compared in the PLA2g6 KO mice as compared to the age- and diet-matched wild type (WT) controls (n=3). Van Gieson elastic fiber staining was conducted to compare elastin present in the arterial vessels (n=3). We found that aging ($p<0.01$), or high fat high sucrose (HFHS) diet ($p<0.005$) significantly increased pulse wave velocity in WT, but not in PLA2g6 KO mice. Van Gieson staining, quantitative reverse transcription polymerase chain reaction and immunoblot analysis of SMC layer of thoracic aorta from the aged animals revealed significant fragmentation of elastin in WT ($p<0.05$), but not in PLA2g6 KO mice at 24 months. Rather, a significant increase of Sp1 transcription factor was detected in the arterial SMC layer of aged PLA2g6 KO mice as compared to that of WT controls ($p<0.05$). Preservation of elastin content and protection against HFHS diet-induced arterial stiffening can be fully recapitulated in a cell-specific KO mouse model in which impairment of PLA2g6/Ca^{2+} signaling was genetically targeted to SMC. Importantly, there is no ventriculomegaly detected in the KO groups of the constitutive and cell-specific KO mouse model, as compared to the control mice (littermates without inducible PLA2g6 KO at 4 months, and WT at 8 months) at young (4-8 months) and old

(24 months) age, respectively. Our results demonstrate that impairment of PLA2g6 gene does not lead to hydrocephalus and prevents these animals from age-induced elastin fragmentation, thereby, preserving compliant arteries.

Title: Neuroprotection after ischemic stroke using a CXCR2 antagonist

Authors: *A. M. BEDOLLA[1], F. LUO[2], A. CASEY[2], K. A. SCHMIDT[2], Y. LUO[2];
[1]Neurosci., [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Intro: Ischemic stroke causes weakening of the blood brain barrier allowing a peripheral immune response to respond to the stress and damage in the brain. This can result in secondary damages to the ischemic tissue. Our data showed that the KC/GRO (also called CXCL1/CXCR2) pathway are significantly upregulated during pathological brain edema, which might contribute to expansion of ischemic injury. Previous studies have shown that inhibition of the CXCR2 signaling, which is important for the recruitment of peripheral immune cells, prior to or at the onset of stroke supports a better outcome after ischemia. However, this timeline is not suitable for potential clinical translation. The goal of this current study is to examine whether acute post-stroke treatment of KC/GRO pathway inhibitors still have neuroprotective effects in stroke.
Methods: A transient 60-minute medial cerebral artery occlusion (MCAO) was used to induce ischemia; reperfusion was allowed for 72 hours before sacrificing the animals. The drug Repertaxin (a small-molecule inhibitor of CXCR1 and CXCR2) was administered via subcutaneous injection in two doses (15mg/kg), 3 hours and 12 hours post stroke. MRI was used to assess infarct volume and edema severity at 8 hours, 24 hours, and 48 hours post stroke. Behavioral measurements were used to assess functional outcomes. Number of Neutrophils, T-cells, and natural killer cells were quantified in brain tissue using fluorescent immunohistochemistry.
Results: Our results show that post-stroke treatment of Repertaxin resulted in a decreased mortality rate in the treatment group compared with the control MCAo group (n=18, p=0.04). In

addition, there was a decrease in infarct size and edema severity (n=12, p=0.004) in stroke mice treated with Repertaxin compared with the control MCAo group (n= 12, p=0.003). Adhesive removal test alleviated deficits on motor sensory function in Repertaxin treated mice compared to MCAo control group (n=12, p=0.04).
Conclusion: These results suggest that the protective effects of the KC/GRO pathway inhibitor are still attainable even administered 3 hours after stroke and we are currently investigating the precise underlying molecular mechanisms for the observed beneficial effects in stroke animals.

Title: Cognitive function and brain morphometry in Mexican workers occupationally exposed to solvents

Authors: *D. ATILANO-BARBOSA[1], E. H. PASAYE-ALCARAZ[1], R. E. MERCADILLO-CABALLERO[2];
[1]Univ. Nacional Autónoma de México, Queretaro, Mexico; [2]Univ. Autónoma Metropolitana-Iztapalapa, Mexico City, Mexico

Abstract: Solvents are volatile substances that evaporate when they encounter the ambient temperature, these substances can be hydrocarbons such as degreasers, refrigerants, anesthetics, etc. Like most aromatic hydrocarbons, the lipophilic and water-soluble property of solvents cause damage to organs of the body such as the brain and spinal cord. It has been reported that solvents causes deficits in coordination, balance, reflexes, language, memory, attention and decision making. Damage to the central nervous system could be the reason for cognitive and motor impairment related to occupational exposure to industrial solvents. Studies have shown that volatile solvents have inhibitory effects on glutamatergic receptors. These findings could explain the symptoms of lethargy, sedation, disarticulated speech and ataxic gait due to occupational exposure. Brain imaging studies have reported ventricular enlargements, brain atrophy and lesions in the cerebral white matter in workers exposed occupationally to industrial solvents. Nevertheless, most of neuropsychological and neuroimaging research related to occupational exposure to solvents have been case studies and group comparison studies with lack of quantitative analysis based on standardized neuropsychological assessments, normalization of

brain images and statistical analysis on brain differences. In addition, developing countries, such as Mexico, have a high number of workers with respiratory disorders due to volatile industrial compounds where the use of some of these substances has been banned in other countries due to health risks. In this sense, occupational exposure to solvents has adverse effects in brain morphometry and cognitive function in mexican workers.To test this hypothesis, we analyzed the cognitive performance and brain morphometry of a group of 10 workers with a mean exposure of 5 years to solvents with a paired control group of 10 non-exposed subjects. For brain morphometry analysis, brain structural images where acquired using MR (magnetic resonance) then VBM (voxel-based morphometry) analysis was implemented using FSL software. Neuropsychological assessment with standardized and validated tests in mexican population was implemented for cognitive performance analysis. We find that the exposed group shows significant decrease gray matter volume in cerebellar cortex compared to control group. Deficit in working memory was present in exposed participants compared to controls. These results indicate that occupational exposure to industrial solvents has adverse effects in cerebellar cortex and working memory performance in a sample of mexican workers.

Title: Repeated closed-head injury in adolescence impacts oxycodone intravenous self-administration in male and female Sprague-Dawley rats

Authors: *A. K. LEONARD, N. J. SANDSTROM, M. M. CLASEN;
Dept. of Psychology, Program in Neurosci., Williams Col., Williamstown, MA

Abstract: Epidemiological evidence shows that opioid use disorder and traumatic brain injury (TBI), each a serious public health concern in its own right, are highly comorbid. Preclinical studies suggest that inflammation and neuronal damage from TBI increase drug preference and drug-seeking behavior, but with just one prior study investigating opioids. Building on human and rodent evidence that repeated TBI in adolescence may be a particularly strong risk factor for later drug use and abuse, the current study investigated how repeated closed-head injury in adolescent Sprague-Dawley rats affected the intravenous self-administration (IVSA) of

oxycodone in adulthood. Eighteen rats (n = 9 male) received 5 consecutive impacts at 24-hr intervals beginning on PND 40, with 12 (n = 6 male) undergoing a sham procedure. This yielded four groups (FI, FS, MI, and MS, where F or M refers to the sex of the animal [female or male] and I or S refers to the type of head injury [impact or sham]). Of this initial group of 30 rats, 21 remained patent and completed all facets of oxycodone IVSA testing (e.g., the acquisition of oxycodone IVSA, dose-response, progressive ratio, forced abstinence and cue/drug + cue - induced reinstatement; n = 5-6 per group). In most stages, increased variability was observed in FI and MI rats without significantly differing from either FS or MS rats. During drug + cue - induced reinstatement testing, FI rats appeared to respond more than both FS and MI rats, however, these differences were not significantly different ($p = 0.06$). After the conclusion of oxycodone IVSA, neuroinflammation and structural damage were assessed with Iba1 and Cresyl Violet staining. Tissue staining revealed severe neurodegeneration (indexed by ventricle size) in both FI and MI rats, with preliminary analysis suggesting a potential correlation between injury severity and intensity of drug-seeking behavior. Although the small number of subjects utilized limits the conclusion of the present work (n = 5-6 per group), this preliminary research suggests that repeated adolescent TBI increases the variability in oxycodone self-administration in male and female adult rats, and that these effects might be more pronounced in females.

Title: Repetitive head trauma induces elevated post-concussive aggression in young-adult male *Drosophila*

Authors: *D. C. LEE[1], K. VALI[2], S. R. BALDWIN[2], J. R. FEQUIERE[2], M. A. FERNANDEZ[2], J. C. FRAGEAU[2], F. LONGO[2], S. S. MADHOUN[2], P. MINGIONE, V[2], T. R. O'TOOLE[2], G. R. TANNER[1];
[1]Physiol. and Neurobio., [2]Univ. of Connecticut, Storrs-Mansfield, CT

Abstract: Repeated concussive head trauma—termed traumatic brain injury (TBI)—can induce chronic traumatic encephalopathy (CTE), a neurodegenerative disease with symptoms ranging from memory loss, to general cognitive deficits, to elevated aggression. We adapted a methodology using a high-impact trauma device (Katzenberger et al., 2013; 2015) that induces TBI while reducing mortality, thus permitting post-TBI behavioral analyses. We subjected young-adult male *Drosophila* of the wild-type Canton-S strain to a battery of TBI-inducing high-impact concussive events on day five post-eclosion as adults. Three days after the TBI protocol ("banging"), pairs of male flies were assayed for aggressive behaviors. Aggression in banged flies was significantly elevated, as compared with that in unbanged flies. These increases in aggressive behavior were not the result of basal motility changes, as measured by a negative geotaxis assay. In addition, the increase in post-TBI aggression appeared to be specific to concussive trauma: neither cold exposure nor electric shock—two alternate types of trauma—significantly altered aggressive behavior in male-male pairs. We conclude that this assay may be used as a model for the study of post-TBI elevations of aggression.

Title: On the application of APP immunohistochemical staining to detect TBI-induced axonal degeneration in the mouse

Authors: *G. XIONG[1], H. METHENY[1], K. A. FOLWEILER[1], A. S. COHEN[1,2];
[1]Children's Hosp Philadelphia, Philadelphia, PA; [2]Anesthesiol. and Critical Care Med., Perelman Sch. of Medicine, Univ. of Pennsylvania, Philadelpha, PA

Abstract: Immunostaining with an antibody against amyloid precursor protein (APP) has been considered the "Gold-standard" to detect traumatic brain injury (TBI)-induced neuropathology in white matter bundles, shown as intensely stained varicosities and spheroids. It has been suggested that these varicosities/spheroids represent the interruption of axonal transport, which results in APP accumulation and swelling in damaged axons. However, direct evidence for the axonal identity of these APP-stained structures is insufficient. Here we used APP immunofluorescent staining in order to raise the contrast of brain samples after TBI, compared to

the immunoperoxidase protocol widely used. Basal APP staining was routinely seen in both excitatory and inhibitory neuronal cell bodies, without positive staining in axons. Oligodendrocytes also demonstrated basal staining in both naïve and TBI mice. In TBI brains, large-sized varicosities/spheroids or clusters were seen in the external capsule (ec) and fimbria. Many spheroids could also be found in the caudate putamen and stratum moleculare-lacunosum of hippocampal area CA1. Occasionally, pre-terminal axons (with normal-sized varicosities) might be seen in severely damaged cortex. At 3 hr (after TBI) heavily stained axonal blebs were seen connecting their cell bodies via the remaining proximal axons in the cortex and hippocampus. From 10 hr to 2-3 d the remaining axonal segment became very swollen, exhibiting as a spheroid. At 5 and 7 but not 14 d, heavily stained cell bodies with proximal dendrites could be seen in the cortex, hippocampus and thalamus. These findings suggest that the initial injury to proximal axons in gray matter areas may trigger neurodegeneration after TBI. In transgenic mice expressing tdTomato in a subset of neurons, APP-stained varicosities/spheroids in white matter were clearly disdinct from deformed axons labeled with the red fluorescence but negative to APP. We also confirmed this mutually negative staining/labeling pattern in white matter with the axonal marker neurofilament light chain. This piece of negative evidence lead us to costain APP-positive structures with non-axonal markers in white matter. We witnessed multiple large patches of intracerebral hemorrhages using TER, a red blood cell marker. Clusters of densely packed spheroids could be identified at the center of these hemorrhages. They were distributed radially from the blood vessel lumen, suggesting that they might be blood- or vessel-derived structures. The present study suggests that in addition to axonal structures, non-axonal characteristics should be taken into account when interpreting APP immunostaining data after TBI.

Title: Impaired pattern separation behavior due to altered activity onto dentate granule cells following mild traumatic brain injury

Authors: *R. T. SOMACH[1], B. AMADI[2], H. METHENY[3], A. S. COHEN[4];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Lincoln Univ., Oxford, PA; [3]Dept. of Anesthesiol. and Critical Care Med., Children's Hosp. of Philadelphia, Philadelphia, PA; [4]Anesthesiol. and Critical Care Med., Children's Hosp Philadelphia Univ. of Pennsy, Philadelphia, PA

Abstract: Cognitive deficits are one of the most common outcomes following mild Traumatic Brain Injury (mTBI) including symptoms of impaired planning ability, memory deficits. In some patients, these symptoms resolve within 3 months, but other patients have persistent cognitive deficits for a year or more after injury. There is currently no way to recognize which patients will have long term deficits and there are no treatments for these cognitive impairments, highlighting the importance of basic research in understanding the effects of mTBI on cognitive abilities. One of the cognitive processes that is affected after injury is pattern separation, which is the ability to discriminate between similar representations. The dentate gyrus (DG), a hippocampal subregion, has been shown to be involved with pattern separation due to the low basal activity levels of the dentate granule cells (DGC's). During pattern separation, a distinct, but small, subset of DGC's are activated for any particular stimulus. The DG is also a region that is especially vulnerable to mTBI. Previously, it has been shown that there is an increase synaptic efficacy following mTBI in the DG. This increased synaptic efficacy is thought to be due in part to a reduced level of inhibition on the DGC's. We hypothesized that more DGC's would be active during a pattern separation task following injury as compared to sham injured animals, which would reduce the effective pattern separation ability of the DG. We hypothesized that the activation of many DGC's would be due to a lack of inhibition following injury. We tested these hypotheses by using the Lateral Fluid Percussion Injury (LFPI) model of mTBI in 6-8 week old mice. One week following injury, we trained the animals on a modified spatial object recognition task in order to test pattern separation behavior. We then took brain sections and stained the DG of these animals for c-Fos expression to determine the activation of DGC's following injury and pattern separation behavior. We also stained the DG for VGAT, a vesicular GABA transporter, to determine the levels of inhibitory activity on the DGC's after this behavioral task. Our results reinforce previous findings that performance on a pattern separation task is impaired after injury, and may be associated with differential activation of DGCs.

Title: Early changes in dentate neurogenesis and network function following concussive brain injury in mice

Authors: *L. CORRUBIA[1], D. SUBRAMANIAN[2], A. IRFAN[2], V. SANTHAKUMAR[2,1]; [1]Pharmacology, Physiol. & Neurosci., Rutgers New Jersey Med. Sch., Newark, NJ; [2]Molecular, Cell and Systems Biol., Univ. of California Riverside, Riverside, CA

Abstract: Traumatic brain injury is a global epidemic that results in a variety of debilitating symptoms such as memory dysfunction and epilepsy. We previously described that rats experiencing brain injury showed a robust early increase in hippocampal adult neurogenesis occurring alongside increases in excitability of the hippocampal dentate gyrus (DG) and seizure susceptibility. Suppressing the aberrant neurogenic burst (Neuberger et al., 2017) attenuated both DG network hyperexcitability 7-days post-injury and subsequent increase in seizure susceptibility, suggesting a role of adult born granule cells (abGCs) in injury induced dentate network pathology. Moreover, abGCs generated after controlled cortical impact in mice exhibit altered morphology and migration, implicating potential for improper network integration (Ibrahim et al., 2016; Villasana et al., 2015). This study was conducted to test the hypothesis that concussive brain injury in mice results in early alterations in the generation and migration of abGCs born after injury, and that abGCs contribute to post-traumatic circuit dysfunction. Adult 6-8 week old mice receiving mild to moderate lateral fluid percussion injury (FPI) at 1.5 atm and age-matched sham-injured controls were examined for cell loss and changes in neurogenesis using immunohistological techniques and stereology. In-vivo local field potential (LFP) recordings were used to examine changes in DG network physiology. Fluoro-Jade staining to reveal degenerating neurons identified an increase in cell death in the ipsilateral dentate hilus and cell layer 4 hours after FPI compared to sham controls. Immunostaining for DCX, a marker for newly born neurons, identified an increase in ectopic expression of DCX+ neurons in the outer 2/3rd's of the granule cell layer on the side of injury as early as 3 days post-injury (N=3/group, p=0.023 by t-test). However, the total population DCX+ neurons in mice 3 days after FPI was not different from controls. Mice 7-9 days after FPI showed a reduction in paired-pulse facilitation of dentate GC population spikes in response to afferent stimulation indicating deficits in feedback inhibition. Kainic acid (7.5 mg/kg, i.p) elicited increased susceptibility and more severe seizures in mice three weeks after FPI compared to controls. These data demonstrate an early dysregulation of dentate neurogenesis and feedback inhibition after FPI in mice. The results provide a strong platform to analyze whether abnormal circuit integration of abGCs born after injury contributes to altered dentate physiology and epileptogenesis after concussive brain injury.

Title: Unilateral hemisphere-wide damage is dependent upon the interplay between hemorrhage location and seizure duration and may be mediated by an age-dependent upregulation of matrix metalloproteinase-9 in a model of severe traumatic brain injury

Authors: *B. A. COSTINE-BARTELL, G. PRICE, M. LI, J. SHEN, K. J. STALEY, A.-C. DUHAIME;
Massachusetts Gen. Hosp., Boston, MA

Abstract: Hemispheric hypodensity (HH) is a radiological pattern of severe injury where the hemisphere underlying a subdural hematoma (SDH) exhibits damage that evolves over hours to days, spans multiple vascular territories, and often results from abusive head trauma. Using our model of unilateral HH, we tested the effect of age on the amount and distribution of tissue damage in piglets of similar maturity to human infants (1-week-old, "infants") vs. toddlers (1-month-old, "toddlers"). Male, Yorkshire piglets (n = 26) were randomized to receive focal injuries that were scaled to brain size (cortical impact, SDH, mass effect) and focal seizures, global apnea, and hypoventilation, or piglets received sham surgeries. Tissue sections were coded for analysis. Both ages required intensive care, but "infants" had worse neurologic scores and persistent metabolic acidosis. At 24 hours post-injury, "toddlers" had wide-spread hypoxic-ischemic-type damage encompassing most of the ipsilateral cortex with sparing of the contralateral hemisphere while "infants" had less damage that was bilateral. The proportion of piglets that had unilateral HH was greater in "toddlers" vs. "infants" (67 vs. 11%). SDH was not correlated to damage in either age, but indirectly produced a focal subarachnoid hemorrhage that was positively correlated to damage in both ages. Seizure duration was equivalent between ages and positively correlated with hemispheric damage in "toddlers" but not "infants". When piglets were binned into seizure length (greater or less than one hour), unilateral HH only occurred when seizures where greater than 1 hour. "Toddlers" had greater MMP-9 upregulation and blood brain barrier (BBB) disruption than "infants" that was predominately unilateral. In sections with over 30% damage, damage was equivalent between ages, but "toddlers" had greater MMP-9 upregulation and BBB disruption. In plasma, pro-MMP-9 increased in both ages 1-4 hours post-injury and returned to baseline levels by 24 hours, but active-MMP-9 was greater in "toddlers" than "infants" 1-4 hours post-injury and remained elevated at 24 hours. In conclusion, both ages had the same duration of seizures, but damage was positively correlated to seizure duration in "toddlers" that had greater and ongoing conversion of pro- to active-MMP-9 and greater BBB disruption, which may be the mechanism by which damage spreads through the ipsilateral hemisphere with sparing of the contralateral hemisphere. Future studies will determine if inhibition of seizures and/or MMP-9 reduces brain damage in our model potentially resulting in therapeutics for children with severe brain injury.

Sch., Monash Univ., Melbourne, Australia

Abstract: Tau hyperphosphorylation (p-tau) has been implicated in neurodegenerative diseases, and in post-traumatic epilepsy. EpiBioS4Rx Project 2 investigated the temporal patterns of p-tau forms after severe brain trauma induced by lateral fluid percussion injury (LFPI) in rats and whether they are modified by sodium selenate (SS), a protein phosphatase 2 (PP2A) activator. Protein expression was studied using immunochemistries (ICH) [Einstein] or Western blot (WB) [Monash] analyses. Male 11-week old Sprague-Dawley rats were randomized into naïve (n=11, ICH), sham (n=5-6/timepoint/ICH or WB) and LFPI (n=5-6/timepoint/ICH or WB) groups. A left parietal 5mm craniotomy was performed in sham and LFPI rats. LFPI rats were subjected to ~3.1atm pulse at the craniotomy. Rats had the brain either perfused for ICH or frozen for WB, at 2 days, 1, 2, 4 or 8 weeks post-surgery; naïve were age-matched. To determine if SS modified p-tau, LFPI rats (n=5/timepoint/dose) received a bolus injection of SS (0, 0.013, 0.04mg/kg, subcutaneous (sc)) immediately after LFPI followed by minipump to deliver SS (0, 0.33, 1mg/kg/day, sc) for either 2 or 7 days. ICH and WB assays using AT8, AT180, anti-PP2A/PR55 or tau5 antibodies were performed. In ICH, somatic and extrasomatic/extracellular signal densitometry of AT8, AT180, or PR55 immunoreactivity (-ir) was done at the ipsi- and contralateral primary motor (M1) and lateral [somatosensory (S2a,b); granular insular (GI)] cortices using ImageJ. Increase in both somatic and extrasomatic/extracellular AT8-ir was seen

in the left M1 and lateral cortices only at 2 days post-LFPI, compared to other groups. Shams showed increased AT8-ir at the left M1 cortex, 7 days post-craniotomy. In contrast, somatic AT180-ir was increased 8 weeks post-LFPI at the left S2a,b and GI. PR55-ir did not change. For WB, the ratio of AT8, AT180, PR55 or tau5 over GAPDH (glyceraldehyde 3-phosphate dehydrogenase) and PP2A enzymatic activity was determined. Although no differences were found in AT8/GAPDH, AT8/tau5 ratio was increased in LFPI rats at the perilesional cortex at 2 days post-LFPI. No difference in PR55 or tau5 expression was found in WB. In addition, SS did not alter AT8- or AT180-ir after 2 or 7 days of treatment. PP2A activity assays are ongoing. We show site and time-specific p-tau changes which may be candidate for therapeutic targets: an early (2 days) transient focal increase in both somatic and extracellular AT8-ir and a late (8 weeks) increase in somatic AT180-ir at the ipsilateral to LFPI cortex. However, SS treatment up to 7 days did not alter AT8-ir or AT180-ir p-tau. A longer exposure of SS may identify any potential effect of the drug on AT180 site.

Title: RhoA siRNA local delivery by PgP nanocarrier reduces secondary injury after traumatic brain injury

Authors: C. MACKS[1], D. JEONG[1], M. LYNN[2], ***J. LEE**[1];
[1]Bioengineering, Clemson Univ., Clemson, SC; [2]Neurosurg., Greenville Hlth. Syst., Greenville, SC

Abstract: Traumatic brain injury (TBI) is one of the leading causes of disability and death following injury. Many studies have demonstrated that diverse extracellular inhibitors of neuroplasticity including both CSPGs (chondroitin sulfate proteoglycans) and MAIs (myelin associated inhibitors) in the CNS may act through common intracellular signaling pathway, RhoA and Rho kinase (ROCK) and neurite growth inhibition in response to MAIs and CSPGs

can be overcome by Rho/ROCK inhibitors. In addition, levels of the cyclic adenosine monophosphate (cAMP) drop due to increased degradation by phosphodiesterases 4 (PDE4) following TBI. Rolipram (Rm), a hydrophobic drug, prevents the degradation of cAMP and is able to inhibit production of neurotoxic cytokines and reduce the apoptosis. The goal of our work is to develop neuron-specific nanotherapeutics for combinatorial delivery of Rm and siRNA targeting RhoA. To achieve this goal, we synthesized cationic, amphiphilic copolymers (poly(lactide-co-glycolide)-g-polyethylenimine : PgP) as Rm and siRhoA carrier. In our previous study, we demonstrated that RhoA knockdown by PgP/siRhoA nanoparticles can maintain knockdown for up to 4 weeks accompanied by a reduction in apoptosis, cavity size, and astrogliosis. In this study, we investigated the effect of RhoA knockdown by the PgP/siRhoA on secondary injury such as inflammatory response, apoptosis, and neuronal cell death in a rat TBI model. The TBI model was generated by controlled cortical impact (CCI) devise armed with a 3 mm tip (3.5 m/sec, depth: 2mm). Animals were divided to 4 groups: 1) Sham, 2) TBI, 3) PgP/siRhoA (20 ug siRhoA), and 4) PgP/siNT (20 µg siRNA negative control). Immediately after injury, nanoparticle solution (20 µl) were injected in the lesion site and brains were harvested at 7 days post-inury for RhoA gene expression by RT-PCR. For histological analysis, rats were euthanized at 7days post-injury by caridac perfusion with 4% PFA. Brains were collected, fixed in 4% PFA, and cryosectioned (30 um). Sections were stained with cresyl violet for lesion volume and IHC was performed using antibodies against ED1 (macrophages/microglia) and GFAP (astrocytes). TUNEL assay was performed for apoptosis. We observed significant knockdown of RhoA expression with PgP/siRhoA compared to saline injection group at 7days post-injury. We also observed that RhoA knockdown by PgP/siRhoA polyplex nanoparticle decreases lesion volume, improves neuronal survival, reduces inflammation cell infiltration, and reduces astrogliosis compared to untreated TBI group. In the future, we will evaluate the synergistic effect of rolipram and siRhoA on secondary injury in a rat TBI model.

Title: Automated and manual brain mapping and neuroinflammation in striatum and hippocampus following alcohol exposure and traumatic brain injury

Authors: *L. A. SHAPIRO[1], A. WANG[2], S. DEY[2], S. MUKHERJEE[4], K. O'NEILL[3], W. DAVIS[3], M. RAMIREZ[3], G. HOLLINGSWORTH[3], K. MIMS[3], X. WANG[1], J. WANG[1];

[1]Texas A&M Hlth. Sci. Ctr., Bryan, TX; [2]Engin., [3]Texas A&M Univ., College Station, TX; [4]Texas A & M, Temple, TX

Abstract: In the United States, Traumatic Brain Injury (TBI) accounts for approximately 2.5 million visits to the Emergency Room (ER) each year. Many TBI patients who present in the ER have alcohol in their blood. For example, a study looking at a community hospital from 1994 to 2004 found that approximately 37%-51% of patients with a TBI had alcohol in their system. Numerous other studies support these findings. Therefore, understanding the impact of alcohol on a TBI is important to understand altered risk factors.

Alcohol use may not only be a contributing factor for TBI, but also might be a co-morbidity, as previous studies have shown an increased risk of alcohol abuse after a TBI. Considering the large numbers of patients that have alcohol present in their system at the time of a TBI, and the fact that TBI increases alcohol usage, it is important to better understand how alcohol use prior to, and after a TBI, might alter TBI pathogenesis.

TBI is known to induce a significant neuroinflammatory response, in the acute, sub-acute and more chronic time points after injury. Alcohol has also been shown to alter inflammatory trajectories, and studies examining alcohol use in the context of TBI support an altered neuroinflammatory response. However, the influence of alcohol before and after a TBI, on neuroinflammation, has not yet been fully explored. We tested the hypothesis that alcohol use before and after a TBI, will alter the neuroinflammatory response in the hippocampus and striatum.

Twenty male C57BI/6 mice were individual housed and allowed free access to water and 20% ethanol (EtOH) solution, every other day, for six weeks. Alcohol consumption was monitored and considered when separating the mice into sham and TBI treatment groups, to an ensure equal distribution of alcohol consumers in both groups. TBI or sham was induced under anesthesia, after which mice were allowed to recover for 3 days, followed by ad libitum access to alcohol, every other day, for four more weeks. One week prior to sacrifice, behavioral tests were conducted followed by sacrifice.

Perfused brains were sliced on a vibratome, and immunolabeled for astrocytes (anti-GFAP) and microglia (anti-IBA-1). Using custom automated brain mapping software, we quantified dopamine D1 or D2 receptor-expressing neurons throughout the entire brain, and also performed manual counts of the astrocytes and microglia in the hippocampus and striatum. The results revealed that alcohol use before and after a TBI results in behavioral deficits, as well as prolonged neuroinflammation in the hippocampus and striatum. Thus, alcohol consumption may alter the post-traumatic pathogenic trajectory.

Title: Neurodegenerative disease markers coincide with diffuse axonal injury in a mouse model of traumatic brain injury

Authors: D. F. HAVLICEK[1], Y. TONG[1], E. JOSE[1], J. F. CRARY[2], ***P. J. BERGOLD**[3]; [1]Physiol. and Pharmacol., SUNY-Downstate Med. Ctr., Brooklyn, NY; [2]Pathology, Icahn Sch. of Med. At Mount Sinai, New York, NY; [3]SUNY-Downstate Med. Cen., Brooklyn, NY

Abstract: Traumatic brain injury (TBI) selectively damages white matter and increases the risk of developing neurodegenerative disorders, including Alzheimer's disease and Parkinson's disease. Alzheimer's disease is characterized by aggregates of hyperphosphorylated tau (pTau) and amyloid beta (Aβ), while Parkinson's disease is characterized by aggregates of α-synuclein (α-syn). Tau, Aβ, and α-syn are normally located in axons and presynaptic termini, suggesting that axonal injury following TBI may alter the cellular localization of these proteins, leading to their pathological aggregation. We are testing this hypothesis in sham and injured C57BL/6 mice 14 days after experimental closed head injury (CHI). A unilateral dorsal impact by CHI produced a diffuse white matter injury in both hemispheres. We assessed white matter damage across the brain using Bielschowsky silver stain to visualize axons and luxol fast blue stain to visualize myelin. These studies showed that CHI produced a heterogenous white matter injury, yet consistently damaged axons and myelin in the cingulum, thalamus, ventral olfactory tract, ventral striatum and basal forebrain. The hippocampal CA2 region was also selectively damaged. These areas were also immunopositive for aggregates of pTau, Aβ, and α-syn. These results suggest that markers of neurodegeneration coincide with diffuse axonal injury. Our laboratory previously showed that the drug combination of minocycline and N-acetylcysteine prevents white matter injury after TBI (Haber et al. 2017; Sangobowale et al. 2018). We are currently evaluating if these drugs also prevent the aggregation of pTau, Aβ and α-syn after CHI.

Title: Microglia markers: Distinguishing surveillance and reactive states with immunohistochemistry

Authors: *J. B. BAUN[1], B. TIPTON[2], C. ZURHELLEN[3], H. T. YORK[3], L. S. BELAYEV[4], R. C. SWITZER III[1];
[1]Neurosci. Associates Inc, Knoxville, TN; [2]Lab., [3]Neurosci. Associates, Knoxville, TN; [4]Neurosci. Ctr., LSUHSC, New Orleans, LA

Abstract: Assessing neuroinflammation based on immunohistochemical (IHC) displays of microglia and astrocytes is a key dimension in characterizing different disease states and the results of physical or chemical perturbations to the brain and spinal cord.The antibody Iba1 (ionized calcium-binding adapter molecule) has proven to be a real workhorse for assessing the state of microglia in that it is not species restricted and the antigen is robust and not susceptible to long term exposure to formaldehyde fixative. Iba1 allows visualization of the full range of morphologic changes: surveillance states, ‘reactive’ hypertrophy, amoeboid. The reactive morphologic states span a wide range of extremes: barely different than surveillance state to gnarly processes. To quantify degrees of reactivity across such a gradient of morphologic changes is a considerable challenge. Some image analysis systems can characterize the range by examining individual microglia.Other histologic IHC markers for microglia preceded the discovery of Iba1 and others have emerged since. In the course of applying some of these other antibodies to tissues from a rat MCAO stroke model we found that the OX42 clone of CD11b antibody robustly stained reactive microglia in and around the affected ischemic zone in rats but microglia on the contralateral side were less visible to varying degrees suggesting different degrees of expression of the antigen detected by OX42. The gradient of change of microglia visibility and hypertrophy observed with the OX42 was much ‘steeper’ than with Iba1; that is, a much improved signal to noise across the spectrum of change. This attribute allows image analysis methods to parse out different degrees of reactivity and provide more clear cut quantitative data.We strove to find a clone of CD11b that would perform similarly in mice. Only one of those that we tried (Life Sciences LSC294688) came close to matching the performance of the OX42.Antibodies against CD68, a lysosome marker, are often used to indicate microglia reactivity, but as we reported earlier (SfN: C.Segovia et.al.; abstract 726.10/w8; 2013) not all hypertrophied microglia are necessarily CD68-positive. CD68+ve microglia were a subset of those positive for OX42 in the rat stroke model, but in the mouse, using a transgenic AD model, the CD68+ve microglia appeared to be equal in number to those positive for the LSC

antibody.Another marker not usually considered to identify reactive microglia is ferric iron. Taken together, these different markers for reactive states of microglia provide the means to make a multidimensional assessment of neuroinflammation.

Title: BCAS1 expression demonstrates a reduction in early myelinating oligodendrocytes following traumatic brain injury

Authors: *A. AVITUA[1], T. DISTEL[2], B. FORD[2];
[1]Neurosci., [2]Sch. of Medicine, Biomed. Sci., Univ. of California, Riverside, Riverside, CA

Abstract: Currently, there are over 5 million Americans living with a disability as a result of traumatic brain injury (TBI). This number grows with over 2.5 million TBIs occurring in the U.S. each year. Following TBI, individuals may experience a number of impairments such as: migraines, tinnitus, learning and memory deficits, post-traumatic epileptogenesis, and problems with motor function to list a few. Unfortunately, we lack the clinical interventions necessary to prevent these symptoms from manifesting. Through this research, we aim to have a better understanding of endogenous repair and regeneration following TBI in order to minimize the effect of these symptoms and help those suffering with a TBI-related disability live a better quality life. In this study, we utilized the controlled cortical impact model of TBI and examined brain tissues 24 and 72 hours following injury. Histology was performed to visualize neuronal damage and oligodendrocytes following TBI. At 24 hours and 3 days post-TBI, we observed numerous injured neurons as measured by fluorojade B staining in the perilesional area. Using an antibody that labels myelinating oligodendrocytes, anti-breast carcinoma amplified sequence 1 (BCAS1), we observed potential sites of active myelination. The BCAS labeling was colocalized with expression of Olig2, a marker for oligodendrocytes. BCAS expression was found in cerebral cortex and throughout the brain compared to naïve animals. The numbers of BCAS1 positive cells decreased at 24 and 72 hours following TBI. This data demonstrates markers of cell death and BCAS1-positive cells in post-mortem tissue following TBI. These results are valuable in contributing to our knowledge of the role of BCAS1-positive cells in repair and regeneration and may aid in the development more effective treatments to reverse or prevent disabilities that can arise following TBI.

Title: Ultrastructural analysis of microvascular injury and neuroinflammation in traumatic brain injury and chronic traumatic encephalopathy

Authors: *K. J. BABCOCK[1], M. ERICSSON[2], E. S. FRANZ[1], O. MINAEVA[1], J. A. MONCASTER[1], B. R. HUBER[3], A. C. MCKEE[1], L. E. GOLDSTEIN[1];
[1]Boston Univ. Sch. of Med., Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]VA Boston Healthcare, Boston, MA

Abstract: Traumatic microvascular injury (TMI) and neuroinflammation are hallmark features of traumatic brain injury (TBI) and sequelae, including chronic traumatic encephalopathy (CTE). The diagnostic lesion of CTE, a progressive neurodegenerative disease associated with sports- and military-related neurotrauma, is abnormal accumulation of hyperphosphorylated tau protein in a patchy distribution around small blood vessels in the depths of cortical sulci. This neuropathological association points to a mechanistic link between TMI and chronic neurotrauma-related pathologies, including CTE. Previous work from our lab on human and mouse brains indicate that acute neurotrauma disrupts the normal integrity of small blood vessels leading to abnormal blood-brain barrier (BBB) function and perivascular neuroinflammation. This project seeks to confirm and extend these findings by conducting a systematic ultrastructural (transmission electron microscopy, TEM) analysis of postmortem brain samples from neuropathologically-confirmed human CTE cases and mice subjected to lateral closed-head concussive impacts. TEM examination revealed ultrastructural changes consistent with diverse axonal pathologies (abnormal myelination, reduced axoplasm, axon-myelin collapse) as well as microvascular injury (dysmorphic capillaries with thickened and highly tortuous basal lamina encircled by swollen, edematous astrocytic endfeet with dilated endfeet). These results provide further evidence that neurotrauma-induced microvascular and axonal injury are mechanistic drivers underpinning both acute and chronic effects of neurotrauma.

Title: Interleukin 13 ameliorates neuroinflammation and promotes functional recovery after traumatic brain injury

Authors: *W. MIAO, Y. GAO;
State Key Lab. of Med. Neurobiology, and Inst. of Brain Sci., Fudan Univ., Shanghai, China

Abstract: Objectives: Traumatic brain injury (TBI) is a leading cause of death and long-term disability. In addition to the initial primary insult, secondary brain injuries occur after TBI due to various cellular processes, including the activation of immune cells. Microglia play essential roles in the neuroinflammatory responses after TBI Our previous studies showed that microglia could shift towards pro-inflammatory or anti-inflammatory polarities at different stages after central nervous system injury, which correlated to the functional outcomes. IL-13, as an anti-inflammatory cytokine secreted by microglia, has been reported to protect against white matter demyelination and spinal cord injury through immunomodulation. The function of IL-13 in TBI remains to be investigated. **Methods:** TBI was induced in male C57BL/6J mice by controlled cortical impact system. IL-13 was intranasally administrated immediately after TBI and repeated every day for 6 days. A batch of behavior tests was performed to evaluate the long-term sensorimotor functions after TBI. Microglial phenotype was detected using immunohistochemical staining of M1 marker CD16 and M2 marker CD206. The mRNA expression levels of inflammatory factors were measured by qRT-PCR. Primary cultured microglia was used to evaluate the effect of IL-13 on inflammatory responses and phagocytotic ability of microglia. **Results:** Intranasal administration of IL-13 after TBI accelerated functional recovery after TBI, as revealed by increased time to fall off in Rotarod test, reduced number of foot faults in grid walking test, and improved scores in hang wiring test, up to 28 days after TBI. IL-13 reduced tissue loss at 6 days after TBI. Furthermore, IL-13 inhibited the production of pro-inflammatory factors and reduced the number of proinflammatory M1 microglia at 6 days after TBI. *In vitro* studies confirmed that IL-13 treatment inhibited the production of proinflammatory cytokines in primary microglia in response to LPS stimulation, and inhibited the ability of microglia to engulf PI-labeled dead neurons. **Conclusions:** IL-13 treatment improved neurological outcomes after TBI through inhibiting inflammatory responses and adjusting microglial phenotype. IL-13 may represent a potential immune therapy to promote long-term recovery from TBI.

Title: Effects of aqueous extract of cola nitida on post-natal behavioural indices and histological alterations in the cerebellum of Wistar rat

Authors: ***F. A. ATIBA**[1], I. IMOSEMI[2], A. MALOMO[3];
[1]Anatom. Sci., Univ. of Witwatersrand, Johannesburg, South Africa; [2]Anat., [3]Neurosurg., Univ. of Ibadan, Ibadan, Nigeria

Abstract: *Cola nitida* (CN, kolanut) is popular fruit in Nigeria and West Africa. It is used for industrial, snacking, stimulant and cultural purposes. Pregnant women commonly consume kolanut during the first trimester to alleviate the features of morning sickness and dizziness. There is however, dearth of information on the effect of CN on the developing cerebellum. This study was designed to investigate the effects of graded doses of aqueous extract of CN on the structure of the developing cerebellum in Wistar rats.
Fresh CN fruits were purchased from kola plantation in Sagamu, Ogun State, Nigeria in the month of August, 2015. The fruits of kolanut were identified and authenticated at the Federal Research Institute of Nigeria, with voucher FHI number: 109605. Aqueous extract of CN seed was obtained by wetting prepared cubes of CN with water, milling and filtration. The filtrate was concentrated with rotary evaporator, and stored in the refrigerator at 4°C. Forty pregnant Wistar rats were randomly divided into four groups of ten rats each. They were given crude extracts of CN dissolved in water in graded doses of 400, 600, and 800 mg/kg/body weight orally during pregnancy to day 28 after birth, while the control group received water only. On days 1, 7, 14, 21 and 28 after birth, the pups (n=5) were weighed, sacrificed and perfused with neutral buffered formalin and their brains dissected out, weighed and the cerebellum preserved in 10% formol-saline. Paraffin sections of the cerebellum were stained with haematoxylin and eosin for cerebellar cytoarchitecture, cresyl violet stain for Purkinje cell count, glial fibrillary acidic protein, GFAP, for estimation of gliosis and B-cell lymphoma 2 (Bcl2) for apoptotic neuronal cells. Data were analysed using ANOVA at $\alpha_{0.05}$.
The CN-treated rats had, a significant reduction in the body and brain weights and reduction in behavioural indices compared to the control. Histology showed in the CN-treated group, persistent external granular layer of Post-natal Day (PND) 21 and distortion of Bergmann glial. The Purkinje cells in the treated groups showed reduction in density, loss of dendrites and multiple layering. The white matter of the treated groups showed neurodegeneration depicted by

spongiosis. Treatment also elicited over-expression of GFAP, with evidence of reactive astrogliosis. The intensity estimation for Bcl2 showed increase in all the treated groups. Aqueous extract of *Cola nitida* treatment disrupted the normal cellular development, migration and cyto-architecture of Wistar rat cerebellum.

Title: The hepatic regeneration does not induces vesicle pools in locus coeruleus neurons

Authors: A. A. BARRIENTOS BONILLA[1], P. B. PENSADO GUEVARA[1], A. D. C. SÁNCHEZ GARCÍA[2], *D. HERNANDEZ-BALTAZAR[3];
[1]Facultad de Química, Farmacéutica Biológica, Univ. Veracruzana, Xalapa, Veracruz, Mexico; [2]Patología Exptl., Inst. Nacional de Neurología y Neurocirugía "Manuel Velasco Suárez", Ciudad de Mexico, Mexico; [3]CONACYT-Instituto de Neuroetologia., Xalapa, Veracruz, Mexico

Abstract: Introduction. During hepatic regeneration, the noradrenaline produced in the *locus coeruleus* favors the synthesis of Hepatocyte Growth Factor and Epidermal Growth Factor. In last years, the model of partial hepatectomy (PH) in rats has been used to determine the cellular processes associated with the anatomical and functional recovery of the liver. An interesting finding is the presence of hepatocelullar intracytoplasmic vesicles in stages of high proliferation, which suggest celullar stress in liver and *locus coeruleus*. **Objective.** In this work, we evaluated the lipid or protein content in the vesicle pools of the hepatic cells and *locus coeruleus* neurons. **Methods.** Male Wistar rats (218-240 g) were distributed in 3 groups (n = 3): Intact group, and PH groups (48 h and 144 h post surgery). Changes in *locus coeruleus* and hepatic citoarchitecture as well as the vesicular content was evaluated by hematoxylin-eosin, oily red, Masson's trichrome stain and immunohistochemistry for tyrosine hydroxylase (TH). **Results**. Forty-eight hours after PH, hepatic cells and neurons immunoreactive to TH do not exhibit patterns of cell death. Unlike the cells of liver, the neurons of the *locus coeruleus* no showed vesicle pools. The hepatocellular intracitoplasmic vesicles not exhibited collagen or lipid content. **Conclusion**. Hepatic regeneration does not favor the accumulation of vesicles in *locus coeruleus* neurons. This study was partially supported by Catedras CONACYT project (ID1840).

Abstract: Apoptosis is triggered in the developing mammalian brain by sedative, anesthetic or antiepileptic drugs during late gestation and early life. Whether human children are vulnerable to this toxicity mechanism remains unknown, as there are no imaging techniques to capture it. Apoptosis is characterized by distinct structural features, which affect the way damaged tissue scatters ultrasound compared to healthy tissue. We evaluated whether apoptosis, triggered by the anesthetic sevoflurane in the brains of neonatal rhesus macaques, can be detected using quantitative ultrasound (QUS). Neonatal (n=15) rhesus macaques underwent 5hr of sevoflurane anesthesia. QUS images were obtained through the sagittal suture at 0.5 and 6hr. Brains were collected at 8hr and examined immunohistochemically to analyze apoptotic neuronal and oligodendroglial death. Significant apoptosis was detected in white and gray matter throughout the brain, including the thalamus. We measured a change in the effective scatterer size (ESS), a QUS biomarker derived from ultrasound echo signals obtained with clinical scanners, after sevoflurane-anesthesia in the thalamus. Although initial inclusion of all measurements did not reveal a significant correlation, when outliers were excluded, the change in the ESS between the

pre- and post-anesthesia measurements correlated strongly and proportionally with the severity of apoptotic death. We report for the first time *in vivo* changes in QUS parameters, which may reflect severity of apoptosis in the brains of infant nonhuman primates. These findings suggest that QUS may enable *in vivo* studies of apoptosis in the brains of human infants following exposure to anesthetics, antiepileptics and other brain injury mechanisms.

Title: Tracking secondary injury and recovery in mouse models using 3D optical imaging

Authors: C. D. PERNICI[1,2], B. S. KEMP[2], ***T. A. MURRAY**[2];
[1]Pharmacol. and Toxicology, Univ. of Utah, Salt Lake City, UT; [2]Ctr. for Biomed. Engin. and Rehabil. Sci., Louisiana Tech. Univ., Ruston, LA

Abstract: We have developed a high-resolution, optical system for deep brain imaging in Thy1-YFPH mice to monitor cellular damage and recovery over several weeks after diffuse brain injury. We tracked the same axons in a subcortical white matter track at six time points after traumatic brain injury (TBI). To accomplish this, we developed a high-resolution gradient index (hrGRIN) lens system that is compatible with the fluid percussion injury model and precision, time-lapse multiphoton microscopy. Baseline images acquired before injury were used to normalize post-injury data for each mouse which minimized inter-animal variability and reduced the number of mice required for experiments. As expected for diffuse brain injury, a small percentage of axons developed undulations (Fig. 1, dashed arrow). Later, some of these axons developed varicosities (Fig. 1, arrow) and ultimately detached forming a proximal terminal bulb (Fig. 1, asterisk). Other undulated axons returned to their baseline state. Similarly, a small percentage of axons with varicosities resolved over time (Fig. 1, arrowhead). Notably, secondary injury was also tracked as new damage at each time point. Thus, the hrGRIN system will be useful to monitor both the effect of therapeutics on reparative mechanisms and on mitigation of secondary injury. In another application, the hrGRIN system was used to image microglia in Layers 5-6 of the cortex in Cx3cr1-ROSA26-tdTomato mice before and after middle carotid

artery occlusion, a model of ischemic stroke. Ramified cellular processes were prominent in pre-injury images. After injury, cells became de-ramified, adopting brushy and ameboid morphologies associated with activation. Time-lapse images revealed motile microglia moving around the vasculature. In summary, the hrGRIN system has the spatial resolution to observe varicosities on axons and fine ramified processes of microglial cells. It also has the temporal resolution necessary to observe motile microglial cells over seconds and minutes and also the precision to track the same axons over multiple imaging sessions for up to 80 days.

Title: Subpial vasogenic edema with rotational trauma in young children

Authors: A. SCHOLL[1], C. J. SCHMIDT[3], *R. J. CASTELLANI[2];
[2]Pathology and Neurosci., [1]WVU Sch. of Med., Morgantown, WV; [3]Wayne County, Detroit, MI

Abstract: The pathophysiology of traumatic brain injury in young children, in particular the massive cerebral swelling and encephalopathy that often occurs in this setting, is poorly understood. As an initial step toward the investigation of complex metabolic cascades in brain injury in young children, we explored brain immunoreactivity for IgG in traumatic brain injury

versus asphyxiation. The study was approved by WVU institutional review board. IgG immunoreactivity in this setting is a surrogate for brain microvascular dysfunction, as IgG traverses the disrupted blood brain barrier. Study subjects included 9 decedents with acute blunt force trauma (age range 2.5 months to 16 months) and 7 subjects with asphyxial deaths due to unsafe sleep environments (age range 0.5 months to 6 months). All subjects presented for autopsy at the Wayne County Medical Examiner's Office in Detroit, Michigan. Among the deaths from blunt force trauma, 5 were associated with subdural hemorrhage, suggesting rotational injury biomechanics. Survival in the trauma subjects ranged from 0 to 38 hours. All asphyxia subjects were found dead. Both the trauma group and the asphyxia group showed variable IgG immunoreactivity around small blood vessels in gray and white matter. This suggests that asphyxia causes measurable changes to the brain microvasculature. In addition, a striking pattern in trauma subjects with subdural hematoma was a pronounced subpial immunoreactivity for IgG (see figure). The basis for this pattern requires additional research, although it is noteworthy that aquaporin 4 expression in astrocytic foot processes is increased in the subpial region. An older study also implicated the subpial region as a means of spreading of brain edema in experimental hypertensive brain injury. The association with subdural hemorrhage suggests a rotational component, possibly with traction on superficial veins that might co-occur with traction on bridging veins and bridging vein rupture. More studies are needed to confirm this finding and elucidate its pathogenic basis.

Title: The behavioral effects of blocking PDGF-R in a rat model of traumatic brain injury

Authors: *N. KALYNOVSKA[1], M. HAMER[2], P. GIFFORD[1], A. JULLIENNE[1], J. TANG[1], W. PEARCE[1], J. H. ZHANG[1], A. OBENAUS[2], R. E. HARTMAN[1];
[1]Loma Linda Univ., Loma Linda, CA; [2]Univ. of California Irvine, Irvine, CA

Abstract: Traumatic brain injury (TBI) leads to a variety of neurological and behavioral deficits. Prior studies by our group have suggested that platelet-derived growth factor (PDGF) contributes to neuroinflammation following intracerebral hemorrhage (ICH), and that imatinib (a PDGF-R blocker) reduces edema following ICH. We hypothesized that blocking the PDGF receptor would reduce TBI-induced brain edema and improve vascular function, therefore improving behavioral outcomes. Young adult male rats were given a controlled cortical impact TBI or a sham procedure (craniectomy) and treated with imatinib or vehicle (0.1% DMSO). Vehicle-treated rats had increased lesion size that was prevented by imatinib. We also measured behavioral performance on several tests of sensorimotor and neurological function. In general, TBI animals with more severe damage performed worse on a neurological test battery, made more errors on a foot fault test, and traveled less distance on a balance beam. Sham rats performed similarly to naïve controls on the neurological test battery, but TBI rats demonstrated significant deficits at 1d, 3d and 7d post-TBI. Imatinib and vehicle treatment slightly reduced performance 1d and 3d, but by 7d, TBI rats treated with imatinib were performing slightly better than TBI only or TBI+vehicle rats. Sham rats made slightly more foot fault errors than naïve controls, and TBI rats made significantly errors than shams at 1d post-TBI. Imatinib treatment slightly improved performance in both groups. TBI rats still demonstrated foot fault deficits, although attenuated, at 3d post-TBI, but the deficits had dissipated by day 7. On the balance beam test, shams traveled less distance than naïve controls, and TBI rats traveled less than shams 1d, 3d, and 7d post-TBI. Both vehicle and imatinib treatment increased distance traveled in shams, but not TBI rats, at 1d. In summary, the sham procedure induced behavioral deficits, but the addition of TBI made those deficits (observed for up to 7d post-injury) significantly worse. Treatment with imatinib prevented the vehicle (DMSO)-induced exacerbation of the brain injury and tended to improve overall performance, suggesting that blocking PDGF-R may ultimately play a role in preventing brain damage and behavioral deficits observed following TBI.

Title: Identifying common and distinct behavioral phenotypes associated with 3 types of hemorrhagic brain injury in rats

Authors: *W. HARDEMAN[1], M. HAMER[2], P. GIFFORD[1], J. TANG[1], W. PEARCE[1], J. H. ZHANG[1], A. OBENAUS[2], R. E. HARTMAN[1];
[1]Loma Linda Univ., Loma Linda, CA; [2]UCI, Irvine, CA

Abstract: Brain injuries can induce a variety of behavioral deficits depending on the type of injury, size and location of the lesion, and demographic characteristics of the patient. However, individual variability in responses to brain injury can produce a wide range of deficit profiles, from complete lack of observable deficits despite a large lesion to relatively significant deficits despite a small (or even no) lesion. Additionally, the passage of time can ameliorate or exacerbate behavioral deficits associated with brain damage, depending again on complex interactions between the injury, the environment, and the individual. In this study, adult male rats received one of three forms of hemorrhagic injury (traumatic brain injury [TBI], subarachnoid hemorrhage [SAH], or intracerebral hemorrhage [ICH]), and their performance on a number of behavioral assays was recorded over the course of 7d. In general, specific overall performance profiles were associated with each injury type. For example, TBI, ICH, and SAH rats differed in their grouped (average) on the foot fault assay, balance beam, and wire hang tests. Additionally, the sham procedures associated with each type of brain injury induced behavioral changes, demonstrating the importance of characterizing multiple control groups. However, it was generally impossible to determine the type, extent, or even existence, of a lesion based on the performance of an individual rat on an individual task. Due to biological variability (similar to that observed in humans), control rats sometimes performed worse on tests than rats with even relatively large lesions (and vice versa). However, we provide evidence that, when the overall pattern of behavioral performance across a wide variety of tests is analyzed, the accuracy of predicting the type and extent of brain injury increased dramatically. These data demonstrate that, in both humans with brain injuries and animal models of those injuries, testing a variety of

behavioral domains will allow for more accurate diagnoses, despite the incredibly wide range of performance observed across individuals.

Title: Microglia elimination recovered peripheral inflammation-induced sleep but prolonged traumatic brain injury-induced sleep in mice

Authors: ***K. R. GIORDANO**[1,2], T. R. F. GREEN[1,2], J. B. ORTIZ[1,2], M. SABER[1,2], Y. HUR[1,2], H. MORRISON[3], J. LIFSHITZ[1,2,4], R. K. ROWE[1,2,4];

Abstract: Sleep is regulated by circadian and physiological processes, such that inflammation and cytokine production may disrupt the chemical balance required to maintain a healthy sleep profile. Traumatic brain injury (TBI) initiates inflammation and microglia activation, with subsequent sleep disturbances that can exacerbate inflammation and neurological symptoms after TBI. As such, a dynamic feedback loop links sleep, inflammation, and TBI. We hypothesized that microglia elimination with a CSF-1R inhibitor (PLX5622) would attenuate cytokine levels and differentially regulate sleep after peripheral-induced and TBI-induced inflammation. Mice were administered PLX5622 or control diet (21d) and baseline sleep was measured. PLX5622 eliminated microglia (<0.5% remained) without significant differences in physiological sleep or peripheral cytokine levels (IL-6, TNF-α, IL-1β) compared to mice on control diet. Mice on PLX5622 and control diet received lipopolysaccharide (LPS; 1.2mg/kg i.p) or midline fluid percussion injury (mFPI) and sleep was recorded for 3 days. LPS increased sleep (cumulative minutes/day) regardless of diet ($F(1,8)=11.28$, $p<0.01$). In LPS mice on control diet, sleep remained increased, whereas in mice on PLX5622, sleep returned to baseline by day 3 post-injection, with elevated peripheral IL-6 at day 1 post-injection ($F(2,10)=25.99$, $p<0.0001$). TBI increased sleep regardless of diet ($F(1,4)=17.91$, $p<0.01$). In mFPI mice on control diet, sleep returned to baseline by day 2 post-injury, whereas in mFPI mice on PLX5622, sleep remained higher than baseline over 3 days post-injury. Regardless of diet, peripheral cytokine levels were

not elevated (1 day post-injury). Thus, microglia elimination recovered sleep disturbances after peripheral-induced inflammation, but prolonged sleep disturbances after TBI, which establishes a role for microglia in the feedback loop among sleep, inflammation, and TBI. Microglia represent a plausible therapeutic target to mitigate inflammation, using sleep outcomes as a pharmacodynamic measure in treating TBI and other neuroinflammatory diseases.

Title: Human ESC-Derived interneuron precursors grafted into the hippocampus control seizures and cognitive function in a model of temporal lobe epilepsy

Authors: D. UPADHYA[1], S. ATTALURI[1], B. HATTIANGADY[1], B. SHUAI[1], Y. LIU[2], Y. DONG[2], S.-C. ZHANG[2], ***A. K. SHETTY**[1];

Abstract: Temporal lobe epilepsy (TLE) is drug-resistant in ~35% of patients. An alternative therapy that is efficient for reducing spontaneous recurrent seizures (SRS) is therefore needed. Grafting of mouse/rat medial ganglionic eminence (MGE) interneuron precursors has shown great promise for suppressing seizures in rodent models of TLE. However, clinical translation of MGE cell grafting strategy to TLE patients will require rigorous testing of MGE cells generated from human pluripotent stem cells (hPSCs). In this study, we examined the efficacy of human embryonic stem cell (hESC)-derived hMGE cells grafted into the hippocampus of F344 rats exhibiting Kainate-induced chronic TLE. Chronically epileptic rats (CERs) showing robust SRS received bilateral intrahippocampal grafting of hMGE cells expanded from hESCs transduced with Designer Receptors Exclusively Activated by Designer Drugs (DREADDs, hSyn-hM4D(Gi)-mCherry) through CRISPR/Cas9 technology. Four months after grafting, we employed injections of clozapine-N-oxide (CNO) to activate DREADDs in graft-derived neurons at specific periods during video-EEG recordings or behavioral studies. CNO is a drug that activates DREADDs receptors to block the activity of neurons expressing DREADDs. CNO injections (3 mg/Kg) were given every 8 hours for 2-3 days to activate DREADDs. Video-EEG

recordings were also made for 4-7 days after the washout of CNO. Before CNO injections, CERs receiving grafts displayed considerably reduced frequency of SRS than CERs receiving no grafts and normal hippocampus-dependent cognitive function in an object location test (OLT). Activation of DREADDs by CNO injections resulted in increased SRS activity and impaired cognitive function in an OLT. In contrast, EEG recordings obtained after CNO washout period revealed a pattern of SRS activity that was comparable to the pre-CNO period. Administration of CNO to CERs receiving no grafts did not alter any parameters of SRS, however. Triple immunofluorescence for human nuclear antigen (a marker of all human cells), mCherry (reflecting the expression of DREADDs in hESC-derived cells) and GABA/parvalbumin/neuropeptide Y, revealed the presence of mCherry in virtually all GABA-ergic interneurons derived from hMGE grafts, implying that an increased frequency of SRS after CNO administration correlated with the expression of DREADDs in graft-derived neurons. The results underscore that interneurons derived from hESC-hMGE cell grafts in the hippocampus are directly involved in suppressing SRS and improving hippocampus-dependent cognitive function in chronically epileptic animals.

Title: Single intranasal administration of MSC-derived A1-exosomes thwarts moderate TBI-induced long-term cognitive and mood impairments

Authors: *M. KODALI[1], D.-K. KIM[2], B. SHUAI[3], R. UPADHYA[3], A. VOGEL[3], S. ATTALURI[3], D. J. PROCKOOP[3], A. K. SHETTY[3];

Abstract: A significant percentage of people with moderate or severe traumatic brain injuries (TBIs) develop chronic neuroinflammation and persisting cognitive and mood dysfunction. The chronic effects are driven primarily by excessive inflammation in the early phase, which can prompt tissue damage and chronic neuroinflammation. In patients, the chronic effects produce severe behavioral deficits months or years after recovering from the acute symptoms. Many

drugs have been shown to reduce neuroinflammation following TBI, but none have been incorporated into the standard medical care because of limited functional efficacy or undesirable side effects. Therefore, there is a need for alternative therapeutic strategies. One strategy is to administer exosomes secreted by mesenchymal stem cells (MSCs), which have shown similar or better efficacy than MSCs for modulating inflammation in several disease models. Exosomes are particularly attractive for application in neurological disorders as they can readily cross the blood-brain barrier, quickly get incorporated into neurons and microglia following intranasal (IN) administration, and are unlikely to cause thrombosis. Our previous study showed that intravenous administration of MSC-derived A-1 exosomes is efficacious for reducing inflammation in the hippocampus, and improving learning and pattern separation function in the early post-injury period (Kim et a., PNAS, 2016). In this study, we investigated the efficacy of a single intranasal (IN) administration of A1-exosomes early after moderate TBI for thwarting long-lasting impairments in cognitive, memory and mood function. Nine-week-old mice were first subjected to unilateral controlled cortical impact injury using a velocity of 5m/s, dwell time of 300ms and injury depth of 0.8 mm. Two hours after the induction of TBI, mice received intranasal administration of A-1 exosomes (~5 billion/nostril, total, 10 billion) or vehicle. The mice were examined for cognitive and mood function using a series of behavioral tests at 7 months post-TBI. Animals that received vehicle after TBI displayed cognitive dysfunction, recognition memory problems, pattern separation deficits as well as anhedonia. Remarkably, animals that received A-1 exosome treatment after TBI showed similar cognitive, memory and pattern separation function as naïve control animals. These animals also exhibited a higher level of neurogenesis in the hippocampus contralateral to injury. Analyses of microglia and astrocytes are currently in progress. Thus, IN administration of A-1 exosomes shortly after moderate or severe TBI has promise for preventing long-term cognitive and mood impairments.

Title: Functional analysis of granule cells generated during post-traumatic hippocampal neurogenesis

Authors: *A. K. WILSON[1], E. SCHNELL[2,3];
[1]Res. and Develop. Div., [2]Operative Care Div., Portland VA Med. Ctr., Portland, OR;
[3]Anesthesiol. and Perioperative Med., OHSU, Portland, OR

Abstract: Individuals with penetrating or severe traumatic brain injury (TBI) are at an increased risk of developing posttraumatic epilepsy (PTE). In a number of animal models, hippocampal neurogenesis increases after TBI, and these new neurons contribute to hippocampal network function. These neurons develop a number of morphologic abnormalities that suggest differential acquisition of inputs during their maturation, which might have functional consequences at the network level. However, it is unclear how different granule cell input pathways might be differentially affected, and whether aberrantly wired granule cells contribute to hippocampal hyperexcitability or alternatively might protect against hyperexcitable circuit function in other regions. To evaluate this, we are using a controlled cortical impact (CCI) model of TBI in conjunction with the transgenic pulse labeling of newborn neurons to identify granule cells born after TBI for both morphologic and functional analysis. Similar to previous results, we find a significantly increased number of labeled neurons in mice after CCI when compared with sham animals, and these neurons demonstrate aberrant cell morphology after TBI. We are using slice electrophysiology to determine how these aberrant cells incorporate into circuits using whole-cell recordings of both newly born neurons as well as target cells. Through this work, we hope to assess the hypothesis that the aberrant development and growth of neurons generated after TBI might lead to hyperexcitable circuit formation.

Title: Propriospinal neurons mediate rehabilitative recovery of skilled forelimb reaching after cervical injury

Authors: *G. M. SMITH[1], K. M. KEEFE[2], C. LI[3], L. G. KIRBY[4], I. S. SHEIKH[2];
[2]Neurosci., [1]Temple Univ., Philadelphia, PA; [3]Ctr. for Substance Abuse Res., Temple Univ. Sch. of Med., Philadelphia, PA; [4]Ctr. for Substance Abuse Res. and Dept Anat. and Cell Biol, Lewis Katz Sch. of Med. At Temple Univ., Philadelphia, PA

Abstract: Cervical injury to the spinal cord results in diminished or complete loss of skilled forelimb mobility, depending on the severity of the injury. Such, goal-directed reaching and grasping behaviors are primarily driven by corticospinal neurons. After spinal cord injury (SCI), rehabilitation is thought to mediate re-organization and plasticity of spared supraspinal-propriospinal circuits leading to partial recovery of function. Whether plasticity along these circuits is instrumental in promoting recovery of skilled forelimb patterning remains elusive. Bilateral lesions of the corticospinal tract and dorsal columns at C5 results is a 50% loss in pellet retrieval that recovers to normal levels over a 4 weeks period of training. To determine the pathways contributing to recovery, we injected retrograde transportable lentivirus expressing tetracycline-inducible hM4Di-mCherry (inhibitory DREADD) into the rat C6 -T1 spinal cord, the region containing the majority of spinal motor neurons responsible for forelimb targeted reaching and grasping. This virus supports selective up take at synaptic terminals and retrograde transport to their somas. A secondary injection of AAV2-rtTAV16 (Tet-On) into either C3/C4 spinal cord, red nucleus or both limited expression within regional neuronal population innervating the C6-T1 spinal cord. Reversible silencing of C3-C4 propriospinal neurons using clozapine-N-oxide caused partial loss of this recovery with near complete loss of recovery only when both PN and RN pathways were co-silenced. Tracing studies demonstrated that C3/C4 propriospinal neurons not only established vGlut2 + synapses onto C6-T1 spinal motor neurons but also extended an axon branch into the lateral reticular nucleus, thought important in forming an internal motor copy for adjustment of forelimb patterning during movement. Anterograde tracing of the corticospinal tract (CST) shows sprouting of severed CST fibers in the upper cervical spinal cord and red nucleus after training. These finding demonstrate the role of spared pathways on recovery of forelimb reaching behaviors after rehabilitative training.

Title: Blockade of $5HT_7$ receptor enhance respiratory recovery following daily acute intermittent hypoxia in rats with chronic cervical spinal contusion

Authors: *K.-Z. LEE, M.-J. WU;
Natl. Sun Yat-sen University, Dept. Biol. Sci., Kaohsiung, Taiwan

Abstract: Intermittent hypoxia can elicit respiratory neuroplasticity to augment respiratory motor activities following hypoxia (i.e., long-term facilitation). This type of respiratory neuroplasticity is primarily mediated by activation of Gq-protein coupled 5-HT2 receptors but constrained by Gs-protein coupled 5-HT7 receptors. Accordingly, the present study hypothesized that inhibition of 5-HT7 receptors can enhance the effect of intermittent hypoxia on the respiratory function following cervical spinal cord injury. The ventilatory behaviors of unanesthetized mid-cervical contused rats were measured before, during and after daily acute intermittent hypoxia [10 episodes of 5 min of hypoxia (10 % O_2, 4 % CO_2, 86 % N_2) with 5 min of normoxia intervals for 5 days] at 8 weeks post-injury. Animals were daily received either 5-HT7 receptor antagonist (SB269970, 4 mg/kg, i.p.) or vehicle (DMSO) 5 min before daily acute intermittent hypoxia. The results demonstrated that intermittent hypoxia induced a similar increase in the tidal volume between two groups at the first day; however, the baseline tidal volume was significantly greater in animals received 5-HT7 receptor antagonist at 2-3 days during daily acute intermittent hypoxia. These results suggested that blockade of 5-HT7 receptors can augment intermittent hypoxia-induced respiratory neuroplasticity to enhance respiratory recovery following chronic cervical spinal cord injury.

Abstract: A single session of repeated non-invasive stimulation using the principles of spike-timing dependent plasticity (STDP) improves voluntary motor output in humans with spinal cord injury (SCI). Here, we applied the principles of STDP in multiple-spinal cord segments by using transcutaneous electrical stimulation of the spinal cord between L2-L3 and L4-L5 spinal segments timed with transcranial magnetic stimulation (TMS) of the leg representation of the primary motor cortex. Twenty-two individuals with chronic incomplete cervical, thoracic, or lumbar SCI were randomly assigned to the 20 sessions of stimulation (STDP+exercise) or sham (sham STDP+exercise) group. Stimulation or sham sessions were composed of 180 pairs of stimuli applied for ~30 min followed by lower-limb exercise for ~45 min. During STDP, electrical stimuli were applied at spinal cord segments ~1-2 ms after corticospinal volleys evoked by TMS arrived at corresponding corticospinal-motoneuronal synapses. We found that the size of corticospinal responses elicited by TMS and maximal voluntary contraction in targeted muscles increased when exercise was combined with STDP but not sham-STDP. Both measurements were further improved with repeated number of sessions in the STDP group. Clinical functional outcomes improved after both protocols but to a greater extent after STDP than sham-STDP. Our findings indicate that multisegmental stimulation of spinal synapses is an effective strategy to enhance exercise-mediated recovery in humans with SCI.

Abstract: Transcutaneous electrical stimulation of the spinal cord (TESS) promotes functional recovery in humans with spinal cord injury (SCI) but its mechanisms of action remain largely unknown. We hypothesized that TESS-aftereffects on recovery relate to contributions from cortical and subcortical networks. Here, we examined motor evoked potentials elicited by cortical and subcortical stimulation of corticospinal axons and the activity in intracortical circuits in arm muscles before and after a commonly used TESS protocol (30 Hz pulses with a 5 kHz carrier frequency) and sham-TESS for 20 min between the C5-C6 spinal segments in humans with and without chronic incomplete cervical SCI. We found that the size of subcortically but not cortically evoked motor responses increased in proximal and distal arm muscles for 60 min after TESS, but not sham-TESS, in controls and SCI participants. Intracortical inhibition increased after TESS in both groups. Stimulation at 30Hz, without the 5 kHz carrier frequency, facilitated subcortical motor evoked responses without changing intracortical inhibition, suggesting that the 5 kHz carrier frequency contributed to the cortical effects. Notably, performance in hand and arm functional tasks improved after TESS, but largely, when TESS was used with the 5 kHz carrier frequency. These results demonstrate for the first time parallel effects of TESS on cortical and subcortical networks, having an excitatory effect at the spinal level and an inhibitory effect at the cortical level. We argue that this dual effect supports the recovery of limb function following SCI.

Title: Techniques for spinal cord stimulation to restore bladder function in rats

Authors: S. J. ILHAM[1], N. NOLTA[1], C. HARDY[2], P. SMITH[2], ***M. HAN**[1]; [1]Biomed. Engin., Univ. of Connecticut, Storrs Mansfield, CT; [2]Univ. of Connecticut Hlth., Farmington, CT

Abstract: Spinal cord injury (SCI) causes motor and sensory deficits that can severely impact the quality of life including interruption of voluntary bladder control. Epidural electrical

stimulation is a commonly used treatment for emptying the bladder in SCI patients, but low efficacy and incomplete voiding are persistent problems mainly due to the broad spread of the electrical field. Studies in the feline model have shown that chronic intraspinal stimulation of the dorsal gray commissure in the sacral spinal segment can induce micturition by innervating the sacral parasympathetic nucleus and Onuf's nucleus. Applying a similar technique in the rat model may enable refinement of stimulation targets and urodynamic evaluation. We have established robust surgical and measurement procedures in the rat model, including: (1) suprapubic catheterization to the urinary bladder, (2) dorsal laminectomy to expose the lumbar-sacral spinal cord, (3) stimulus target localization comprising of an automated stimulation waveform generation in the perigenital skin and evoked cord dorsum recording with a surface electrode via a differential recording system, (4) cystometric evaluation involving pressure transducer for the bladder pressure and load cell to quantify voiding, and (5) post-mortem immunohistochemical staining of neurons and glial cells. We have completed four non-survival surgeries involving all of these procedures, and confocally-imaged the spinal cord tissues enabling quantification of tissue responses to stimulation. This work will enable testing of a less-invasive focused ultrasound stimulation using a miniatured ultrasound transducer as well as intraspinal stimulation using penetrating microelectrode arrays in both non-survival and survival experiments.

Title: Tracking rehabilitation as an effect mediator, moderator or covariate in spinal cord injury interventional clinical trials: The international spinal cord injury physical therapy - occupational therapy basic data set

Authors: *E. C. FIELD-FOTE[1], K. D. ANDERSON[2], L. A. T. JONES[3], R. RUPP[4], V. K. NOONAN[5], L. A. HARVEY[6], M. W. M. POST[7], S. J. MULROY[8], M. SCHMIDT-READ[9], A. M. BRYDEN[2], M. J. MULCAHEY[9], F. BIERING-SORENSEN[10];
[1]Crawford Res. Inst., Shepherd Ctr., Atlanta, GA; [2]Case Western Reserve Univ., Cleveland, OH; [3]Univ. of Colorado, Boulder, CO; [4]Heidelberg Univ. Hosp., Heidelberg, Germany; [5]Rick Hansen Inst., Vancouver, BC, Canada; [6]Univ. of Sydney, Sydney, Australia; [7]De Hoogstraat Rehabil. Ctr., Utrecht, Netherlands; [8]Rancho Los Amigos Natl. Rehabil. Ctr., Downey, CA; [9]Thomas Jefferson Univ., Philadelphia, PA; [10]Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Background & Purpose: Nearly all interventional trials use the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) as the primary or secondary endpoint of neurologic recovery. Since physical and occupational therapies (PT-OT) promote use-dependent plasticity that has the potential to impact the ISNCSCI scores, it is important to consider the influence of these therapies when provided in conjunction with clinical interventional trials.
Methods: To facilitate efficient tracking of therapy content and dose (time), an international workgroup under the auspices of the International Spinal Cord Injury Society (ISCoS) Data Set Committee developed a standardized collection and reporting tool and accompanying syllabus: The International Spinal Cord Injury PT-OT Basic Data Set. During the process of developing the data set, the workgroup solicited input from numerous sources including from PTs and OTs at the institutions where the workgroup members are affiliated, and at the 2017 ISCoS meeting. Taking all feedback into consideration, the workgroup modified the data set over multiple iterations.
Results: The draft version of the PT-OT Data Set contains 7 items. International audience feedback about how the data set and the syllabus meet its goals is invaluable. This poster will provide an interactive opportunity for discussion and feedback will be incorporated into the dataset refinement process.

	ITEM	TIME (in minutes)					
ACTIVITY-DIRECTED INTERVENTIONS							
A	Bed/seated control activities: balance, seated transfers, bed mobility	<10	10-19	20-29	30-44	45-60	>60
B	Standing control activities: standing, balance, standing transfers weight bearing	<10	10-19	20-29	30-44	45-60	>60
C	Walking, stairs (inside, outside)	<10	10-19	20-29	30-44	45-60	>60
D	Gross motor UE: dressing, washing, manual wheelchair mobility	<10	10-19	20-29	30-44	45-60	>60
E	Fine motor UE: grooming, self-feeding, buttoning, zipping, adjustment of clothing	<10	10-19	20-29	30-44	45-60	>60
IMPAIRMENT-DIRECTED INTERVENTIONS							
F	Strength training (including electrical stimulation for strength)	<10	10-19	20-29	30-44	45-60	>60
G	Endurance training (including electrical stimulation for endurance)	<10	10-19	20-29	30-44	45-60	>60
TOTAL INTERVENTION TIME							
	Sum of time spent on individual items	<10	10-19	20-29	30-44	45-60	>60

Discussion & Conclusions: The intent of the PT-OT Basic Data Set is to provide a uniform

mechanism to efficiently track the content and dosing of PT-OT sessions without undue burden on therapists.

Title: The troublesome trio of spasticity: Clonus, spasms, stiffness - Characteristics and impact

Authors: E. C. FIELD-FOTE[1], C. L. FURBISH[1], N. TRIPP[2], W. SWEATMAN[3], M. HAYAT[2], *S. P. ESTES[4], A. W. HEINEMANN[5];
[1]Shepherd Ctr., Atlanta, GA; [2]Georgia State Univ., Atlanta, GA; [3]Georgia Gwinnett Col., Lawrencefille, GA; [4]Shepherd Center/Crawford Res. Inst., Atlanta, GA; [5]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Background: Spasticity is among the most prevalent and problematic secondary conditions following spinal cord injury (SCI). Multiple definitions of spasticity exist, however some have limited relationship with the way this phenomenon is experienced by persons with SCI.
Methods: Investigators at 6 SCI Model System Centers in the US collaborated on a REDCap-based survey study. Questions were intended to identify characteristics of spasticity as experienced by persons with SCI. For example: for hyperreflexia (clonus): “My spasticity causes my legs to shake”; for spontaneous spasms: “My spasticity causes my legs to move on their own”; for hypertonia (stiffness): “My spasticity causes my legs to be stiff”. We quantified relationships among characteristics of spasticity and scores on measures of spasticity-related impact on function and quality of life (SCI-SET and PRISM).
Results: Survey results from 1,200+ individuals with SCI were acquired. Data were collapsed across injury level and severity; only data related to leg spasticity are reported here.
Characteristics of spasticity experienced *Often/Very Often* were [% of respondents]
Stiffness (hypertonia) [64.6%]
Spontaneous spasms [56.9%]
Clonus (hyperreflexia) [50.3%]

Impact of spasticity, based on the SCI-SET query *"During the past 7 days, how have your spasticity symptoms affected…*" elicited *Negative* responses from ≥50% of respondents for 15 of 35 items. The 2 items with highest % of *Negative* responses were *"your feeling of physical comfort* (70.3%)" and *"your feeling of control over your body* (68.8%)". The single item for which respondents most often reported spasticity had a positive influence was *"ability to change positions in bed"* (8.6%).
Impact of spasticity, based on the PRISM query *"In the past 7 days, my abnormal muscle control or involuntary muscle movement…"* elicited responses of *Often/Very Often* from ≥20% of respondents for the items: 1) "*caused me to depend on others",* 2) *"bothered me a lot",* 3) *"made me feel out of control of my body",* 4) "*kept me from being as happy as I could be",* 5) *"made me feel frustrated".*
Discussion: While the classic definition of spasticity (Lance, 1980) is convenient for scientists with its exclusive focus on stretch reflexes, the definition has only a limited relationship with spasticity as experienced by persons with SCI. The comprehensive definition adopted by an international consensus group (the SPASM Consortium, 2005) is a more accurate reflection of the phenomenon. Broader understanding of spasticity would promote efforts to identify interventions that can address this common and problematic secondary sequela of SCI.

Title: The application of correlational bandits in large decision spaces to spinal cord injury clinical treatments

Authors: *Y. QIN, J. W. BURDICK;
Caltech, Pasadena, CA

Abstract: This work describes the Gaussian process bandits problem's application in the search for the optimal strategy from large decision spaces in a clinical setting. Spinal cord injury patients can achieve partial recovery of lost muscle functions through electrical stimulation applied through an epidural multi-electrode array to the spinal cord. The challenge of this treatment is to determine the stimulus pattern that leads to the best patient performance, as the performances vary significantly when given different stimulus patterns. The optimal stimulus

pattern, which consists of the active electrodes and their polarities, amplitudes, and pulse train frequency, varies significantly across patients and is time-variant. Therefore, the clinicians must determine the optimal pattern from an extremely large decision space for each patient through a laborious approach. This problem, as well as many others, can be modeled as a recommender system with unknown prior distributions. Each decision gives a stochastic reward and new decisions are made based on the previous rewards. To maximize the total reward in a finite number of trials, we need to balance the exploration of various strategies and the exploitation of the currently optimal strategies. Additionally, geometrically similar stimulation patterns are expected to lead to similar rewards since they generate similar electric fields in the spinal cord. We derived this correlational property as the kernel function. The Gaussian process - Upper Confidence Bound (GP-UCB) algorithm was implemented for stimulation pattern selection. We also used supervised learning methods such as Random Forest to extract areas in the spinal cord and their corresponding features that are closely associated with the patients' performances. The performance of the GP-UCB algorithm was evaluated in simulation experiments as well as using offline clinical data collected from two quadriplegic patients with the electrode array implant. We show that the algorithm converges faster in the simulation experiments comparing to the epsilon-greedy method in the independent bandits setting. Given the confined search space of a limited number of stimulation patterns in the clinical data, the GP-UCB algorithm is able to propose the stimulation pattern with the relatively best performance faster than the epsilon-greedy method with no arm correlations.

Mexicano del Seguro Social, Guadalajara, Mexico

Abstract: Several neuropathologies associated with the degeneration of the corticospinal tract show impairment of motor functions. Rehabilitation protocols promote the functional recovery of such pathologies, in part, because they favor the expression of compensatory plastic mechanisms. However, there is little evidence of changes in the synaptic contacts between the terminals of the corticospinal tract and its postsynaptic counterpart in the spinal motoneurons, after a rehabilitation program after anterograde lesion of the corticospinal tract. Stereotaxic lesion with kainic acid in the primary motor cortex was induced in adult female rats. 15 days later, motor function was evaluated in a Rota-rod device and immediately afterwards they were integrated into a rehabilitation protocol in a treadmill type continuous band for 7 continuous days. The following day, the motor performance in the Rota-rod was evaluated. In parallel, the numerical density of dendritic spines was quantified in motor neurons of a thoracic-lumbar segment of the spinal cord. The pharmacological lesion caused a poor motor performance that improved after the rehabilitation stage. Likewise, the density of dendritic spines increased after rehabilitation. The appearance of the clinical symptoms of neurological damage caused by the degeneration of the corticospinal tract is accompanied by spontaneous plastic responses at the synaptic level. In accordance with the present results, such plastic processes were enhanced by induced rehabilitation. This suggests the design of rehabilitation strategies that consider the plastic capacity of the spinal circuits in conditions of Wallerian degeneration of the corticospinal tract.

Title: Enhancement of motor function with vagus nerve stimulation following a C7/C8 spinal cord injury

Authors: *M. TORRES[1], M. DARROW[2], Z. HAIDER[6], M. SOSA[3], J. TRAN[6], F. SMITH[6], S. A. HAYS[4], M. P. KILGARD[5];
[1]Baylor Col. of Med., Houston, TX; [2]Texas Biomed. Device Center/Bioengineering, Univ. of Texas at Dallas, Plano, TX; [4]Bioengineering, [5]Behavioral and Brain Sci., [3]Univ. of Texas at Dallas, Richardson, TX; [6]Texas Biomed. Device Ctr., Richardson, TX

Abstract: There are over 12,000 spinal cord injuries that occur on an annual basis within the United States of America. Recently, we have successfully demonstrated a novel therapy to treat motor dysfunction in animal models of stroke and spinal cord injury (SCI) by pairing motor

training with vagus nerve stimulation (VNS). We describe a design to test the hypothesis that repeated pairing of VNS with a motor behavioral task will drive enhancement of motor function following a bilateral spinal cord contusion injury at C7. VNS repeatedly paired with forelimb movement results in robust neural plasticity in motor cortex. Pairing VNS with the isometric pull task following spinal cord injury to the C5 level has driven significant enhancement or motor function compared to rehabilitation alone. We hypothesize that VNS paired with motor movements will also enhance plasticity and drive recovery on the isometric pull task. This study will determine whether VNS therapy will be effective for patients with an injury to this specific level, or with damage to motor neuron pools, and further assess plasticity. To test whether VNS could improve recovery of motor function after SCI, specifically damaging motor neuron pools, we have trained rats on the isometric pull task, a motor task designed to test forelimb strength. Rats were trained to pull the handle at a force of 120 grams with their right forelimb. After each rat was proficient at the task, the rat underwent surgery during which it will receive a bilateral SCI with the IH impactor at the C7/C8 level (Infinite Horizons impactor). Pairing VNS with the isometric pull task significantly enhanced peak pull force when compared to rats that underwent rehabilitative training on the isometric pull task without VNS. We have also investigated other motor assessments as well as changes occurring in the spinal cord due to plasticity.

Title: Strengthened descending neural pathways mediate improvements in upper extremity function following transcutaneous electrical stimulation and activity based therapy in an individual with a cervical, complete spinal cord injury

Authors: *D. M. ROUFFET[1], Y. P. GERASIMENKO[2], S. J. HARKEMA[1], J. M. D'AMICO[1]; [1]Kentucky Spinal Cord Injury Res. Ctr., Univ. of Louisville, Louisville, KY; [2]Pavlov Inst. of Physiol, St Petersburg, Russian Federation

Abstract: Spinal cord injuries (SCI) at the cervical level leads to severe upper extremity (UE) impairments that decrease independence with daily tasks and impair an individual's quality of life. Transcutaneous electrical stimulation (tcES) is a non-invasive technique of neuromodulation that can be used to facilitate functional recovery after SCI. The aim of this study was to evaluate if tcES delivered to the cervical spinal cord during activity-based-therapy (ABT) can improve UE function and induce plastic changes in an individual with a chronic and complete SCI at the cervical level (C3, AIS A). A 36 y/o male completed a series of 80 training sessions during which he received tcES combined with ABT. Bipolar and modulated (5kHz) current was delivered to the participant's cervical spinal cord for a minimum of 1h per training session with ABT over 80 sessions. Clinical, biomechanical and neurophysiological assessments were completed before, at the mid-point and after training. Clinical assessments included UE touch (monofilament) and temperature discrimination across dermatomes and Capacity of Upper Extremity test (CUE-T). For the biomechanical assessments, we assessed UE kinematics during forward reach and force modulation during hand grip. For the neurophysiological assessments, transcranial magnetic stimulation evoked potentials (MEPs) in UE muscles were measured to assess changes in corticospinal tract integrity; while acoustic startle reflex responses (ASR) were recorded from UE, trunk and leg muscles to assess changes in the reticulospinal pathway. Improvements in touch and temperature discrimination sensation at C6, C7 and T1 as well as an increase in the number of upward reaches performed over 30s were detected. An increase in reaching distance (+80%) and finger displacement velocity (x3) as well as a decrease in shoulder displacement (-45%) were seen during forward reach. Force production during hand grip increased (x3) in both hands. MEPmax increased in 15 out of 18 UE and trunk muscles recorded. The incidence of ASR responses increased in 18 out 22 UE and trunk muscles recorded. Our results indicate that tcES combined with ABT strengthened the spared connections and/or promoted the emergence of new connections along the corticospinal and reticulospinal pathways in an individual with a complete injury. These plastic changes are likely to have contributed to

improvements in the sensory and motor performances detected from the clinical and biomechanical assessments. Further studies are required to evaluate how training interventions that combine tcES and ABT can facilitate neural plasticity and improve UE function after spinal cord injury.

Title: Deep brain stimulation of the mesencephalic locomotor region to improve motor function after incomplete spinal cord injury

Authors: *A.-S. HOFER, M. I. SCHEUBER, A. M. SARTORI, M. E. SCHWAB;
Inst. for Regenerative Med., Univ. and ETH Zurich, Schlieren, Switzerland

Abstract: Functionally or anatomically incomplete spinal cord injury (SCI) is characterized by sparing of some fibers still connecting the brain with the spinal cord caudal to the lesion. Loss or severe impairment of motor control and locomotion is common, with limited potential for functional recovery. As a novel strategy for the treatment of large but incomplete spinal cord injuries, we suggest deep brain stimulation (DBS) of the midbrain locomotion center (mesencephalic locomotor region, MLR), which initiates and controls locomotion. Acute electrical stimulation experiments in rats with incomplete spinal cord injury conducted in our lab showed that hindlimb locomotor function improves during DBS of the MLR in chronic SCI. While only limited responses were observed up to seven days after injury, MLR-DBS was able to reestablish a high degree of locomotion five weeks after injury, even in animals with initially very severe functional deficits and white matter lesions up to 80-95%. In order to consider DBS of the MLR as a potential treatment for incomplete spinal cord injury in humans, an evaluation of whether DBS-enabled locomotor training leads to long-term reestablishment of physiological movement patterns under voluntary movement control is necessary. We hypothesized that repeated electrical stimulation-induced locomotion after incomplete SCI can enhance anatomical

rearrangements and thus lead to permanent improvement of motor function. The long-term effects of daily repeated MLR-DBS during physical training after incomplete spinal cord injuries in rats were analyzed. Functional readouts are parameters from kinematic analysis during overground locomotion and BBB scoring. Anatomically, we study the branching pattern of spared reticulospinal fibers (from nucl. gigantocellularis) in the lumbar spinal cord. The project's results are directly translated to a clinical study on MLR-DBS in human patients with chronic SCI.

Abstract: Body Weight supported treadmill training (BWSTT) has been shown to rehabilitate treadmill walking after spinal cord injury (SCI) in animals. However, whether this form of training has the capacity to translate to over ground walking associated with improved stepping remains unresolved. The circular Bi-ambulatory Rodent Trainer (cBART) is a useful tool to train and to assess the animals in their natural, quadrupedal gait. CBART is constructed with cost effective and easily accessible materials. The rotating arm made from PVC pipe is attached to a caster bracket base. One end of the arm is modified to attach a harness that secures the animal and the other end has adjustable counter weight to provide body weigh support. Sliding the counter weight at one end modifies body support. A video camera is attached on the lever arm to capture continuous rat locomotion. The animals can ambulate with weight body support in a circular path over ground with their right or left hindlimb and forelimb in view (Marvin et.al.,

2015). In this study, we compared the effect BWSTT versus training with cBART on the recovery of locomotor function in spinally contused rats. Spinally contused rats received BWSTT for 8 weeks. One group of rats then received quadrupedal over ground walking using cBART in addition to treadmill training. Following eight weeks of exercise training, tests of locomotor recovery were performed. Preliminary data suggests, forward ankle movement as a measure of initiation of step in the hindlimb, paw placement, plantar paw placement and, hip-ankle-toe (HAT) excursion angle as a measure for multiple joint function improved significantly in the combined BWSTT+ cBART (n=8) trained group when compared to BWSTT(n=8) alone. These results suggest BWSTT combined with cBART over ground training is optimal for improved locomotor recovery in spinally contused rats. Additional analysis is being performed to examine intralimb and interlimb coordination. These findings have implications for improving rehabilitation strategies after spinal cord injury and can address whether current BWSTT therapies alone provide optimal training for locomotor recovery.

Abstract: Severe spinal cord injury interrupts descending sympathetic projections that modulate cardiovascular function. This interruption leads to frequent bouts of hypertension (autonomic dysreflexia) and orthostatic hypotension, conditions that lead to increased risk for cardiovascular disease and potentially death. Here, we developed a conceptual and engineering framework to design an electrical spinal cord neuroprosthesis that targets the sympathetic circuitry within the spinal cord in closed loop to prevent the development of these conditions. We first developed a rodent model of sympathetic dysfunction after spinal cord injury. For this, we visualized catecholaminergic fibers originating from the brainstem autonomic centers in TH:Cre rats who underwent a severe upper thoracic contusion. We found a near complete interruption of TH+ descending sympathetic axons, which led to an immediate decrease in resting hemodynamics and to the development of aberrant cardiovascular reflexes. To target the sympathetic circuitry within the spinal cord with epidural electrical stimulation, we mapped the hemodynamic responses to stimulation applied at each level of the thoracic and lumbar segments. We identified highly-specific hotspots that effectively modulated hemodynamics. We then used intersectional neuroanatomical tracing and activity-dependent signalling pathways to uncover the connectome of the spinal cord and splanchnic ganglia circuits engaged by the stimulation. Using optogenetic manipulations, we established causal relationships between the modulation of these circuits and the hemodynamic response to the stimulation. We then combined CT scans, MRI sequences and computational modelling to design a neuroprosthesis that targets cardiovascular hotspots in the spinal cord. This neuroprosthesis was fabricated using e-dura technology. We therefore have termed this implant *autonomic e-dura*. Stimulation via our *autonomic e-dura* can be controlled in closed loop to precisely modulate blood pressure in both acutely and chronically injured animals.

Title: Exercise accelerates epigenetic changes after spinal cord injury

Authors: *J. HYUN[1], J. HONG[2];
[1]Rehabil. Med., Dankook Univ. Col. of Med., Cheonan, Korea, Republic of; [2]Dankook Univ., Cheonan, Korea, Republic of

Abstract: Spinal cord injury (SCI) is a major devastating lesion which cause various pathophysiological mechanisms. Recent studies reported that epigenetic changes induced by SCI might modulate regeneration-associated genes (RAGs) which control the regeneration capacity and neuronal growth. Epigenetic changes are widely considered to play an important role, but experimental evidence to support this hypothesis has not been addressed. Physical exercise has beneficial effects on the modulation of neuronal plasticity and promoting intrinsic growth capacity through epigenetic modulation in the brain. This study was carried out to investigate whether treadmill exercise affects epigenetic change and functional recovery after SCI. We made contusion models at thoracic spinal cord using adult Sprague-Dawley rats, and performed dot blotting of 5-methylcytosine (5mc) and 5-hydroxymethylcytosine (5hmc), and real-time PCR to analyze the expression level of Ten-eleven translocation (TET) family, RAGs, and pro-inflammatory cytokines as well as histological and functional assessments. Rats which were placed in the treadmill without running were considered as controls. Within the motor cortex of the brain of rats which received treadmill exercise for 12 weeks, the staining intensity and the expression level of 5hmC of cortical neurons were significantly increased. The mRNA levels of TET family (TET1, TET2, and TET3) of brain tissues were also increased more in the exercise group than in control at 12 weeks after SCI. Pro-inflammatory genes including interleukin-1 beta, interleukin-6 and tumor necrosis factor alpha were decreased, and RAGs were increased more in the exercise group. Therefore, we concluded that the 12-week treadmill exercise promotes the epigenetic changes and improves functional recovery after SCI.

Title: The problem of whiplash and possible treatment

Authors: *G. HOLSTEGE[1], H. SUBRAMANIAN[2];
[1]Rijksuniversiteit Groningen, Groningen, Netherlands; [2]Boston Scientific Neuromodulation, Los Angeles, CA

Abstract: Whiplash Associated Disease (WAD) is a disease many people suffering from. More than 75% of the cases are caused by car accidents, in which the car driver, waiting in line in traffic, because of a red traffic light or a traffic block, is hit by another car from behind. In most cases this accident is completely unexpected for the driver of the front car, which means that the neck muscles of this driver were relaxed during the accident. During the collision the body of the driver in the front car is pushed forward with the head staying behind, resulting in a sudden and strong stretching of the relaxed anterior neck muscles. Subsequently, when the front car stops, the body of the driver is pushed backward leaving the head in an anterior position resulting in very strong stretching of the posterior neck muscles. This strong flexion-extension movement often causes large damage of the neck muscles and of the facet joints, capsules and ligaments of the upper cervical vertebrae. These neck muscles and upper cervical facet joints and ligaments send a large amount of information to the spinal cord regarding the position of the head in space. In the upper cervical spinal cord this information is relayed to higher brain levels of which the mesencephalic periaqueductal gray (PAG) and adjoining areas are the most important. Other information regarding the position of the head originates from the vestibular nuclei and from the visual system. Based on this information the mesencephalon determines the position of the head and the eyes. In WAD-patients the damaged neck muscles and upper cervical vertebrae deliver inappropriate proprioceptive information to the PAG, resulting in a mismatch between this information and the incoming information from the undamaged vestibular and visual systems. This mismatch may cause balance disturbances, dizziness, headache, forgetfulness, central hypersensitivity to noise and sound, emotional instability, fatigue and problems with sleep, the common symptoms in WAD patients.The strength of this mismatch differs strongly between patients, probably depending on the strength of the inappropriate information from the upper neck. The solution might be to remove the incoming information from the facet joints, capsules and ligaments of the upper cervical vertebrae to the upper cervical spinal cord (C1-C3). In three healthy cats we have cut the dorsal roots of the C1-C3 spinal cord, which did not result in any problems in these cats. A similar approach in humans might lead to treatments of WAD, a disorder with an estimated yearly cost in Europe of at least 10 billion EUR.

Title: Single joint CPM is beneficial for reducing multi-joint muscle tone in people with chronic SCI

Authors: *Y.-J. CHANG[1], G.-S. LI[1], M.-D. YU[1], C.-Y. FANG[1], M.-J. HSU[2];
[1]Chang Gung Univ., Taoyuan, Taiwan; [2]Kaohsiung Med. Univ., Kaohsiung, Taiwan

Abstract: Hypertonia is a common condition in patients with spinal cord injury that might be fluctuated by posture changes. It can be attributed to the adaptation of spinal circuitry and soft tissue property. Previous studies demonstrated that short range ankle CPM with a relatively fast speed could reduce spasticity and decrease H/M ratio. However, whether the effect is focal on a single joint and/or specific to a fixed posture is not clear. The purpose of this study was to evaluate the effect of focal ankle CPM training on reducing muscle tone at sitting/standing postures and on multi-joints of low extremities. Nine individuals with chronic SCI received 8 weeks of ankle CPM with one hour/day, five days/week for 8 weeks. H/M ratio of soleus was tested at sitting and standing with supported by a suspension system. MAS of ankle, knee, and hip flexors/extensors were tested before and after training. The results showed that, after training, the H/M ratio reduced only in sitting but not in standing. MAS decreased in all joints ($p<.05$). This study concludes that single joint ankle CPM can reduce the muscle tone. The treatment effect can be irradiated to multiple joints but is posture specific.

Abstract: Traumatic lesion of the spinal cord (SCI) induces anatomical changes in the brain [1]. Structural analysis of the brain of subjects with SCI has shown cortical atrophy and cortical reorganization of the sensorimotor system.
Here we investigate the brain structure of a group of six SCI patients after a long-term multi-step training protocol, called the Walk Again Neurorehabilitation (WANR), that integrates brain-machine interfaces with visuo-tactile feedback and locomotion training [2].
Following this protocol for more than two years, six patients originally diagnosed with chronic complete SCI (AIS A, thoracic lesion, 6-12 years post-injury), experienced significant clinical improvement in the sensory (mean 7.25 dermatomes) and motor (14.6 myotomes) domains. As a result of the training, all patients were reclassified as AIS C.
T1-weighted volumetric brain images were obtained with this group of patients (SCI-W) and compared with a control group of SCI patients naïve to the protocol (SCI-C, all patients classified as AIS A, thoracic lesion, 1-14 years post-injury). We used the Freesurfer processing pipeline to detect statistical differences in cortical thicknesses and volumes between the groups. We found significant cortical thinning (t-test $p<.05$, clustering at $p<.01$) in the SCI-C group compared to SCI-W patients, in the prefrontal regions, cuneus, and fronto-parieto-temporal junctions - therefore association cortex.
A second analysis using the data from 10 healthy subjects (H-C) (OpenfMRI database, Washington University), showed a statistical difference between the H-C and the SCI-C groups in the associative regions and no difference when comparing with the SCI-W group. In other words, we found that the structural frontoparietal network in patients that followed the WANR was closer to the ones of the healthy subjects compared to control SCI patients. These areas are engaged in goal-directed tasks.
We hypothesize that the plastic mechanisms involved in the recovery after the WANR protocol occurred through recruiting of compensating parallel associative networks, instead of enhancing primary cortical pathways. Further longitudinal analysis with a group of SCI patients throughout the WANR protocol will clarify this point.

Title: Enhancing propriospinal axon sprouting to promote relay circuits bypassing a spinal cord contusion injury

Authors: *J. CHEN, T. J. CAMPION, R. SMIT, I. P. JUNKER, E. KOSTOFF, G. M. SMITH; Temple Univ. Sch. of Med., Shriners Hosp. Pediatrics Res. Ctr., Philadelphia, PA

Abstract: Contusive spinal cord injuries (SCI) from following traumatic injury cause extensive damage to the spinal cord, which result in the loss of lower limb function. Unfortunately, long projecting supraspinal neurons, like the corticospinal tract (CST), fail to spontaneously regenerate through the lesion or when induced to regenerate only grow short distances. Alternatively, descending propriospinal neurons (DPSNs) bypassing the lesion show a higher potential for reconstruction of a new functional circuits across the injury. Based on our previous result, retrograde genetic tracing shows numerous preserved DPSNs bypassing the contusion lesion site. We are attempting to enhance plasticity along the supraspinal-propriospinal pathway using selective expression of neurotrophins within specific neuronal populations. To target lesioned supraspinal plasticity to propriospinal neurons either NT-3 or BDNF was expressed using retrogradely transported lentivirus injected within the ventral horn within the lumbar spinal cord. Neurotrophin-3 or BNDF has been shown by multiple groups including ours to induce robust sprouting of CST and reticulospinal axons, respectively. To promote propriospinal axon sprouting onto spinal motor neurons, retroAAV encoding Glial Derived Neurotrophic Factor (GDNF) was injected into transient demyelinated sciatic. This method shows robust expression within spinal motor neurons. GDNF promotes the sprouting and regrowth of propriospinal neurons. One week after viral injections a contusive SCI was made at thoracic 10 (T10) using a 200 kilodyne contusive force. After SCI, animals were behaviorally examined weekly using the BBB open field assessment, ladder test, and the ink-blot footprint test. Anterograde and retrograde tracer were injected into the somatomotor cortex or lumbar ventral horn, respectively, 8 weeks after contusion. Three week later, rats were euthanized for analysis of axon sprouting. Our preliminary results indicate GDNF enhanced axon sprouting of DPSNs and enhanced hind limb locomotor function of contused rats after T10 SCI.

Title: Effects of complex treadmill training on sensorimotor function and on neuropathic pain after an incomplete spinal cord injury: A case series

Authors: *C. DAMBREVILLE, M. GAGNÉ, P. SIMARD, C. RAHN, C. MERCIER, A. K. BLANCHETTE, L. J. BOUYER;
CIRRIS-Université Laval, Quebec, QC, Canada

Abstract: INTRODUCTION: The control of locomotion results from interactions between descending control, spinal pattern generators and sensory feedback. After incomplete spinal cord injury (SCI), gait control is impaired and neuropathic pain often develops. Current gait rehabilitation uses treadmill training to strengthen sensory feedback on spinal circuits. However, locomotor recovery remains incomplete and chronic neuropathic pain often develops. Studies in animal models suggest that locomotor recovery and neuropathic pain might be competing for some shared neural circuits. The aims of this study were therefore twofold: 1) use a more complex treadmill training paradigm that better recruits descending control; and 2) demonstrates the clinical feasibility of this paradigm and evaluate its effects on sensorimotor function and on neuropathic pain. METHODS: 10 participants with an incomplete SCI (AIS C-D; 2-130 mo post lesion) came to the laboratory for 18 sessions (PRE and POST tests plus 16 training sessions) over 4 weeks to undergo complex gait training consisting of stepping onto virtual targets projected on a screen in front of them (80, 100, 120% of step length; pseudo-random order) during treadmill walking. Locomotor recovery (gait speed, 6 min walk test, MiniBest test) and neuropathic pain (International Spinal Cord Injury Pain Basic Data Set) were assessed PRE and POST training. Participants' satisfaction was measured using a custom-designed questionnaire POST training.Finally, the excitability of the corticospinal pathway was assessed PRE-training using TMS (25 MEPs during control walking compared to 25 during stepping onto targets). RESULTS: MEP size increased by 43.9+/-50.3% (n=10; p=0.02) during complex walking compared to control walking. After training, significant improvements ($p<0.05$) were measured in preferred and maximal walking speed, endurance, and dynamic balance. A decrease of 35%+/-22% was measured in the 4 participants that presented neuropathic pain. Participants'

satisfaction regarding this training was excellent (41.8/45 +/- 3.4).CONCLUSION: Complex treadmill training consisting of stepping onto virtual targets that modulate step length is feasible in persons with an incomplete SCI and sufficient to increase descending drive on the locomotor circuits. Complex treadmill training leads to improvement in clinical measures of gait performance and reduction in neuropathic pain when present. It could therefore be used in the clinic to improve sensorimotor function recovery and decrease neuropathic pain in this population.

Title: Forced expression of KLF6 in cortical neurons promotes recovery of forelimb function after corticospinal tract injury

Authors: *A. A. KRAMER, G. OLSON, D. M. GROSS, M. G. BLACKMORE;
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Spinal cord injury disrupts communication by severing axon tracts, notably the corticospinal tract (CST), which is responsible for fine motor function. In cases of partial injury, one strategy to enhance recovery is to stimulate sprouting from spared axons, leading to compensatory innervation of distal targets. We showed previously that viral delivery of the transcription factor KLF6 enhances CST regeneration and sprouting after spinal injury. Despite this growth phenotype, however, treated animals showed no improvement in forelimb function on a horizontal ladder task. Here we examined the effect of KLF6 on performance in a fine motor task, pellet retrieval in the Montoya staircase. Adult mice were pre-trained in the retrieval task and then received unilateral pyramidotomy and cortical injection of AAV-KLF6 or control with AAV-EGFP tracer. Mice were then tested twice weekly in the staircase for thirteen weeks post-injury. KLF6 treated mice showed a significant improvement in the skilled forelimb reaching task over time, with behavioral improvement emerging in the last three weeks of testing. Consistent with prior findings, KLF6-treated animals also showed a significant elevation of cross-midline sprouting by CST axons. Notably, behavioral improvements in the KLF6 group were significant but partial, leaving room for further recovery. In ongoing work we are testing

the hypothesis that physical rehabilitation may act to fine tune the innervation by sprouting axons, leading to further gains in function when combined with KLF6 treatment. Together this work aims to identify the tools necessary to achieve behavioral improvement and to direct appropriate axonal integration following central nervous system injury.

Title: Exercise mediated recovery of function after partial spinal cord injury is associated with trunk motor cortex reorganization

Authors: *B. NANDAKUMAR[1], G. H. BLUMENTHAL[2,1], K. A. MOXON[1];
[1]Univ. Of California, Davis, CA; [2]Biomed. Engin., Drexel Univ., Philadelphia, PA

Abstract: Previous work from our lab and recent studies from others have shown that a combination of rehabilitative approaches including exercise and activation of spinal circuits can significantly improve functional outcome in complete SCI animals. This recovery is accompanied by significant reorganization in the trunk motor cortex that is required for functional improvement. To determine if cortex plays a similar role after more clinically relevant contusion injury, we repeated this experiment in a contusion model using treadmill exercise. Importantly, unlike the complete SCI model, rodents and humans with partial SCI injuries are likely to develop chronic neuropathic pain (CNP). It has been suggested that CNP may impede motor learning at the spinal level, limiting recovery of gait, but cortical plasticity may also play a role. **Methods:** In this study, the effect of exercise therapy on functional recovery (locomotion and CNP development) and cortical reorganization was assessed in female Sprague Dawley rats (n=22) with a T10 mid thoracic contusion (SCI). In a subset of animals (n=12), treadmill exercise therapy was initiated 1-week post injury for 25min, 5 days/week for 5 weeks post SCI. At level (trunk) CNP and locomotor recovery (BBB scores) were assessed once a week for 5 weeks post injury. At week 6, all animals underwent motor cortex mapping (ICMS). Average responsiveness score and cortical area devoted to trunk muscle activation were used to evaluate cortical reorganization. **Results:** Consistent with previous work, this level of exercise therapy did not impact neuropathic pain development ((χ^2 (1, 22) =0.105, p>0.05). However, exercise therapy significantly improved locomotor recovery (ANOVA: F (1, 20) =16.946, p=0.001) such

that the injured animals could take weight supported steps with consistent co-ordination (BBB score: 16+/- 2). Regardless of whether the animal had therapy, post SCI ICMS did not elicit activation of hindlimb musculature. Animals that received exercise therapy had significantly higher probability of exclusively activating trunk musculature within the trunk and deafferented-hindlimb motor cortex. In addition, these animals had significant reorganization of the forelimb motor cortex. Preliminary data comparing the trunk representation in animals that developed pain compared to those that did not suggests that CNP may impede the effect of exercise therapy on cortical reorganization of the trunk. **Conclusion:** These results support earlier studies documenting the role of the trunk motor representation after therapy in the recovery of function but also caution that CNP may interfere with this role.

Title: Intraspinal microstimulation in the ventral horn modulates neural transmission dorsal horn sensory neurons

Authors: *M. F. BANDRES[1,4], V. MELERO[4], L. DA SILVA[4], J. G. MCPHERSON[2,4,3,1]; [1]Biomed. Engin., [2]Physical Therapy, [3]Anesthesiol., Washington Univ. in St. Louis, St. Louis, MO; [4]Biomed. Engin., Florida Intl. Univ., Miami, FL

Abstract: Spinal cord injury (SCI) results in dramatic changes in neural excitability below the lesion, leading to debilitating motor impairments, dysregulation of reflexes, and neuropathic pain. In general, voluntary motor output is reduced below the lesion, whereas the spinal effects of sensory feedback are pathologically increased. Spinal stimulation-based therapies seeking to restore motor impairments after SCI often fail to consider modulation of neural transmission in spinal sensory pathways, including pathways integral to SCI-related neuropathic pain. Here, we characterized the effects of intraspinal microstimulation of the ventral horn (vISMS), an emerging therapeutic approach for motor rehabilitation, on the firing dynamics of sensory neurons in the superficial and deep dorsal horns. All experiments were approved by the FIU IACUC and conducted in adult male Sprague-Dawley rats under urethane anesthesia (n=15). After T13-L2 laminectomy, microelectrode arrays were implanted at the L5 dorsal root entry

zone. Electrodes locations for vISMS targeted Rexed's laminae 8-9 and electrode locations for quantifying transmission in sensory pathways spanned laminae 2-6. Prior to, during, and after vISMS, we mechanically stimulated the L5 dermatome by applying controlled forces ranging from non-painful to painful. Primary outcome measures included the number and type of neurons recruited/derecruited during vISMS, changes in the firing frequency of active neurons, and the spatiotemporal profile of neural activity throughout the ventral and dorsal horns (quantified via stimulus-triggered averages of multi-unit neural data, peristimulus time histograms of single-neuron spike times, and measures of correlation amongst simultaneously active units). We found that even short periods of vISMS could modulate neural transmission in pain and non-pain-related pathways of the dorsal horn. On average, we find that neural transmission is either reduced or unchanged in a majority of identified sensory neurons during and/or after vISMS ~70% of all neurons; approximately evenly distributed), with neural transmission increasing in the remaining third of neurons. Our results suggest that it may be possible to design vISMS paradigms that reduce transmission in spinal pain pathways while continuing to increase spinal motor output. Future work is required to fully characterize the mechanisms by which vISMS modulates spinal pain transmission, to optimize these effects, and to establish limits for avoiding unintended increases in pain transmission.

Abstract: Neuropathic pain caused by nerve injury presents with severe spontaneous pain and a variety of comorbidities, including deficits in higher executive functions. None of these clinical

problems are adequately treated with current analgesics. Targeting of the mitogen activated protein kinase-interacting kinase (MNK1/2) and its phosphorylation target, the mRNA cap binding protein eIF4E, attenuates many types of nociceptive plasticity induced by inflammatory mediators and chemotherapeutic drugs but inhibiting this pathway does not alter nerve injury-induced mechanical allodynia. We used genetic manipulations and pharmacology to inhibit MNK-eIF4E activity in animals with spared nerve injury, a model of peripheral nerve injury (PNI)-induced neuropathic pain. We assessed the presence of spontaneous pain using conditioned place preference. We also tested performance in a medial prefrontal cortex (mPFC)-dependent rule-shifting task. WT neuropathic animals showed strong signs of spontaneous pain and were significantly impaired in the rule-shifting task while genetic and pharmacological inhibition of the MNK-eIF4E signaling axis protected against and reversed spontaneous pain and PNI-mediated cognitive impairment. Additionally, pharmacological and genetic inhibition of MNK-eIF4E signaling completely blocked and reversed maladaptive shortening in the length of axon initial segments (AIS) in the mPFC of PNI mice. Surprisingly, these striking positive outcomes on neuropathic pain occurred in the absence of any effect on mechanical allodynia, a standard test for neuropathic pain efficacy. Our results illustrate new testing paradigms for determining preclinical neuropathic pain efficacy and point to the MNK inhibitor tomivosertib (eFT508) as an important drug candidate for neuropathic pain treatment.

Title: Role for endocannabinoids in manipulative therapy analgesia?

Authors: *S. M. ONIFER, R. S. SOZIO, C. R. LONG;
Palmer Ctr. for Chiropractic Res., Palmer Col. of Chiropractic, Davenport, IA

Abstract: Chronic pain is quite prevalent and causes significant disabilities and socioeconomic burdens. Manipulative therapies are used to manage chronic pain. There is a critical knowledge gap about mechanisms and sites of action in manipulative therapy pain relief, especially the short-term analgesia that occurs following a treatment. Endocannabinoids are an activity-dependent neurotransmitter system that acts as a short-term synaptic circuit breaker. Both

clinical and basic science research evidence suggest that endocannabinoids contribute to short-term manipulative therapy pain relief. Doctors of chiropractic, osteopathic physicians, and physical therapists commonly use spinal manipulative therapy (SMT) to manage chronic low back pain with or without a neuropathic pain component. We previously utilized reverse translation and reductionist approaches to develop an adult rat model of SMT analgesia in peripheral neuropathic pain produced by spared nerve injury (SNI). To begin investigations of endocannabinoids involvement in SMT pain relief, we determined whether modulating the endocannabinoid system systemically has analgesic effects on peripheral neuropathic pain produced by SNI. Our target was the catabolic enzyme fatty acid amide hydrolase (FAAH) of the endocannabinoid anandamide (N-arachidonoylethanolamine), a CB1 receptor agonist. We used URB597 because it is a brain permeant inhibitor of FAAH that when administered intraperitoneally increases rodent brain anandamide levels and AM281, a potent and selective CB1 receptor antagonist/inverse agonist. Male Sprague Dawley rat sciatic nerve tibial and common peroneal branches were transected while sparing the sural branch (SNI). Rats were tested for hindpaw mechanical sensitivity 15-18 days after SNI. Following testing, they were randomly assigned to 4 groups (n = 4 each group) that received 2 intraperitoneal injections separated by 1 minute: 1) vehicle (DMSO: ALKAMULS® EL 620: 0.9% sodium chloride) and vehicle (Vehicle group), 2) AM281 and vehicle (AM281 group), 3) vehicle and URB597 (URB597 group), or 4) AM281 and URB597 (AM281 + URB597 group). Mechanical sensitivity testing was repeated 15, 25, 40, 55, 70, and 90 minutes after the second injection. SNI produced behavioral signs of mechanical hypersensitivity. URB597 significantly reduced mechanical hypersensitivity at 15 - 70 minutes compared to Vehicle and at 15 - 40, 70, and 90 minutes compared to AM281. AM281 + URB597 significantly attenuated this analgesic effect at 15 - 40 and 90 minutes compared to URB597. The results indicate that endocannabinoids are a treatment target for peripheral neuropathic pain produced by SNI.

Title: Cytoarchitectural changes induced by chronic cephalic pain are reversed by HDAC6 inhibition

Authors: *Z. J. BERTELS[1], H. SINGH[2], I. DRIPPS[1], P. SHAH[1], J. CHMURA[2], S. M. BACA[3], M. M. RASENICK[2], A. A. PRADHAN[1];

Abstract: Migraine is an extremely prevalent neurological disorder and it is estimated to affect 14% of the world population, making it the third most prevalent disease worldwide. Chronic migraine is an especially disabling disorder and is defined as 15 or more headache days a month. Despite its high prevalence migraine therapies are often only partially effective or are poorly tolerated. A greater understanding of migraine pathophysiology would allow for development of novel therapeutic targets. Changes in dendritic morphology and neuroplasticity have been associated with other chronic pain conditions. Microtubules form the backbone for cell morphology, and are made up of heterodimers of α and β tubulin. Tubulin dynamics are regulated by a variety of post-translational modifications, including α-tubulin acetylation. Acetylated tubulin has been correlated with more stable microtubules that are more flexible and less prone to breakage. Endogenously α-tubulin is acetylated by α -tubulin N-acetyltransferase I (αTAT1) and deacetylated through histone deacetylase 6 (HDAC6). The aim of this study was to determine if chronic migraine-associated pain and aura resulted in altered neuronal cytoarchitecture, and if HDAC6 inhibition could reverse these changes and correspondingly alleviated these symptoms. Male and female C57BL/6 mice went through a previously established model of chronic migraine using the human migraine trigger nitroglycerin (NTG). Following the chronic migraine model Golgi stain revealed that in key cephalic pain processing regions there was decreased neuronal complexity that was reversed by the HDAC6 inhibitor, ACY738. Correspondingly, ACY738 also blocked migraine-associated pain. Additionally, we tested the effects of cortical spreading depression (CSD), a physiological correlate of migraine aura, and observed decreased neurite outgrowth in the cortex after repeated CSD events. Pretreatment with ACY738 not only resulted in decreased CSD events, but also reversed cytoarchitectural alterations. Together our results demonstrate that migraine pathophysiology is associated with disrupted neuronal cytoarchitecture and that HDAC6 inhibitors could be a novel therapeutic target for this disorder.

Title: *In vivo* and *in vitro* effects of human mesenchymal stem cell exosomes on nerve injury-induced neuropathic pain

Authors: *J.-K. CHENG[1,2], S.-J. SHIUE[1], J.-M. HSU[1,2];
[1]Mackay Mem. Hosp., Taipei, Taiwan; [2]Med., Mackay Med. Col., New Taipei City, Taiwan

Abstract: Aim of Investigation: Nerve injury-induced neuropathic pain is difficult to treat. In this study, we used purified human umbilical cord mesenchymal stem cell (UCMSC) exosomes as a therapeutic in the L5/6 spinal nerve ligation (SNL) pain model and explored the possible analgesic mechanisms. The cell type-specific localization of exosomes in dorsal root ganglion (DRG) and their effects on SNL-induced glial activation and neuro-inflammation were also examined.
Methods: Male Sprague-Dawley rats (250-300 g) received right side L5/6 SNL, intrathecal catheterization and infusion pump implantation under anesthesia. Von Frey hair and radiant heat tests were used to measure the mechanical and thermal sensitivity of affected hindpaw. Seven days after SNL, rats were sacrificed. L5/6 spinal cord, DRG and peripheral nerves were removed and used for double fluorescent immunohistochemistry and Western blotting assay. PC12 and HEK293 cells were used to test the *in vitro* effects of UCMSC exosomes.
Results: Isolated UCMSC exosomes range in size from 30 to 160 nm and contain CD63, HSP60 and CD81, exosome markers. After SNL, single intrathecal injection exosomes reversed SNL-induced mechanical and thermal hypersensitivities of rat right hindpaw at initial and well-developed pain stages. Moreover, continuous intrathecal infusion of exosomes achieved excellent preventive and reversal effects for SNL-induced pain. Lots of Exo-green-labelled exosomes could be found in ipsilateral L5 spinal cord, DRG and peripheral axons suggesting the homing ability of UCMSC exosomes. They also appeared in the central terminals and cell bodies of $IB4^+$ and $CGRP^+$ nociceptors in DRG. The exosome suppressed SNL-induced up-regulation of c-Fos, CNPase, GFAP, Iba1, TNF-α and IL-1β, while enhanced the level of IL-10, GDNF and BDNF in the ipsilateral L5/6 DRG. *In vitro*, the exosomes not only protected PC12 and HEK293 cells against inflammatory agent formaldehyde acid, but also induce neurite outgrowth of PC12 cells.
Conclusions: We showed the analgesic effects of human UCMSC exosomes may involve their actions on neuron and glial cells, with anti-inflammatory and pro-neurotrophic abilities. Intrathecal infusion of exosomes derived from human UCMSCs may be considered as a novel therapeutic alternative for nerve injury-induced pain.

Title: Recombinant GABAergic cells and locomotor training as a combined treatment to attenuate SCI-induced chronic pain in rats

Authors: *S. JERGOVA, E. DUGAN, M. HERNANDEZ, B. SCHACHNER, S. M. RUTTENBERG, L. E. ROBAYO, M. RESTREPO, J. SAGEN;
Univ. of Miami Sch. of Med., Miami, FL

Abstract: Spinal cord injury (SCI) initiates a cascade of pathophysiological events that may lead to development of chronic pain, refractory to pharmacological treatment. Multifactorial approaches targeting key events is necessary to be identified in order to prevent or attenuate development of chronic pain. Reduced inhibitory GABAergic signaling in the spinal pain processing sites, enhanced excitatory NMDA signaling and elevated level of inflammatory mediators represent such key events. The goal of this study was to evaluate the analgesic effect of a multitargeted approach using intraspinal grafts of GABAergic progenitors expressing NMDA antagonist serine-histogranin in combination with intensive physical exercise. Male Sprague Dawley rats underwent spinal clip compression injury and developed hypersensitivity in the hind paws. Treadmill training was initiated at 5 days or 5 weeks post SCI, with GABAergic cells grafted at 4 weeks post SCI. Tactile allodynia, heat and cold hyperalgesia were monitored weekly up to 15 weeks. Our results show that combined treatment significantly reduced established hypersensitivity (with late training) or in some animals even prevented its development (with early training). The behavioral outcome in animals with recombinant grafts was more robust and stable compared to animals with nonrecombinant cells, although both groups show significant recovery from pain related behavior compared with non-transplanted and sedentary controls. The level of inflammatory cytokines in the spinal tissue was reduced in treadmill trained animals and further reduced in animals with combined treatment. Immunohistochemical and biochemical analysis showed the presence of recombinant cells in the spinal tissue as well as the attenuation of GABA loss in the trained animals compared to the SCI controls. Reduced expression of KCC2 transporter involved in GABAergic inhibition in the sedentary SCI rats compared to trained SCI animals further was also detected. Volume analysis of spared tissue in the injury site showed reduced cavitation in the trained animals compared to sedentary ones.Our findings support the hypothesis that the combined approach is beneficial for management of chronic SCI induced pain. Direct intervention within the spinal pain-processing

sites by intraspinal transplants and indirect modulation of the inflammatory response by physical exercise showed the most promising potential for attenuation of chronic neuropathic pain.

Title: Selective neuronal silencing using novel synthetic botulinum molecules alleviates chronic pain states

Authors: *M. MAIARU[1], C. LEESE[2], I. ECHEVERRIA-ALTUNA[1], J. ARSENAULT[3], B. DAVLETOV[2], S. HUNT[1];
[1]Univ. Col. London, London, United Kingdom; [2]Univ. of Sheffield, Sheffield, United Kingdom; [3]The Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Previous studies showed that persistent pain states were substantially relieved by targeting and ablating small populations of spinal neurons that convey pain-related information to the brain. Here, we designed botulinum conjugates that are safe to construct, nontoxic, and act relatively quickly after intrathecal injection to silence pain processing neurons in the spinal cord. We have conjugated the silencing domain of BoNT/A, BOT, to either substance P, SP, or dermorphin, Derm, to reversibly inhibit key substance P receptor, NK1R, or mu-opiate receptor, MOR, expressing neurons in the pain pathway and produce a long-term amelioration of persistent pain states. We used two models of persistent pain; a model of an inflammatory pain state, induced by injection of Complete Freud's Adjuvant, CFA, into the ankle joint and a model of a neuropathic pain state, the Spared Nerve Injury model, SNI. SP-BOT and Derm-BOT were injected intrathecally when the pain state was fully developed. The targeting of conjugates was monitored using immunochemistry: lumbar spinal cord sections were stained for cleaved SNAP25 using a specific antibody and tyramide amplification followed by staining for MOR or NK1R to confirm specificity. The injection of SP-BOT or Derm-BOT had no effect on baseline mechanical threshold in naïve mice. However, the injection of SP-BOT, 100ng/3µl, following CFA injection as well as given before or after SNI surgery, reduced the mechanical hypersensitivity typically observed in these pain models. Importantly, the injection of SP-BOT was not effective in alleviating mechanical hypersensitivity when injected in NK1R knockout mice. Derm-BOT conjugates, 100ng/3µl, also reduced the mechanical hypersensitivity when

injected intrathecally after SNI surgery or CFA injection. The reduction in mechanical hypersensitivity was to the same extent as i.t. morphine and no additive effects were seen when morphine was injected i.t into mice pretreated with Derm-BOT. Immunohistochemistry demonstrated subsets of cleaved SNAP 25-positive neurons in the dorsal horn of conjugate injected mice. Double staining with either NK1R or MOR antibodies indicated that uptake of conjugates was specific: cSNAP was found in either NK1R positive neurons following SP-BOT injection or in MOR positive neurons following Derm-BOT treatment. We have shown that a single injection of SP-BOT or Derm-BOT produce long lasting relief in models of inflammatory and neuropathic pain. The data strongly suggests that botulinum-conjugated molecules could represent an opioid-free alternative for the treatment of chronic pain.

Title: A novel target for osteoarthritis pain

Authors: *L. M. MINNEMA[1], J. J. WHEELER[2], S. K. MISHRA[3], B. D. X. LASCELLES[1]; [1]NC State Univ., Raleigh, NC; [2]Mol. Biomed. Sci., North Carolina State Univ., Raleigh, NC; [3]Lab. of Neurophysiol., Col. Vet. Medicine, NC State Univ., Raleigh, NC

Abstract: Chronic pain is a significant health problem posing an enormous economic burden to our society. The lack of therapeutic options, particularly for chronic pain, is driving the current opioid epidemic in humans. One of the potential limitations in developing therapeutics is a lack of understanding of the precise mechanisms in the target disease condition. Here, we identified molecular targets using naturally occurring osteoarthritis (OA) in pet dogs and human patients and now going back to investigate the molecular mechanism in a mouse model of OA with an ultimate goal of developing possible therapeutics. Here, we used male mice to study chronic pain – making the plausible assumption that females are intrinsically more variable than males. All behavioral assays were performed blinded. Data are presented as mean ±SEM. For more than two groups, ANOVA was used and for two groups, we performed student's t-test using GraphPad Prism Software to determine the significance. The p-value for significance was set at 0.05. To decipher the molecular signaling cascades in chronic pain, we used an intra-articular injection of monoiodoacetate (MIA) to induce OA in mice and compared them to mice injected with saline (control). Employing cellular, pharmacological, physiological, and mouse behavioral assays, we demonstrate that a peripheral ligand and receptor expressed on sensory neurons are

involved in chronic pain. Next, we showed when ligand injected exogenously into the mouse hind paw could cause widespread pain hypersensitivity, which corroborates with MIA-induced pain hypersensitivity. Finally, we blocked the ligand/receptor interaction using an antibody specific against the receptor and showed attenuation of pain hypersensitivity in mice. Overall, our study provides an underlying mechanism behind chronic pain associated with OA and offers potential new targets for developing therapeutics.

Title: Cannabidiol is a potential therapeutic treatment for chronic pain: Analgesic and anxiolytic effects in an animal model of chronic constriction injury (CCI)

Authors: *G. K. CARDOSO[1], A. W. ZUARDI[2], J. A. D. CRIPPA[2], J. E. C. HALLAK[2], C. R. A. LEITE-PANISSI[1];
[1]Dept. Psychology, Univ. of São Paulo, Ribeirão Preto, Brazil; [2]Dept. Psychiatric, Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: Emotional and cognitive disorders often accompany chronic pain. In the general population, chronic pain incidence is 6% to 8%, and its impact on the quality of life, mood, and sleep exceeds the burden of its causal pathology. Considering the nociceptive modulation, the cannabinoid system is an important endogenous system participating in circuitry pain sensitivity. In this perspective, the cannabidiol (CBD) is considered to be a promising strategy for the treatment of neuropathic pain. Our study aimed to evaluate the effect of systemic treatment with CBD (3 days) in rats submitted to sciatic nerve constriction (CCI) and submitted to open field (OP) and nociceptive (NT) tests. For this study, 80 rats (220 g) Wistar were used (CEUA - USP # 2018.1.103.58.5). The rats were submitted to the surgical procedure (CCI or false operated / SHAM) on day zero, and the development of neuropathy was followed for three weeks by nociceptive tests (von Frey, hot plate and acetone). On the 23rd day, the animals were submitted to the to the open field test. Nociceptive tests were performed on the 24th day, after 3 days of

CBD treatment. The two-way ANOVA test was used, followed by the Bonferroni test, $p < 0.05$. The results showed that treatment with CBD for three days at different doses (0.3, 3, 10 and 30 mg/kg ip) had an antiallodynic effect (i - von Frey: $F(4, 24) = 237.2$; $P < 0.0001$; ii - acetone: $F(4, 24) = 172.3$; $P < 0.0001$ and iii - hot plate: $F(4, 24) = 375.4$ $P < 0.0001$) in the injured rats. In the open field test the CBD showed an anxiolytic type effect ($F(4, 25) = 6.748$, $P = 0.0008$) in the injured animals. When we evaluated the synergy of the dual profile of the CBD at 3 mg/kg (von Frey, (ii) acetone and (iii) hot plate = $P < 0.0001$ and OP: $P = 0.0005$) was shown to perform better in both the analgesic effect on the nociceptive test battery and the anxiolytic effect in the open field test. These results corroborate with the literature on the analgesic and anxiolytic effects of CBD, emphasizing the dose of 3mg/kg as the dose with better pharmacological performance. This synergistic effect offers favorable perspectives for new pharmacological approaches in the treatment of neuropathic pain.

Title: Analgesic efficacy of various NTS2-selective neurotensin(8-13) analogs in a rat model of bone cancer pain

Authors: *C. LAGARD[1], M. VIVANCOS[1], M. CHARTIER[1], R. FANELLI[2], M. DESGAGNÉ[1], A. RENÉ[2], J. CÔTÉ[1], J.-M. LONGPRÉ[1], E. MARSAULT[1], F. CAVELIER[2], P. SARRET[1];
[1]Inst. de Pharmacologie de Sherbrooke, Sherbrooke, QC, Canada; [2]Inst. des Biomolécules Max Mousseron, Montpellier, France

Abstract: In recent years, the tridecapeptide neurotensin (NT) and its minimal biologically active fragment NT(8-13) have emerged as major modulators of nociceptive transmission. They exert their analgesic activity by interacting with two distinct 7-transmembrane domain receptors termed as NTS1 and NTS2. These receptors are attractive targets for the development of new analgesic compounds that could represent promising alternatives to opioids. However, the NT peptide is also implicated in other physiological functions, such as hypotension and hypothermia, which are exclusively mediated by NTS1 activation. In this context, the NTS2 receptor, which is mainly expressed in the central nervous system, represents a target of interest for the

development of new chemical entities with enhanced analgesic effects and minimal adverse effects. In order to improve NTS2-selectivity, we synthesized a series of linear NT(8-13) analogs harboring reduced amide bond and/or site-specific modifications with unnatural amino acids. We also designed conformationally constrained analogs via ring-closing metathesis macrocyclization between the proline residue in position 10 and the side chain of alkene-functionalized amino acid in position 8. Radioligand binding studies demonstrated that these substitutions or macrocyclization step improved the selectivity towards NTS2 by 1,000- to 10,000-fold over NTS1. Strong analgesic effects were also observed following intrathecal injection (i.t.) in acute (tail-beam) and tonic pain (formalin) models, with no apparent change in body temperature or systemic blood pressure. We thus evaluated if a single i.t. injection of these NTS2-selective compounds could exert analgesic action in a bone cancer pain model, which consists in the injection of syngeneic MRMT-1 breast cancer cells into the femoral bone cavity of female Sprague-Dawley rats. We found that the most promising linear compound named JMV5335 (H-Lys-Ψ[CH2NH]Lys-Pro-*N*-*h*Trp-Ile-TMSAla-OH) exerted powerful and sustained analgesic effects 14 days after surgery, as measured with the von Frey filament test. However, no significant changes were observed in burrowing behaviors, spontaneous pain or postural deficits (dynamic weight bearing), probably attributable to the acute treatment. Effectiveness of macrocyclic compounds has yet to be confirmed. Altogether, these results demonstrate that NTS2-selective compounds have been optimized to have better analgesic effects in acute, tonic and chronic bone cancer pain models, without any significant adverse effects.

Title: Treatment-based classification system for low back pain combined to dry needling improved symptoms of patients with non-specific low back pain

Authors: *C. FUSARO, A. F. NASCIMENTO, T. A. L. MARQUES;
Sao Francisco Univ., Bragança Paulista, Brazil

Abstract: Non-specific low back pain is one of the most common chronic pain conditions and pharmacological treatment remains a mainstream therapy for it. However, it is not fully efficient, therefore, non-drug therapies, such as Treatment-based classification system (TBC) for low back pain and Dry needling, are of great interest. The aim of this study was to assay efficiency of Dry

needling plus TBC for low back pain in patients with non-specific low back pain. 30 volunteers with low back pain (20 men and 10 women), 18-50 years-old, were selected. Exclusion criteria were Red Flags plus low back surgeries or fractures and neurological diseases. The outcomes were pain (Visual Analogue Scale -VAS), disability (Oswestry disability Index - ODI) and pain related fear (Fear Avoidance Belief Questionnaire - FABQ for physical activities and work). Volunteers were categorized into 1 of 4 subgroups of TBC and randomized in 3 groups (n=10): G1 - TBC for low back pain; G2 - Dry needling; and G3 - TBC for low back pain + Dry needling. Interventions were performed once a week, for 4 weeks, at the School-Clinic of Physiotherapy from São Francisco University, Bragança Paulista, Brazil. VAS, ODI and FABQ were applied before the first session as baseline. VAS and ODI were repeated after the end of each session, and FABQ after the last session. Questionnaires were applied by a blinded tester. Procedures were approved by ethics committee in human's research from Sao Francisco University (2.440.282). Results showed that G1, G2 and G3 improved pain in each of the four sessions when compared to baseline ($p<0.001$, One-way ANOVA, Dunnett's test), but there was no difference among groups ($p>0.05$, One-way ANOVA, Dunnett's test). Disability reduced in the last session of G1 when comparing to baseline ($p=0.0484$, One-way ANOVA, Dunnett's test). There was no reduction in disability for G2 and G3 ($p>0.05$, One-way ANOVA, Dunnett's test). Finally, pain related fear for work reduced in the last session of G2 ($p=0.0051$) and G3 ($p=0.0213$), but not of G1 ($p=0.0911$), when comparing to baseline (paired T-test). Pain related fear for physical activities did not reduce in any group ($p>0.05$, paired T-test). The present study demonstrated that TBC for low back pain and Dry needling are efficient in reducing low back pain when applied alone. However, pain response was not amplified by a combination of both. Disabilities were reduced only by TBC for low back pain, and Dry needling alone or combined to TBC for low back pain reduced pain related fear for work. Together, these findings suggest that in patients with low back pain associated to disabilities and pain related fear the combined use of these therapies is a efficient strategy.

Title: p66shc-PLGA nanoparticles alleviate mitochondrial dysfunction mediated pain behaviors

Authors: *N. SHIN[1], H. SHIN[2], D. KIM[3];
[1]Dept. of Med. Sci., [2]Dept. of Anat., Chungnam Natl. Univ. Col. of Med., Dajoen, Korea, Republic of; [3]Dept. of Med. Sci., Chungnam Natl. Univ., Daejeon, Korea, Republic of

Abstract: AIMS: Reactive oxygen species has been suggested as a key player in neuropathic pain, causing central sensitization by glia activation and loss of GABAergic interneuron in spinal dorsal horn. However, it remains unclear as to what type of reactive oxygen species changes what aspect of glia activation and GABAergic interneuron for central sensitization in neuropathic pain conditions. In this study, we investigated whether mitochondrial superoxide affects both excitatory in spinal dorsal horn neurons after peripheral nerve injury.
RESULTS: Downregulation of mitochondrial superoxide level by p66shc-PLGA nanoparticles alleviated neuropathic mechanical hypersensitivity caused by L5 spinal nerve ligation. In SNL model (Spinal nerve ligation model), superoxide product DHE and Mitochondrial ROS signal was highest at 9 days postoperatively. In SNL condition, the DHE and Mitochondrial ROS signal, pain behavior and inflammatory cytokine and decreased after p66shc-PLGA nanoparticles in spinal dorsal horn. In addition, Mitophagy regulatory factor and inflammatory cytokine level were attenuated in microglia and neuronal cell line by p66shc-PLGA nanoparticle co-treatment after H_2O_2 treatment.
CONCLUSION: These results suggest that, high levels of mitochondrial superoxide through p66shc in spinal dorsal horn neurons and microglia increase sensory threshold after peripheral nerve injury and contribute to neuropathic mechanical hypersensitivity.

Title: GABAergic circuits within DRG filtering nociceptive transmission and as potential target for chronic pain therapeutic

Authors: *H. HAO[1], N. GAMPER[3], X. DU[2];
[1]Dept. of Pharmacol., Hebei Med. Univ., Shijiazhuang, China; [2]Hebei Med. Univ., Hebei, China; [3]Univ. Leeds, Leeds, United Kingdom

Abstract: It was discovered in our previous study that DRG cell bodies contain a fully functional GABAergic system that can modulate nociceptive signals before they enter the CNS. Our findings indicated that peripheral somatosensory ganglia may represent a new type of "gate" within the somatosensory system and call for a substantial revision to current understanding of how somatosensory information is generated and processed. However, there is still lack of direct *in vivo* evidence on this hypothesis. In this study, we developed a method of *in vivo* electrophysiological recording from the peripheral and central (dorsal root) branches of the L5 spinal nerve of rats , and demonstrated that i) dorsal root ganglia contain tonic GABAergic function in physiological situation; ii) GABAergic circuit in DRG particularly "gating" peripheral nociceptive inputs induced by various types of noxious stimuli; iii) transplantation of embryonic GABAergic progenitor cells from the mouse medial ganglionic eminence into adult mouse DRG effectively alleviated chronic pain induced by inflammation or peripheral nerve injury.

Title: Neuroinflammation is associated with lower pain intensity and milder symptoms in patients with painful knee osteoarthritis

Authors: *V. PALADA[1], E. FREYHULT[2], A. SIDDIQAH AHMED[1], K. KULTIMA[2], C. I. SVENSSON[1], E. KOSEK[1];
[1]Karolinska Institutet, Stockholm, Sweden; [2]Uppsala Univ., Uppsala, Sweden

Abstract: The primary aim was to identify inflammatory substances potentially involved in neuroinflammation and neuroimmune communication between blood and CNS in patients with painful knee osteoarthritis (OA) by novel multiplexed proximity extension assay (PEA) which

allows the simultaneous analysis of 92 human inflammatory proteins. In an exploratory part of the study, we investigated associations between the protein levels in cerebrospinal fluid (CSF) and serum with clinical symptoms.
Methods: OA patients (n=40) were recruited from a waiting list for total knee replacement. The patients rated knee and global pain intensity (VAS) and knee-related symptoms (KOOS). Pressure algometry was used to assess pressure pain thresholds (PPTs) and conditioning pain modulation (CPM) was determined. CSF and serum were collected just prior to the surgical procedure. The samples were analyzed by multiplexed PEA immunoassay using Proseek Multiplex inflammation panel (Olink Proteomics, Uppsala, Sweden). P-values were adjusted for multiple comparisons.
Results: Seven CSF inflammatory proteins were all negatively correlated to VASknee and positively correlated with KOOS. We found higher CSF protein levels in VASknee subgroups of patients without pain or mild pain compared to patients with moderate pain. Furthermore, ten inflammation associated proteins showed significant correlation between CSF and serum. No significant associations were found between protein levels in serum and clinical symptoms.
Conclusion: Our results suggest that inflammatory proteins in CSF are associated with less intense knee pain and milder symptoms in patients with painful knee OA which provides novel targets for pain relief and new insights into the profile of neuroinflammation in OA.

Title: Persistent hyperalgesia modulated by high-fat diet and voluntary physical activity: The role of nucleus accumbens

Authors: *A. D. BRANDÃO, I. J. M. BONET, M. F. PAGLIUSI, JR, G. G. ZANETTI, C. H. TAMBELI, C. A. PARADA, A. S. VIEIRA, C. R. SARTORI;
Dept. of Structural and Functional Biol., Univ. of Campinas, Campinas, Brazil

Abstract: Persistent hyperalgesia (PH) is highly prevalent among humans with obesity and sedentary lifestyle. It is known that the nucleus accumbens (NAc) is critically involved in PH and in motivation for voluntary physical activity (PA). In addition, high-fat diet (HFD) alters

peripherical and central signaling by increasing inflammatory cytokines and brain gene expression alterations. However, the relationship between HFD, gene expression alterations in NAc, PA, and PH still remain unknown. To address these questions, we used male C57BL/6J mice (at six weeks old) to test whether twelve weeks of HFD facilitates the development of PH by applying a modified model of prostaglandin E2 (PGE)-induced persistent hyperalgesia with a short-term (PH-ST) induction protocol. In this PGE-induced PH-ST protocol, the mice received seven successive daily intraplantar injection of PGE, which produce a non-persistent hyperalgesic state. In a second experimental design, we tested whether six weeks of voluntary PA could prevent the development of PH promoted by HFD. To test this effect, after six weeks on HFD, a second cohort of mice were placed in a home cages with a running wheel, where mice had free access to voluntary PA, before the PH-ST protocol. Finally, we extracted the brain from all mice and microdissected slices to isolate and process NAc samples for transcriptome analysis. All procedures were approved by the animal ethics committee at the University of Campinas (4243-1). The analysis of variance with repeated measures (ANOVA-RM) showed that the HFD-PGE group presented a significative increase of PH when compared to the groups fed with standard diet (SD) ($F_{(2,60)}$=12.52, p<.001). The Newman-Keuls post-hoc test revealed that the HFD-PGE group (3.85 ±0.61g) had increased PH seven days after the end of the PH-ST when compared with the SD-PGE group (0.48 ±0.58g, p=.001). Moreover, the HFD-PGE group presented the same mechanical nociceptive threshold at day 7 when compared to day 1 after the end of PH-ST (p = .89). On the second experimental design, the ANOVA-RM showed that the HFD-PGE-PA group, which did voluntary PA, presented a decreased on PH ($F_{(2,62)}$=4.32, p=.01) from day 1 (3.95 ±0.93g, p=.008) to day 7 after the end of PH-ST (2.5 ±1.38g). Our results corroborate recent findings that the HFD contributes to the development of PH. Furthermore, our results showed that voluntary PA could prevent the development of PH. The analysis of gene expression alterations in NAc through transcriptome technique may reveal the potential target and molecular pathways underling the HFD-induced development of PH, as well, the effects of voluntary PA on preventing this nociceptive sensory response.

Title: Quantifying the effects of kilohertz-frequency spinal cord stimulation on superficial dorsal horn neurons

Authors: *S.-W. KUO[1], T. ZHANG[3], W. M. GRILL[1,2];
[1]Biomed. Engin., [2]Neurobio. & Surgery, Duke Univ., Durham, NC; [3]Boston Scientific Neuromodulation, Valencia, CA

Abstract: Kilohertz-frequency SCS (KHF-SCS) is applied clinically as a paresthesia-free treatment for chronic pain. The mechanisms of action of KHF-SCS remain elusive but appear to be distinct from those of conventional SCS, as demonstrated by the longer duration of the clinical therapeutic onset of KHF-SCS and the relative inability of KHF-SCS to activate dorsal column axons at intensities below motor threshold. Therefore, we sought to quantify the effects of KHF-SCS on superficial dorsal horn (SDH) neurons directly beneath the SCS electrodes. We previously reported heterogeneous responses from SDH neurons during 30 sec of SCS at either 50 Hz or 10 kHz, which suggested that the minimum amplitude to suppress neuronal activity was frequency- and neuron type-dependent. To investigate further the effects of KHF-SCS, we prolonged stimulation time to 30 min and applied SCS at 50 Hz, 1.2 kHz and 10 kHz in randomized order at 40% motor threshold intensities. Extracellular single-unit recordings, targeting dorsal horn depths <350 μm, were performed in healthy, urethane-anesthetized rats while spinal cord surface temperature was measured using a microprobe-type thermocouple. Neuronal responses were characterized in response to 1 Hz sciatic nerve electrical stimulation applied at 3x C-fiber threshold intensity. Of seven neurons receiving 50 Hz and KHF-SCS, three were low threshold (LT) neurons and four were high threshold (HT) neurons. C-fiber responses (latency > 90 ms) evoked by sciatic nerve stimulation were suppressed in 2 of 4 HT neurons by all SCS frequencies, while the other two HT neurons were non-responders. Of three LT neurons, C-fiber responses were suppressed in one neuron by all SCS frequencies, while the other two were non-responders. No facilitation was observed in either HT or LT neurons. Unconventional mechanisms, such as heating, might contribute to KHF-SCS, but no substantial change in spinal cord surface temperature was detected (<0.1) after either 30 sec or 30 min of KHF-SCS. The results demonstrate heterogeneous effects of KHF-SCS on SDH neurons and indicate the importance of recording such effects in identified neurons to advance our understanding of the mechanisms of action of KHF-SCS.

Title: Analgesic effect of prolonged gum chewing in patients with burning mouth syndrome

Authors: *N. SEKINE, Y. IMAMURA, A. OKADA;
Nihon Univ. Sch. of Dent., Tokyo, Japan

Abstract: Purpose: Primary burning mouth syndrome (BMS) is associated with a chronic idiopathic pain in the apparently normal tongue or other oral mucosa. Interestingly, BMS patients do not usually complain of pain during eating, and they often chew gum to reduce their pain. However, the analgesic mechanism has not been elucidated. Therefore, we aimed to investigate the mechanism of analgesic effect following gum chewing in BMS patients. Methods: Twenty nine female BMS patients with and 25 age-matched female controls were recruited at the Orofacial Pain Clinic of Nihon University Dental Hospital. Both groups were randomly divided into two subgroups each, participants chewed a gum for 5 minutes (5 min group) and those who chewed a gum for 20 minutes (20 min group). Twenty min group also imitated a chewing jaw movement without any occlusal contacts for 20 minutes (air chewing) 30 minutes before the real gum chewing. Visual Analog Scale (VAS), concentration of plasma catecholamines (adrenaline, noradrenaline, dopamine), serotonin and progesterone levels and psychological questionnaires including POMS were obtained before and after the intervention. Results: The intensity of pain reduction following gum chewing was more significant than that after air chewing in BMS. There were no differences in the concentrations of catecholamines between the BMS and the control groups at rest. Adrenaline, dopamine and serotonin concentrations significantly decreased after gum chewing, but did not chang after air chewing in BMS patients. Adrenaline was significantly decreased by air and gum chewing in controls. Progesterone concentration and POMS score did not change in both groups. . Consideration: Chewing gum strongly alleviated the pain of BMS patients. Plasma adrenaline might reflect the analgesic effect of gum chewing. From the difference between the results of gum and air chewing, certain factors such as texture and occlusal pressure might have an important role in inducing pain reduction in BMS patients. Chewing duration may be another important factor especially in reducing the level of serotonin, which is a peripheral inflammatory mediator. These results suggest that reduction of serum levels of adrenaline and serotonin is associated with jaw movement not only in BMS patients but also in controls and it may be subsequently related to pain reduction in BMS patients.

Title: The novel NMDA receptor modulator, NYX-2925, enhances NMDAR-mediated current and LTP, induces changes in cell intrinsic properties, and alters firing properties in layer 5 pyramidal neurons of rat mPFC

Authors: *C. J. KELLY[1], J. R. MOSKAL[1,2], C. N. CEARLEY[1];
[1]Aptinyx, Evanston, IL; [2]Falk Ctr. for Mol. Therapeut., Evanston, IL

Abstract: NYX-2925 is a small-molecule N-Methyl D-Aspartate receptor (NMDAR) modulator capable of enhancing mood, improving cognition, and alleviating centralized neuropathic pain in animal models. We believe the beneficial effects of NYX-2925 are associated with its ability to bind and activate NMDARs and enhance long-term potentiation (LTP) in brain regions involved in learning, executive function, and central control of pain, such as the medial prefrontal cortex (mPFC). Here we show that in the mPFC, NYX-2925 enhances LTP with an inverted U-shaped dose response, with effective concentrations between 1 nM and 500 nM and a loss of effect at a higher concentration of 2 µM. In an effort to understand the mechanistic underpinnings of the observed LTP enhancing effects, we further characterized the NMDA current-enhancing effects of NYX-2925 in rat mPFC layer 5 (L5) pyramidal neurons, and the compound's impact on cell intrinsic properties and firing properties. Using whole-cell patch clamp in L5 pyramidal neurons, we show that NYX-2925 enhances NMDA current maximally at a concentration of 100 nM, with a loss of effect at 2 µM, similar to the LTP effects. At 100 nM, the compound also causes changes in intrinsic membrane properties in these cells, including a slight depolarization of the resting membrane potential and an increase in the hyperpolarization-activated cation conductance (Ih). Ih content within the membrane is known to be upregulated by calcium entry into the cell through NMDARs, which has been shown to result in membrane depolarization, reduced firing, and increased rhythmicity of firing. Consistent with this, our experiments show that NYX-2925 alters firing properties of the L5 pyramidal neurons, leading to a reduction in firing frequency and an increased tendency toward burst firing. Therefore, during LTP induction, we hypothesize that NYX-2925-induced enhancement of Ih contributes to increased rhythmicity of firing and therefore enhanced LTP. These effects are consistent with the long duration of effect of NYX-2925 observed preclinically and support its further investigation as a therapeutic for diseases with disrupted neural plasticity, such as centralized neuropathic pain.

Title: Intensive locomotor training provides sustained alleviation of chronic spinal cord injury associated neuropathic pain: A 2-year study

Authors: *B. SCHACHNER[1], E. A. DUGAN[2], S. JERGOVA[3], J. SAGEN[4];
[1]Miami Project to Cure Paralysis, [2]Biomed. Engin., Univ. of Miami, Miami, FL; [3]Miami Project, [4]Miami Project Cure Paralysis, Univ. of Miami Sch. of Med., Miami, FL

Abstract: Neuropathic pain often accompanies the functional deficits associated with spinal cord injury (SCI) and further reduces a patient's quality of life. Clinical and pre-clinical research is beginning to highlight the beneficial role that rehabilitative therapies such as locomotor training can have not only on functional recovery but also pain management. Our group has previously developed an intensive locomotor training (ILT) protocol for SCI rats and shown that up to 3 months of ILT alleviated pain symptoms partly through a reduction in inflammatory processes. We have extended these findings in the current study to examine the maintenance of developed pain states in the clip-compression SCI animal model as well as the chronic analgesic benefits of ILT up through 24 months post-SCI. Male Sprague-Dawley rats (200-250g) received a clip-compression SCI at the thoracic 7-8 spinal level which produces consistent and reproducible pain symptoms of thermal hyperalgesia, mechanical allodynia, and cold allodynia. The ILT ramping protocol was initiated 4 weeks post-SCI. Behavioral sensory testing was conducted weekly for 24 months. Experimental groups included: SCI only(n=9), SCI+ILT(n=12), and normal, age matched controls (n=6). Lumbar and lesion spinal cord regions were collected (when possible) and examined for protein expression of pro and anti-inflammatory markers (TNFa, IL10, and IL1b). Correlations between protein expression and end-point behavioral data were made were appropriate. The clip-compression SCI animal model produces consistent thermal hyperalgesia, mechanical allodynia, and cold allodynia for up to 2 years post injury. Animals that received ILT

had a reduction or attenuation of these pain symptoms by 2 months post-SCI that continued for the duration of the study (24 months). Survival rates over the 24 months were increased for animals receiving ILT compared to sedentary animals. The clip-compression SCI produced increased expression of inflammatory markers compared to normal, age matched controls while ILT reduced or normalized protein expression of several pro and anti-inflammatory markers. The clip-compression SCI model can provide maintained pain states for up to 24 months and represents a unique animal model of SCI to examine chronic pain in aging SCI animals. The benefits of chronic ILT suggest that sustained and long-term physical therapy can produce powerful and prolonged management of neuropathic pain, partly through regulation of different inflammatory processes. A comprehensive understanding of the long-term benefits of intensive rehabilitative therapies will provide a more beneficial treatment strategy for SCI patients.

Title: CCR2 pepducins alleviate neuroimmune-driven bone cancer pain through allosteric antagonism

Authors: *E. MIDAVAINE, R. L. BROUILLETTE, G. DE ARMAS GUITART, É. BESSERER-OFFROY, V. ZEUGIN, C. MONA, J.-M. LONGPRÉ, E. MARSAULT, P. SARRET;
Pharmacol. & physiology, Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: Bone pain is a profoundly disabling condition with largely unmet analgesic needs for patients coping with bone metastases. The CCR2 receptor along with its chemokine ligand CCL2 are well-known for their role in driving tumor progression and pain hypersensitivity. The CCR2 signaling also orchestrates immune cell recruitment into the sensory nervous system, thus contributing to a heightened pro-inflammatory state and exaggerated nociceptive responses. Decades of failed clinical trials targeting CCR2 at its extracellular orthosteric site provide a rationale for implementing alternative therapeutic strategies. To this aim, we recently developed and characterized CCR2-targeting cell-penetrating palmitoylated peptides (also called pepducins), designed from the intracellular loops (ICL) of CCR2 and acting as allosteric modulators. We investigated the effects of ICL1- and ICL3-derived pepducins on bone cancer

pain development and tumor proliferation. In a MRMT-1 bone cancer pain model in Sprague-Dawley female rats, administration of anti-CCR2 pepducins significantly decreased the allodynic responses as well as the non-reflexive pain behaviors. *In vitro,* pepducins significantly decreased the MRMT-1 cell survival as assessed by WST-1 assay and DAPI cell cycle analysis using flow cytometry. However, pepducins selectively targeting CCR2 were unable to reduce the skeletal tumor burden *in vivo*. Tumor-bearing animals also showed an increase in pain-related neurotransmitters and gap junction protein expression (Cx43) in the lumbar dorsal root ganglia (DRG). This neuronal pain signaling was accompanied by an increased number of $Iba1^+$ and $Iba1^+CD68^+$ activated resident macrophages in DRGs, as well as by an infiltration of peripheral immune cells identified as $CD11b^+CD45^+Iba1^-$ monocytes and $CD3^+$ T cells. Chronic treatment with anti-CCR2 pepducins resulted in a significant decrease in both pain-related neurotransmitter expression as well as bone cancer pain-induced myeloid and adaptive cell infiltration. At the spinal cord level, neurons located in the marginal nucleus showed decreased signaling following CCR2 allosteric modulation, as determined by decreased ERK1/2 and c-Fos activation. Noteworthy, pain hypersensitivity was independent of spinal immune cell infiltration. In conclusion, CCR2 allosteric inhibition may limit tumor burden and improve pain management through decreased peripheral neuroinflammatory signaling.

Title: AAV5 particle kinetics in adult and aged mice following intrathecal injection

Authors: *K. R. PFLEPSEN[1], C. PETERSON[1], K. KITTO[1], L. VULCHANOVA[2], G. L. WILCOX[3], C. A. FAIRBANKS[4];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Neurosci., Univ. of Minnesota Dept. of Neurosci., Minneapolis, MN; [3]Dept Neurosci, Pharmacol, Dermatol, Univ. Minnesota Med. Sch., Minneapolis, MN; [4]Depts Pharmaceut, Pharmacol & Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: The intrathecal (IT) delivery of adeno-associated virus (AAV)-based gene therapeutics is increasingly being investigated as a tool for treating both motor and sensory disorders. Previously published studies rely on the expression patterns of reporter genes such as GFP or other fluorescent markers following gene transfer to determine the biodistribution of such therapeutics in mouse populations. However, this only indicates regions of successful transduction, not the entire distribution profile of AAVs following IT injection. Furthermore, the prevalence of motor and sensory disorders increases with age, so we must consider changes of therapeutic distribution in aged populations when developing AAV therapies. However, there is limited information regarding the distribution of viral particles in aged mouse models following IT delivery. To address these gaps in knowledge, we evaluated the pattern of distribution of viral vector particles following IT delivery of AAV5 in mice. Conscious adult and aged male and female ICR-CD1 mice (4 to 20 months) were injected intrathecally with AAV5-ef1alpha-GFP (1.37 x 10(11) vector genomes in 5 microliters) or saline. Over 48 hrs post-injection animals were serially sacrificed, and whole blood and tissues of interest were immediately collected. Tissues and whole blood were then examined using qPCR to detect the presence of viral DNA. Viral particle distribution was also visualized using IHC targeting a viral capsid protein in whole column slices to determine patterns in particle distribution in relation to central and peripheral nervous system tissues. Viral DNA concentration in adult whole blood reaches a maximum at 6 hrs post-injection. Spinal tissue and dorsal root ganglia (DRG) have early increases in viral DNA. Interestingly, lumbar DRG have a secondary spike in viral DNA concentration 24 hours post-injection. In aged mice, whole blood concentrations increase over 6 hrs post-injection with viral DNA concentrations in other tissues following similar patterns as in adult mice. At 1 hr post-injection, AAV5-ir was observed in the region of the pia mater surrounding the spinal cord parenchyma and surrounding adjacent nerve fibers. This pattern was observed at 2, 6, and 12 hours post-injection but not evident at 24 hours. AAV5-ir was observed in cellular profiles in DRG at 0.5, 2, and 12 hours. This research furthers our evaluation of AAV vectors and their distribution in adult and aged populations for clinical translation.

Title: High frequency kHz spinal cord stimulation (SCS) modulate spinal dorsal horn neurons in neuropathic pain rats

Authors: *K. LEE, D. LEE, Z. KAGAN, K. BRADLEY;
Nevro Corp, Redwood city, CA

Abstract: Paresthesia-free 10kHz spinal cord stimulation has Level I clinical evidence demonstrating clinically-superior, long-term pain relief. Recent studies in normal rats have suggested that 10kHzSCS selectively modulates interneurons in superficial dorsal horn (SDH). In order to see how 10kHzSCS might modulate spinal interneurons to relieve neuropathic pain, we investigated brush and von Frey evoked responses of SDH neurons in neuropathic pain model (L5 spinal nerve ligation) rats. 10-14 days after SNL surgery, laminectomy and electrophysiological recordings were made under urethane anaesthesia. In all experiments, bipolar 10kHzSCS at 30% of motor threshold (MT) was applied via a micro-sized in-line quadripolar electrode array positioned epidurally over the L5-L6 dorsal spinal segments. A 4-pronged, 16-contact extracellular recording electrode was plunged into the SDH (depth from cord surface: 300±50um) within 1mm of the active contacts on the SCS array. First, we used brush and innocuous VF (10g) stimuli on the ipsilateral hindpaw to find the receptive-field center, and to characterize the type of responsive SDH neurons by their firing pattern. We then applied brush and VF (1, 2, 6, 10, 15g) to investigate the input-output relationship (I/O) of SDH neurons before (Baseline) and during 10kHzSCS. In 5 rats, a neuropathic pain condition was confirmed by clear expansion of the receptive field compared to normals. Also, brush-evoked responses of SDH neurons in SNL rats were reduced by ~40%. Three different cell types (Adapting, Non-Adapting, and After-discharging) were identified by 10g VF in neuropathic pain rats, whereas only two types (Adapting and Non Adapting) were previously identified in naïve rats. Compared to Baseline, during 10kHzSCS, there was reduction of slope of the I/O relationship in Adapting cells while the increase of Y-intercept was observed in Non-adapting cells with no change of slope.Conclusions: Per previous studies, Adapting and Non-adapting cells might be regarded as excitatory and inhibitory interneurons, respectively. These data suggest an underlying pain signal pathway and functional relationship between neurons in SDH, which is modulated by 10kHzSCS: Activity(excitatory neuron) = Primary Afferent Input / Activity(inhibitory neuron). Thus, any increase in inhibitory interneuron activity (e.g., by 10kHzSCS), will reduce the influence of afferent drive on excitatory interneurons, and hypothetically provide a profound reduction in pain transmission in SDH.

Title: The effect of a $GABA_A$ $alpha_5$ receptor agonist on mechanical sensitivity following nerve injury

Authors: *R. C. LENNERTZ, III[1], G. LI[2], D. KNUTSON[2], J. M. COOK[2], M. BANKS[1];
[1]Dept. of Anesthesiol., UW - Madison, Madison, WI; [2]Univ. WI-Milwaukee, Milwaukee, WI

Abstract: GABA receptors are targeted by inhibitory interneurons to modulate cortical activity. Peripheral nerve injury diminishes the activity of somatostatin-expressing (SOM) interneurons in somatosensory cortex (S1). Recent studies suggest that SOM neurons suppress dendritic calcium spikes in cortical layer 1 via $GABA_A$ α_5 receptors. Increasing SOM neuron activity in S1 using optogenetics was shown to normalize behavioral mechanical sensitivity following nerve injury. Therefore, we hypothesized that a $GABA_A$ α_5 receptor agonist may augment SOM neuron activity and also decrease mechanical sensitivity following nerve injury. We performed spared nerve injury (SNI) in 7-8 week old C57bl6 mice as a model of neuropathic pain. We assessed paw withdrawal threshold (PWT) as a measure of mechanical sensitivity. Then, we injected the $GABA_A$ α_5 receptor agonist MP-III (1-10 mg/kg) or vehicle in SNI and sham animals 7-10 days following nerve injury. The experimenter was blinded to the content of each injection. We observed a partial improvement in PWT in SNI mice treated with 3 or 10 mg/kg MP-III. There were no changes in PWT in sham mice or in the contralateral paw. There were no differences between male and female mice. Next, we implanted an osmotic pump at the time of the SNI surgery to continuously administer MP-III for 7 days postoperatively. Again, we observed a partial improvement in PWT at POD3 and POD7 that did not persist past the time course of the infusion. We conclude that the $GABA_A$ α_5 receptor agonist MP-III partially improves mechanical sensitivity following nerve injury. Further experiments will need to determine whether MP-III changes cortical activity in S1.

Abstract: Neuropathic pain (NP) is chronic pain state syndrome and has complex underlying pathophysiology. Current NP treatment regimens employ anticonvulsants, antidepressants, and opioids. These single target analgesic treatments have limited analgesic efficacy and show low patients' responsiveness. Simultaneous targeting of multiple pathologic elements in NP is required to develop effective NP medicine. KLS-2031 consists of 2 AAV vectors expressing 3 transgenes (AAV-hGAD65 and AAV-hGDNF/hIL-10) to control the major pathological mechanisms of NP, including nerve injury, neuroinflammation, and neuronal hyperactivity. In this study, we evaluated KLS-2031 as a novel therapeutics for NP. The model system utilized in this study was a rat spared nerve injury model. KLS-2031 was administered one time into a lumbar vertebra 4 intervertebral foramen using micro-catheter for targeted delivery of the drug to peri-dorsal root ganglion space. Pain-related behavior was measured with *von Frey* filament (VFF). The effects of KLS-2031 on nerve injury, stress, and neuronal inflammation were assessed by the expression of activated caspase3 and ionized calcium binding adaptor molecule 1 (Iba1). KLS-2031 showed significant analgesic effect in the SNI model. KLS-2031, the three gene combination vectors, significantly reduced mechanical allodynia in the SNI model compared to the single or two gene combination usage. When the long-term analgesic effect was evaluated with the VFF, the effect was maintained for up to 12 weeks in both female and male rats. Furthermore, KLS-2031 showed to be more potent on reducing the expression of activated caspase3 and Iba1. Pathological features of NP were restored to the normal level when the SNI model received transforaminal epidural injection of KLS-2031. KLS-2031 is being developed as combinational gene therapy to treat multiple aspects of pathophysiology involved in NP. Gene combination approach turned out to be more potent than single gene approach in analgesic effect and restoring pathophysiology of NP. Especially, KLS-2031 effectively normalized the peripheral and central sensitization of pain with a single administration. Based on these result, KLS-2031 could be a promising therapeutic option for refractory NP and be a disease-modifying agent.

Title: Polarization of model superficial dorsal horn (SDH) neurons by kilohertz frequency spinal cord stimulation (KHF-SCS)

Authors: *N. D. TITUS[1], J. E. GILBERT[1], B. J. THIO[1], T. C. ZHANG[2], W. M. GRILL[1]; [1]BME, Duke Univ., Durham, NC; [2]Boston Scientific Corp., Valencia, CA

Abstract: Understanding the mechanisms of action underlying KHF-SCS for chronic pain may lead to improved therapies. Previous single axon recordings in rats showed that extensive activation and block of dorsal column axons by KHF-SCS are unlikely. We hypothesized instead that the oscillating electric field generated during KHF-SCS may directly influence SDH neuron activity; therefore, we modeled the response of a SDH nociceptive-specific cell (NS), GABAergic interneuron (GABA), and vertical neuron to KHF-SCS. The model neurons included realistic biophysical properties determined from both prior literature and particle swarm optimization to match the response of model neurons to published electrophysiological data. In some simulations, we generated baseline activity in the model cells by distributing independent, stochastic synaptic activity across the cells' dendritic arbors. We computed the electric fields generated in the rat spinal cord by a bipolar electrode placed in the epidural space using the finite element method (FEM), applied the FEM calculated potentials to the compartments of morphologically-realistic model neurons, and simulated the effects of 1.2 kHz and 10 kHz SCS on the firing rate (FR) of model neurons. KHF-SCS applied at amplitudes estimated from prior literature to be at or below 40% of motor threshold did not directly activate model neurons; however, KHF-SCS altered patterns of synaptically driven, ongoing activity in the GABA and NS cells in a manner that was dependent on stimulation amplitude, neuron biophysics, and baseline FR. SCS applied at 1.2 kHz or 10 kHz decreased the baseline FR of the NS neuron by up to 30%. Additionally, SCS applied at 1.2 kHz but not 10 kHz increased the baseline FR of the GABA cell by up to 20%. Vertical cell activity was unaffected by KHF-SCS. Finally, we found that the influence of KHF-SCS could be approximated by direct current injections into model neurons, enabling translation of single cell effects determined with biophysically-realistic neurons to a network model of point neurons representing the SDH network. These results suggest the involvement of subthreshold polarization in the analgesic effects provided by KHF-SCS. Acknowledgments: This work was supported by the Boston Scientific Corporation.

Title: Effects of conventional and kHz frequency spinal cord stimulation (SCS) in a network model of nociceptive processing in the superficial dorsal horn

Authors: *J. E. GILBERT[1], N. D. TITUS[1], T. ZHANG[2], W. M. GRILL[1];
[1]Duke Univ., Durham, NC; [2]Boston Scientific Neuromodulation, Valencia, CA

Abstract: SCS is an effective therapy for neuropathic pain but most animal and computational modeling studies investigating pain and SCS mechanisms focused on the responses of deep dorsal horn wide-dynamic-range (WDR) neurons. Neuropathic pain also involves disinhibition of the superficial dorsal horn (SDH) via loss of glycinergic and GABAergic inhibition and depolarizing shifts in the reversal potential of inhibitory synapses. These changes unmask abnormal feedforward excitation to SDH nociceptive-specific (NS) neurons, and disinhibition may underlie hyperalgesia and allodynia, two features of neuropathic pain. Therefore, we sought to understand how both conventional SCS and novel sub-perception SCS, typically applied at kHz frequencies faster than the refractoriness of dorsal column axons, interacts with the SDH network to reduce pain transmission. We implemented a computational model of SDH neuronal circuitry to characterize the roles of feedforward excitation and different modes of inhibitory control in determining NS neuron activity. We validated the model by comparing network responses to corresponding data from mechanical and electrical stimulation. We modeled conventional SCS as synaptic inputs to the dorsal horn network via activation of dorsal column Aβ afferents and the field effect of kHz frequency SCS as current injections into both NS and GABAergic SDH neurons titrated to produce firing rate effects equivalent to those from direct simulations of kHz frequency SCS. Both conventional SCS applied at 50 Hz and kHz frequency SCS suppressed model NS neuron activity. Furthermore, the combination of field effects due to kHz frequency SCS and SDH network amplification of these effects reduced model NS neuron

activity more than the direct field effects of kHz frequency SCS did alone. The magnitude of the effects from kHz frequency SCS and observed shifts in the optimal frequency of conventional SCS following pain progression were both dependent on the mechanism of disinhibition in the dorsal horn, suggesting a dependence of efficacy on pain etiology. This work synthesizes heterogeneous experimental recordings from superficial dorsal horn neurons into a computational network model that replicates experimental responses and that enabled quantification of SDH neuronal responses to different modes of SCS under diverse neuropathic pain conditions.

Abstract: Chronic pain is a major healthcare issue which poses a large burden on individuals and society. Converging lines of evidence from animals and humans indicate that chronic pain is associated with substantial changes of brain structure and function. However, the functional significance of these changes is only incompletely understood. In particular, it remains unclear how these changes relate to clinical parameters and whether they can be reversed by appropriate therapy. Interdisciplinary multimodal pain therapy (IMPT) is a multimodal treatment provided by an interdisciplinary team collaborating in assessment and treatment using a shared biopsychosocial model and goals. IMPT has been proven effective in the treatment of chronic pain. However, the effects of IMPT on brain function remain to be elucidated. A better understanding of these effects promises insights into the functional significance of brain changes in chronic pain and the brain mechanisms of IMPT. To this end, we analyzed clinical data and resting-state electroencephalography (EEG) recordings of 24 chronic pain patients (age 52.2 ± 17.1 years (mean ± standard deviation), 13 female, predominantly chronic back pain), obtained directly before and six months after IMPT which was provided in a day-clinic setting in a multidisciplinary pain center over a period of 20 days. IMPT was performed according to standards defined by the German Pain Society and included physio- and psychotherapy as well as individual pharmacotherapy. At follow-up six months post IMPT, a significant decrease in average pain intensity (Numerical Rating Scale, 5.3 vs. 4.5, $p = .021$) as well as pain affect (Short-Form McGill Pain Questionnaire affect scale, 5.1 vs. 3.7, $p = .016$) and pain-related disability (Pain Disability Index, 28.6 vs. 23.3, $p = .039$) was found. Moreover, subjective therapeutic benefit from IMPT positively correlated with an increase in the EEG peak frequency from baseline to follow-up ($r = .46$; $p = .029$). Further analyses will relate changes in clinical data to EEG-based connectivity and network measures. Moreover, we will apply a machine learning approach to distinguish between IMPT responders and non-responders. These analyses will advance the understanding of functional plasticity of the brain in chronic pain. Moreover, they might help to identify easily available EEG-based markers and predictors for chronic pain treatment.

Title: Dynamics of resting-state electroencephalography in chronic pain patients

Authors: S. TA DINH[1], E. S. MAY[1], C. GIL AVILA[1], H. HEITMANN[1], M. M. NICKEL[1], L. TIEMANN[1], V. D. HOHN[1], T. TOELLE[1], J. GROSS[2], L. LEAL-TAIXÉ[1], ***M. PLONER**[1]; [1]TU Muenchen, Munich, Germany; [2]Univ. of Münster, Münster, Germany

Abstract: Chronic pain is characterized by ongoing pain that persists past normal healing time and lacks the warning function of acute pain. It is associated with significant sensory, cognitive and affective abnormalities, has detrimental effects on quality of life and is a leading cause of disability worldwide. Converging lines of evidence from animals and humans indicate that the brain plays an important role in chronic pain. However, the brain mechanisms of chronic pain are not fully clear yet. We have previously used resting-state electroencephalography (EEG) to define abnormalities of brain function in chronic pain and to establish a brain-based marker of chronic pain. In chronic pain patients and pain-free controls, we systematically analyzed measures of brain activity and brain connectivity. A support vector machine enabled us to differentiate between patients and controls based on frontal connectivity in the theta (4 to 7 Hz) and gamma (60 to 100 Hz) frequency bands. However, classification accuracy was 57 percent, which was significantly above chance level but far from being clinically useful.Here, we aimed to further exploit the potential of resting-state EEG to advance the understanding of the brain pathology of chronic pain and to establish an EEG-based marker of chronic pain. To this end, we assessed the dynamics of brain activity and brain connectivity by analyzing the raw time series EEG data in 101 chronic pain patients (age 58.2 ± 13.5 years (mean ± standard deviation), 69 female)and 84 matched, pain-free controls (age 57.8 ±14.6 years, 55 female). In particular, we aimed to increase the performance of the classification by implementing deep learning on the raw time series data. Moreover, we assessed themoment-to-moment variablity of brain activity by analyzing measures of neuronal variability such as multiscale entropy. Results show that the application of a convolutional neural network architecture to the raw resting-state EEG data yielded an accuracy of 70 percent for the classification of chronic pain patients vs. healthy controls. These findings constitute another step forward towards a brain-based marker of chronic pain. Furthermore, though deep learning networks are generally hard to interpret, the

combination of multivariate pattern analysis and variability analysis might help to understand abnormalities of brain function in chronic pain patients.

Title: Dissecting the role of CCL2 in neuropathic pain development

Authors: *J. H. RICHARDS, S. J. CHHAYA, M. R. DETLOFF;
Neurobio. & Anat., Drexel Univ. - Col. of Med., Philadelphia, PA

Abstract: Neuropathic pain is recognized as a neuroimmune disorder, but the mechanisms of this disorder remain unclear. The lack of effective pain relief through current therapies may be due to our limited understanding of the reciprocal relationship between neuronal dysfunction and the immune response to nerve injury in the development and maintenance of pain. The neuronal and immune mechanisms of pain intersect at the dorsal root ganglia (DRG), and we are interested in examining the interaction between macrophages and primary nociceptive neurons of the DRG. We previously showed that spinal cord injury (SCI)-induced neuropathic pain corresponds to a sustained macrophage presence in the DRG. Others report that reducing macrophage chemoattractant molecule CCL2 signaling by knockdown of its receptor can prevent pain development after peripheral nerve injury. Acutely after SCI, CCL2 protein was significantly elevated in the DRG at 24 hours that returned to normal levels by 72h. To better understand the relationship between this transient increase in DRG CCL2 and pain development by recruitment of macrophages, a unilateral injection of recombinant rat CCL2 or vehicle was administered to the C7 and C8 DRG of the uninjured Sprague Dawley rat and assessed the development of neuropathic pain over time. Neuropathic pain was assessed using von Frey and mechanical conflict avoidance paradigm. As expected, all rats exhibited temporary forepaw hypersensitivity due to the surgical procedure. Rats that received CCL2 exhibited persistent forepaw hypersensitivity that did not resolve compared to naïve and vehicle-treated rats ($p<.05$). Rats were sacrificed at 5 and 20 days post injection, and RNA was isolated from C7 and C8 DRGs. Preliminary qPCR analysis revealed that there was a 5 fold increase in CCL2, and concomitant increase in CD68, a macrophage marker at 5 days post SCI. Surprisingly, the

M2/anti-inflammatory macrophage marker Arg1 was significantly elevated and the M1/proinflammatory macrophage marker iNOS was decreased compared to vehicle and naïve animals ($p<.05$). Further qPCR analyses are underway. These data support the hypothesis that CCL2 may be acting to reduce injury-induced inflammation and decrease nociceptor dysfunction.

Title: Macrophage recruitment to the dorsal root ganglia modulates pain after spinal cord injury

Authors: *S. J. CHHAYA, J. H. RICHARDS, J. S. DOWLING, M. R. DETLOFF; Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Spinal cord injury (SCI) damages sensory systems and causes chronic, intractable neuropathic pain, which is driven by nociceptor sensitization in the dorsal root ganglia (DRG). Inflammation in the DRG in response to SCI may contribute to nociceptor dysfunction and pain development. Little is known of the immune signaling events that transpire in the DRG after SCI that could induce pathological changes in the nociceptor and drive pain. We have previously shown that an increase in DRG macrophages is associated with pain at chronic timepoints post-SCI. This study aimed to determine whether macrophage recruitment to the DRG after SCI is essential to pain development and if macrophage phenotype and cytokine release can dictate pain. Rats received a moderate, C5 contusion that causes neuropathic pain in a subset of rats as assessed by von Frey and mechanical conflict avoidance tests. We assessed the acute immune response to SCI in the C7-8 DRGs at 12, 24, 48, 72- and 120-hours post-injury (hpi). Macrophage chemoattractant CCL2 levels were assessed using ELISA and qPCR, along with mRNA expression of macrophage phenotype markers and cytokines, and ED1 labeling with immunohistochemistry. A subset of SCI rats received INCB3344, a CCR2 antagonist intravenously acutely after SCI (0-72hpi) to prevent macrophage recruitment to the DRG. Time course experiments revealed a rapid transient increase in CCL2 mRNA in the DRG at 12hpi, followed by recruitment of ED1+ cells. Rats administered INCB3344 from 0-3dpi had fewer macrophages in the DRG at 7 dpi compared to vehicle-treated rats. Surprisingly, this induced transient pain that partially recovered by 28dpi. Macrophages of INCB treated rats were pro-inflammatory by 28dpi; yet, multivariate statistical analysis on early DRG immune environment

revealed that rats were distributed into two distinct clusters acutely after SCI based on mRNA expression- those with a large fold-change in anti-inflammatory markers in the DRG, or with near-normal expression. Our data supports the hypothesis that there is a dichotomy in the peripheral immune response to SCI in the DRG that may influence pain development. While macrophages at 28dpi are pro-inflammatory and associated with pain, early macrophage recruitment may be anti-inflammatory and necessary to prevent pain. Future studies will examine the influence of macrophages on nociceptor electrophysiological dysfunction as a mechanism of DRG neuroimmune interactions contributing to SCI-induced neuropathic pain.

Title: Tet1 overexpression mitigates neuropathic pain through rescuing the expression of μ-opioid receptor and Kv1.2 in the primary sensory neurons

Authors: *J. XIAO, Q. WU, G. WEI, Y.-X. TAO;
Rutgers, the State Univ. of New Jersey, Newark, NJ

Abstract: Peripheral nerve injury downregulates the expression of the μ-opioid receptor (MOR) and voltage-gated potassium channel subunit Kv1.2 by increasing their DNA methylation in the dorsal root ganglion (DRG). Ten-eleven translocation methylcytosine dioxygenase 1 (TET1) causes DNA demethylation. Given that DRG MOR and Kv1.2 downregulation contribute to neuropathic pain genesis, this study investigated the effect of DRG TET1 overexpression on neuropathic pain. Overexpression of TET1 in the DRG through microinjection of herpes simplex virus expressing full-length TET1 mRNA into the injured rat DRG significantly alleviated the fifth lumbar spinal nerve ligation (SNL)-induced pain hypersensitivities during the development and maintenance periods, without altering acute pain or locomotor function. This microinjection also restored morphine analgesia and attenuated morphine analgesic tolerance development after SNL. Mechanistically, TET1 microinjection rescued the expression of MOR and Kv1.2 by

reducing the level of 5-methylcytosine and increasing the level of 5-hydroxymethylcytosine in the promoter and 5' untranslated regions of the Oprml1 gene (encoding MOR) and in the promoter region of the Kcna2 gene (encoding Kv1.2) in the DRG ipsilateral to SNL. These findings suggest that DRG TET1 overexpression mitigated neuropathic pain likely through rescue of MOR and Kv1.2 expression in the ipsilateral DRG. Virus-mediated DRG delivery of TET1 may open a new avenue for neuropathic pain management.

Title: Injectable PLGA coated ropivacaine produces a long lasting analgesic effect on incisional pain and neuropathic pain

Authors: *Y. TAO, X. TIAN, F. LIN, F. JI, A. BEKKER;
New Jersey Med. School, Rutgers, Newark, NJ

Abstract: The management of persistent postsurgical pain and neuropathic pain remains a challenge in clinic. Local anesthetics have been widely used as a simple and effective treatment for these two disorders, but the duration of their analgesic effect is short. We here reported a new poly lactic-co-glycolic acid (PLGA)-coated ropivacaine that was continuously released in vitro for at least 6 days. Peri-sciatic nerve injection of PLGA-coated ropivacaine dose-dependently attenuated paw incision-induced mechanical allodynia and heat hyperalgesia during the incisional pain period and spared nerve injury-induced mechanical and cold allodynia for up to 12 days post-injection. This injection did not produce detectable inflammation, tissue irritation and pathological nerve changes in the sciatic nerve at the injected site, although a mild and transient motor function compromise was observed in the higher dosage-treated groups. Given that PLGA is an FDA-approved medical material and that ropivacaine is used currently in clinical practice, the injectable PLGA-coated ropivacaine represents a new and highly promising avenue in the management of postsurgical pain and neuropathic pain.

Title: CCL2 attenuates opioid-induced inhibition of nociceptive signaling in the spinal cord in a microglia-dependent manner

Authors: *M. HELEŠ, P. MROZKOVA, D. SULCOVA, P. ADÁMEK, D. SPICAROVA, J. PALECEK;
Inst. of Physiology, Czech Acad. of Sci., Prague, Czech Republic

Abstract: Opioid therapy, while remaining an effective tool for the treatment of many acute and chronic pain states, is mostly ineffective in neuropathic pain and may even lead to opioid-induced hyperalgesia. Neuropathic pain is often accompanied by neuroinflammation and increased levels of different cytokines and chemokines. Our study focused on the effect of CCL2 (C-C motif chemokine ligand 2) and activation of TRPV1 (transient receptor potential vanilloid 1) on the analgesia induced by activation of MOR (μ-opioid receptor). MOR, TRPV1 and CCL2 receptors (CCR2) are present in presynaptic membranes of nociceptive primary afferent neurons in the spinal cord dorsal horn and modulate synaptic transmission at first nociceptive synapse. To study the modulation of opioid analgesia we used whole-cell patch clamp recordings of miniature (mEPSC) and dorsal root stimulation-evoked excitatory postsynaptic currents (eEPSC) from superficial dorsal horn neurons in rat spinal cord slices. We used the application of MOR agonist DAMGO ((D-Ala2,N-Me-Phe4,Gly-ol5)-enkephalin) (1μM), incubation with CCL2 (10nM) and SB366791 (10 μM) as a TRPV1 antagonist. To evaluate the possible contribution of microglia activation, we applied minocycline (100 μM). In our experiments acute application of DAMGO depressed frequency of mEPSC to 60.8 ± 4.0 % ($P<0.001$, n=16) and amplitudes of eEPSC to 33.0 ± 5.3 % of the control value ($P<0.001$, n=15) while induced increase of eEPSC amplitudes 15 minutes later. Incubation with CCL2 (2 h) partially diminished the DAMGO-induced inhibition of mEPSC (82.4 ± 3.9 %, n=11) and eEPSC (97.4 ± 10.7 %, n = 11). Incubation with minocycline attenuated the CCL2 induced effect. Pretreatment with SB366791 did not change the DAMGO-induced inhibition of eEPSC but prevented the eEPSC amplitudes increase present under control conditions 15 min later. In conclusion, our data suggest that paradoxical hypersensitivity during opioid withdrawal may be at least partially mediated by

TRPV1 receptors and that CCL2 attenuates the inhibitory effect of DAMGO in a microglia activation-dependent manner.

Title: Spinal cytochrome p450c17-induced astrocyte activation is mediated by p38 mitogen-activated protein kinase phosphorylation in a mouse model of neuropathic pain

Authors: S.-R. CHOI[1], A. J. BEITZ[2], *J.-H. LEE[1];
[1]Dept. of Vet. Physiol., BK21 PLUS Program for Creative Vet. Sci. Research, Res. Inst. for Vet. Sci. and Col. of Vet. Medicine, Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept Vet & Biomed Sci., Univ. of Minnesota Col. of Vet. Med., Saint Paul, MN

Abstract: It has been suggested that peripheral nerve injury induces spinal astrocyte activation and leads to the development of neuropathic pain. We have recently demonstrated that cytochrome P450c17 is increased in spinal astrocytes and plays a critical role in the development of neuropathic pain following peripheral nerve injury. However, whether or how spinal P450c17 modulates pathological changes in astrocytes remain unclear. Here we investigated whether P450c17 modulates astrocyte activation and whether this process is mediated by p38 mitogen-activated protein kinase (MAPK) and leads to the development of mechanical allodynia in a mouse model of neuropathic pain. Chronic constriction injury (CCI) of the sciatic nerve induced a significant increase in glial fibrillary acidic protein (GFAP) expression in the superficial dorsal horn (SDH, laminae I-II) and nucleus proprius (NP, laminae III-IV) regions of the spinal cord. Repeated daily (from days 0-3 post-surgery) intrathecal (i.t.) administration of the P450c17 inhibitor, ketoconazole significantly inhibited the CCI-induced pathological activation of astrocytes. In addition, i.t. administration of ketoconazole significantly inhibited the CCI-induced increase in p38 MAPK phosphorylation, which is expressed in GFAP-positive astrocytes in the SDH and NP regions. I.t. administration of a sub-effective dose of the p38 MAPK inhibitor, SB203580 potentiated the pharmacological effect of ketoconazole on the development of mechanical allodynia as well as astrocyte activation in the spinal cord of CCI mice. Collectively these results suggest that spinal cytochrome P450c17 activates astrocyte via p38 MAPK

phosphorylation, ultimately leading to the development of mechanical allodynia induced by peripheral nerve injury.
Key Words: MAP kinase; Astrocyte; Neuropathic pain.

Title: Amitriptyline and duloxetine loaded PLGA nanoparticles prolong the analgesic duration through enhanced targeting to microglia

Authors: *S. KIM[1], J. SHIN[2], S. LEE[3], D. KIM[3];
[1]Med. Science, Anat., Chungnam Natl. Univ. of Med., Daejeon, Korea, Republic of; [2]Dept. of Med. Sci., Chungnam Natl. Univ. Col. of Med., Daejeon, Korea, Republic of; [3]Anat., Chungnam Natl. Univ., Daejeon, Korea, Republic of

Abstract: Neuropathic pain caused by functional disorders or pathological changes of the nervous system and various mechanisms has been revealed in previous study but still no treatment has been developed. Both amitriptyline (AMI) and duloxetine (DLX) are potent analgesic agents and are currently used as analgesics in clinical practice. Although AMI and DLX are known as a reuptake inhibitor of serotonin (5-HT) and noradrenaline (NA) from synapse cleft to primary neuron, these drugs have recently been reported to also act on microglia activation. Since microglia activation control is known to be capable of sustaining analgesic action, PLGA nanoparticles were introduced to enhance microglial cell targeting of AMI and duloxetine DLX. Despite AMI and DLX injected group showed analgesic effect on neuropathic pain by spinal nerve ligation (SNL) in rats, the duration time of mitigation was 4 h. We confirmed that AMI and DLX-encapsulated PLGA nanoparticles significantly alleviated mechanical allodynia for 5 days compare to AMI and DLX treatment. Both microglial activation and proinflammatory mediators were notably reduced in spinal dorsal horn with histological and cytokine analysis. Taken together, these data suggest that AMI and DLX encapsulating PLGA nanoparticles can improve for therapeutic duration for neuropathic pain.

Title: Inhibitory input from the lateral hypothalamus to the ventral tegmental area regulates mesolimbic BDNF signaling to mediate pain sensation

Authors: Y. MA[1,2], *G. ZHANG[1,2], Y. BIAN[1,2], Y. XU[1,2], H. LI[1,2], X. KONG[1,2], Y. NIU[1,2], S. SHA[1,2], A. MANNAN[1,2], J. YANG[1,2], H. ZHANG[1,2], J.-L. CAO[1,2,3];
[1]Jiangsu Province Key Lab. of Anesthesiology, Xuzhou Med. Univ., Xuzhou, China; [2]Jiangsu Province Key Lab. of Anesthesia and Analgesia Application Technology, Xuzhou Med. Univ., Xuzhou, China; [3]Dept. of Anesthesiology, Affiliated Hosp. of Xuzhou Med. Univ., Xuzhou, China

Abstract: The mesolimbic pathway is a collection of dopaminergic (DA) neurons that project from the ventral tegmental area (VTA) to the ventral striatum which include nucleus accumbens (NAc), and this pathway is involved in pain regulation. However, how the mesolimbic pathway is regulated in pain sensation is not clear, especially at a circuit level. VTA receives heavy GABAergic inputs from lateral hypothalamus (LH) which mediates an array of physiological and pathological processes including pain sensation. This study was to detect a possible role for LH-VTA GABAergic circuit in mediating intrinsic analgesia and pain sensation under both physiological and pathological conditions. To determine the role of LH-VTA GABAergic projection in pain regulation under a physiological state, a cocktail of AAV encoding cre-inducible enhanced halorhodopsin 3.0 and channalrhodopsin (AAV-DIO-NpHR and AAV-DIO-ChR2) was injected into the LH of vGAT-Cre mice followed by a bilateral optical fibers implantation in the VTA. Then, paw withdrawal latencies (PWLs) and paw withdrawal thresholds (PWTs) were measured during 5 sessions at a time interval of 2 h: baseline-yellow laser (8 s on - 2 s off) on-laser off-blue laser (20 Hz, 10 ms) on- laser off. Our behavioral tests found that in comparsion with the baseline or laser off timepoints, there is a robust increase in

PWLs and PWTs with yellow laser, which is an intrinsic analgesic property and could be prevented by the treatment of naloxone (2 mg/kg, i.p.) as observed in morphine treated mice. And a significant decrease in PWLs and PWTs was observed when the blue laser was on. Our recent study revealed that the activity of VTA-NAc DA circuit and VTA-generated brain-derived neurotrophic factor (BDNF) expression in the NAc is essential for pain sensation (Zhang et al., *Biol Psychiatry* 2017). Surprisingly but consistently, our molecular study found a robust increase of BDNF in the NAc by repeated photoactivation of the LH-VTA GABAergic projection. Furthermore, photoinhibition of this projection in a persistent inflammatory pain model, mice treated with Completed Freund's Adjuvant, showed similar analgesic effects. The study indicated that the LH-VTA GABAergic projection act as a novel circuit for intrinsic analgesia and pain sensation, and the consistent findings with our own and others (Nieh et al., *Neuron* 2016) prompt us to speculate that excitation of LH-VTA GABAergic neurons might disinhibt VTA-NAc DA neurons via the downstream GABAergic neurons in the VTA to regulate intrinsic analgesia and pain sensation.

Title: Schwann cell-mediated immune response participates in paclitaxel-induced peripheral neuropathy pathogenesis

Authors: *M. KOYANAGI, S. IMAI, M. MATSUMOTO, Y. IWAMITSU, M. SAIGO, M. NTOGWA, R. HIRAIWA, T. OGIHARA, T. NAKAGAWA, K. MATSUBARA;
Dept. of Clin. Pharmacol. and Therapeut., Kyoto Univ. Hosp., Kyoto, Japan

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) is one of the most common dose-limiting adverse reactions caused by taxanes. Severe CIPN often results in discontinuation of chemotherapy or a drop in quality of life. However, the precise mechanisms underlying CIPN pathogenesis are not fully understood, so that there is no effective way to prevent or treat CIPN. We have previously shown that paclitaxel preferentially impairs myelin-forming Schwann cells,

rather than sensory neurons, and induce dedifferentiation of Schwann cells. Considering the supportive role of Schwann cells in the maintenance of peripheral nervous system, we have assumed that such direct effect of paclitaxel on Schwann cells should be a trigger of CIPN. Here, we found that treatment with paclitaxel (0.01 μM) significantly increased the mRNA expression of an inflammatory factor, X, in dedifferentiated rat primary cultured Schwann cells. Likewise, upregulation of the factor was specifically induced in the mouse sciatic nerve but not in other peripheral organs at the onset of mechanical hypersensitivity after multiple injections of paclitaxel (20 mg/kg, i.p.). The elevation of the factor and significant macrophage infiltration into the sciatic nerve were concurrently observed in paclitaxel injected mice. Furthermore, murine macrophage cell line, RAW264.7, showed a chemotaxis response toward the culture medium containing the inflammatory factor derived from paclitaxel-treated Schwann cells. Consistent with this data, we found that the perineural application of the factor induced infiltration of macrophages into the sciatic nerve and mechanical hypersensitivity in mice. In conclusion, we propose here that the inflammatory factor derived from dedifferentiated Schwann cells chemoattracts macrophages into the peripheral nerve after paclitaxel treatment. These Schwann cell-dependent peripheral immune responses should play a crucial role in the development of paclitaxel-induced CIPN.

Title: Modulation the NFκB mediated inflammatory cytokines and oxidative stress contribute to ameliorative effect of osthole in painful peripheral neuropathy

Authors: *G. SINGH, Jr, P. SINGH, R. BHATTI;
Guru Nanak Dev Univ., Amritsar, India

Abstract: Background Chemotherapy-induced peripheral neuropathy is a common adverse effect of several commonly used cancer treatments, including vinca alkaloids, taxanes and platinum agents. NFκB is an important transcription factor, which regulates a diverse array of cellular process, includings immunological response, inflammation and apoptosis. Increased expression of NFκB plays a vital role in the pathogenesis of several inflammatory diseases including neuropathy. **Aim** Current investigation has been design to explore the effect of osthole on vincristine induced neuropathic pain in rats. **Method** Rats were divided into four groups, each

group containing six animals. The first group was normal control that was treated with vehicle daily for a period of 14 days. The second group was vincristine control and received vincristine (100 µg/kg, i.p.) in two 5 days cycle with 2 day break between cycle. The third and fourth groups received gabapentin (60 mg/kg, i.p.) and osthole (10 mg/kg i.p.) respectively daily for 14 days starting from day 1. At the end of 14 days, blood and tissue were harvested for biochemical and histological examination. **Results** Osthole was found to produce significant reduction in pain perception as compared to vincristine group. Osthole significantly ameliorated vincristine induced inflammatory changes including NFκB, iNOS, COX-2 and inflammatory cytokines. **Conclusion** Osthole could provide a useful lead in developing new drugs in investigation of painful neuropathy.

Title: IL-23 induces persistent mechanical pain hypersensitivity via macrophage-neuron interaction in female mice

Authors: *X. LUO, Q. HE, S. BANG, R.-R. JI;
Anesthesiol., Duke Univ. Med. Ctr., Durham, NC

Abstract: 2016 National Health Interview Survey (NHIS) data indicates that an estimated 20.4% (50.0 million) of U.S. adults had chronic pain, with higher prevalence of chronic pain reported among females. However, female-dominant pain pathways remain less studied and unknown. Recently, we discovered that male and female macrophages equally contribute to chemotherapy-induced peripheral neuropathy (CIPN) but macrophage toll-like receptor 9 (TLR9) signaling is only required by males, implicating the sexual polymodality of macrophages in chronic pain. Interleukin-23 (IL-23) is released by pro-inflammatory macrophages, but the contribution of IL-23 and IL-23 receptor (IL-23R) signaling to chronic pain remains unclear. We found that intraplantar administration of IL-23 induced mechanical allodynia only in female but not male mice. IL-23-evoked mechanical allodynia in females was prevented by intraplantar treatment of IL-23R antagonist or *Il-23r* siRNA. Of note, C-fiber ablation by resiniferatoxin or deletion of *Trpv1* abolished IL-23-induced mechancial allodynia in females, suggesting a requirement of C-fibers and TRPV1. Additionally, IL-23 induced mechanical allodynia in female nude mice and female *Rag1* knockout mice, implicating that IL-23-mediated pain may not require T cells or B cells signaling. We also examined the role of IL-23/IL-23R in CIPN, induced by four injections of paclitaxel (PTX) in both sexes. In dorsal root ganglia (DRG), F4/80-positive macrophages expressed IL-23 in both sexes. PTX caused a great increase in IL-23 mRNA levels in female DRG than male DRG. FACS analysis further indicated that PTX-treated females exhibited a larger population of IL-23/F4/80-positive macrophages than males in DRG. Interestingly, IL-23R was expressed by TRPV1-positive neurons. IL-23R antagonist or *Il-23r* siRNA reduced mechanical allodynia only in females, but IL-23R antagonist had no effect in female CIPN mice lacking *Tprv1*. Finally, IL-23 was also capable of inducing mechanical allodynia in male mice primed with estrogen, suggesting that estrogen may contribute to IL-23/IL-23R-mediated pain in females. Together, our findings establish the IL-23/IL-23R signaling axis as a novel female-dominant signaling pathway in chronic pain via macrophage-neuron interaction. Our study constitutes a critical step forward in our understanding of sexual dimorphism in chronic pain.

Title: Axon-glia interactions are disrupted in chemotherapy-induced peripheral neuropathy

Authors: *A. JOSHI[1], A. K. SINGH[2], A. KAVELAARS[2], C. J. HEIJNEN[2], M. RASBAND[1]; [1]Baylor Col. of Med., Houston, TX; [2]Symptom Res., Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract: Chemotherapy induced peripheral neuropathy (CIPN) is a severe, dose-limiting side effect of chemotherapy treatment. Several mechanisms have been proposed for the development of CIPN with major attention on axonal dysfunction. However, whether axon-glia interactions are altered in CIPN remains unknown. The spectrin cytoskeleton is crucial for the formation and maintenance of paranodal axon-glia junctions flanking nodes of Ranvier. Importantly, the spectrin cytoskeleton is susceptible to proteolysis by calpain, which is activated in CIPN. Thus we hypothesize that paranodal junctions are disrupted in CIPN. To induce the peripheral neuropathy, we injected Cisplatin (CIS, cumulative 23mg/kg) or Paclitaxel (PTX, 12mg/kg) intraperitoneally in mice. After 4 weeks of the treatment, both CIS and PTX induced significant mechanical allodynia. The intraepidermal nerve fiber density in the paw skin was significantly reduced in treated mice. To examine the membrane domain organization, we performed immunohistochemistry of sural and saphenous nerves using nodal and paranodal markers. Notably, CIS and PTX both disrupted paranodes as shown by abnormal localization and distribution of nodal and paranodal proteins. The phenotype of paranodal disruption was comparable when we used another high dosage regimen for PTX (cumulative 200mg/kg). Taken together, our results suggest that paranodal axon-glia interactions are disrupted in CIPN, which may contribute to the pathogenesis of CIPN.

Title: Further characterization of TLR5 expression in mouse dorsal root ganglion and spinal cord: Implications in mechanical allodynia and chronic itch

Authors: *M. MATSUDA[1,4,5], Z. WANG[1], C. JIANG[1], Z.-Z. XU[1], Q. HAN[1], R.-R. JI[1,2,3]; [1]Dept. of Anesthesiol., [2]Dept. of Neurobio., [3]Dept. of Cell Biol., Duke Univ. Med. Ctr., Durham, NC; [4]Dept. of Anesthesiol., Kyoto Okamoto Mem. Hosp., Kyoto, Japan; [5]Dept. of Anesthesiol., Kyoto Prefectural Univ. of Med., Kyoto, Japan

Abstract: Mechanical allodynia, induced by normally innocuous low-threshold mechanical stimulation, represents a cardinal feature of neuropathic pain. Although large, myelinated group A fibers, in particular A beta fibers, have previously been implicated in mechanical allodynia, an A-fiber-selective pharmacological blocker is still lacking. Recently, we reported a new method for targeted silencing of A-fibers in neuropathic pain. We found that Toll-like receptor 5 (TLR5) is co-expressed with neurofilament-200 in large-diameter A-fiber neurons in the dorsal root ganglion (DRG). Activation of TLR5 with its ligand flagellin, together with QX-314, leading to TLR5-dependent blockade of A-fiber neurons of mouse DRGs and inhibition of mechanical allodynia after nerve injury and chemotherapy (Xu et al., 2015). To further characterize TLR5 expression in DRG and spinal cord, we generated *Tlr5*-GFP reporter mice. Surprisingly, GFP-TLR5 only labels a very small portion of DRG neurons (<0.1%), with an average diameter of 29.82 ± 6.95 μm (18.57 - 38.11) and an average area of 482.7 ± 202.4 sq. μm (223.3 - 693.9). In contrast, RNAscope analysis of *Tlr5* mRNA expression reveals a larger population of 10-30% DRG neurons that are co-localized with NF200, and the percentage of TLR5-positive neurons varies based on the number of the mRNA-positive puncta in each neuron. Strikingly, in the spinal cord dorsal horn, GFP-TLR5 labels axonal arborization in ventral lamina II and lamina III, (lamina vIIi-dIII), indicating a subset of A beta fibers. In a mouse model of chronic itch, induced by implantation of cutaneous T cell lymphoma (CTCL) cells, flagellin/QX-314 co-application effectively suppressed spontaneous chronic itch, suggesting a possible role of TLR5-expressing A fibers in chronic itch. In summary, TLR5 labels different types of DRG neurons, depending on how the TLR5-positive neurons are defined. It is likely the majority of TLR5-expressing DRG neurons are A-fiber neurons especially Aβ-fiber neurons. Importantly, targeting TLR5-expressing afferents may provide new therapeutics for treating mechanical allodynia and chronic itch.

Abstract: Macrophage activation and recruitment to sites of injury or infection is a vital component of immune function following tissue insult. M1 macrophages stimulate the immune system and release pro-inflammatory cytokines, while M2 macrophages reduce inflammation and promote tissue growth and repair. M1 macrophages secrete high levels of IL-12, a pro-inflammatory cytokine, and oncostatin-M (OSM). OSM is a member of the IL-6 cytokine family that is pro-inflammatory in endothelial tissues but also promotes cancer cell plasticity and metastasis through a STAT3-dependent pathway. The function of OSM and its receptors in the peripheral nervous system has not yet been established. Expression of OSM receptor is upregulated in dorsal root ganglia (DRG) of cancer patients with neuropathic pain associated with compression of tissue by the growth of bone metastases, suggesting involvement in nociception. The current study explored the effects of OSM on cultured human and rat DRG neurons and also determined its effect on the behavioral responses of adult rats to mechanical and thermal stimuli. Immunohistochemistry in tissue excised from a cancer patient with radiculopathy showed macrophage infiltration into the DRG co-localized with the expression of OSM. These results support evidence from analyses of mRNA expression suggesting increased OSM activity in patients with neuropathic pain. *In vitro* studies of dissociated human DRG neurons showed that OSM (10 ng/ml) treatment induced spontaneous discharges and abnormal membrane oscillations. Intrathecal OSM (10 ng) produced long-lasting mechanical hyperalgesia in adult rats but did not alter withdrawal latencies to heat stimuli. Immunohistochemistry in rat

DRG tissue showed co-localization of the OSM receptor (OSMR) with mostly IB4-positive neurons and a few CGRP-positive neurons. Further, OSMR expression did not co-localize with TRPV1 expression, indicating that the sensitization induced by OSM does not impact neurons involved in processing noxious heat. Rat DRG neurons also exhibited spontaneous activity and abnormal membrane oscillations following OSM (10 ng/ml) treatment. Further studies confirmed that this effect was limited to capsaicin-insensitive neurons. Calcium imaging also showed that cells responding to OSM (10 ng/ml) did not respond to capsaicin (1 μM), and vice versa. These results suggest that increased levels of OSM following macrophage infiltration into the DRG contribute directly to the sensitization of the subpopulation of nociceptors expressing OSMR, and this mechanism could provide a novel target for the treatment of neuropathic pain in cancer patients. Abstract: Neuroimmune interactions contribute to abnormal pain states and one relatively understudied aspect of this is through the action of human autoantibodies. One such rare neurological condition is Paraneoplastic Syndrome where a peripheral tumor can trigger an immune response against a neuronal auto-antigen. In this syndrome, anti-CV2 autoantibodies targeting collapsin response mediator protein 5 (CRMP5) are associated with a painful axonal asymmetric polyradiculoneuropathy in ~80% of patients. The anti-CV2 autoantibodies targeting collapsin response mediator protein 5 (CRMP5) are associated with neuropathic pain in patients. CRMP5 is an understudied onconeural protein highly expressed in the developing brain. In

adults, CRMP5 expression is lost in the brain but retained in sensory neurons, nerves and synapses present in the spinal cord. Using patients' autoantibodies and transgenic mice, we tested the hypotheses that (i) CRMP5 is anti-nociceptive and (ii) disruption of CRMP5 functions contributes to neuropathic pain. After identifying the epitope on CRMP5 targeted by the anti-CV2 antibodies, we found that anti-CV2 autoantibodies induced mechanical allodynia through a spinal mechanism. This could be recapitulated by triggering auto-immunity against CRMP5 in rats, thus providing us with a novel model of auto-immune CRMP5 neuropathy. We further established that auto-immunity targeting CRMP5 was sufficient to elicit allodynia. In investigating the mechanism(s) in a rat model of neuropathic pain, we found that CRMP5 expression was lost at post-synaptic sites in the dorsal horn of the spinal cord. Restoring CRMP5 expression reversed mechanical allodynia in rats with neuropathic pain. On the contrary, knockdown of CRMP5 expression in the spinal cord induced mechanical allodynia. These results show that CRMP5 expression levels contribute to mechanical allodynia. We are now exploring the physiological role of CRMP5 in pain sensations using CRMP5 knockout transgenic mice. Together, these data shows that CRMP5 antagonism in anti-CV2 autoimmune neuropathy or CRMP5 loss of expression in neuropathic pain, underlies mechanical allodynia. Regulating CRMP5 anti-nociceptive functions could be a novel therapeutic target for chronic pain.

Title: Arginase II attenuates neuroinflammation & pain behaviors after nerve injury in mice

Authors: *L. T. PHAM, Y. JIN, N. SHIN, D. KIM;
Anat., Chungnam Natl. Univ., Daejeon, Korea, Republic of

Abstract: Microglia phenotypes have been divided into two groups: M1 & M2 microglia based upon their promotion to inflammatory pathogenesis. Arginase-ll (Arg-II) is an enzyme involved in arginine metabolism & expressed in microglia in central nervous system. In this study, we attempted to determine whether the presentation of Arg-II is in M1 or M2 microglia phenotype & its regulation on neuroinflammatory process. Finally we investigated loss of Arg-ll exaggerates microglia activation & pain behaviors after nerve injury-induced neuropathic pain. Spinal nerve transection (SNT) experimental model was used in this study to induce neuropathic

pain in mice. As a result of peripheral nerve injury, SNT induced microgliosis, astrogliosis in spinal cord, & upregulation of inflammatory signals in both WT & Arg-ll KO mice. Notably, these inflammatory implications were significantly increased in Arg-ll KO group compared to WT group. We also observed the more robust microgliosis, & lower pain threshold in ArG-ll KO group than those in WT group. Furthermore, our data revealed the higher upregulations of M1 pro-inflammatory cytokines, such as IL1β, IL6, NO & the lower downregulations of M2 anti-inflammatory cytokines, including Arginase-l, IL10, IL4, in Arg-ll KO mice. Additionally, the stronger expression of iNOS, ROS, & the decrease in the expression of CD206, YM1, Foxp3 in Arg-ll KO Group were found compared to WT group. These results suggested that Arg-II promote contribution to inflammatory resolution. The reduction or loss of Arg-ll results in the stronger development of neuroinflammation in spinal dorsal horn, & then pain behaviors after nerve injury-induced neuropathic pain.

Title: Pain pathology-dependent differential alteration of sensory ganglia Tmem100 in inflammatory pain and neuropathic pain

Authors: *H. YU[1], **S. SHIN**[1], F. WANG[2], H. XU[2], H. XIANG[2], B. ITSON-ZOSLE[2], Q. H. HOGAN[3];
[1]Dept. of Anesthesiol., Med. Col. of Wisconsin, Milwaikee, WI; [2]Dept. of Anesthesiol., Med. Col. of Wiscosin, Milwaikee, WI; [3]Dept. of Anesthesiol., Med. Col. of Wiscosin, Zablocki VA Med. Ctr., Milwaikee, WI

Abstract: Transmembrane protein 100 (Tmem100) is expressedin dorsal root ganglia (DRG) neurons and plays a role in modulating interactions between transient receptor potential ankyrin type 1 (TRPA1) and vanilloid type 1 (TRPV1) ion channels, both of which are crucial for nociception. However, it is not defined whether peripheral nerve injury induces changes in Tm100 expression. This study shows that Tmem100 is expressed in both neurons and perineuronal glial cells in the rat DRG. The plasma membrane and intracellular localization of Tmem100 are identified in 83±6.6% of IB4-positive and 48±6 % of calcitonin gene-related

peptide-positive neurons, as well as in medium- and large-sized neurons, with its immunopositivity colocalized to TRPV1 (94±5%) and TRPA1 (96±3%). Tmem100 is also detected in the perineuronal satellite glial cells and in some microglia. Tmem100 protein is significantly increased in the lumbar DRGs in the complete Freund adjuvant inflammatory pain. By contrast, ligation of the rat L5 spinal nerve diminishes Tmem100 expression in the associated DRG, with immunoblot and immunohistochemistry showing reduced Tmem100 protein levels in both neurons and satellite glial cells, whereas Tmem100 is unchanged in the adjacent L4 DRG. The spared nerve injury model also reduces Tmem100 protein in the DRGs. Our data demonstrate a pain pathology-dependent alteration of DRG Tmem100 protein expression, upregulated during CFA inflammatory pain but downregulated during neuropathic pain. Additionally, viral-mediated overexpression of Tmem100 in astrocyte and microglia cell lines and in SGCs isolated from rat DRG significantly blunt their proliferation in culture, suggesting that Tmem100 likely plays a role in control SGC proliferation.

Title: Detailed characterization of myeloid cell number and phenotype after nerve injury

Authors: *Z. LIANG, Z. HORE, P. HARLEY, F. DENK, S. B. MCMAHON;
King's Col. London, London, United Kingdom

Abstract: Objective and Rationale: Chronic pain is a major public health problem affecting more individuals in the United States than cancer, heart disease and diabetes combined. Millions of suffers are unable to work or are pushed into devastating opioid addiction as a result of medication overuse. Neuropathic pain, arising from damage or disease of nerves themselves, is particularly intractable. In part, it is caused by immune and inflammatory cells driving the development of hypersensitivity in peripheral sensory neurons. The detailed kinetics and phenotype of this inflammatory response are still relatively poorly understood. Here we set out to generate a detailed time-course of immune cell responses in sciatic nerve and its dorsal root ganglia (DRG) in a mouse model of neuropathic pain.
Methods: We induced partial sciatic nerve ligation (PSNL) in adult C57BL/6J male and female mice (n = 6) and extracted immune cells from lumbar DRG (L3-L5) and sciatic nerve, 0.5cm

either side of the suture. We then performed flow cytometry and fluorescence-activated cell sorting (FACS) at various time points after the surgery, including day 1, day 3, day 7, day 15 and day 28. Different myeloid cell populations were selected for FACS (20 cells each), amplified using the SMARTer protocol and sent for RNA sequencing.
Results: The number of immune cells (as measured by CD45) dramatically increased and remained elevated in ipsilateral nerve until day 28. In detail, we observed early infiltration of neutrophils (Ly6G+) and monocytes (Ly6C+), accompanied by a gradual increase in the number of resident (CD11b+, MHCII-, Ly6C-) and activated (CD11b+, MHCII+, Ly6C-, CD11c-) macrophages. In contrast to nerve, differences in immune cell numbers were much less stark in the DRG. Several previously undescribed populations could be observed in both tissues, such as a permanent CD11b+/Ly6G+ population in DRG and a Ly6C+/MHCII+ in nerve after injury. Our results also pointed towards sexually dimorphic responses in aspects of this immune response. However, the precise size of this effect remains unclear, since variability between biological replicates was inherently large, despite our best efforts to standardize protocols.
Conclusions: Detailed description of inflammatory cell responses to traumatic nerve injury in male and female mice may help reveal the contribution of different immune cell populations to peripheral sensitization at different time-points. Our results will aid to define the immunological phenotype of several distinct populations and may help reveal potential opportunities for novel analgesic drug development.

Title: Real time imaging of mitochondrial dynamics in the dorsal root ganglion following nerve injury

Authors: *J. M. MWIRIGI[1], C. PAIGE[2], V. PRAKASH[3], S. SHIERS[2], T. J. PRICE[4];
[1]Brain and Behavioral Sci., [2]Cognition and Neurosci., Univ. of Texas At Dallas, Richardson, TX; [3]Univ. of Texas At Dallas, Dallas, TX; [4]Sch. of Behavioral and Brain Sci., UTD, Richardson, TX

Abstract: Mitochondria are dynamic and motile organelles that respond rapidly to oxidative stress and cellular energy demands. Their morphological changes, as determined by fission and fusion, have been linked to the progression of neuropathic pain as well as neurodegenerative disorders like Parkinson's, Alzheimer's and Huntington's. However, little is known about specific pathology underlying mitochondrial dysfunction after peripheral nerve injury or how pharmacological interventions affect these changes. Our goal was to evaluate mitochondrial dynamics following peripheral nerve injury by characterizing axonal mitochondrial density, movement in axons and fusion-fission events, as determined by mitochondrial length, using spinning disc confocal imaging with mitochondrial dyes. To do this, we dissociated dorsal root ganglia (DRG) from mice with spare nerve injury (SNI), a model of neuropathic pain. We then stained mitochondria with mitotracker green and used spinning disk microscope to capture time lapse videos. We observed a significant increase in axonal mitochondrial density in DRG cultures obtained from SNI mice when compared to naïve cultures. Representative kymograph images depict a larger proportion of mitochondria moving anterogradely in axons of DRG neurons from SNI mice. Interestingly, we found that the SNI-mitochondria are trafficked at lower velocities. Previous studies have shown that calcium overload in damaged mitochondria may contribute to decreased mitochondrial motility. Additionally, mitochondrial length varied considerably within the SNI group but was generally greater than naïve group indicating either that a significant percentage remained in the fused state or that there is a failure of fission in DRG neurons after injury. Collectively, our findings highlight the benefit of real time imaging of DRG neurons to gain greater insight into specific mitochondrial dysfunction after nerve injury. Our findings likely have important implications for therapeutic approaches to neuropathic pain.

Title: Proton sensing receptor OGR1 in peripheral afferents modulates neuron activities and immune cell infiltration to maintain chronic pain state

Authors: Y. CHIN, Y.-H. LU, *W.-H. SUN;
Natl. Central Univ., Taoyuan, Taiwan

Abstract: Neuropathic pain is a complex, chronic pain state that is usually accompanied by a lesion or disease of the nervous system, causing severe disturbance to the quality of life. Chronic excessive inflammatory response after injury may contribute to the maintenance of persistent pain. Although the role of immune cells and cytokines in mediating allodynia and hyperalgesia has been extensively studied, it has not been completely elucidated how chronic pain state is maintained. According to hyperalgesic priming hypothesis, the maintenance of chronic pain state requires protein kinase Cε activation. Ovarian Cancer G Protein-Coupled Receptor 1 (OGR1), a proton-sensing receptor expressed in small-diameter dorsal root ganglion (DRG) neurons, macrophages and neutrophils, is fully activated at pH6.8 and mediates Gq protein-protein kinase C pathway. However, it remains unclear which role OGR1 plays in neuropathic pain. To address this question, I used shRNA specific to OGR1 gene to suppress OGR1 gene expression in peripheral afferents to explore OGR1 function in the model of chronic constriction injury (CCI) of the sciatic nerve. CCI induced long-term hyperalgesia at least 14 weeks. Suppression of OGR1 gene expression reversed mechanical hyperalgesia from week 4 after CCI surgery. OGR1 knockdown also reduced granulocyte infiltration at week 2 and 4, and decreased intracellular calcium increase at week 4. Therefore, hyperalgesia shortening in OGR1 knockdown mice could be attributed to a decrease in calcium signals in DRG neurons and a reduction of granulocyte infiltration in the sciatic nerve. Accordingly, these results suggested that OGR1 may regulate neuron activities to modulate immune cell infiltration, further regulating the maintenance of chronic pain.

Title: Whole system immune phenotyping of male and female mice reveals striking sex differences and similarities in the immune response to injury

Authors: V. L. TAWFIK[1], Q. J. BACA[1], ***N. A. HUCK**[1], E. S. HAIGHT[1], E. A. GANIO[1], H. SHEN[1,2], A. CULOS[1], M. S. GHAEMI[1], J. CLARK[1], N. AGHAEEPOUR[1], B. GAUDILLIERE[1]; [1]Anesthesia Dept., Stanford Univ., Stanford, CA; [2]Dept. of Orthopedic Surgery, The First Affiliated Hosp. of Soochow Univ., Suzhou, China

Abstract: Impaired recovery after surgery is characterized by chronic post-surgical pain and affects 30% of patients. Enhanced Recovery After Surgery (ERAS) pathways highlight the significance of protracted surgical recovery; however, the elements of these protocols that may improve recovery are uncertain. We undertook the current study to determine the whole system immune response to surgery in a tibial fracture mouse model of orthopedic trauma in order to identify key pathologic responses that could be targets for ERAS protocols. One week after injury, both male and female mice demonstrated a profound decrease in mechanical threshold and weight bearing, which returned to baseline by 7 weeks. In parallel, we collected serial blood samples for whole system immune phenotyping by mass cytometry at baseline, 12 hours, 1 week and 7 weeks after injury. This revealed similar immune cell frequencies at baseline between the sexes, with 11 of 13 cell type frequencies unchanged. We next evaluated intracellular signaling pathways within each cellular population and found several with near identical intracellular signaling responses in both sexes (ex. neutrophils) and others with sexually dimorphic intracellular signaling responses (ex. myeloid dendritic cells). Strikingly, at all time points after injury the number of significantly different features between sexes was increased and a majority were in the adaptive immune response. To reveal whole system dynamics of the response to injury we used a recently developed elastic net (EN) model approach to complex mass cytometry datasets. The EN revealed that at 12 hrs and 1 week the sex-specific response to injury was divergent. This study provides, for the first time, a whole system immune profile of male and female mice at baseline and after orthopedic surgery. Our data suggest that differences in the adaptive immune response to surgery underlie sex differences, a finding that implies the need for sex-specific personalized ERAS protocols.

Abstract: Chronic pain is a common and often debilitating problem that affects 100 million Americans. A better understanding of pain's molecular mechanisms is necessary for developing safe and effective therapeutics. Microglial activation has been implicated as a mediator of chronic pain in numerous preclinical studies, however, the heterogeneity of microglia has thus far been underappreciated. In order to unveil the time and sex-dependent contributions of microglia to chronic pain in males and females, we utilized a clinically-informed mouse model of complex regional pain syndrome (CRPS) and monitored microglia throughout disease progression using the novel microglial marker, Tmem119. Mice developed the cardinal signs of CRPS after tibial fracture-casting (allodynia, unweighting, warmth and edema). In a mechanical-conflict avoidance paradigm this injury resulted in mice taking longer to cross from a non-noxious aversive brightly lit chamber through a chamber with noxious aversive floor probes compared to baseline. Evaluation of spinal cord sections from these mice demonstrated that both males and females exhibited microglial activation as evidenced by increases in CD11b; however, activation was attenuated and delayed in females. Expression of Tmem119 also varied between sexes with increases only noted in male microglia after injury. Most interestingly, two distinct subpopulations of microglia were observed based on their relative expression of Tmem119, size and granularity, and the relative abundance of these Tmem119-defined subsets changed after injury in a sex-specific fashion. Our findings suggest that the response of microglia to injury is not "one size fits all" but rather may vary depending on individual cell phenotype, timing after injury and sex of the subject.

Title: Transcriptome analysis of repopulated spinal cord microglia identifies potential targets to block the acute-to-chronic transition in a mouse model of pain

Authors: *S. WU, E. S. HAIGHT, T. E. FORMAN, D. J. CLARK, V. L. TAWFIK;
Dept. of Anesthesiology, Perioperative and Pain Med., Stanford Univ., Stanford, CA

Abstract: Acute pain after injury or surgery is common and treatable, importantly, however, an estimated 5-30% of patients transition from acute to chronic pain with the mechanisms underlying this transition representing a major knowledge gap. Microglial activation in the spinal cord dorsal horn contributes to the acute to chronic pain transition, however, their exact contribution remains unknown. We used *Cx3CR1*^{CreER};*R26*^{iDTR} mice to transiently deplete microglia in the clinically-informed tibial fracture/casting mouse model of complex regional pain syndrome (CRPS). We found that microglial depletion during the acute phase decreased allodynia and abrogated the chronic phase of CRPS. Microglia repopulated after 3 days in the context of ongoing injury, suggesting they exhibited a “pro-resolution” phenotype. We isolated these microglia from the spinal cord and performed transcriptome analysis to comprehensively identify differentially expressed genes in repopulated microglia that may explain their contribution to pain resolution. The top expressed genes defined a microglia-specific signature confirming our FACS-based isolation technique. A wide range of genes were dysregulated in spinal cord microglia of CRPS mice, which included 12 out of 17 significantly upregulated genes reported in a nerve injury pain model. The CRPS-induced changes of all identified genes were attenuated in repopulated microglia. Our transcriptome analysis of repopulated microglia identified a number of candidate genes that may contribute to the resolution of pain. Further functional studies focusing on each gene need to be rigorously performed to validate their potential in the treatment of pain.

Title: A new model of pain-cognition interactions

Authors: *A. Y. LIN[1], M. MCANDREWS[3], A. YU[2], D. A. SEMINOWICZ[4], M. MOAYEDI[2]; [1]Dent., [2]Fac. of Dent., Univ. of Toronto, Toronto, ON, Canada; [3]Krembil Neurosci. Ctr., Univ. Hlth. Network, Toronto, ON, Canada; [4]Dept of Neural & Pain Sci., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Background: Pain poses a large health and economic burden on society. It is a complex experience with sensory, motor, affective and cognitive dimensions. Little is known about the underlying mechanisms of the interaction between pain and cognitive function in healthy people[1]. A prevalent model of pain-cognition interactions is that pain distracts from a task, resulting in slower task performance or reduced accuracy[2]. Here, we propose a different model: that pain itself is perceived as a task by the brain - and thus competes for limited cognitive resources dependent on its assigned value[3].
Objective/Hypothesis: The objective of this study is to determine whether pain poses a cognitive load. Specifically, we aim to test whether competing tasks are negatively affected by pain because of increased cognitive load. We hypothesize that participants' performance on a cognitive task will be slower and less accurate when they experience pain.
Methods: Twenty-six right-handed healthy participants (13 women) performed a computerized version of the cognitive-branching task designed to utilize the brain's working memory and multitasking system (1). Each participant completed the task with (3) no stimulus (baseline), (2) tonic heat pain, and (1) a salience-matched non-painful somatosensory stimulus (tonic electrical stimulus). Reaction times and error rates on the task were recorded for each condition and analysed using a two-way, repeated measures ANOVA.
Results: Salience and intensity ratings were matched between pain and electrical stimuli. In the pain condition, participants demonstrated slower reaction times ($p<0.05$), but no difference in error rates ($p>0.05$), compared to baseline. No differences were observed between electric and baseline conditions ($p>0.05$).
Conclusions: Pain affects task performance by potentially posing a cognitive load rather than simple distracting from a competing task. This was demonstrated by the differences in task performance between the pain condition and salience matched, non-painful electric condition.
Significance: This study provided insight into a different model of pain in which individuals perceive pain as a task and prioritize it based on its assigned value.

Title: The coil orientation dependency of pain sensation induced by transcranial magnetic stimulation

Authors: *K. TANI[1], S. TANAKA[2];
[1]Lab. of Psychology, [2]Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: Background and aims: Transcranial magnetic stimulation (TMS), one of cortical stimulation methods, is widely used to evaluate the neurophysiological or neuropsychological function in healthy and stroke patients. However, TMS often accompanies an uncomfortable pain sensation on stimulation spot as a side effect (Rossi et al., 2009). Considering that this pain sensation seems to be derived mainly from the muscle, it is possible that the pain sensation may depend on the direction of electric current induced by TMS relative to the muscle fiber. In this study, we assessed whether pain threshold was different between TMS coil orientations. **Methods:** Seven healthy subjects (2 females and 6 males, aged 21-23 years) participated in this study with written informed consent. This study was approved by the ethical committee of Hamamatsu University School of Medicine. The position and orientation of TMS coil on subjects' head were monitored with a neuro-navigation system. Single-pulse TMS was applied over the scalp just above the left Broca's area (BA), and coil orientation was changed ranged from 0° to 180° relative to inferior-superior direction in steps of 30°. Subjects were asked to report weather they felt pain after each TMS. The pain threshold was defined as the minimum stimulation intensity (%) that induced the pain sensation more than five out of ten stimulations. Significance was set at $p < 0.05$. **Results:** Mean (±SE) pain threshold was 33.9(±4.3) % for 0°, 29.8(±3.2) % for 30°, 29.4(±3.9) % for 60°, 31.4(±5.7) % for 90°, 33.4(±5.3) % for 120°, 36.1(±5.8) % for 150°, and 35.1(±4.4) % for 180°, respectively. One-way repeated-measure ANOVA revealed a significant main effect of the coil orientation [$p = 0.04$]. Post-hoc tests showed that the pain threshold in 60°condition were significantly lower than from that in 150° condition [$p = 0.04$]. **Conclusion:** Results showed that the pain threshold with the electric current in the anterosuperior direction tended to be lower than with that with electric current in the anteroinferior direction. The direction-specific pain threshold may be related to the directional specificity in the temporalis muscle fibers. This research was supported by Committee to Promote Research on the Possible Biological Effects of Electromagnetic Fields of the Ministry of Internal Affairs and Communications, Japan.

Title: Real and imagined acupuncture modulate opioidergic and dopaminergic networks in analgesic process

Authors: *J. CAO, Y. TU, S. ORR, G. WILSON, J. PARK, J. LIU, R. L. GOLLUB, J. KONG; Dept. of Psychiatry, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Introduction: Acupuncture and guided imagery have proven to be effective in treating pain. Our previous study introduced a novel intervention for pain relief called video-guided acupuncture imagery treatment (VGAIT), which integrates acupuncture with imagery and has demonstrated its potential clinical value for pain management. Much less is known about the intrinsic brain functional connectivity responsible for this analgesia processing. **Methods:** 27 healthy subjects were recruited for a crossover-design study that included five sessions (a training and familiarity session and four intervention sessions administered in a randomized order). We investigated changes in pain threshold and resting state functional connectivity (rsFC) modulated by real acupuncture on the right leg, sham acupuncture, VGAIT, and VGAIT control. Accumulating evidence has shown that the brain activity and functional connectivity (FC) in the opioidergic descending pain modulatory system (DPMS) and dopaminergic reward system play indispensable and interactive roles in relieving pain. Thus, periaqueductal gray (PAG) and ventral tegmental area (VTA), key regions of these two systems, respectively, were chosen as seed regions to perform rsFC analysis. **Results:** We found that real acupuncture and VGAIT can significantly increase subjects' pain thresholds, while sham acupuncture and VGAIT control did not significantly modulate subjects' pain thresholds. The fMRI rsFC results revealed that compared with sham acupuncture, real acupuncture produced significant PAG-precuneus (Pcu) rsFC decreases and greater VTA-amygdala (AMY)/hippocampus (HIP) rsFC increases. The decreased PAG-Pcu and increased VTA-HIP rsFCs were significantly associated with subjects' heat pain threshold changes applied on the contralateral forearm. VGAIT induced significant decreases of PAG rsFC with precentral (PreCG)/posterior cingulate cortex (PCC)/Pcu, middle cingulate cortex (MCC), and medial prefrontal cortex (mPFC), as well as VTA rsFC decreases with caudate (CAU) and MCC, compared to VGAIT control. Direct comparison between real acupuncture and VGAIT showed that VGAIT significantly decreased functional connectivity between PAG-PreCG/Pcu, VTA-CAU/anterior cingulate cortex (ACC)/nucleus accumbens (NAc), and VTA-MCC rsFCs compared to real acupuncture. **Conclusions:** Our findings

demonstrate the important roles of the DMPS and reward system in acupuncture and VGAIT analgesia, and they shed light on the development of new pain treatment methods.

Title: Investigating the neural basis of pain sensitivity in fibromyalgia syndrome using functional magnetic resonance imaging

Authors: *H. WARREN[1], G. IOACHIM[2], J. M. POWERS[3], P. W. STROMAN[4];
[1]Ctr. for Neurosci. Studies, [3]Dept. of Biomed. Sci., [4]Ctr. for Neurosci Studies, [2]Queen's Univ., Kingston, ON, Canada

Abstract: Chronic pain affects roughly 20% of the population, negatively impacting both the economy and patients' quality of life. In most chronic pain conditions, the underlying cause of the pain is difficult to diagnose, and the efficacy of treatments for these conditions are highly subjective and often only marginally effective. To improve diagnostic and treatment quality, a better understanding of the underlying neural mechanisms involved in chronic pain conditions is required.

Many chronic pain conditions appear to involve abnormalities within the central nervous system, including altered descending pain modulation. Recent imaging studies have found evidence that the net effect of descending pain modulation is the sum of both 'reactive' and 'continuous' modulation components such that the state before the experience of a noxious stimulus can influence how pain is perceived. We therefore hypothesized that the continuous component of descending pain modulation is altered in chronic pain conditions.

To test our hypothesis, we used functional magnetic resonance imaging (fMRI) to compare the neural responses to pain in two participant groups: female participants with fibromyalgia syndrome (FM), a chronic pain condition that affects 2-4% of the population, and age-matched (within two years) female participants without a chronic pain condition, which we defined as healthy controls. This study was limited to females because FM is up to 9 times more prevalent in women than in men.

Each participant underwent two fMRI sessions. One session involved fMRI of the brainstems and cervical spinal cords, the other session involved brain fMRI, in order to investigate neural

responses to pain throughout the central nervous system. During the imaging sessions, the participants underwent a 'threat-safety' paradigm. In the 'threat' portion of the paradigm, a thermal stimulus was administered to the palm of each participant's right hand to elicit a calibrated pain response. In the 'safety' portion of the paradigm, participants were not given the painful heat stimulus. The 'threat' and 'safety' runs were interleaved in a randomized order, and in each run the participants were notified one minute into the run whether they were going to experience the 'threat' or not.
Analyses of connectivity and temporal properties of BOLD responses across regions of the CNS known to be involved in pain processing demonstrate differences in the continuous component of descending pain modulation between controls and participants with FM. The results further our understanding of how descending pain modulation is altered in FM.

Title: Altered resting state functional connectivity of the hypothalamus in fibromyalgia and the modulation effect of mind-body intervention

Authors: *J. KONG[1], Y. HUANG[1], S. YU[1], M. CHENG[1], J. LIU[1], J. PARK[1], G. WISON[1], C. WANG[2];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Tufts Med. Ctr., Boston, MA

Abstract: Background: Fibromyalgia (FM) is a multidimensional, complex disorder with devastating effects on quality of life with decreased productivity and increased healthcare costs. The hypothalamus is a functionally diverse region of the brain that regulates vital bodily functions, such as stress, immune response, autonomic and endocrine functions, sleep, and fluid homeostasis. This study aims to investigate the functional connectivity changes of the hypothalamus in fibromyalgia patients and the modulation effect of mind-body intervention.
Method Fibromyalgia patients and matched healthy control subjects (HC) were recruited. Resting state fMRI scans were applied in fibromyalgia patients before and after 12-week Tai Chi intervention and once in HCs. The bilateral medial hypothalamus (MH) and lateral hypothalamus (LH) were used as regions of interest. Data analysis was conducted on 20 patients and 19 HCs

using CONN. **Results** Fibromyalgia patients showed significant symptom reduction as measured by Revised Fibromyalgia Impact Questionnaire scores after Tai Chi intervention. Resting state functional connectivity (rsFC) analysis using the MH as seed showed that fibromyalgia patients significantly increased rsFC with the bilateral subcallosal cingulate cortex and decreased rsFC with the amygdala, thalamus, cerebellum, and PAG compared to HCs at baseline. After Tai Chi intervention, fibromyalgia patients showed increased (normalized) rsFC with the left amygdala, thalamus, PAG, and cerebellum. Functional connectivity analysis using the LH as seed found that fibromyalgia patients are associated with increased rsFC with the right temporal pole and decreased rsFC with the right occipital inferior gyrus/cerebellum. After the intervention, fibromyalgia patients showed greater rsFC with the bilateral rACC and MPFC, left PCC, and right MTG/STG. **Conclusion**: Elucidating the role of the hypothalamus in fibromyalgia and the modulation effect of Tai Chi may deepen our understanding of the pathophysiology of fibromyalgia as well as the mechanisms underlying mind-body intervention and facilitate, development of new pain management methods.

Title: Sensorimotor functional connectivity to the salience network is spatially heterogeneous in healthy humans

Authors: A. K. HEGARTY, M. S. YANI, A. M. ALBISHI, L. A. MICHENER, *J. J. KUTCH; Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstract: Resting-state functional connectivity analyses typically group sensorimotor body regions as a homogenous network. We have recently shown that patients with chronic pain exhibit reproducible changes in resting-state functional connectivity between specific sensorimotor regions and the salience network, a network known to be important in pain processing. Therefore, we wanted to determine if inconsistencies in functional connectivity between the salience network and various sensorimotor regions would emerge even in healthy individuals, which may provide important insights about which body regions may be particularly prone to chronic pain development. Using electromyography and tasked-based functional

magnetic resonance imaging (fMRI) in 20 participants, we first localized distinct regions-of-interest spanning a large range of sensorimotor cortex, ranging from medial (gluteal) to intermediate (shoulder) to lateral (hand). Then, using an age and sex-matched set of 154 participants from a repository dataset of resting-state fMRI, we found that the medial, intermediate, and lateral sensorimotor areas exhibited significant heterogeneity in functional connectivity to the salience network. We further examined these inconsistencies by plotting the continuous functional connectivity to the salience network. On a flattened map of sensorimotor cortex, we also observed heterogeneity with relatively high functional connectivity to the salience network for trunk and face regions, and low functional connectivity for extremities including the hands and feet. We conclude that sensorimotor cortex can not be considered spatially homogeneous in its interaction with other large-scale brain networks. Different sensorimotor regions on the body surface may be prioritized differently for pain and threat assessment by the salience network.

Title: Photosensitivity thresholds are associated with chronic pain levels in TBI and PTSD

Authors: *N. M. BALBA[1], A. MCBRIDE[5], S. D. MIST[2], K. D. JONES[6], B. NARDOS[1], R. J. OLSON[5], S. C. HARDMAN[5], M. L. CALLAHAN[5], M. P. BUTLER[3], M. M. LIM[4], M. M. HEINRICHER[4];

Abstract: Chronic pain is in part driven by sensitization of pain-processing circuits in the central nervous system. Traumatic brain injury (TBI) and post-traumatic stress disorder (PTSD) are neurobiological conditions which are independently linked to an increased risk of chronic pain and self-reported photosensitivity. Individuals with comorbid TBI+PTSD have an even higher risk of developing these symptoms. However, the relationship between chronic pain and photosensitivity within these disorders remains unclear. The purpose of this study was to examine differences in chronic pain and photosensitivity in individuals with a history of TBI

and/or PTSD. Subjects completed a battery of self-report surveys relating to chronic pain, neurological functioning, and TBI/PTSD symptomology before being tested for pressure pain thresholds (using pressure algometry) and visual photosensitivity thresholds (VPT). Participants were then categorized into one of three groups based on a semi-structured, validated diagnostic interview for TBI and criteria from the PTSD Checklist for DSM 5 (PCL-5) survey for diagnosis of PTSD. Groups included: 1) Controls: subjects with no TBI or PTSD (n=31); 2) TBI: subjects with TBI, but no PTSD (n=76); and 3) TBI+PTSD: subjects with both TBI and PTSD (n=45). Only 5 subjects in this sample were classified as PTSD without TBI, and are not reported here. Using the Symptom Impact Questionnaire (SIQR) as a measure of chronic pain severity, we found that subjects suffering from comorbid TBI+PTSD had significantly higher levels of chronic pain and lower VPTs compared to Controls (P <0.01) and TBI subjects (P <0.01). VPTs were significantly correlated with chronic pain severity in the Control (R = -0.37, P = 0.05) and TBI groups (R = -0.32, P <0.01), but this correlation was strongest in the TBI+PTSD group (R = -0.40, P = 0.01). VPTs were also significantly correlated with pressure pain thresholds in the TBI+PTSD group (R = 0.41, P <0.01), but not in the Control (R = 0.21, P =0.29) or the TBI groups (R = 0.20, P = 0.10). Using a multiple linear regression model, we found that VPTs were a better predictor of chronic pain complaints (β = -0.16, P = 0.01) than other diagnostic measures including pressure pain thresholds (β = 0.001, P = 0.98). Taken together, these results suggest that photosensitivity levels could be used as a marker for individuals in whom central sensitization drives chronic pain, and could be applied to other populations that suffer from chronic pain. Future studies will use functional magnetic resonance imaging (fMRI) to see if these behavioral results relate to differences in cortical activity between groups in response to pressure pain and light stimuli.

Title: Functional ultrasound and fMRI neuroimaging in somatosensory processing studies, acute and neuropathic pain models for preclinical drug discovery

Authors: A. SHATILLO, *A.-M. KÄRKKÄINEN, T. MIETTINEN, J. KOPONEN, K. KUPTSOVA, D. MISZCZUK;
Charles River Discovery, Kuopio, Finland

Abstract: Advancements in development of effective pain-relief therapies in acute and chronic pain conditions are of utmost importance to alleviate the suffering of the patients and lift the socio-economic burden of the disorders that involve nociceptive system. In turn, these advancements are impossible without implementing of the new testing paradigms, objective assays and models to evaluate pain and efficacy of new compounds in preclinical setting.
In this work we used functional neuroimaging to setup and characterize several models of acute (electrical and chemical stimulation) and neuropathic (oxaliplatin-induced) pain in rats and mice. We applied state-of-the-art imaging techniques that measure local changes in brain perfusion in response to painful stimuli - functional ultrasound (fUS) and functional magnetic resonance imaging (fMRI).
Functional ultrasound is a novel, non-invasive imaging technique based on ultrafast plane-wave acquisition of the doppler ultrasound signal with real-time data processing, which enables high-sensitivity imaging of relative cerebral blood volume (rCBV) changes with high resolution. The fUS readout is based on the same physiological mechanisms as functional MRI (fMRI).
Functional MRI experiments were performed in 7T Bruker PharmaScan MRI scanner in anesthetized rats (Wistar, males) with T2*-weighted gradient echo sequence for blood-oxygen level dependent (BOLD) contrast. Two different noxious stimulation paradigms for acute pain fMRI experiments were used - electrical forepaw stimulation (10 Hz, 1-1.5 mA, 4x30s blocks) and injection of pain-inducing compounds (5% formalin or allyl isothiocyanate, AITC) into the plantar surface of the hind paw.
Chemotherapy-induced peripheral neuropathy (CIPN) was induced in mice (C57BL/6J, males) by oxaliplatin (4.5 mg/kg; i.p.) or vehicle treatment every 3 - 4 days for a period of 21 days. At the end of oxaliplatin challenge, mice were tested for cool allodynia followed by fUS imaging (fUS prototype, Iconeus, Paris, France) with unilateral hind paw and whiskers stimulation (4x30s intervals with 1 min of rest in between).
Both fUS and fMRI data were preprocessed and analyzed in a similar fashion, by extracting the signal time series from corresponding brain areas for the response profile analysis and statistical mapping by correlating it to the stimulation model. Various extent of the sensory and pain networks activation was detected, correlating with stimulation intensity.
Provided data and methodology established in this study, demonstrates the utility and benefits of the functional neuroimaging for drug testing in therapeutic area of pain and in sensory processing disorders.

Title: Appetitive and aversive learning and brain plasticity in the development of chronic back pain

Authors: *H. FLOR, K. USAI, M. LÖFFLER, F. NEES;
Dep. Cognitive and Clin. Neurosci., Central Inst. of Mental Hlth. Heidelberg Univ., Mannheim, Germany

Abstract: We sought to determine if the previously reported shift from nociceptive to emotional processing in the pain chronicity process might be related to maladaptive emotional learning and related brain plasticity. In a still ongoing combined cross-sectional and longitudinal study we examined 40 patients with subacute back pain, 40 chronic back pain patients and 40 healthy controls in an aversive and appetitive pavlovian conditioning paradigm as well as an instrumental monetary reward versus pain relief task during functional magnetic resonance imaging. Ratings of valence and arousal and skin conductance responses were also recorded. In comparison to controls, the chronic back pain group showed enhanced aversive and reduced appetitive learning with a stronger activation of limbic areas during aversive and sensorimotor in contrast to striatal areas during appetitive conditioning. In addition, the response to the unconditioned appetitive stimulus (pleasant touch) was dampened in the chronic back pain patients. We also found divergent subregion-specific response patterns in the insula for appetitive versus aversive learning within and between groups. For the chronic pain patients, we also found a stronger response to pain relief than monetary reward with a shift of the striatal response. The development of chronic pain has been predicted by limbic-prefrontal connectivity during learning and moderated by stress and anxiety. Our data suggest that emotional pavlovian and instrumental conditioning may be an important mediator of the shift of nociceptive to emotional/motivational brain circuits in the chronicity process and supports treatment interventions that reverse aversive and enhance appetitive pain-related memories. Supported by the Deutsche Forschungsgemeinschaft (Collaborative Research Center 1158 (Heidelberg Pain Consortium)).

Catholique De Louvain, Brussels, Belgium; [3]Neurophysics Group, Dept. of Neurology, Charité, Charité - Univ. Med. Berlin, Berlin, Germany; [4]Ctr. for Cognition & Decision Making, Natl. Res. Univ. Higher Sch. of Econ., Moscow, Russian Federation

Abstract: Neuroscientific research on human somatosensation has largely focused on cortical processes. However, before somatosensory stimuli reach the brain, some processing already occurs in the dorsal horn of the spinal cord. Since a detailed understanding of spinal somatosensory processing is still lacking, we carried out a study in which we non-invasively recorded somatosensory evoked potentials (SEPs) from the human spinal cord - as well as the peripheral nervous system and the brain - in order provide a comprehensive picture of human somatosensation.
In 40 healthy participants (10 measured so far) we separately stimulated the median and tibial nerve with non-painful electrical impulses and recorded the resulting SEPs from target areas in the cervical and lumbar spinal cord (as well as the peripheral nerves and the brain) with surface electrodes - 64 on the scalp and 36 electrodes organized in rectangular patches around the 6th cervical (SC6) and the 1st lumbar vertebra (L1). We aimed to extend the findings of earlier studies on spinal SEPs by making use of an adequately powered sample-size, a much higher spinal electrode density, state-of-the-art recording equipment, and artefact removal methods (e.g. addressing prominent cardiac influences).
Initial data showed clear spinal cord potentials with the expected mean amplitude and latency for both median (N13 over SC6: -1.2 μV, 13.1 ms) and tibial nerve stimulation (N22 over L1: -0.5 μV, 22.7 ms). These potentials were reproducible as evidenced by an odd-even split of the epochs in the data. We also recorded clear peripheral and cortical potentials for both types of stimulation (i) median nerve: N6 at biceps: -3.5 μV, 5.9 ms; N9 at Erb's point: -1.1 μV, 9.6 ms; N20 at primary somatosensory cortex: -1.0 μV, 18.4 ms; ii) tibial nerve: N8 at knee: -2.2 μV, 8.8 ms; P38 at primary somatosensory cortex: 1.9 μV, 41.5 ms). All reported potentials are grand averages over 10 participants.
Future analyses of the whole sample will address the spinal responses in more detail and will also investigate how the amplitude of spinal responses is related to responses in peripheral nerves and the brain. We hope that this study will provide a comprehensive understanding of somatosensory stimulus processing at all levels of the neuraxis.

Title: Placebo modulation of pain networks in the human brainstem and spinal cord investigated by means of fMRI

Authors: *P. W. STROMAN, J. M. POWERS, G. IOACHIM, H. WARREN;
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: The placebo effect is a positive cognitive modulation of behaviors, and in terms of pain refers to the experience of reduced pain as a result of expecting lower pain. This effect is important because it reveals cognitive and affective influences on human pain perception, and can confound investigations of the effectiveness of pain therapies, or contribute beneficially to pain relief. Although it is expected that descending pain regulation in the brainstem (BS) and spinal cord (SC) may play a role in the placebo effect, these neural mechanisms have rarely been studied. In the present study we used functional magnetic resonance imaging (fMRI) of the human BS/SC to investigate the neural basis of the placebo effect in studies involving noxious heat stimuli applied to the hand, with the expectation of lower pain in some trials.Twenty healthy people completed questionnaires to characterize personality traits, and participated in quantitative sensory testing, sham MRI training, and then fMRI studies. The placebo effect was investigated by informing participants 1 minute into each trial whether the “Base” temperature would be applied, which was calibrated to evoke moderate pain, or a temperature 1 °C lower would be applied (the “Placebo” temperature). The 30-second duration noxious heat stimulus was applied to the hand one minute later (at the 2-minute mark), allowing time for participants to anticipate the stimulus. After each trial (4.5 minutes total) the participants were asked to rate the peak pain intensity and unpleasantness experienced during the stimulation period. Unbeknownst to the participants, the same temperature was actually applied in each trial.Behavioral results confirmed that participants experienced lower pain when the lower temperature stimulus was expected. Pain intensity ratings (0-100 scale) decreased from an average of 49 ± 10 (mean ± sd) for the “Base” state to 43 ± 12 for the “Placebo” state ($p < 10^{-3}$, paired t-test). FMRI results were analyzed by means of structural equation modeling and demonstrated significant connectivity between SC, BS, and thalamus regions. Connections were also identified with significant correlations across participants between the change in connectivity values between states, and the change in unpleasantness ratings between states. BOLD responses and connectivity between regions were observed to depend significantly on both pain sensitivity and on the study state

(Base vs Placebo). Overall, the results demonstrate that the placebo effect is modulated by a network of regions that are known to be involved with descending pain regulation, autonomic regulation, and integration of sensory and autonomic functions.

Title: Brainstem and spinal fMRI during the expectation of pain: Exploring coordinated networks

Authors: *G. IOACHIM[1], J. M. POWERS[1], P. W. STROMAN[2];
[2]Ctr. for Neurosci Studies, [1]Queen's Univ., Kingston, ON, Canada

Abstract: Spontaneous variations in activity of brainstem (BS) and spinal cord (SC) regions may arise from a number of functions such as autonomic regulation, sensory, and motor functions. Recent evidence suggests that changes in a person's cognitive/emotional state are linked to changes in identified BS and SC resting-state networks, indicating that these networks likely play a role in the integration of homeostatic autonomic functions. Several studies have also shown that placebo and nocebo effects can involve brainstem regions, which could be of particular interest for research involving predictable painful stimuli. The aim of this study was to investigate how these BS and SC resting-state networks change when participants are specifically expecting pain. Previously, data were obtained from the cervical SC and brainstem in 17 healthy participants during a stimulation paradigm that involved a predictable noxious heat stimulus. Participants experienced both trials with (expect-pain condition) and without the heat stimulus (expect-no-pain condition), in a random order, but were informed 1 minute into each trial whether to expect heat or not. Blood oxygenation-level dependent (BOLD) fMRI data were obtained at 3 tesla, with T2-weighted single-shot fast spin-echo imaging. For the current study we investigated functional connectivity in the entire 3D region with structural equation modelling (SEM) during each run (baseline period, after participants were told whether to expect a painful stimulus, while feeling pain/no pain, and after pain). SEM results showed extensive connectivity within and across BS and SC regions both when participants were expecting pain, and when they were expecting no pain. Furthermore, significant differences in connectivity between regions of the BS and SC were also identified between the two conditions. Importantly,

a large proportion of identified connections in the expect-no-pain condition were also present in previously described resting-state BS/SC networks. In contrast, there were a number of unique connections identified in the expect-pain condition, including in the period of time when participants knew to expect pain (but had not felt the painful stimulus yet).These results indicate that connectivity across BS/SC networks is influenced by the expectation of pain in ways distinct from other cognitive tasks. The known functions of the regions involved in the connections unique to the expect-pain condition support the conclusion that the BS/SC networks identified during the expectation of pain likely serve to integrate autonomic regulation functions with pain processing.

Title: Sex-differences in brain modular organization in chronic pain

Authors: *C. FAUCHON[1], D. MEUNIER[2], K. S. HEMINGTON[1,3], J. CHENG[1,3], R. BOSMA[1,3], N. OSBORNE[1,3], A. ROGACHOV[1,3], A. KIM[1,3], R. INMAN[1,4], K. D. DAVIS[1,3,5]; [1]Krembil Res. Inst, Univ. Hlth. Network, Toronto, ON, Canada; [2]Inst. Neurosci Timone, Aix Marseille Univ., Marseille, France; [3]Inst. of Med. Science, Univ. of Toronto, Toronto, ON, Canada; [4]Dept. Of Medicine, Univ. of Toronto, Toronto, ON, Canada; [5]Dept. Surgery, Univ. of Toronto, Toronto, ON, Canada

Abstract: Objective and rationale:
Some chronic pain conditions show a sex-specific prevalence. There are also sex differences in antinociceptive brain circuitry in patients with chronic pain and in healthy individuals. Patients with chronic pain exhibit brain abnormalities of inter- and intra-network functional connectivity (FC) within the dynamic pain connectome. Brain network topology can provide further insight into these sex differences. Here, we modeled the brain as a modular network using graph analysis based on resting-state fMRI (rsfMRI) data in males and females with chronic pain.
Methods:
We acquired rsfMRI data from males (n=45) and females (n=20) with chronic low back pain (cLBP) associated with ankylosing spondylitis, and age/sex-matched healthy controls (HC). Data were preprocessed and parcellated based on the human connectome project atlas using Nipype to

create 360 anatomical regions (nodes). For each subject, timeseries data were extracted and thresholded, and FC matrices were generated by computing Pearson correlations between every node, using the neuropypcon package. The modular analyses were run on the average Z-correlation matrix for each group to segregate the brain network into modules of regions with high FC. Inter- and intra-modular connectivity and other global and nodal networks metrics were computed. Permutation tests were applied between groups.

Results:

Males with cLBP and HCs had the same modular structure with 6 modules, whereas females with cLBP had an 8 module topology. Networks common to both sexes were 1) frontoparietal, 2) occipital, 3) sensorimotor and salience, 4) parietal superior, 5) temporal and subcortical regions, and 6) ventro-medial prefrontal cortex (vmPFC). In both healthy and cLBP females groups, the frontoparietal module was split in two modules and females with cLBP had an extra module in the mid cingulate cortex (MCC). Both males and females with cLBP had more inter-modular connections and less intra-modular connections compared to HCs. These findings were more pronounced in females with cLBP who had a significant increase of connections in MCC, vmPFC, anterior insula and parietal regions and a decrease of connections in the operculo-insular region, SMA and PCC compared to HCs. In contrast, in the males with cLBP, inter-modular connectivity was greater in the subcortical, prefrontal and parietal cortices and decreased in premotor and cingulate motors regions compared to HC.

Conclusions:

Brain network organization in patients with chronic pain show sex differences. Therefore, a framework to assess the efficacy and side effects associated with pain treatment targets should consider sex differences.

Title: Age related changes in autonomic nervous response to different levels of painful stimulation

Authors: M. MIYAMAE[1], *A. NAKAE[2], K. NOMURA[2], C. KISHIMOTO[2], Y. MINEGISHI[1], R. URABE[1], K. NAKAI[1], T. YANAGIDA[2];

Abstract: Background: To prescribe an appropriate amount of analgesics is often challenging for doctors because pain is a subjective symptom. To avoid the misuse of prescription opioids, objective evaluation of pain is necessary. The autonomic nerve response to pain is useful for evaluating pain objectively, but it is a fact that autonomic nerve response is affected by age. This study aimed to clarify age-related changes in autonomic responses to painful stimulation. Methods: After receiving the approval of the ethical committee of Osaka University, we recruited 157 healthy subjects and obtained written informed consent. The subjects were divided into three groups namely; young group (20-29 years old), middle-aged group (30-59 years old), and elderly group (60- years old). After checking the sensitivity to pain using Pathway(Medoc, Israel), participants were applied 30 seconds stimulation of 36℃, 48℃ and two more temperatures between 36℃ and 48℃. During stimulation, subjects evaluated their amount of pain using CoVAS (Medoc, Israel). Using pulse oximeter, information regarding PR (Pulse Rate), PWA (Pulse Wave Amplitude), and PI (Perfusion Index) were obtained. SCR (Skin Conductance Response) data was also obtained. In analyzing these data, Tukey's HSD test was performed to find the differences between groups. Results & Discussions: Through VAS analyses, it was confirmed that stimulation temperature was appropriately set for each participant. AT 48℃ stimulation PR significantly increased among the young and middle-aged groups ($p<0.001$), but not among the elderly group.The AUC at the 48 ℃ was significantly higher among the young group than in the middle-aged and elderly groups ($p<0.014$). PWA has decreased significantly among all levels stimulation in the young group ($p<0.024$), but only at the 48 ℃ stimulation in the middle-aged and elderly groups ($p<0.034$). The AUC was significantly lower in young group compared to the middle-aged group at lower temperature that we set by between 36℃ and 48℃, and in middle-aged and elderly groups at higher temperature we set between 36℃ and 48℃ ($p<0.023$). SCR increased significantly between almost all temperatures among young group ($p<0.002$), and we couldn't find the same differences among middle-aged and elderly groups. Conclusions: Only among younger generation, autonomic response to various amounts of pain is useful for monitor pain objectively. Only strong pain may be detected by autonomic responses from middle-aged generation to elderly.

Title: An investigation of PGE2-mediated pain relief following virtual reality

Authors: C. J. RINCONES, H. RHODES, B. G. GARCIA-GONZALEZ, ***J. A. BOYETTE-DAVIS**;
St. Edward's Univ., Austin, TX

Abstract: Virtual reality (VR) has received increasing attention in neuroscience research for its potential therapeutic applications. Recent literature has investigated its use in physical therapy, surgery, therapy, and most recently physicians have been using it as a type of distraction therapy for minor painful procedures. Little has been done to investigate the mechanistic ways VR might reduce pain; however, there is a plethora of evidence to support that prostaglandins, chemicals found to increase inflammation, play a role in pain. It was postulated that VR could potentially mediate the release of these inflammatory mediators and therefore decrease pain. The current study explored the relationship between prostaglandins, specifically PGE2, and calming VR. Seventy-nine participants (average age: 20) experienced the cold pressor test (CPT), an experimentally induced painful stimulus, while simultaneously viewing a calming VR scene (7 males, 33 females). This group was compared to a control group who did not experience VR (7 males, 32 females). Time and ratings of pain were collected for both participant threshold and tolerance during the CPT. Additional data was collected regarding pain catastrophizing (PCS) and retroactive pain levels. No differences were found for pain threshold ($p = .417$), pain tolerance ($p = .403$), or PCS total scores ($p = .197$) between the two groups. However, males took significantly longer to reach pain tolerance than females ($p = .002$) indicating a higher pain tolerance. Tolerance ratings were positively correlated with PCS total scores ($r = .293$, $p = .009$), and PCS was also positively correlated to both retroactive pain ratings ($r = .223$, $p = .048$) and pain frequency ($r = .355$, $p = .001$). These results confirm previous findings regarding gender differences in pain, and add to the literature on PCS as an important mediator of pain perception. Moreover, ELISA immunoassays were used to quantify pain-induced PGE2 release. Analyses revealed that PGE2 modulates these effects. This study establishes the necessity of further exploring the parameters of VR efficacy before a wide spread implementation of VR in the clinical field and further underscores the importance of considering pain catastrophizing in investigations of therapeutic outcomes for pain.

Title: The neural basis for music analgesia in the human brain and brainstem

Authors: *J. M. POWERS, G. IOACHIM, P. W. STROMAN;
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Music has been used to treat pain for thousands of years, and its effect has been characterized in behavioural studies and with functional magnetic resonance imaging (fMRI). It is hypothesized that music exerts an analgesic effect through descending modulation within the periaqueductal gray-rostral ventromedial medulla (PAG-RVM) opioidergic pathway. The aim of this study was to investigate the neural basis of music analgesia. Specifically, we hypothesize that the amygdala and other limbic structures contribute to analgesia produced by listening to music, because of the involvement of these regions with the affective component of pain. FMRI was carried out at 3 tesla with data spanning the brain and brainstem, in order to investigate the effects of music on a network of pain-related regions. Twenty healthy participants (23 ± 3 years of age) each underwent a 1-hour stimulus training session in a sham MRI lab followed by a 1.5-hour session of repeated fMRI acquisitions. During all fMRI acquisitions, noxious stimulation was applied to the hand with an MRI-compatible robotic contact thermal heat stimulator (RTS-2, SpinalMap Inc.). Participants were instructed to bring in 6 selections of their favourite music, which they would describe as being highly pleasant, stimulating, happy, and familiar. During 6 of the fMRI runs participants listened to music, and in 6 runs there was no music; this was done in a randomized order. Behavioural results confirmed that participants experienced a significant decrease in pain unpleasantness scores from 27 ± 15 (mean ± s.d.) during the “No-Music” condition to 23 ± 14 during the “Music” condition ($p < 0.006$, paired t-test). Pain intensity was not found to be significantly different ($p < 0.14$). Structural equation modeling (SEM) demonstrated networks of brain/brainstem regions with significant connectivity and revealed differences between runs with and without music as well as across periods of the stimulation paradigm. The results indicate that music influences pain perception within a network including the amygdala, anterior cingulate cortex, PAG, hippocampus and thalamus. This work contributes to a new view of how human pain is regulated in healthy people, and aids our understanding of the continuous modulation of pain. Moreover, it provides a critical baseline of research for future studies into how pain processing is altered in chronic pain conditions.

Title: Insular and hippocampal resting state functional connectivity is associated with chronic pain duration in community dwelling older adults

Authors: *Y. CRUZ-ALMEIDA, P. VALDÉS-HERNÁNDEZ, N. EBNER, P. LYSNE, D. RAMIREZ;
Pain Res. & Intervention Ctr. of Excellence, Univ. of Florida, Gainesville, FL

Abstract: Chronic pain is common in older adults negatively impacting quality of life. Emerging evidence suggests that longer pain duration may modify brain structure in persons with chronic musculoskeletal pain, but little is known about its potential impact on brain function. We investigated such effects in chronic pain elders (60-82, M=72±6, n=38) enrolled in the Neuromodulatory Examination of Pain and Mobility Across the Lifespan (NEPAL) study with a large variability in self-reported chronic pain duration (PDUR, Mean=10±13 years, <1—56). They underwent a resting state functional MRI (fMRI) connectivity (FC) scan as a neurobiological proxy of the brain's repeated encoding of the pain experience. Whole brain 3T fMRIs were preprocessed with SPM12 and normalized with DARTEL to account for our sample's large morphometric variability. Using CONN, fMRIs signals were denoised and averaged within region-of-interest (ROIs), to calculate all-to-all ROI-to-ROI z-transformed correlations (FCs). ROIs were defined from the atlases Brainnetome (A246), AAL116 and 32 empirical resting state network (RSN) nodes. GLM was fitted for each FC as dependent variable, PDUR as independent variable of interest and age, sex as nuisance regressors. PDUR and age were not correlated (r=0.20, p=0.100), justifying age as a covariate. Significance of PDUR effect was evaluated with a T-contrast thresholded using False Discovery Rate $q<0.05$ (FDR) across 77,000 connections. Results indicated that FC between the left dorsal dysgranular insula and the left caudal hippocampus (cHipp-L) positively correlated with PDUR ($p_{FDR}<0.03$). To loosen the conservative threshold criterion that such amount of connections yields, we excluded atlas246 resulting in 10,000 connections. This time, PDUR positively correlated with FC between left hippocampus and "salience" RSN frontal-lateral node, $p_{FDR}<0.02$ (left) and $p_{FDR}<0.03$ (right). These nodes mostly contain the frontal operculum, the dorsal agranular insula and the opercular inferior frontal gyrus, related to pain somesthesis/monitoring/discrimination. In general, the salience network is involved in detecting salient stimuli and self-awareness through sensory/emotional/cognitive integration, while the hippocampus is crucial for memory. Thus, enduring pain across the lifespan may gradually shape the way cognition and pain perception interact with memory systems to eventually imprint its chronic effects on human behavior.

Title: Reduced tactile acuity in chronic low back pain is linked with structural neuroplasticity in primary somatosensory cortex and is modulated by acupuncture therapy

Authors: H. KIM[1], I. MAWLA[2], J. LEE[2], J. GERBER[2], K. WALKER[2], J. KIM[1], A. WASAN[3], R. R. EDWARDS[4], J. KONG[2], T. KAPTCHUK[5], R. GOLLUB[2], B. R. ROSEN[2], ***V. NAPADOW**[2];
[1]KIOM, Daejeon, Korea, Republic of; [2]Massachusetts Gen. Hosp., Boston, MA; [3]Univ. of Pittsburgh, Pittsburgh, PA; [4]Brigham and Women's Hosp., Boston, MA; [5]Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Patients suffering from chronic Low Back Pain (cLBP) show impaired somatosensory processing and reduced tactile acuity, i.e.reduced ability to resolve fine spatial details with the perception of touch. The mechanism(s) underlying this reduced tactile acuity are unknown but may include changes in peripheral mechanoreceptors or central circuits (e.g. neuroplasticity in primary somatosensory cortex, S1). Further, little is known about the linkage between changes in tactile acuity and amelioration of cLBP by somatically-directed therapeutic interventions, such as acupuncture. In this longitudinal neuroimaging study, we evaluated healthy control (HC, N=50) adults and cLBP patients (N=102) with structural brain imaging (T1 for Voxel Based Morphometry, VBM; Diffusion Tensor Imaging, DTI) and tactile acuity testing using two-point discrimination threshold (2PDT) over the lower back (site of pain) and finger (control) locations. Patients were evaluated at baseline and following a 4-week course of acupuncture, with patients randomized to either verum (genuine) acupuncture, sham acupuncture (with or without somatosensory afference), or no-intervention usual care control. Compared to HC, cLBP patients demonstrated reduced acuity (greater 2PDT, p=0.01) over the low back, but not on the finger (p=0.29), suggesting that chronic pain affects tactile acuity specifically at body regions encoding the experience of clinical pain. Gray matter volume in the S1-back representation region was elevated in cLBP and correlated with greater 2PDT-back scores (r=0.27, p=0.02). DTI

assessment of Fractional Anisotropy (FA) in S1-adjacent white matter revealed that, compared to HC, cLBP patients demonstrate reduced FA in S1-back regions (p=0.01). Following verum acupuncture therapy, tactile acuity over the back was improved (reduced 2PDT) and greater improvements were associated with reduced S1-back gray matter volume (r=0.52, p=0.03) and increased S1-back adjacent white matter FA (r=-0.56, p=0.01). These changes and associations were not seen for non-verum control interventions. While low back pain reduction was greater following verum compared to control interventions (repeated measures ANOVA, Group x Time interaction on LBP bothersomeness, F[1,67]=3.99, P=0.0498), neuroanatomical and tactile acuity changes were not linked with clinical outcomes after 4-weeks of therapy. Thus, S1 neuroplasticity in cLBP may represent early mechanistic changes in somatosensory processing that are linked with improved tactile acuity and predict longer-term improvements in clinical pain severity following successful therapy.

Title: Developed implantable needle-type sensor devices for use in the simultaneous *in vivo* visualization of brain centers involved in nociception

Authors: *R. B. REBUSI, Jr[1], M. C. GUINTO[1], J. OLOROCISIMO[2], Y. OHTA[1], M. HARUTA[1], K. SASAGAWA[1], J. OHTA[1];
[1]Material Sci., [2]Biol. Sci., Nara Inst. of Sci. and Technol., Ikoma, Japan

Abstract: The lateral capsular subdivision of the central nucleus of the amygdala (CeLC), known as its nociceptive center, receives and relays nociceptive signals and is responsible for the sensation and emotional response to pain. This amygdalar region receives serotonergic input from a portion of the dorsal raphe nucleus of the midbrain (DRN) which secretes Substance P, a neuropeptide important for pain perception. It is currently uncertain as to what role the DRN has in nociception and its processing in relation to its downstream amygdalar counterparts.
In this study, we aim to elucidate the direct nociception neural pathway bridging the DRN to the CeLC by the use of implantable needle-type devices developed by our laboratory. This device is composed of a CMOS-based image sensor chip embedded on a flexible substrate with a μ-LED light source. It has a width of 0.7 mm, a thickness of 0.2 mm, and an insertable length of 3 mm. These dimensions allow for minimally injurious implantations, even simultaneous ones, that only

affects brain regions by the implantation path and target. The use of a CMOS-based image sensor gives useful visual data, even if limited. All of these allows for high output *in vivo* studies not limited by a weight burden or extensive injury.
For the methodology, two devices are to be simultaneously implanted adjacent to the CeLC and the DRN of GCaMP6 mice. These transgenic mice have neurons that express Ca^{2+}-calmodulin-binding GFP constructs that will fluoresce with appropriate light stimulation during neuronal actional potentials. The implantation method for these two nuclei has been refined with the proper sterotaxic coordinates and implantation paths finalized. Complications arising from straightforward implantation methods, such as overlying blood vessels and ventricles, have been addressed with the use of angled implantations and stricter animal maintenance. Bi-phasic pain induction will be via the subcutaneous injection of 2% formaldehyde in the upper arm, opposite to the implanted brain hemisphere. Nociception will be confirmed by the devices recording neuronal activity and the observation of animal behavior.
We have already acquired separate recordings of the target brain regions in mice that underwent the formalin test and the results have shown neuronal activity in both regions concurrent with pain perception, as interpreted from behavioral observations. The next steps are to confirm the reproducibility of the separate recordings, and then to apply the optimized methodologies on double implantations to procure simultaneous nociception-linked neural recordings.

Title: Dynamic reconfiguration of functional brain network during sustained pain

Authors: *J.-J. LEE, C.-W. WOO;
Ctr. for Neurosci. Imaging Res., Sungkyunkwan Univ., Suwon-si, Korea, Republic of

Abstract: Pain is not just a simple reflex to nociceptive input, but it is rather constructed through complex interactions among multiple brain systems over time. However, it remains poorly understood how the patterns of brain activity and connectivity dynamically change over the period of experiencing sustained pain. Here, we used functional magnetic resonance imaging to investigate the dynamic changes in functional brain network architecture during 20 minutes of experiencing capsaicin-induced tonic pain in 48 participants. The network-level analysis results showed that the network transitivity and assortativity were significantly decreased in the tonic pain condition compared to the control condition ($p < .05$ for both), whereas the characteristic path, global efficiency, and network-level modularity were not changed ($p = .09$, .10, and .57). When we examined the temporal dynamics in these network attributes from the initiation to the remission of pain, the assortativity, modularity, and global efficiency increased over time, while transitivity and characteristic path decreased. Furthermore, we developed machine-learning models designed to track the changes in pain ratings within each individual based on some node-level network measures, including eigenvector centrality. These models showed the high levels of predictive performance (average $r = 0.66$), providing a promising network-based neuroimaging biomarker for tonic pain. The brain regions with high positive predictive weights included primary somatosensory cortex, dorsal anterior cingulate cortex, dorsomedial and dorsolateral prefrontal cortex, right dorsoparietal insula, and right inferior parietal lobule. We further characterized the mesoscale network dynamics over the time-course of the experimental tonic pain using a temporal community detection method. This study provides a new insight into how dynamic interactions among multiple brain systems construct and process pain experience over time, which could potentially advance our mechanistic understanding of sustained (e.g., chronic) pain.

Title: Imaging pain modulation from cortex to spinal cord

Authors: *V. OLIVA[1], A. WILSON[2], R. HARTLEY-DAVIES[2], R. MORAN[3], A. E. PICKERING[1], J. BROOKS[2];
[1]Univ. of Bristol, Bristol, United Kingdom; [2]Clin. Res. Imaging Centre, Univ. of Bristol, Bristol, United Kingdom; [3]King's Col. London, London, United Kingdom

Abstract: Distraction from pain is a robust strategy to transiently decrease pain perception. Previous studies have shown this process to involve pain modulatory nuclei in the brainstem (Brooks et al, J Neurosci 2017) and the spinal cord (Sprenger et al., Curr Biol 2012) but this has never been achieved with supratentorial structures to define the actions of the entire descending pain modulatory system.
The challenges of imaging spinal cord are numerous: tissue heterogeneity adjacent to the cord causes spatial fluctuations in the magnetic field, cardiac and respiratory processes cause physiological noise and movement in the cord which is complicated by the challenge of obtaining a sufficiently uniform magnetic field over the large field of view. Using approaches similar to those adopted by Islam et al. (Magn Reson Med, 2019) and Finsterbusch et al. (Neuroimage, 2013) we sought to simultaneously obtain fMRI data from brain, brainstem and spinal cord during an attentional analgesia paradigm.
We recruited 22 healthy volunteers who received thermal stimuli on their left forearm (C6 dermatome) at two temperatures (painful/warm), whilst simultaneously performing a rapid serial visual presentation task with two levels of difficulty (Brooks et al 2017).
Whole CNS functional images were acquired with a 3T Siemens Skyra MRI scanner and slice specific z-shim offsets, which were chosen for the spinal cord and low medulla, and had an in-plane resolution of 1.77mm and 4mm slice thickness. In addition, we recorded cardiac and respiratory waveforms during imaging to regress physiological noise from functional data. Imaging data were pre-processed as per Brooks et al. (2017) and analysed in FEAT (FSL). A group analysis for brain was performed in FEAT and for brainstem in RANDOMISE.
A main effect of temperature contrast showed brain activation in pain related areas (e.g. insular cortex, $Z > 2.3$, cluster corrected $p < .05$). In the brainstem we found activation in the RVM (TFCE corrected, $p < .05$). In the spinal cord we observed activity in the C6 segment of the spinal cord ($Z > 2.3$, uncorrected, n=13).
The use of a large field of view in the z-direction poses challenges for image acquisition, but it allows us to build a complete map of pain perception and its cognitive modulation: from spinal cord detection of a nociceptive stimulus, through brainstem relays modulating its intensity, to the cortical/cognitive representation of pain in higher brain regions.

Title: A role for predictive coding in pain perception?

Authors: *U. HORN, F. EIPPERT;
Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Pain is a useful and important warning signal of impending or actual tissue damage, but knowledge of the factors that determine how the experience of pain derives from nociceptive input is still rather coarse. Here we used the framework of predictive coding in order to ask whether the experience of pain might be best characterized not just as passively arising from nociceptive stimulation, but as an active inferential process, in which the central nervous system constantly generates predictions about the sensory inputs it receives and adjusts these predictions in light of new sensory input. We acquired data from 40 healthy participants (6 obtained so far) using a probabilistic heat-pain paradigm that allows for i) varying predictive information and nociceptive input across trials, ii) a temporal dissociation of prediction and prediction error signals and iii) a characterization of prediction and prediction error influences on the subjective perception of pain. In each participant, we recorded trial-wise cue- and outcome-induced skin conductance, pupil dilation, and cardiac responses as well as ratings of perceived pain on a VAS (converted to values from 0 to 100). An analysis of the first 6 participants' (skin conductance, pupil dilation, rating) data revealed that cue-based physiological responses before the onset of heat-stimulation followed the predicted probability of receiving pain. Outcome-based responses showed that painful heat resulted in larger responses than non-painful heat (averaged standardized logarithmic skin conductance amplitudes following stimulation: 0.42 and 0.15, averaged standardized logarithmic pupil dilation amplitudes: 0.26 and 0.19 (a.u.)) consistent with average pain ratings of 73.8 and 19.5. Due to the small sample size, we were not able to reliably quantify prediction error signals in the data - this issue will be revisited with the full sample. In the future, we will i) extend these analyses to the whole sample of participants, ii) use a model-based approach in order to distinguish between different explanatory models (e.g. an intensity coding model vs different predictive coding models), and iii) use this paradigm in combination with functional magnetic resonance imaging (fMRI) of spinal cord responses. Together, this should allow us to ascertain whether predictive signals significantly contribute to the various components of pain processing - from the level of dorsal horn responses to subjective perception.

Abstract: The patient-clinician relationship can powerfully shape pain and placebo response, but the brain mechanisms are unknown. We simultaneously recorded functional MRI (i.e. hyperscanning) in patient-clinician dyads, who interacted via on-line video, while clinicians (acupuncturists) treated evoked pain in patients (fibromyalgia). We hypothesized that placebo analgesia and non-verbal communication would be supported by concordant fMRI response in ventrolateral Prefrontal Cortex (vlPFC), anterior Insula (aINS), and Temporoparietal Junction (TPJ), which are implicated in social mirroring, empathy, and theory-of-mind. Each patient was matched with a clinician (n=37 dyads). Each dyad was unique and scanned under one of two conditions: 1) after having established therapeutic alliance through a clinical intake by the clinician (Social interaction, n=19), or 2) no such intake (No interaction control, n=18). During block-design fMRI, patients received 12 moderately painful cuff pressures to the left leg while the clinician applied (real sub-sensory threshold microcurrent / sham, double-blind) electro-acupuncture stimulation (EA) to reduce cuff pain. Facial expression was assessed via Affectiva software. While cuff pressure was identical for all stimuli, patients' pain was significantly decreased during both real ($p=0.01$) and sham ($p=0.01$) EA treatment compared to overt no-treatment. Correspondingly, clinicians rated vicarious pain as decreased with treatment (real/sham combined), relative to no-treatment ($p<0.0001$). Therapeutic alliance was higher for Social interaction relative to No interaction control ($p<0.0001$). Further, higher facial mirroring was associated with higher therapeutic alliance and stronger placebo analgesia ($r=-0.52$, $p=0.03$). A conjunction analysis of patients' and clinicians' brain response during anticipation of pain/treatment demonstrated consistent activation of vlPFC, aINS, and TPJ. Furthermore, patients' right TPJ activity showed higher dynamic (trial-to-trial) concordance with clinicians' social mirroring circuitry (vlPFC, aINS, TPJ) for Social Interaction relative to No-Interaction dyads. Finally, placebo-related increase in vlPFC activity during evoked pain (Treat-NoTreat) mediated the relationship between patient-clinician concordance in right TPJ during anticipation and placebo analgesia (Total effect (a*b): -1.799**, $p=0.006$). TPJ is a key node in social mirroring and theory-of-mind processing, and brain-to-brain coupling of TPJ activity between interacting patients and clinicians may support therapeutic alliance and psychosocially facilitated analgesia.

Title: Spinal and cerebral integration of bilateral nociceptive inputs in left-handed individuals

Authors: *S. NORTHON, N. RUSTAMOV, M. PICHE;
Dept. of Anat., Univ. Du Quebec A Trois-Rivieres, Trois-Rivières, QC, Canada

Abstract: It has been suggested that some pain-related information is processed preferentially in the right cerebral hemisphere. Considering that functional lateralization can be affected by handedness, spinal and cerebral pain-related responses may be different between right- and left-handed individuals. This has critical implications for brain imaging and neuromodulation studies on pain and pain modulation mechanisms. A recent study in right-handed individuals showed that the spinal nociceptive flexion reflex (RIII-reflex) and pain-related gamma oscillations in prefrontal, cingulate and sensorimotor regions are increased by concurrent nociceptive inputs from the contralateral limb. Moreover, this study indicates that RIII-reflex facilitation is due to descending motor pathways. The objective of the present study was to examine whether these processes are affected by handedness. The RIII-reflex as well as pain-related evoked potentials (ERP) and spectral perturbations (ERSP) were compared between ten right-handed (5F, age: 24.4 ± 3.5) and ten left-handed (6F, age: 24.4 ± 6.8) participants. The RIII-reflex, ERP, ERSP and pain perception were induced by painful transcutaneous electrical stimulation of the sural nerves and left hypothenar area. Stimulation intensity was adjusted individually at 120% of RIII-reflex threshold for the lower limbs and 120% of pain threshold for the left hypothenar area, in five conditions of 21 stimuli each: three unilateral conditions (right and left sural nerve and left hypothenar area) and two bilateral conditions (both sural nerves; right sural nerve with left hypothenar area). The amplitude of the RIII-reflex, ERP, ERSP as well as pain ratings were compared between groups and conditions using a mixed ANOVA. A significant difference was observed between conditions (main effect of condition) for RIII-reflex amplitude ($p<0.001$), the N100 ($p<0.001$), theta oscillations ($p<0.001$) and gamma oscillations ($p=0.005$). Planned comparisons revealed that these responses were increased in bilateral compared with unilateral conditions. However, these effects were not significantly different between right- and left-handed individuals. These results suggest that spinal and cerebral integration of bilateral nociceptive inputs is similar between right- and left-handed individuals. They also imply that

pain responses measured in this study may be examined independently of handedness. However, it remains to be clarified whether cortical sources of pain responses are lateralized differently between right- and left-handed individuals.

Abstract: Characterizing a reliable neural signature of pain is critical for translational applications. Many prior fMRI studies have examined circuits recruited by induced pain in healthy participants. However, synthesizing these data to identify convergent patterns of pain-related brain activation can be challenging due to the heterogeneity of experimental designs and samples. Here, we address this challenge by conducting a comprehensive meta-analysis of fMRI studies of induced pain in healthy participants. Following pre-registration, two independent reviewers evaluated 4,927 abstracts returned from a broad search of 8 databases, with 222 fMRI experiments meeting inclusion criteria. We analyzed these experiments using Activation Likelihood Estimation with rigorous type I error control (voxel height $p<0.001$, cluster FWE $p<0.05$). Our results reveal a convergent pattern of pain-related activation in the secondary somatosensory cortex, anterior and posterior insula, anterior cingulate cortex, and thalamus. Notably, this network was consistently recruited despite variation in experimental design and sample composition, including stimulation technique, location of pain induction, and participant

sex. Taken together, these findings suggest that pain induction in healthy volunteers consistently recruits a core brain network, encouraging translational applications in drug development and clinical trials using fMRI.

Title: Experiences of discrimination are differentially associated with pain-related brain structure in male and female individuals from different race groups with or at risk for knee osteoarthritis

Authors: *E. L. TERRY[1], J. J. TANNER[1], J. S. CARDOSO[1], K. T. SIBILLE[1], S. LAI[1], H. DESHPANDE[2], G. DEUTSCH[2], B. R. GOODIN[2], L. A. BRADLEY[2], C. C. PRICE[2], R. B. FILLINGIM[1];
[1]Univ. of Florida, Gainesville, FL; [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Non-Hispanic Black (NHB) individuals report higher rates of discrimination compared to their non-Hispanic White (NHW) counterparts. Further, NHB males report the highest rates of discrimination. Exposure to discrimination that is perceived as stressful might result in dysregulation of biopsychosocial and physiological processes and contribute to poorer pain-related outcomes in NHBs. Functional neuroimaging studies of discrimination and psychosocial stress suggest higher perceived discrimination associates with anterior cingulate cortex (ACC) activity and functional connectivity between the amygdala and pain-related cortical regions (e.g., insula, prefrontal cortex). The associations between brain structure and experiences of discrimination, however, remain largely unexplored. Moreover, no neuroimaging studies have investigated relationships between experiences of discrimination and pain-related brain region structure by ethnicity and sex. The current project is a sub-study of an ongoing

multi-site (University of Florida and University of Alabama at Birmingham) observational cohort investigation. Participants were 143 older adults with knee pain, including 27 NHB males, 23 NHW males, 41 NHB females, and 52 NHW females. All participants completed the Experiences of Discrimination questionnaire and Magnetic Resonance Imaging (MRI). High resolution three dimensional (3D) T1-weighted images were processed using FreeSurfer 6.0. Pre-selected cortical thickness (insula, ACC, primary somatosensory (S1), dorsolateral prefrontal (DLPFC), and medial prefrontal (MPFC) cortex) and volumes (amygdala, thalamus, hippocampus) were exported to SPSS for analyses. Partial correlation analyses were stratified by race and sex and adjusted for age, education, body mass index, study site, and pain intensity. Results revealed higher experiences of discrimination were associated with thicker S1 ($r = .55$, $p = .01$), DLPFC ($r = .48$, $p = .02$), insula ($r = .41$, $p = .06$), and rostral ACC ($r = .35$, $p = .11$) in NHB males, while higher experiences of discrimination were associated with thinner insula ($r = -.55$, $p = .02$), S1 ($r = -.47$, $p = .05$), MPFC ($r = -.62$, $p = .01$), and caudal ACC ($r = -.42$, $p = .08$) in NHW males. In NHB females, higher experiences of discrimination were associated with smaller amygdala ($r = -.39$, $p = .02$) and thicker DLPFC ($r = .33$, $p = .05$), while higher experiences of discrimination were associated with thicker caudal ACC ($r = .27$, $p = .07$) in NHW females. These results suggest experiences of discrimination might affect different structural brain components based on both race/ethnicity and sex in individuals with or at risk for knee osteoarthritis.

Title: Differences in the association of neuropathic pain with S1 and caudal ACC thickness in individuals from different ethnic/race groups with or at risk for knee osteoarthritis

Authors: *J. CARDOSO[1], J. TANNER[2], E. L. TERRY[1], K. T. SIBILLE[3], S. LAI[4], H. DESHPANDE[5], G. DEUTSCH[5], B. R. GOODIN[6], L. A. BRADLEY[7], C. PRICE[2], R. B. FILLINGIM[1];

Imaging and Therapeut., [6]Dept. of Psychology, [7]Div. of Clin. Immunol. & Rheumatology, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Research provides extensive evidence that neuropathic pain leads to reorganization of the somatosensory cortex. Moreover, non-Hispanic Blacks (NHB) with chronic pain experience greater pain intensity and disability compared to their Non-Hispanic White (NHW) counterparts. Despite this, limited research has examined racial and ethnic differences in neuropathic pain and its association with brain structures previously shown to be relevant to various chronic pain conditions. The current project is a sub-study of an ongoing prospective study being conducted at the University of Florida and the University of Alabama at Birmingham. The study recruited community-dwelling adults with chronic knee pain, between the ages of 45 and 85 years. Sixty seven participants self-identified as NHB and 74 as NHW. High-resolution anatomical MRI (T1-weighted MP-RAGE, $1mm^3$ resolution) data were acquired at both sites on a 3 Tesla Philips Achieva. Images were processed using FreeSurfer 6.0 (Fischl, 2012). All subjects completed the PainDETECT questionnaire to assess neuropathic pain features. Grey matter volumes and thickness for pre-selected brain structures (i.e. ACC, S1, amygdala) were exported to SAS software, version 9.4 (SAS Institute Inc., Cary, NC) for analysis. Partial correlations and analysis of covariance were performed to assess the relationship between grey matter and neuropathic pain. For the ANCOVA portion of the analysis, groups of varying levels of neuropathic pain were set according to past publications. Analyses were stratified by ethnicity/race and all models were adjusted for: age, sex, body mass index, income, study site, pain catastrophizing, clinical pain intensity, and cognitive function. For NHBs, analysis revealed an association between having more neuropathic pain features and greater cortical thickness in S1 ($r=.35$, $p < .01$ and $F=3.8$, $p <0.5$). For NHWs, more neuropathic pain features were marginally associated with greater cortical thickness in the caudal ACC ($r= 0.2$, $p < 0.11$ and $F=2.86$, $p=0.06$). Taken together, our study suggests that there are ethnic/race differences in the associations between neuropathic pain symptoms and cortical thickness in pain-related brain sites.

Title: Effects of common anesthetic regimens on sigma-1 receptor PET imaging

Authors: S. T. REYES[1], A. ROMERO[1], B. VAN DER WILDT[1], J. CASTILLO[1], C. R. MCCURDY[3], S. BISWAL[1], C. PACHARINSAK[2], J. DEMARTINI[1], ***F. T. CHIN**[1]; [1]Radiology, [2]Comparative Med., Stanford Univ. Sch. of Med., Stanford, CA; [3]Medicinal Chem., Univ. of Florida, Gainesville, FL

Abstract: Background: Sigma-1 receptors (S1Rs) are a unique class of receptors that have been linked to a variety of neurological conditions such as obsessive-compulsive disorder, addiction, and pain. We previously reported a correlation of increased S1R expression at sites of neuropathic pain utilizing positron emission tomography (PET) imaging using ^{18}F-FTC-146, a S1R antagonist. The versatility of applications for ^{18}F-FTC-146 across species brought forth a range of anesthetic drugs that can be used for non-human species and questioned how these drugs may affect S1R binding. In this pilot study, we studied mice under different commonly used anesthetic cocktails (AC) to evaluate how ^{18}F-FTC-146 PET may be affected.
Methods: 6-Week-old wild type mice were anesthetized with the following ACs (N=4/group) and subsequent 60-min dynamic PET scan after tracer injection (106 ± 29 µCi): 1) Isoflurane (IF) induction at 5% and maintenance at 1.5% 2) intraperitoneal injection (IP) of Ketamine (90 mg/kg) and Dexmedetomidine (1.8 mg/kg) 3) IF induction 5%, maintenance 1% with IP of Midazolam (5 mg/kg), Xylazine (10 mg/kg) and Ketamine (100 mg/kg) 4) Induction with IF 5% maintenance 2% to place catheters, turn off IF and maintain with 5% Guaifenesin (loading dose 1 ml/kg then 2 mL/kg/h CRI) and Propofol (150 mg/kg/h CRI) with oxygen mask. Mice were perfused post-scan and harvested organs were counted for biodistribution analysis. Standard uptake values (SUV) for whole brain were calculated using Pmod3.7.
Results & Discussion: Image analysis of whole brain showed AC 1, 2, and 3 gave average SUV curve peaks from 3.16-3.55 in brain and mice given AC 1 and 2 exhibited no difference in washout rate. Since Ketamine is a known S1R antagonist, it was interesting to find that it had no effect on ^{18}F-FTC-146 uptake when compared to mice given IF only. AC 3 afforded more rapid washout in the brain prompting follow-up studies to examine whether the presence of xylazine or midazolam contributes to this phenomenon. Additionally, mice given AC 3 showed 5-fold higher bone uptake of injected dose indicating possible metabolic effect promoting radiodefluorination of ^{18}F-FTC-146. AC 4 showed an average peak on the SUV curve of 2.39 and demonstrated a

shallow slope to indicate slow washout. One-way ANOVA test showed that when comparing the 30-40 min timeframe for each AC to IF, AC 2 and 4 were not significantly different unlike AC 3. In order to assess IF as a control anesthesia for ^{18}F-FTC-146, follow-up studies with varying IF mass doses will be performed.
Conclusion: In this study, we found that AC 3 used in rodents and horses does significantly decrease ^{18}F-FTC-146 binding with the S1R and would affect the PET imaging data.

Title: Performance based traits and their reorganization in chronic pain

Authors: *D. RECKZIEGEL, R. JABAKHANJI, B. YIP, T. J. SCHNITZER, A. APKARIAN; Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Heterogeneity of patients, even within a specific chronic pain condition, is a commonly accepted clinical concept. Identifying measurable phenotypic characteristics of patients that are most predictive of individual variability in treatment outcomes remains a challenge in the field of chronic pain, largely due to the lack of standardization, and long duration of assessments. The recently developed NIH Toolbox is a comprehensive set of neuro-behavior tools allowing quick assessment of multiple areas of neurological functioning. It was validated based on a nationally representative sample, enabling comparison of individual outcomes to age-, sex- and education-adjusted normative data. Here we used the toolbox to characterize neuro-behavior traits in healthy and chronic back pain individuals (CBP). We hypothesize that measures can be divided into meaningful principal domains (traits), some of which are reorganized with chronic pain, and others may be predictors of treatment outcomes. Data included in the analyses were from N=1047 individuals: N=994 were from a publicly available dataset of healthy subjects, N=53 were from individuals with CBP (ongoing clinical trial). Participants were tested in a range of abilities (NIH Toolbox): 6 cognitive (assessing episodic memory, attention, working memory, language, executive function, and processing speed), 17 emotional (regarding negative affect, well-being, and social relations.), 5 motor

(including dexterity, strength, balance, endurance, and locomotion), 1 odor, and 2 taste. We first analyzed the scores of N=994 individuals in all 31 items using factor analysis. Next, we analyzed demographic-adjusted standardized T-scores from each latent variable in CBP relative to normative data, and tested for associations between traits and pain.
We find that the battery measurements can be divided into five meaningful principle domains: positive emotion, cognition, negative emotion, motor and taste. CBP participants displayed means that were one or more standard deviation below that of the normative data in three of these domains: cognition, motor, and taste, but not emotion. Taste, and especially perceived bitter taste intensity, was associated with pain severity (Pearson's $r = 0.45$, $p < 0.01$).
We demonstrate five performance-based traits, with three being disrupted in chronic pain. Importantly, both negative and positive emotion traits remain unperturbed. These findings are surprising as we would expect both coping and suffering to impact emotional traits. Whether the identified traits are predictive of treatment outcomes remains to be tested.

Title: Neural correlates of perceptual echoes in marmoset primary visual cortex

Authors: *J. SCHWENK[1,2], E. ZAVITZ[3], R. VANRULLEN[4], N. S. PRICE[3], F. BREMMER[1,2]; [1]Neurophysics Dept., Univ. of Marburg, Marburg, Germany; [2]Ctr. for Mind, Brain and Behavior, Universities of Marburg and Gießen, Germany; [3]Physiology, Monash Univ., Clayton, Australia; [4]CNRS, CerCo, Toulouse, France

Abstract: Recently it has been demonstrated that the steady-state response to random luminance input is dominated by a large oscillatory component at late temporal lags, the perceptual echo (VanRullen & MacDonald, 2012). This component has been studied in detail in humans using EEG recordings, and shown to predict perceptual performance over time. It has been proposed that the oscillations originate in V1, travelling in waves across the cortex as a mechanism to coordinate temporal and spatial processing (rhythmic sampling) (Lozano-Soldevilla & VanRullen, 2019). However, the direct neural correlates of the echo response have not been

identified so far.
Here, we aimed to investigate the perceptual echo response in areas V1 and V2 of the common marmoset (Callithrix jacchus). Extracellular recordings were performed so far in one adult monkey under anesthesia (sufentanil + nitrous oxide), while the animal was stimulated with random luminance sequences of 10 s duration. Signals were recorded from 96-channel arrays positioned on the border between V1 and V2, either in the left or the right hemisphere. Position and extent of the stimulation patch were chosen to match the summed receptive field covered by all units in the array.
The presented sequences were cross-correlated with the LFP to obtain the field impulse response function (IRF) at each electrode. The preliminary results reveal a brief oscillatory component in the IRF starting after the large initial response (~50 ms). This component was in the theta range (5 Hz), and exhibited phase propagation across the array, consistent with the behavior of a travelling wave. Correlation of the stimulus sequences and spike trains shows a similar oscillatory component in the response of a subset of neurons. The oscillations in LFP and single-unit IRFs were tightly linked at individual electrode locations.
With these findings we present first evidence at a cortical level of late oscillatory components in the visual impulse response function. The observed properties of the oscillations suggest that they represent a mechanism similar to the perceptual echoes previously described in the EEG. Thus, our results provide an important first step to understanding the neural basis of this phenomenon.

Title: Action potentials representing visual motion direction are phase-locked to the LFP in area MT in anaesthetised marmosets

Authors: *B. H. OAKLEY[1,3], E. ZAVITZ[1,3], M. A. HAGAN[1,3], Y. T. WONG[1,2], N. S. C. PRICE[1,3];
[1]Dept. of Physiol., Monash Univ., Melbourne, Australia; [2]Dept. of Electrical and Computer Systems Engin., Monash Univ., Clayton, Australia; [3]ARC Ctr. of Excellence for Integrative Brain Function, Monash Univ. Node, Clayton, Australia

Abstract: Visual perception relies on communication between distinct cortical areas, each of which serves a distinct role in visual processing. This communication depends primarily on action potentials or "spikes", but the role of the local field potential (LFP) in influencing or co-ordinating this spiking remains unclear. In awake primate area V1, action potentials are phase-locked to the LFP and orientation selectivity is modulated by the phase of the gamma-band oscillations. This is consistent with the theory that communicating areas may rely on transient increases in coherence between these oscillations, to ensure the propagation of signals from one area to another. In this paradigm, the sending area entrains the oscillatory activity in the receiver, such that information arrives during the receiving area's excitatory period. In awake macaques, attention has been shown to determine which of two visually stimulated V1 populations entrains a downstream area, though it is not known whether this entrainment occurs in the absence of attentional modulation. Here, we test this by recording simultaneously from neurons in two connected visual areas, V1 and MT, in four sufentanil-anaesthetised marmosets. We implanted a 96-channel Utah array in V1, followed by a 32-channel laminar array in MT, ensuring we were recording from overlapping receptive fields. As previously seen in V1, we found that MT spiking is phase-locked to the LFP, and the spikes occurring in the spike-preferred phase contain more information about the direction of motion of the presented stimulus. This phase-dependence persists even when controlling for spike-count differences between phases by using phase-bins with varying widths, to ensure any increases in tuning strength are not due to higher numbers of spikes. Surprisingly, this phase-locking is in the alpha/beta bands, rather than gamma as previously shown. However, we also observe increases in gamma-band power during stimulus presentation, as well as increases in local spike-field coherence in the gamma-band LFP. These results suggest phase-locked stimulus information is present even in the absence of attentional modulation, and therefore represents a fundamental characteristic of inter-area communication.

Title: Cortical electrocorticogram (ECoG) has high information content

Authors: *S. KANTH, S. RAY;
Indian Inst. of Sci., Bangalore, India

Abstract: Neural activity in the brain can be recorded at several levels of resolution by using different electrodes. Microelectrode arrays record spiking activity of nearby neurons as well as provide a signal called local field potentials (LFP) that is thought to index population synaptic activity. Though arrays are quite invasive, these signals have good spatial resolution. On the other hand, electroencephalography (EEG) records activity at the scalp and is non-invasive, but has low spatial resolution and poor signal-to-noise ratio. Between these extremes lies the electrocorticogram (ECoG), which uses subdural disc electrodes placed on the cortical surface. ECoG is less invasive than intracranial electrodes but has better resolution than EEG and has been used to localize epileptic seizures. These electrophysiological signals have also been used in Brain Machine Interfaces (BMIs). Knowing which of them is the most informative can help make better choices for BMI implants. However, a fair comparison of these signals has been difficult due to variations in recording set ups, tasks, species etc. To address this issue, we designed a custom array that had both ECoG (3x3 array, 2.3 mm diameter separated by 1 cm, AdTech Inc) and microelectrodes (9x9 array, 400-micron separation, Blackrock Microsystems), allowing simultaneous recording of spikes, LFP and ECoG. We recorded signals from the primary visual cortex (V1) of 2 macaques. On some sessions, we also recorded simultaneous EEG. To ensure that the results were not biased towards any one type of signal based on receptive field size or other properties, we presented a large set of full screen natural images (5 categories, 16 images in each) and their grayscale and scrambled versions, while the monkey fixated at the center. This mimics a “natural” situation of decoding the external world using popular electrode arrays of different types. For performing the comparison, we used both information theoretic and decoding approaches. Surprisingly, we found that ECoG signals were the most informative, outperforming LFP and spikes in decoding image identity, and vastly superior to EEG. For all signals, gamma frequencies (30-80 Hz) had high information, and other frequencies supplied non-redundant information. Using more electrodes led to increased accuracy, as did using spikes and LFP together. Combining a few ECoGs had better accuracy than combining LFP and spikes from a much larger number of electrodes. High ECoG performance was due to the responses having more variability across images, as measured by signal coefficient of variance. These results have strong implications for BMIs, where ECoGs are finding increased application.

Title: Evidence for interaction between steady-state visually evoked potential tags at nearby flicker frequencies

Authors: *S. SALELKAR, S. RAY;
Indian Inst. of Sci., Bengaluru, India

Abstract: The steady-state visually evoked potential (SSVEP) is an oscillatory response to periodic visual stimulation, detectable in the electroencephalogram (EEG) recorded over the posterior scalp. Due to its high signal-to-noise ratio, relative immunity to artifacts and modulation by cognitive processes, the SSVEP has been the workhorse in frequency tagging studies, which involve the simultaneous presentation of two temporally modulated stimuli. In visual attention studies using frequency tagging, it has been seen that paying attention to one stimulus increases the SSVEP amplitude at the tagging frequency of that stimulus and simultaneously decreases the SSVEP amplitude at the unattended frequency. This has been explained using a “push-pull” or “spotlight” mechanism of attention. However, could the change in SSVEP amplitude be merely due to the presence of competing temporal frequencies, without any top-down cognitive modulation? If so, does it depend on the separation between the tagging frequencies or stimulus properties (such as orientations)? To address this question, we recorded spiking activity and local field potential (LFP) from the primary visual cortex (V1) as well as EEG from two awake macaque monkeys while they passively fixated sinusoidal counterphase gratings or plaids. Consistent with previous results, stimulus frequencies in and around the alpha range (8-16 Hz) produced the largest SSVEP responses. We, therefore, analyzed the modulation of SSVEP responses at 8 Hz and 16 Hz (“target” frequencies) as a function of stimulus frequencies in the lower delta (2 Hz) to high beta (30 Hz) range (“mask” frequencies) around the target frequency. We found that the target SSVEP response was reliably suppressed by the mask counterphasing at a different temporal frequency. We also found that target SSVEP suppression was generally asymmetric along the temporal frequency axis, with greater suppression at lower temporal frequencies of the mask than at higher temporal frequencies. Further, the strength of this asymmetry depended on the relative orientation difference between the target and the mask, with similar orientations causing significant suppression and orthogonal orientations causing little or no suppression. To explain the results, we adapted the well-known normalization model to SSVEP responses and characterized the suppression as a function of the difference in temporal

frequencies and orientations of the target and mask components. Our results provide evidence for interaction between temporal frequencies independent of effects of cognitive modulation, and suggest exercising caution in the interpretation of frequency tagging studies.

Title: Stimulus information, and correlated trial-to-trial variability, are distributed widely throughout interlaminar subpopulations in v1

Authors: *D. J. DENMAN[1,2], C. REID[1];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Physiol. and Biophysics, Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: All sensory stimuli are represented by large populations of single neurons. Recently developed electrophysiology technologies have enabled simultaneous observation of spike times from large numbers of neurons. In spite of the shift to population recording, the extent to which spike count and/or spike timing (and their variability) contribute to population coding has mostly remained in the domain of model-based approaches. Here we assess, empirically, response variability and the stimulus information across several timescales in populations of up to 200 simultaneously recorded neurons. We first describe the statistics of responses to repeated stimuli at several temporal scales (20 - 3 Hz), recorded in awake mice across dorsal lateral geniculate (dLGN) and primary visual cortex (V1) using high-density electrophysiology (Neuropixels). We use a linear support vector decoder as probe for stimulus information in populations selected from these recordings. By varying the temporal resolution used for decoding we found that, despite considerable trial-to-trial variability, populations contain additional stimulus information in relative spike times (< 40 msec). Notably, optimal decoding populations were always distributed widely across V1 layers, whether using spike counts, times, or both. To assess how trial-to-trial variability impacts the population representation, we compared optimal decoding populations to the shared variability across layers in V1 and dLGN, including both shared variability in spike count and spike timing (jitter). We found strong layer- and structure-dependent correlations in rate variability and jitter within subpopulations. Layer- and structure-specific trial shuffling allow us to reveal the impact - on population representation accuracy and

its structure - of shared variability across sets of laminae. In summary, we find stimulus identity is best represented by the concurrent activity of overlapping subpopulations across all layers of V1, suggesting that the brain utilizes spike times distributed across at least all V1 layers, and likely across visual areas, to represent visual stimuli.

Title: On the relationship between gamma amplitude and frequency in awake macaque V1

Authors: *G. SPYROPOULOS[1], J. R. DOWDALL[1], M. L. SCHOLVINCK[1], C. A. BOSMAN[3], B. R. LIMA[4], A. PETER[1], I. ONORATO[1], J. KLON-LIPOK[1], R. ROESE[1], S. NEUENSCHWANDER[5], W. SINGER[2], M. VINCK[1], P. FRIES[1];

Abstract: In cortex, excitation and inhibition are tightly balanced. This E-I balance is directly involved in the generation of the gamma rhythm. Some models implementing E-I balance predict that the amplitude of a gamma cycle is positively correlated with its duration. A previous study concluded that this prediction holds for gamma rhythms in rodent hippocampus. We investigated, whether it also holds for another important system showing strong gamma oscillations, namely the primary visual cortex of the awake primate. The previous study derived gamma amplitude and frequency from the peaks and troughs of the gamma (20-100 Hz) filtered local field potential (LFP). We found that this approach leads to positive amplitude-duration correlations for synthetic noise, i.e. in the absence of a rhythm. Therefore, we used the Hilbert transform of the unfiltered LFP to define periods with strong and pure gamma (i.e. linearly unfolding gamma phase) and then derived local peaks and troughs and thereby gamma-cycle amplitudes and durations. Gamma amplitudes and durations calculated in this way showed a positive correlation. This held, when we removed effects of extrinsic factors, like perturbations after stimulus onset or after microsaccades. Note that the conventional power spectrum in the gamma band also relates gamma amplitude to its frequency, which is the inverse of its duration. We found that the power spectrum is not a good representation of the distribution of cycle-wise ("instantaneous") amplitudes. The distribution of durations aligned with the power-spectral peak, whereas the distribution of amplitudes was shifted to lower frequencies. Furthermore, durations correlated negatively with firing rates and positively with spike-LFP phase locking, with longer

cycles entailing stronger firing rate modulations. Thus, in awake macaque V1, long gamma cycles have higher amplitudes and lower rates, suggesting that slower gamma is due to a stronger inhibition that prolongs the cycle and leads to weaker overall firing. The power spectrum in the gamma range does not primarily reflect the amplitudes of the underlying cycles, but rather the likelihood of the corresponding cycle durations.

Title: Detecting information-limiting noise correlations in early visual cortex

Authors: J. S. MONTIJN[1], R. G. LIU[1], A. ASCHNER[3], A. KOHN[4], *P. E. LATHAM[5], .. IBL COLLABORATION[6], A. POUGET[2];

Neurosci. Unit, Univ. Col. London, London, United Kingdom; [6]Intl. Brain Lab., Geneva, Switzerland

Abstract: If the brain processes incoming data efficiently, information in the relevant neural circuits should match behavioral performance. For instance, if there is enough information in a visual cortical area to determine the orientation of a grating to within 1°, and the code is simple enough to be read out by downstream circuits, then animals should be able to achieve that performance behaviorally. Despite over 30 years of research, it is still not known how efficient the brain is. For tasks involving a large number of neurons, the amount of encoded information is limited by differential correlations, so determining the amount of encoded information requires quantifying the strength of differential correlations. Detecting them, however, is difficult; current methods require recording spikes from thousands of neurons simultaneously, which is not yet

feasible. We report here a new method, which requires on the order of 100s of neurons and trials, a regime which can be attained by current experimental methods. This method relies on computing the alignment of the neural stimulus encoding direction, $\mathbf{f}'$, with the principal components (PCs) of the noise covariance matrix, $\mathbf{\Sigma}$. It can be shown that the presence of differential correlations implies that fluctuations along $\mathbf{f}'$ are proportional to the square root of the number of neurons, N. For large N, this implies that $\mathbf{f}'$ is one of the noisiest directions of $\mathbf{\Sigma}$, and is therefore be spanned by a small number of its largest PCs. Our method compares the alignment between $\mathbf{f}'$ and the PCs of $\mathbf{\Sigma}$ against that expected if correlations were removed by shuffling the data. Using simulations with a leaky-integrate-and-fire neuron model of the LGN-V1 circuit, we confirmed that this method can indeed detect even small levels of differential correlations, consistent with those that would limit orientation discrimination thresholds to ~0.1°. We applied this technique to V1 recordings in awake monkeys. This revealed differential correlations consistent with a discrimination threshold of 0.5°-3°, which is not far from typical discrimination thresholds. These results suggest that V1 contains about as much information as is seen in behaviour, which would imply that downstream circuits are efficient at extracting the information available in V1.

Title: Aberrant interactions of opposite hemifield inputs to visual cortex in albinism

Authors: *E. J. DUWELL[1], E. N. WOERTZ[2], J. MATHIS[3], J. CARROLL[4], E. A. DEYOE[5]; [1]Biophysics, [2]Cell Biology, Neurobiology, and Anat., [3]Neurol., [4]Ophthalmology & Visual Sci., [5]Radiology, Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Albinism is an inherited disorder characterized by disrupted melanin synthesis in the eye, and often in the skin and hair. This retinal hypopigmentation is accompanied by pathological decussation of temporal retinal afferents at the optic chiasm during development, ultimately resulting in overlapping representations of opposite hemifields in visual cortex of each hemisphere. We reported at SFN 2018 that this aberrant overlap results in fMRI imaging voxels with bilateral dual pRFs. How such conflicting inputs might interact to determine a dual-pRF

voxel's BOLD response is unknown. To test this, we used a paradigm in which the right and left hemifields were stimulated simultaneously with separate sinusoidal gratings, each having a variety of contrasts (0, 8, 20, 45, 100%). We then measured the BOLD response of individual 2.5mm cubic voxels to each contrast combination. Each fMRI run consisted of 5 blocks. Within each block, a given hemifield was stimulated sequentially with each contrast while the grating presented to the opposite hemifield was fixed at one of the 5 contrasts. The latter contrast was then incremented sequentially across blocks. We examined the responses of approximately 2300 voxels in one subject with albinism. Most visually responsive voxels, both single and dual-pRF, exhibited BOLD responses that increased within a block as a function of contrast presented to the primary pRF component. However, for approximately 20% of dual-pRF voxels, the gain of this function increased dramatically across blocks in response to the contrast presented to the opposite hemifield pRF component. This phenomenon was often observed in clusters dual pRF voxels, but was not observed in single-pRF voxels. These results demonstrate for the first time that aberrant retino-cortical projections in albinism may produce cortical voxels with dual inputs from opposite hemifields that interact in a multiplicative or otherwise nonlinear fashion. The consequences of such unique cortical physiology remain unclear but may provide a substrate for as-yet undocumented perceptual aberrations.

Title: Change in avalanches and visual tuning during optogenetic drive of interneurons in mouse visual cortex

Authors: *T. L. RIBEIRO, M. VICTOR, A. VAKILI, D. PLENZ;
Sect Critical Brain Dynamics, Natl. Inst. of Mental Health, NIH, Bethesda, MD

Abstract: Neuronal avalanches are spatiotemporal clusters of activity that reflect balanced neuronal propagation in the brain. Avalanches are power-law distributed and therefore scale-free, which is in line with expectations from so-called critical dynamics. Criticality has been suggested to optimize information processing. Yet, the link between avalanches, the balance in excitatory-inhibitory (E-I) and information processing is poorly understood. Here we study this

relationship in the visual cortex of awake mice subject to visual stimuli.We employed two-photon imaging of head-fixed mice positioned on a running wheel to infer spiking activity in neurons. Retinotopic mapping was performed to discriminate areas of the visual cortex. Viral-injection into cortical layer 2/3 resulted in robust expression of the genetically encoded calcium indicator (GECI) GCaMP7s. In order to measure effects of changes in the E-I balance, we also injected transgenic mice (PV-Cre, SST-Cre and VIP-Cre) with Cre-dependent opsins C1V1 or Chrimson allowing us to optically drive those interneurons. A chronic cranial window was centered over the primary visual cortex (V1) and mice were subjected to passive viewing of drifting bars at different angles (2 s each, randomly chosen) at maximum contrast interspaced by 2 s of gray screen. During the experiment, for randomly selected trials, optogenetic drive of the opsin-expressing cells was achieved by either wide-field stimulation with a LED or individual-cell stimulation through a spatial-light modulator (SLM). At any point, mice could self-initiate locomotion. Pupil diameter was assessed continuously to measure the animal's state of arousal. More than ~150 neurons were recorded consistently in a ~500 x 500 μm area at a frame rate of ~30 Hz.Spiking increased during locomotion and sub populations of neurons were identified to have preferred orientations. We analyzed neuronal avalanche statistics in those populations with and without visual stimulus present as well as with and without optogenetic drive, separating periods of locomotion from quiet resting. Power law statistics was found to be robustly maintained during visual stimulation independent of orientation. However, avalanche dynamics as well as tuning properties changed during stimulation of interneurons. We conclude that visual cortex maintains critical state dynamics and a particular E-I balance during visual processing.

Title: The structure of population activity in area MT of awake marmosets studied using two-photon microscopy

Authors: *J. J. PATTADKAL[1], B. ZEMELMAN[1], N. J. PRIEBE[2];
[1]Neurosci., The Univ. of Texas at Austin, Austin, TX; [2]Univ. Texas, Austin, Austin, TX

Abstract: Area MT neurons in primates are motion-sensitive signaling the direction and speed of objects and integrating multiple motion components to yield complex representations of object movement. Because MT neurons are selective for specific motion components, population level

measurements are required to access object motion representation. To study these population level representations we used marmosets *C. jacchus*, whose lissencephalic brains allow us to monitor the activity of a large population of neurons at single cell resolution using the calcium indicator GCaMP. We expressed GCaMP6f using an AAV fitted with the inhibitory neuron-specific h56D promoter (Mehta et al, 2019). Marmoset MT inhibitory neurons are directionally selective and were organized in space according to their direction preference. We recorded from a large number of neurons responding to random dots motion stimuli and then used unsupervised dimensionality reduction techniques to examine the low dimensional trajectories of the population activity. Population trajectories in this low dimensional space formed segregated paths where population responses to proximate directions are mapped to nearby locations. The trajectories were markedly different from those during spontaneous activity. These data are consistent with a model for motion processing in which population responses are dominated by a single attractor, instead of multiple attractors. Our observations were corroborated by changes in the average correlation of neurons between stimulus-driven and spontaneous network activity. On average, pairwise residual correlation between cells during stimulus periods were lower than correlations between cells during spontaneous activity (medians: 0.05±0.001 versus 0.08±0.001 s.e.m., respectively). We also found that the correlations had only a small dependence on the difference in preferred directions between cells. The correlations, however, did rely on the distance between the two cells, decreasing as the distance between cells increased. The falloff with distance was faster for stimulus period correlations than for the spontaneous correlations (exponential space constants: 117 versus 248 microns, respectively). These population measurements provide direct insight into the dynamics of sensory networks in awake primates.

Abstract: How much information does neural population activity encode about the world? Such information has been estimated in small neural populations, but little is known about how it scales when moving to populations of sizes relevant to mammals. To characterize this scaling, we simultaneously recorded the activity of hundreds of neurons from area V1 of mice stimulated with drifting gratings. We found that information about drift direction initially increased with larger population sizes, but later leveled off, suggesting a finite asymptotic limit of information available to the animal. As comparisons to trial-shuffled recordings revealed, this limitation was induced by noise correlations. Information scaling was quantitatively well-matched by an information scaling model endowed with information-limiting, differential correlations. We used this match to obtain a Bayesian estimate of the information asymptote. This estimate was consistent across different drift direction discriminations, and with known mouse direction discrimination performance. Furthermore, we found asymptotic information to increase for higher grating contrast, and higher mouse running speeds, consistent with previously reported analyses using smaller populations. Our information scaling model allowed us to estimate the population size required to reach some fraction of the asymptotic information, which suggested a widely distributed population code whose "distributedness" is only weakly modulated by the amount of encoded information, as controlled by contrast and running speed. Furthermore, we did not find any evidence for the existence of a most informative sparse subpopulation that could substitute for the whole population. Our work thus provides, to our knowledge, the first characterization of the structure and scaling of information in mammalian neural population codes that extrapolates beyond population sizes recorded in the experimental setup.

Title: Characterization of network activity changes during repeated natural movie stimuli in mice

Authors: *R. IYER, J. SHANG, B. HU, I. MAGRANS DE ABRIL, S. MIHALAS;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The mammalian central nervous system has a vast complexity with hundreds of cell types (Tasic et al. 2018) and intricate patterns of mesoscopic (Harris et al. 2018) and microscopic (Seeman et al. 2018) organization. At the same time the details of this organization are plastic. The gold standard for measurements of plastic changes involves patch-clamp methods (Bi and Poo, 1998). However such experiments are difficult to do at scale. Changes in activity distributions of IT neurons between novel and familiar stimuli have been previously observed and used to infer plasticity rules using rate based models (Lim et al. 2015).
Recent advancements in extracellular recordings allow simultaneous recording of up to tens of thousands of neurons in the central nervous system using the Neuropixels system (Jun et al. 2017). In this study we extend the characterization of plastic changes in the network to higher order terms by making use of simultaneous recordings of large numbers of neurons across multiple visual areas in response to a short natural movie which was presented a hundred times. Consistent with previous studies, we observe changes in selectivity of individual neurons to a particular frame of the movie. We observe subsets of neuron pairs which show significant and consistent changes in their covariance through the repetition of the the movie, and the change is positively correlated to the signal correlation of the neuron pairs. As an additional control, we plan to explore if the observed changes can be attributable to changes in network states arising due to behavioral covariates such as locomotion, pupil size etc.
The recorded network is expected to be at a dynamic equilibrium, in which inputs from the environment sculpt the network, and the connectivity is expected to be defined by covariance of features in natural scenes (Iyer and Mihalas, 2017). However, the repeated presentation of a movie which is short enough to not cover well the set of covariances observed in natural scene statistics, can potentially push the network towards a new equilibrium that could account for the observed changes.
Simulations using simple networks of leaky integrate and fire (LIF) neurons with spike time dependent plasticity (STDP) together with a fast homeostatic mechanism show qualitatively similar changes in single neuron selectivity. We plan to use different machine learning approaches to analyse the neural responses, to infer the evolution of STDP rules from neural activity and other biophysical parameters.

Title: Synaptic mechanisms of state-dependent neural activity in mouse primary visual vortex

Authors: *D. B. NESTVOGEL, D. A. MCCORMICK;
Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: Sensory processing in the neocortex is strongly modulated by spontaneous synaptic membrane fluctuations. The dynamics of these fluctuations are directly linked to the behavioural state of the animal. At low levels of arousal, the pupil of the animal is constricted and large, low frequency fluctuations dominate the membrane potential of cortical neurons. When the animal is aroused, the pupil is dilated, the animal oftentimes engages in running and the membrane potential exhibits high-frequency fluctuations. Results from recent studies employing imaging and extracellular recording techniques indicate that facial movements such as whisking predict state-dependent action potential firing more accurately in visual cortex than other measures previously used for this sake such as pupil diameter and locomotion. In the present study, we made use of in-vivo whole cell recordings in the visual cortex of awake mice to address this issue on the synaptic level. By monitoring spontaneous animal behaviour with a high speed camera, we find that whisker pad movements explain the variability and timing of spontaneous synaptic fluctuations more accurately than other behavioural measures such as pupil diameter and locomotion. Specifically, our results show that the coupling of whisker pad movements to membrane depolarization in excitatory V1 cells occurs on a rapid time scale of tens of miliseconds, which indicates that a fast transmitter system may mechanistically account for these state-dependent changes. In an additional set of experiments, we study the occurrence of the previously described 3-6 Hz oscillation in visual cortex in relation to facial movements. Previous studies have shown that this oscillation is the dominant LFP pattern at rest, but that it may also occur at periods when the animal is aroused. To further dissect the circuit mechanism on how this oscillation is generated, we simultaneously record in the thalamus and visual cortex. Preliminary results indicate that the 3-6 Hz oscillation is indeed state-dependent and that it relies on thalamocortical connections in order to occur. In summary, our results provide new insights into the exact timing and relationship between facial movements of mice and spontaneous patterns of synaptic activity in the visual cortex.

Title: Network interactions in the mouse visual cortex are predictive of perceptual decisions

Authors: *J. G. ORLANDI[1], S. GRZELKOWSKI[2,1], M. ABDOLRAHMANI[1], R. AOKI[1], D. LYAMZIN[1], A. BENUCCI[1];
[1]Lab. for Neural Circuits and Behavior, RIKEN Ctr. for Brain Sci., Wakoshi, Japan; [2]FNWI, Univ. van Amsterdam, Amsterdam, Netherlands

Abstract: Decision making involves the processing of neural signals through feedforward and recurrent networks in cortical and subcortical brain regions. These networks are concurrently being driven by a multiplicity of other cognitive signals related to the animal interactions with the environment. Hence, isolating features of the neural dynamics that are causally related to the decision making process has proved to be challenging.
Here we focused on perceptual decisions in mice trained in a two-alternative forced choice orientation discrimination task. We analyzed GCaMP signals recorded during the behavioral task from mice (n=8, Thy1-GCaMP6f) implanted with a cranial window over occipital-parietal areas, providing access to the widefield activations of 10-12 cortical areas. We reasoned that a necessary property - although not sufficient - for neural activations to be causal in the decision-making process is to carry predictive information on the animal choices or task outcome. Standard dimensionality reduction analysis of the simultaneously recorded areas could only differentiate trial-averaged activations for left-right choices, with large variability across animals. Importantly, choices or outcomes (correct, incorrect, time-out response) could not be decoded from individual trials. We next trained a family of non-linear supervised classifiers using the pairwise interactions between responses, thus relying on a measure of inter-area functional connectivity. The classifiers successfully decoded choices and outcomes from individual trials, more robustly for choices than for outcomes.
To isolate the contribution of motion-execution signals (needed to select the target stimulus, see Abdolrahmani et al, bioRxiv 2019), we further trained the classifiers on the recorded body movements, including saccadic ones. As expected, the classifiers could decode choices from body movements when considering time windows proximal to the choice execution, but performed at chance level at preceding times. On the contrary, neural activity and connectivity features carried predictive power significantly before motor execution, possibly reflecting pre-motor or choice-related signals. The analysis of the internal structure of the classifiers will allow us to identify the dynamical signatures of the cortical interactions carrying most weight for the classification performance. In conclusion, the observed predictive components in the large-scale activations of occipital-parietal visual areas suggest a causal involvement of the inter-area interactions for the decision-making process.

Title: Cortical mechanisms underlying saccadic suppression

Authors: *S. DENAGAMAGE[1], M. P. MORTON[1], J. H. REYNOLDS[3], M. P. JADI[2], A. S. NANDY[1];
[1]Neurosci., [2]Psychiatry, Yale Univ., New Haven, CT; [3]SNL-R, Salk Inst., La Jolla, CA

Abstract: Primates use ballistic eye movements called saccades to shift their field of view and bring objects of interest to the center of the retina for detailed examination. To maintain perceptual stability during rapid retinal motion, the visual system actively anticipates upcoming saccades and suppresses visual processing accordingly. This phenomenon, termed saccadic suppression, results in well characterized decreases in visual sensitivity during peri-saccadic stimulus detection tasks. Correspondingly, the firing rates of cells in the visual cortex drops during saccades. The mechanisms underlying the changes in neural activity that accompany saccadic eye movements remain poorly understood. We hypothesize that the laminar architecture of the sensory neocortex, which is strongly conserved across visual cortical areas, plays a key role in mediating saccadic suppression. To investigate this possibility, we recorded spontaneous extracellular activity across cortical layers using linear array probes in area V4. Our findings indicate that spiking units in different cortical layers vary in the timing and degree of peri-saccadic firing rate modulation. Notably, a significant proportion of narrow-spiking (putative inhibitory) input layer units increase their firing rates in response to a saccade, and may play a significant role in suppressing the firing of other units. We also find that saccade onset increases low-frequency local field potential (LFP) power and may generate a low-frequency LFP phase reset, inducing increased phase-locking of spikes during and immediately after a saccade. Overall, our results suggest that inter- and intra- laminar interactions between distinct neural populations regulate the effects of saccadic suppression in the visual cortex.

Title: Physiological correlates of perceptual threshold

Authors: ***M. P. MORTON**[1], S. DENAGAMAGE[1], J. H. REYNOLDS[3], M. P. JADI[2], A. S. NANDY[1];
[1]Dept. of Neurosci., [2]Dept. of Psychiatry, Yale Univ., New Haven, CT; [3]SNL-R, Salk Inst., La Jolla, CA

Abstract: Little is known about the physiological underpinnings that cause correct ('hit') or incorrect ('miss') responses at perceptual threshold. We hypothesized that physiological states in the sensory neocortex help determine whether a trial at threshold will be a hit or a miss. To study threshold behavioral performance, we analyzed cortical layer-specific electrophysiological recordings in visual area V4 collected while monkeys performed a cued attention task that required them to detect an orientation change. Here, we specifically analyze the subset of trials that occurred near perceptual threshold ('target'). We defined perceptual threshold to be the orientation change at which the psychometric function reached 50% accuracy. Our findings suggest that short-term increases in alertness influence threshold performance. We find that hit trials are characterized by a larger pupil diameter and lower microsaccade rate, indicative of increased arousal and greater perceptual stability. We find that target stimuli evoke higher firing rates in V4 neurons in hit trials compared to miss trials, across all cortical layers. Broad spiking neurons (putative pyramidal cells) in the superficial cortical layers exhibit lower variability in hit trials. Hit trials are also marked by a decrease in co-variability among pairs of neurons in the input layer of the cortex. Thus, we find evidence that hit trials are characterized by periods of increased signal to noise ratios in area V4. These results indicate that short term increases in

arousal, perceptual stability, and privileged processing of sensory stimuli contribute to hits near perceptual threshold.

Title: Dynamic states of population activity in prefrontal cortical networks of freely-moving macaque

Authors: *R. MILTON[1], N. SHAHIDI[2], V. DRAGOI[3];
[1]UTHealth, Houston, TX; [2]Univ. of Texas, Med. Sch. At Houston, Houston, TX; [3]Dept Neurobiol/Anat, Univ. of Texas at Houston Dept. of Neurobio. and Anat., Houston, TX

Abstract: Neural responses in the mammalian cerebral cortex are believed to change dramatically during the course of the day between the 'synchronized' state during sleep and 'desynchronized' state during wakefulness. Although the prevalence of this view seems to suggest that this phenomenon is well established, the previous investigations of the dynamics of cortical population activity at single cell resolution were performed in sensory cortical areas of head-fixed or tethered rodent models. Technical limitations have prevented the analysis of dynamic cortical states beyond sensory areas in larger animals freely moving for several hours. To overcome these limitations, we developed a system integrating wireless transmission of electrical activity, wireless eye-tracking, and real-time video analysis to examine the dynamics of population activity in a high-level, executive area - dorsolateral prefrontal cortex (dlPFC) of unrestrained monkey. This technology allowed us to identify distinct cortical substates during quiet and active wakefulness, and transitions in population activity during drowsiness and rest. We further found that, unexpectedly, putative inhibitory neurons exhibit stronger synchronized fluctuations in population activity than putative excitatory neurons regardless of brain state. Our results show that cortical state in freely moving monkey is controlled by behavioral demands and arousal by asymmetrically modulating the slow response fluctuations of local excitatory and inhibitory cell populations.

Title: Measuring the effects of locomotion on visual activity in the mouse cortex in the Allen Brain Observatory

Authors: G. K. OCKER[1], D. MILLMAN[2], P. LEDOCHOWITSCH[3], M. D. OLIVER[3], R. ABBASI-ASL[4], M. A. BUICE[1], ***S. E. DE VRIES**[1];

Abstract: Animal behavior is known to affect neural activity, broadly, as well as evoked sensory responses in the mouse cortex. Here, we use the Allen Brain Observatory to examine the effect of locomotion on the activity and the visually evoked responses of neurons in the mouse visual cortex. This is a systematic survey of physiological activity in the mouse cortex recorded using 2-photon calcium imaging. Neural activity was recorded in cortical neurons of awake mice who were presented a variety of visual stimuli, including gratings, noise, natural scenes, and natural movies. This dataset consists of over 60,000 neurons recorded in over 1300 imaging sessions, surveying 6 cortical areas, 4 cortical layers, and 14 transgenically defined cell types (Cre lines). In these experiments, mice were free to run on a rotating disk and we observe a range of running behavior and find differences across transgenic lines. We measure the correlation of neural activity with running, finding the stronger correlations in inhibitory neurons (VIP and SST) than pyramidal neurons, and also find stronger correlations in V1 than in the higher visual areas. We measure the effect of running on visual responses and find that, consistent with previous literature, neurons (on average) show increased responses, but with diversity in this effect across areas, layers, Cre lines, and visual stimuli. Finally, we use these data to explore how running effects the ability to decode visual stimuli from the population activity and find that, contrary to other reports, running can decrease the ability to decode grating conditions from populations of pyramidal neurons.

Title: The sensory representation of causally controlled objects

Authors: *K. CLANCY[1], T. D. MRSIC-FLOGEL[2];
[1]Sainsbury Wellcome Ctr. for Neural Circuits and Behavior, UCL, London, United Kingdom;
[2]Univ. Col. London, London, United Kingdom

Abstract: Our ability to exert intentional control over external objects is informed by our sensory experience of them, in a continuous dialog between action and sensory feedback. How such control is represented at the sensory level, or its efficacy judged, however, is not understood. In motor learning, the relationship between an action and its outcome can be learned and re-learned throughout adulthood as animals acquire new motor skills. Brain machine interfaces (BMI) are a novel method for investigating how subjects learn such arbitrary action-outcome relationships. Here we devised a brain machine interface (BMI) task that enabled mice to control a visual feedback cursor using neural activity alone. Transgenic mice expressing the calcium activity indicator gCaMP6s in pyramidal cortical cells were trained to control a visual feedback cursor using areal calcium signals. The activity of two small regions, usually over primary or secondary motor cortex, were arbitrarily assigned control of a visual feedback cursor. Fluorescence from these regions was read-out in real time and transmuted into the position of an onscreen cursor. Animals were trained to guide the cursor to a target location to obtain a reward. We found evidence that parietal and higher visual cortices were engaged when expert animals controlled the BMI for reward, but not in naïve mice still learning the task. Single-cell recordings from parietal cortex showed that the same sensory stimuli elicited larger responses when an animal was controlling the cursor than when passively viewing it. This increase was sensitive to cursor trajectory — responses were greater when the cursor was moving towards the target than away from it. Thus, the sensory representation of a causally controlled object is sensitive to the subject's intention, as well as the object's instantaneous trajectory towards or away from its goal. The heightened sensory representation at the target position might serve as a fixed goalpost for

downstream evaluation, given the animal must relearn a changing sensorimotor contingency on the fly, potentially strengthening the signal to adjudicating areas for informing fluent control.

Title: Reading between the lines: The impacts of reading in virtual reality and other mediums on the visual system

Authors: *T. A. DOTY[1], C. Y. DELGADO[3], A. TORRES LOPEZ[1], S. A. LUNDQVIST[2], M. F. AWAD[4], L. E. KNOX[5], L. LOPEZ CANELA[5], S. A. DREW[6];

Abstract: In recent years, technological advances, including computer screens and tablets, have allowed for more convenient reading. As virtual and augmented reality have become commercially available, new experiences are easier to access while new therapies and training opportunities provide lower traditional occupational risks than their real-world counterparts. However, as technology continues to advance, the need for understanding its health impacts becomes more and more imperative. This experiment aims to understand how the visual system is impacted by reading using different mediums, including virtual reality, augmented reality, computer screens, tablets, and paper. This report will analyze different visual system functions, including vergence facility and accommodative facility, before and after reading for 30 minutes in the previously stated mediums. Participants will also be measured for asthenopia, or visual discomfort, and across mediums. It is hypothesized that virtual reality will elicit the largest negative changes in the visual system as well as the largest increase in visual discomfort symptoms whereas physical paper will elicit the smallest negative changes in both. This study will allow users of such mediums to understand how advances in technology impact their visual system. Preliminary data displays trends of different reading rates where those that read on physical paper read the most pages compared to every other medium. Trends also suggest that those that read in virtual reality have improved accommodation scores compared to all other mediums. Data also suggests that there is an interaction between measure type and if the reader is using virtual reality or not. The data trends to show that those that read in virtual reality also report higher dizziness scores compared to augmented reality. These findings, and others, will be discussed in full.

Title: Cognitive modulation of interacting corollary discharges in the visual cortex

Authors: M. ABDOLRAHMANI, ***D. R. LYAMZIN**, R. AOKI, A. BENUCCI;
RIKEN Ctr. For Brain Sci., Wako-shi, Japan

Abstract: Perception is an active process involving continuous interactions with the environment. During such interactions neural signals called corollary discharges (CDs) propagate across multiple brain regions informing the animal whether the incoming sensory information originates from animal's own actions or from the environment. Under ethologically natural conditions, such CDs co-occur in close temporal proximity and interact with each other. However, how the interactions between concurrent CDs affect the large-scale network dynamics, and in turn help shape sensory perception is currently unknown. We focused on the effect of saccadic and body-movement CDs on a network of visual cortical areas in adult mice (n=15). CDs alone had large amplitudes, 3-4 times larger than visual responses, and could be dynamically described as standing waves (singular-value decomposition; explained variance 88±3%). They spread broadly, with peak activations in the medial and anterior parts of the dorsal visual stream. Inhibition (I) mirrored the wave-like dynamics of excitation (E), suggesting these networks remained E/I balanced. A generalized linear model (explained variance 36.8±3.6%) showed that CD waves superimposed sub-linearly and asymmetrically: the suppression was 1.5±0.2 times larger if a saccade followed a body movement by 0.59+-0.05 ms than in the reverse order. These rules depended on the animal's cognitive state: when the animal was most engaged in a visual discrimination task (measured using pupil area), cortical states had large variability accompanied by an increase in S/N (max amplitude after the stimulus over pre-stimulus variability, $p = 0.001$) improving the reliability in sensory processing. High-variability states were associated with a smaller non-linearity as well ($p = 0.002$). These results suggest that in high variability states CDs and sensory signals are independently encoded, permitting an

efficient read-out by downstream networks for improved visual perception. In summary, our results highlight a novel cognitive-dependent arithmetic for the interaction of non-visual signals that dominate the activity of occipital cortical networks during goal-oriented behaviors. These findings provide an experimental and theoretical foundation for the study of active visual perception in ethological conditions.

Title: Vision tapers escape behaviours in mice

Authors: ***S. ZUCCA**, T. WHEATCROFT, K. J. JEFFERY, A. B. SALEEM, S. G. SOLOMON;
Exptl. Psychology, Univ. Col. London, London, United Kingdom

Abstract: When encountering a sudden danger, such as a predator, escape can be essential for survival. When a place of refuge is available, prey animals usually escape to the refuge. Locating the refuge is likely to be easier in the presence of visual information. We therefore asked how escape behaviors were influenced by the absence of light. We video-tracked mice (n = 16) exploring an open-field with a refuge on one side, and recorded their responses to a train of ultrasonic up-sweeps that lasted three seconds. We compared responses in two conditions: when the environment was well illuminated or when it was completely dark. Sound stimulation evoked running in both light and dark conditions (light: 75%, 35/47 trials; dark: 69% , 33/48 trials). However, the peak speed of the response was significantly reduced in the dark condition (Light: 51.4 ± 1.6 cm/s [median ± s.e.]; Dark: 40.5 ± 1.8 cm/s, p=0.0003, Kruskal-Wallis test). Moreover, in the illuminated environment, most of the running trajectories (80%) ended with the with the animal escaping to the nest, while this fraction dropped dramatically (33%) in dark. We compared the trajectories of these responses with a straight-line path to the refuge location (i.e. homing vector). To quantify the difference, we calculated the angle between the homing vector and a line joining the start and end of each running response. This angle was significantly larger in the dark condition (Light: 4.1 ± 0.9 deg; Dark: 9.6 ± 5.6 deg, p=0.008, circular Kruskal-Wallis test). Our observations suggest that visual cues improve an animal’s ability to find refuge, and

reduce the time needed to get there. The lack of visual cues might also change animals' escape strategy, where reaching the nest may no longer be the optimal response.

Title: Dynamic contrast sensitivity during locomotion in humans

Authors: *B. R. SHANKAR, B. J. SZEKELY, P. R. MACNEILAGE;
Psychology, Univ. of Nevada Reno, Reno, NV

Abstract: During locomotion, high-acuity vision is maintained by reflexive head and eye movements that function to stabilize visual targets on the retina. These stabilization behaviors typically succeed in holding retinal slip to velocities less than about 2 deg/s. With retinal slip in this range, dynamic visual acuity is typically reported to be as good as static visual acuity, suggesting visual mechanisms that work to mitigate the consequences of retinal image motion to improve acuity. Here, we investigate these mechanisms further by measuring contrast sensitivity during locomotion and comparing these measures with contrast sensitivity measured while stationary. This work is motivated by recent observations of increased gain of visual responses in mice during locomotion (Mineault et al., 2016). Recent work in humans has also investigated contrast sensitivity during walking and reported little change in sensitivity but increased surround suppression (Benjamin et al., 2018). Building on this work, we developed a paradigm to deliver visual stimuli contingent on head and eye movement during treadmill locomotion. Stimuli were presented on a ProPixx projector and head movement was tracked using Optitrack. We also have the capability to record eye movements using the Eyelink II. On each trial subjects were presented with a Gabor grating on a grey background for 100 ms. The grating was tilted 45 deg in either the clockwise or counter-clockwise direction and subjects reported the orientation. Michelson contrast was manipulated from trial to trial according to a staircase procedure to find the contrast that led to 75% correct performance. We sought to evaluate how contrast sensitivity depends on locomotor phase, so we measured and compared performance during mid-stance and heel strike. We also measured performance during standing. Performance was comparable during all conditions suggesting that contrast sensitivity is similar under static and dynamic conditions,

like visual acuity, and we found no evidence that contrast sensitivity depends on locomotor phase.

Montreal, Montreal, QC, Canada; [3]Faculté des Sci. de la Vie, Univ. de Strasbourg, Strasbourg, France; [4]Signal Garden inc., Silicon Valley, CA; [5]Inst. of Neurosci. & Pharmacol. (INF), Copenhagen, Denmark

Abstract: Blind individuals often report difficulties while navigating in their environment and detecting objects beyond the peri-personal space. Sensory substitution devices are therefore needed to inform them about the environment via other senses like touch and audition. In this study, early blind (EB, n=11), late blind (LB, n=12) and blindfolded-sighted participants (SC, n=20) were tested for their navigation ability in an obstacle course using the Signal Garden Electrolyte Engine platform installed on an ARCore smartphone. The system uses multiple sensors to either detect obstacles at a distance directly in front of the user (**Detection mode**) or to create a 3D map of the environment (**Avoidance mode**) and informs the user with an auditory feedback. The corridor contained 6 identical obstacles randomly placed across trials but always distanced by 3m from each other. Both modes of the SensoryFusion application were tested. For both modes, the task was to cross the corridor as quickly as possible while detecting or avoiding the obstacles. In the **Detection**mode, the participants had todetect obstacles by pointing at them and estimate the distance between them and the object; in the **Avoidance**mode, the participants had to bypass the obstacles without touching them. Our data show that all three groups performed similarly in the**detection**task (72.2%, 78.9% and 82.6%,). EB and SC showed however a significant improvement in the time taken to cross the corridor between the beginning (first trials) and end (last trials) of training (EB: 310s for first trials versus 236s for last trials, p&lt 0.05; SC: 298s for first trials versus 236s for last trials, p &lt 0.05). LB did not significantly

improve their average crossing time (235s for first trials versus 186s for last trials, p= 0.165). In the **avoidance**mode, all groups had similar performances (90.7%, 84% and 86.9%), but LB and EB were significantly faster to cross the corridor than SC (EB&ltSC: p&lt 0.05). Also, error analysis indicated that different strategies were used by blind and blindfolded-sighted individuals. The SensoryFusion application offers a new and accessible way for sensory substitution with the use of smartphones.

Title: Navigational signals along the visual pathway

Authors: *E. M. DIAMANTI, C. REDDY, S. SCHROEDER, K. D. HARRIS, A. B. SALEEM, M. CARANDINI;
Univ. Col. London, London, United Kingdom

Abstract: The visual system and the navigational system profoundly influence each other. Vision shapes the navigational system's estimates of spatial position, and these estimates in turn influence visual processing. For instance, spatial position powerfully modulates the responses of neurons in primary visual cortex (V1) to otherwise identical visual stimuli (e.g. Saleem et al, 2018). How does this modulation vary along the visual pathway? Is it established earlier than V1, and does it change beyond V1? In addition, does this modulation require that the mouse actively navigates the environment, or is it also present when the mouse is passively viewing the environment's visual scenes?
We recorded activity in V1, six higher visual areas and the thalamic lateral geniculate nucleus (LGN), with 2-photon calcium imaging, while head-fixed mice ran along a virtual corridor with two visually-matching segments. To image cortical activity, we used transgenic mice expressing GCaMP6 in excitatory neurons. To image LGN activity we expressed GCaMP6 in the LGN of wild-type mice and imaged their boutons in layer 4 of area V1. We quantified the degree of

spatial modulation using a spatial modulation index (SMI): a purely visual cell had SMI close to 0 (i.e. it gave similar responses to the visually-matching segments) and a cell that preferentially fired at one position had an SMI close to 1.
Signals related to spatial position were strong both in V1 and in higher visual areas (median SMI between 0.3 and 0.45). In LGN, instead, signals related to spatial position were absent (SMI ~ 0.06). Therefore, responses in LGN were visual, albeit influenced by running speed as shown previously (Erisken et al, 2014).
To investigate the role of active navigation, we compared responses in virtual reality ('VR' mode) to passive presentation of the VR scenes. To determine pure passive viewing periods, we isolated epochs when the mouse was not moving (running speed < 5 cm/s; 'passive' mode). In this mode, in some cortical areas, like areas A and PM, responses were more variable, which suggests that these higher-order areas responded reliably only during active behavior. For the other cortical areas, median SMI in 'passive' mode was significantly reduced, which suggests that spatial modulation markedly decreased. In LGN, instead, there was little room for SMI to decrease relative to 'VR' mode, and indeed the SMI distributions were similar between 'VR' and 'passive' modes.
These results indicate that modulation of visual responses by spatial position is established in cortex. This modulation is present in all visual cortical areas provided that the animal actively navigates the environment.

Title: Cellular imaging of claustrum reveals diverse task-related signals

Authors: *D. R. OLLERENSHAW[1], J. DAVIS[1], E. G. MCBRIDE[1], H. ZENG[2], **S. R. OLSEN**[1], C. KOCH[3];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Structured Sci., [3]Allen Inst. for Brain Sci., Seattle, WA

Abstract: The claustrum is a subcortical gray matter structure with remarkably extensive connectivity with the neocortex yet its function remains elusive. Based on its widespread anatomical connections and physiological activity, the claustrum has been hypothesized to be involved in various complex phenomena including multimodal integration of stimulus

information into a single conscious percept (binding), amplification of cortical oscillations, salience detection, and allocation of selective attention. To probe the function of the claustrum during behavior, we imaged activity in claustrum cells using a Cre line which expresses preferentially in the claustrum under control of the Gnb4 gene. We have performed single-photon fluorescence imaging of the claustrum using implantable gradient index (GRIN) lenses during passive sensory stimulation, visual task performance (change detection), and during home cage exploration and anesthesia. Claustrum cells are rarely responsive to passive sensory stimulation, but show a diverse range of task-related signals, including both increases and decreases of activity in different sets of cells. The claustrum is virtually silent during isoflurane anesthesia, but shows strong locomotion modulation. Together these results suggest claustrum activity reflects an integration of sensory, motor, and task-related signals.

Title: Representation of unexpected stimuli across functionally connected cortical columns during visual behavior in mouse

Authors: F. NAJAFI, N. Y. ORLOVA, D. TSYBOULSKI, S. M. SEID, I. KATO, M. GARRETT, P. A. GROBLEWSKI, R. S. LARSEN, D. R. OLLERENSHAW, D. SULLIVAN, W. WAKEMAN, Q. L'HEUREUX, S. R. OLSEN, *J. LECOQ;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The predictive processing framework for understanding the brain function assumes that the brain contains an internal representation of the world, which is updated by comparing predictions about the external world with the actual sensory inputs. This framework relies on communication across different brain areas in order to generate and update predictions. A major challenge in assessing the predictive processing framework is to simultaneously measure neuronal population activities across multiple cortical areas.
To address this challenge, we have recently developed an advanced two-photon microscope, “multiscope”, that allows us to simultaneously image the activity of neural populations across 8 cortical planes. We leveraged this instrument to measure the activity of 4 cortical layers and 2 cortical areas, while mice were performing a visual change detection task. We used this method, combined with different mouse lines that tagged distinct subclasses of inhibitory and excitatory neurons, to assess how different cell types across two visual areas (V1 and LM) interact and

represent predictions about external stimuli. Our behavioral task involves image change detection: an image is repeatedly flashed, and after a varying number of presentations, it changes to a different image. The animal is trained to detect the change and report it by licking a waterspout. To investigate the neuronal representation of prediction signals, we have omitted the image change in a small subset of trials.
Here, we demonstrate how different cell types (excitatory neurons and inhibitory neurons of VIP and SST subtypes) in all layers of the primary visual cortex as well as a higher order visual area represent prediction signals during visual behavior. Additionally, we have leveraged our simultaneous recordings to study the interactions between cortical columns. Our preliminary findings demonstrate that VIP inhibitory neurons, particularly in superficial cortical layers, signal the violation of prediction significantly more than excitatory or SST cell types. Our correlation analysis of cortical columns reveals how primary and higher order visual areas communicate to represent unexpected sensory perturbations. Altogether, our findings demonstrate the distinct contribution of different cell types across cortical columns in representing predictions about the external world.

Title: Influence of experience and engagement on sensory responses during a visual change detection task

Authors: M. GARRETT, ***R. S. LARSEN**, P. A. GROBLEWSKI, D. R. OLLERENSHAW, A. PIET, N. D. PONVERT, N. H. CAIN, F. NAJAFI, S. NAYLOR, J. LECOQ, S. R. OLSEN; Allen Inst. for Brain Sci., Seattle, WA

Abstract: A fundamental property of the brain is its ability to flexibly process short-term changes in internal state and longer-term changes due to experience and learning. Changes in internal states like engagement, motivation, and arousal modulate sensory perception, potentially sharpening the ability to discriminate between competing options when focused on a goal. To study how neurons dynamically compute information in an experience- and state-dependent

manner, we measured the activity of L2/3 and L5 excitatory cells, and VIP and SST inhibitory neurons in mouse primary visual cortex with 2-photon calcium imaging during goal-directed behavior or during passive viewing. Using a change detection behavioral task in which mice respond when the identity of natural images change, we observed that excitatory neuron responses to image changes were larger during active behavior than passive viewing of the same images. Moreover, the strength of these changes depended on whether the images were novel or familiar. We next compared visual responses to trained, familiar images with responses to novel images that had not previously been associated with reward. While behavioral performance rapidly generalized to new stimuli, the underlying neural representations differed. Responses to highly trained stimuli were more sparse and selective than responses to novel, untrained images. Activity became increasingly sparse with stimulus repetition, suggesting a role for stimulus specific adaptation in facilitating enhanced responses to changes, particularly in excitatory populations. We characterized several response types with different dynamics, including a subset of VIP inhibitory cells exhibiting ramping activity that potentially signaled temporal expectation of a change event. This study forms the foundation for a large-scale dataset, generated on a standardized platform for high-throughput calcium imaging during behavior that will be public data resource for the community (Allen Brain Observatory: http://observatory.brain-map.org/visualcoding/).

Title: Principles of tactile search over the body

Authors: *E. J. HALFEN, J. F. MAGNOTTI, J. M. YAU;
Baylor Col. of Med., Houston, TX

Abstract: Although we can experience touch across our entire body, little is known about how multi-site touches are combined over the body and prioritized by spatial attention. To address these questions, we designed a tactile analog of the classic visual search task. On each trial, participants made a present/absent decision about a target stimulus (e.g., 10-Hz vibration) presented on the body (70% target present trials). When present, the target stimulus could occur alone or simultaneously with distractor stimuli (e.g., 30-Hz vibrations) on other body locations. We systematically varied the number and spatial configurations of the distractors (from 1 to 8)

and alternated the target and distractor frequencies (10-Hz or 30-Hz) to test the impact of these factors on tactile search performance. We found that response times were faster on target-present trials (m = 1568 ms) compared to target-absent trials (m = 2309 ms, $p < 0.0001$). Additionally, response times increased with the number of stimulated sites, consistent with a serial search process (mean slope = 136 ms/site). Moreover, search performance differed depending on the target and distractor frequencies implying that tactile search is a feature-dependent behavior. These results reveal a number of ways in which tactile search behavior is analogous to its visual counterpart. We implemented a simple model to explore how tactile search behavior related to the locations of the target and distractor cues. Our modeling results reveal that tactile cues on the hands make relatively greater contributions to search performance - in isolation or through multi-site interactions - as compared to tactile cues experienced on other body sites. Collectively, our findings identify principles of attentional search that are common to visual and somatosensory search, but they also highlight key differences that may be unique to body-based spatial perception.

Title: Limits of visual orientation discrimination in free behaving mice

Authors: *W.-K. YOU[1], S. P. MYSORE[2];
[1]The Johns Hopkins Univ., Baltimore, MD; [2]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: The laboratory mouse is emerging as a powerful model to study the neural circuit basis of visually-guided behavior. Nonetheless, a detailed understanding of the dependence of visual discrimination performance of mice on stimulus parameters is lacking. Here, we explored systematically the stimulus parameter space for visual discrimination in freely behaving mice. Using a touchscreen-based setup, we measured discrimination performance by manipulating the stimulus size, contrast, duration, and delay in the context of a 2AFC, orientation discrimination task. The metrics of performance were accuracy, perceptual discriminability, decision criterion, and reaction time. Our results revealed that the visual capability of mice, which is known to be several-fold poorer than that of primates, has nonetheless been underrated. In general, shrinking the size of the oriented grating stimulus, lowering the stimulus contrast, shortening the stimulus

duration, or adding a delay before stimulus onset all caused deterioration of mice's discrimination performance. However, mice were able to respond to visual stimuli that were smaller, faster, and in general, more demanding than those typically used in literature. In addition, results revealed important insights into the limits of visual discrimination performance in freely behaving mice. Specifically, we were able to quantify the shortest stimulus duration necessary for successful discrimination, the longest effective stimulus duration, and the length of their visual working memory. Our results provide useful information for the design of future visually-guided experiments in mice.

Title: R A I L: Rodent automated and integrated learning platform for training freely behaving mice on touchscreen-based visual tasks

Authors: *B. A. D. HOLT, J. GARMON, S. P. MYSORE;
Johns Hopkins Univ., Baltimore, MD

Abstract: We present the Rodent Automated and Integrated Learning (RAIL) visual platform, a custom behavioral training system that flexibly and scalably integrates inexpensive Internet of Things (IoT) hardware with open-source web development software tools for neuroscience applications. By applying readily available components to a neuroscience context, this system makes possible affordable implementation of various rodent behavioral paradigms en masse. As proof of concept, we provide behavioral performance results from five freely moving mice trained simultaneously on a visual task, using the latest version of our touchscreen-based visual training box, thereby demonstrating that RAIL delivers training outcomes equivalent to contemporary commercial systems. Our box redesign is more modular than before and possesses expanded hardware capabilities, such as multiple screen configurations and camera feeds, a rugged chassis, and an external view screen. The RAIL box's added modularity allows researchers to account for individual animal bias, as well as to quickly adjust hardware to support new behavioral paradigms. RAIL has the potential to scale up rodent training many fold without prohibitive financial outlay, thereby accelerating behavioral neuroscience research.

Title: Citric acid water as an alternative to water scheduling in behaving mice

Authors: V. AGUILLON-RODRIGUEZ[1], *A. E. URAI[1], F. CAZETTES[2], I. C. LARANJEIRA[2], A. M. ZADOR[1], Z. F. MAINEN[2], A. K. CHURCHLAND[1], .. IBL COLLABORATION[3];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Champalimaud Ctr. for the Unknown, Lisbon, Portugal; [3]UCL, London, United Kingdom

Abstract: Training animals to perform cognitive tasks benefits from a system in which animals obtain their daily water requirements via rewards delivered within the task.This approach represents an effective strategy for achieving stable, accurate behavior (Guo et al. 2014). Water scheduling requires rigorous monitoring of weight and hydration status which can be challenging for some animals. Citric Acid (CA) makes water taste slightly bitter but is harmless to animals. In rats, access to ad libitum CA water allows animals to maintain a healthy weight, with only a subtle impact on willingness to perform behavioral tasks with water rewards (Reinagel, 2018). Here, we extend this approach to mice using a large-scale multi-site collaboration as a test-platform.
We gave mice free access to CA water in their home cage and tracked their weight, health status, water intake and motivation to perform trials for sucrose water rewards. We first observed that free availability of 1% CA water in the home cage caused a rapid, but modest, weight loss in 9 mice (C57/BL6, Lisbon). Body weight stabilized at around 85-90% of baseline levels within a few days and did not further decrease upon switching from 1% to 2% CA water. Intake of ad libitum CA water was around one-third of the intake of regular water. This suggested that mice, like rats, would be motivated to perform trials rewarded with normal water when given ad libitum CA water in their home cage.
To test this, six C57/BL6 mice (CSHL) were trained each weekday, performing a visual decision-making task (Burgess et al. 2017) where correct choices were rewarded with 10% sucrose water (Guo et al. 2014). We used trial counts as a measure of motivation under varying water regimes. As a baseline, when we gave 1mL/day on weekends, trial counts did not change from Friday to Monday. When we gave 2% ad libitum CA water on weekends, trial counts

likewise did not change from Friday to Monday. By contrast, when we provided access to ad libitum 2% CA water throughout the week, trial counts were lower: animals completed only 80% of their baseline trial counts.
Our results suggest that a regimen of 2% CA water on weekends allows animals to maintain their health without diminishing trial counts. While CA water has not been shown to be a viable alternative to water restriction in all cases, we consider it a promising alternative that allows animals more control over their water intake without interference to behavioral performance.

London, London, United Kingdom; [7]Univ. of California Berkeley, Berkeley, CA; [8]Sanworks LLC, Stony Brook, NY

Abstract: The International Brain Laboratory (IBL) is a collaboration of 21 laboratories aiming to understand the neural basis of decision-making. A core goal of IBL is to establish a standardized decision making task in all participating experimental institutions. To support this goal, we implemented a visuo-spatial detection task in which mice report whether a visual stimulus of varying contrast was presented on the left or the right of the screen by moving the stimulus to the center by turning a steering wheel.

We have trained 61 mice in the final standardized implementation of the behavioral task in six institutions (Champalimaud Center for the Unknown, University College London, Cold Spring Harbor, New York University, Princeton and Berkeley). Mice took on average 12.7 ± 6.6 (mean ± s.d.) training days to reach stable psychometric performance as indicated by low bias and lapse rates over multiple days. The training procedure was fully automated to improve reproducibility. When mice showed stable psychometric performance, they transitioned to the final phase of the task in which stimuli were more likely to appear from one of the two sides (80/20 probability, side prior switched in blocks). Mice consistently biased their psychometric function according to the stimulus side prior.
To assess replicability of behavioral results, we trained three classifiers (Random Forest, Naive Bayes and LDA) to decode the laboratory membership of an animal based on behavioral performance and training time parameters. Classifiers were unable to predict in which lab a mouse was trained based on behavioral parameters, arguing there was no significant differences across laboratories.
To further explore which factors may influence animal training and behavior, we scrutinized factors related to environment (e.g., temperature, humidity, light cycle, diet), phenotype (e.g., age, litter, sex, and genetic background) and operation (e.g., trainer, animal-experimenter interaction) factors using metadata shared across IBL laboratories through the Alyx platform (see companion poster). This study provides a deeper understanding of which factors are critical for replicating a behavioral paradigm across institutions. Most importantly, it places the IBL in a position to propose a standardized open-source behavior apparatus and training protocol that can be readily adopted by the neuroscience community.

Title: Signature of exploration in brain state dynamics

Authors: *X. TIAN[1], D. SZCZUPAK[2], A. C. SILVA[3], C. LIU[1];
[1]NINDS/NIH, Bethesda, MD; [2]Natl. Inst. of Hlth., North Bethesda, MD; [3]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: In reality, we always meet such a dilemma to choose old things (exploitation) already known or to explore new things. One strategy to solve this exploitation-exploration dilemma is biased toward the new option, as it is more informative than the old. However, we knew little about where and how the brain plans this strategy at a large scale: How many brain areas are involved in the process; which brain regions and networks contribute most; and how functional dynamics changes of these networks are. To investigate this question, we used the common marmoset (Callithrix jacchus) as our experimental subject, which has a small and smooth brain but sharing similar brain architectures as other primates. To avoided confounding effects from any previous behavior training, we screened our marmoset colony and only recruited animals that engaged in the experiment naturally. Then, we performed longitudinal fMRI acquisition to fully track brain states associated with behavioral improvements, in which marmosets learned a novel decision-making task. In the task, we presented a series of movies to marmosets. After a short delay, the marmosets were required to choose between two pictures, one was a screenshot from the previous movie, and the other was a new picture. To avoid the influence of external rewards biasing the animal's internal strategy, we delivered liquid reward randomly regardless of choice made by the animals (50% chance for both choices). We found that the marmosets preferred choosing the novel stimulus rather than the old cue, suggesting a natural strategy of exploration. By analyzing fMRI dynamic functional connectivity, we identified several distinct brain states, one of which has a significant correlation with the exploration behaviors. By comparing this brain state with other states, we revealed that cerebellar-cortical networks contributed most to the distinct patterns of the brain states. Our findings demonstrate that exploration involves brain-wide networks and the dynamics of the cerebellar-cortical networks is an essential feature.

Title: Expectation dependent responses in ventral visual pathway cortical areas

Authors: *T. S. ALTAVINI[1], G. ASTORGA[1], Y. YAN[2], M. CHEN[1], W. LI[2], D. HARARI[3], S. ULLMAN[3], G. N. REEKE[1], C. S. JIANG[1], W. FREIWALD[1], C. D. GILBERT[1];
[1]Rockefeller Univ., New York, NY; [2]State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China; [3]Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Neuronal responses to visual stimuli are subject to top-down influences, even in early visual areas. Visual perception emerges from an interaction between bottom-up signals carrying information about stimulus characteristics and top-down signals, derived from experience, that convey expectations and perceptual tasks. To investigate the representation of objects and object components in different areas along the ventral visual pathway and how expectation influences these representations, we trained macaque monkeys on a delayed match-to-sample task. Once the animal learned to respond whether a "cue" image matched a subsequently presented "target" image we presented cropped parts of the target image in order to determine which components of the object were more informative for object recognition. This behavioral paradigm allowed us to study how expectation generated by the cue influences neuronal responses to the target. We performed a series of fMRI experiments to identify areas that were responsive to various object categories, including vegetables, animals, man-made objects and faces, and to our ethologically curated library of informative object components. We then implanted multiple electrode arrays in several of these areas, including V1, V4 and TEO and recorded from single neurons while the animal performed the behavioral task. For cells that responded to selected stimuli within our stimulus set (one sample t-test, $p<0.05$), we found that their stimulus selectivity was influenced by cue induced expectation (two-way ANOVA, $p<0.05$). We found a significant interaction between cue and target in all areas recorded, indicating expectation dependent stimulus selectivity.

Title: Mice preferentially depend on increments in V1 activity to detect changes in visual stimuli

Authors: *J. J. CONE, E. A. PAGE, M. L. BADE, J. H. R. MAUNSELL;
Univ. of Chicago, Chicago, IL

Abstract: Changes in the visual scene evoke diverse responses in the neurons of primary visual cortex (V1). How such changes in neuronal activity are decoded by other brain structures during visually guided behaviors remains poorly understood. Although increments or decrements in neuronal activity both convey information, the emergence of ON and OFF channels in the retina suggests that spike rate decrements might play only a minor role in supporting visual perception. To explore this idea, we used optogenetic stimulation of V1 in trained, behaving mice to determine whether increasing or decreasing population activity impairs or improves perception of visual contrast changes. Mice were trained to do a contrast change detection task while head-fixed. They initiated trials by depressing a lever while viewing a display containing a mid-contrast Gabor (SD: 5-8°). After a random delay (600-3000 ms) the Gabor contrast stepped to a higher or lower level. Mice were rewarded for releasing the lever within a brief response window after step onset. The sign and magnitude of the contrast step was randomly selected, with the step sizes on different trials spanning behavioral detection thresholds. To perturb neuronal activity during behavior, we expressed ChR2 in neurons in the portion of the V1 retinotopic map that included the Gabor representation. ChR2 was expressed in either inhibitory (PV+; n=7 mice) or excitatory neurons (Emx+; n=3 mice), allowing us to moderately decrease (PV+) or increase (Emx+) visually-evoked responses in V1. During experimental sessions, optogenetic stimulation was delivered on a randomly selected fraction of near-threshold contrast changes and we measured the resulting change in behavioral detection. Stimulation of excitatory neurons (Emx+) always facilitated detection of either increments or decrements in contrast. Conversely, activation of PV+ neurons always impaired detection of either contrast change. The effects of optogenetic stimulation on V1 population responses were confirmed with electrophysiology. While changes in visual contrast evoke diverse responses in V1 neurons, our data suggest that the brain preferentially decodes information from neurons whose firing rates increase in response to those changes. Ongoing experiments seek to test more generally if there is an asymmetry in the ability of mice to perceive increments versus decrements in activity using animals trained to respond to ChR2-induced changes in V1 activity in the absence of visual stimuli.

Title: Modulation by sounds of visual processing in the primary visual cortex of mice performing an audiovisual discrimination task

Authors: J. P. MCCLURE, Jr., J. CORBO, ***P.-O. POLACK**;
Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ., Newark, NJ

Abstract: Multisensory integration is not restricted to higher-order sensory cortices. Studies in human and rodents have shown that multimodal interactions also occur at the earliest stages of sensory cortical processing. In mice, the presence of sounds improves the representation of the orientation and direction of the visual stimulus by neurons in layer 2/3 of the mouse primary visual cortex (V1). However, sound modulation in the mouse V1 has only been demonstrated in naïve mice passively processing visual and auditory stimuli. Therefore, it remains unclear if the influence of sound on visual processing persists when mice actively process both the visual and auditory stimuli simultaneously. To determine the influence of sound on V1 visual integration during active audiovisual processing, we designed a cross-modal discrimination task for water restricted mice. This task consists in the presentation of one of two pure tones and/or one of two drifting gratings. One stimulus of each modality is a 'Go' signal indicating that a water reward is provided in case of a lick response, while the other stimulus is a 'NoGo' signal generating a timeout in case of licking. Visual and auditory cues are presented either in isolation during unimodal blocks or simultaneously during audiovisual blocks. The analysis of the probability of licking for each unimodal and audiovisual stimulus presentation shows that mice use both visual and auditory cues to determine their behavior. Indeed, mice were significantly more successful at refraining from licking when congruent audiovisual 'NoGo' cues were presented than when each of those cues were presented in isolation. During conflicting audiovisual trials (e.g. NoGo visual cue paired with Go auditory cue or Go visual cue paired with NoGo auditory cue), mice by default licked for water. However, we did not find a difference between the licking probability in response to the unimodal 'Go' trials and audiovisual 'Go' trials likely due to a ceiling effect. We used two-photon calcium imaging to measure the activity of V1 L2/3 neurons while mice were performing the task. At the end of the recording session, we assessed the orientation tuning of the imaged neurons by presenting a series of drifting gratings of 12 evenly spaced orientations. We found that when trained mice performed the task, the activity of V1 neurons tuned to the 'NoGo' visual cue was suppressed during audiovisual blocks. This contrasted with sound modulation measured in naïve mice in which sounds potentiated neurons tuned for the oriented cues. Therefore, our results support the hypothesis that visual processing in V1 is dynamically adapted to the behavioral goal.

Title: Context-switching in a disinhibitory circuit in V1

Authors: *D. VOINA[1], S. RECANATESI[2], B. HU[3], E. T. SHEA-BROWN[2], S. MIHALAS[3]; [1]Applied Mathematics, [2]Univ. of Washington, Seattle, WA; [3]Allen Inst. For Brain Sci., Seattle, WA

Abstract: We investigate minimally complex circuits that perform related but different tasks by using knowledge common to both tasks (transfer learning) and apply them to visual processing of images and visual processing of movies. Experimental evidence suggests that such a circuit exists in the brain's visual area V1, where in addition to excitatory Pyr and inhibitory SST neurons, an additional inhibitory VIP population enables switching between processing of different input types (static and moving). Instead of requiring two circuits to process the two input types, the brain processes scenes using a single circuit, where VIP neurons act as switch units that become activated whenever animals are moving. Could such a flexible circuit operate in both static and moving contexts to perform optimal processing? We use a model for optimal integration of context to predict neuronal connectivities (weights) that achieve optimal processing in the static and moving conditions separately. Instead of using two different sets of weights in two separate circuits, we attempt to find one circuit where VIP neurons interact in a switch-like manner while the Pyr and SST populations remain connected by the weights optimal in the static condition. To find a circuit capable of doing both visual processing tasks, we need to find the VIP contribution during movement that produces the same firing rate statistics as those which would be generated with the set of optimal weights for the movement condition. After finding the VIP contribution by solving a constrained Least Squares problem, we confirm that the network does optimal visual processing of images and, when the VIP are active, of videos. Our network predicts realistic connectivity patterns of Pyr and other neural populations, while also finding the minimal number of VIP neurons that are necessary to achieve an optimal switch circuit. Interestingly, few VIP neurons are required, so that having a low-dimensional switch module added to a circuit could be more favorable than having two separate circuits for the tasks. This provides a concrete example of a model biological circuit - complete with cell type specifications - capable of performing two tasks, further informing the design of bio-inspired multitasking artificial neural networks.

Title: Neural circuits for visual stimulus competition in zebrafish

Authors: *I. P. LAZARTE, J. SEMMELHACK;
Hong Kong Univ. of Sci. and Technol., Sai Kung, Hong Kong

Abstract: All visual animals must be able to pay attention to important stimuli in a dynamic environment in order to survive. Both a frog hunting flies and a fly escaping a hungry frog need to attend to crucial visual information to perform a specific task. Previous studies in anesthetized owls showed that a midbrain structure, the optic tectum (OT), is important for encoding the location of highest priority stimulus in the visual space through excitatory and inhibitory modulation provided by the isthmic nuclei (NI). However, in that paradigm, a behavioral output was not available to support the behavioral relevance of stimulus competition. The purpose of this study is to elucidate the neural circuitry of visual stimulus competition in a behaving animal using larvae zebrafish, a simple vertebrate model system that heavily relies on vision to hunt prey. Using larval zebrafish, we take advantage of their robust prey capture behavior to establish a paradigm where we tracked their response to competing prey, and formulate an algorithm to tell which stimulus it attended to. Using a head-fixed paradigm with eyes and tail free, we simulate prey by projecting a moving dot on a screen in front of the larva. We first determined the size of an optimal prey that reliably evokes prey capture behavior. Then, we added a competing prey separated in the visual field such that fish selected either right or left side. When the two preys are similar in size, we found around 50% chance of the fish selecting either of the two preys. We found that the chance of choosing the optimal prey depends on the size of competing prey. Larger competing prey increases the chance of choosing optimal prey; indicating a weaker competition. On the other hand, smaller competing prey and closer to the optimal prey size decreases the chance of choosing the optimal prey; indicating a stronger competition. By 2-photon functional imaging, we found the most responsive region in the OT, and confirmed that its calcium activity follows a retinotopic pattern, allowing us to separately monitor the activity on the optimal and competing preys projection sides. Preliminary results show activation of the anterior OT by our prey stimuli, and a decrease in activity with the addition of a competing prey. This could be evidence of the inhibitory response of the midbrain circuitry found in owls. We will confirm this by labelling the GABAergic neurons in the NI, and trace their projections to OT by photoactivatable GFP. We will further provide functional evidence of suppression from NI by observing the NI response during the presence of competing

prey, and the changes in OT response by laser ablation of the NI neurons activated by the competing prey.

Title: Context-dependent neuronal modulation in V1 during selective visual attention

Authors: *D. TRAN[1], M. HAJNAL[2], M. EINSTEIN[1], M. VALLEJO[1], A. FOREMAN[1], B. SEDAGHAT[1], R. GOLI[1], T. SHOOSHANI[1], G. ORBÁN[2], P.-O. POLACK[3], P. GOLSHANI[4]; [1]Neurol., Univ. of California Los Angeles, Los Angeles, CA; [2]MTA Wigner Res. Ctr. for Physics, Budapest, Hungary; [3]Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ; [4]UCLA Dept. of Neurol., Los Angeles, CA

Abstract: Numerous studies in non-human primates have found that selective visual attention increases the responsiveness of primary visual cortical (V1) neurons. Yet, the precise mechanisms of this attention-related neuronal gain remain unknown. To further dissect these mechanisms, we performed 128-channel extracellular electrophysiological recording throughout V1 in mice performing a cross-modal visual/auditory attention task. During visual attention, water-restricted mice licked for water reward in response to one oriented drifting grating and had to withhold licking when an orthogonal orientation was presented. During this time, they actively ignored auditory stimuli (high or low tone) presented simultaneously with the visual stimuli. During auditory attention, mice were cued to lick in response to one tone and withhold licking to the other tone, while actively ignoring oriented drifting gratings. Visual and auditory attention sessions were presented in random order. Visual cues elicited a larger response from broad spiking (putative excitatory) V1 units in deep cortical layers (layers V and VI) during visual attention trials compared to auditory attention trials. This change in gain was apparent during both Go and No-Go trials but was not observed during fast locomotion. Narrow-spiking (putative inhibitory) units in superficial cortical layers, on the other hand, fired at higher rates during visual stimulation when animals ignored rather than attended to visual cues. Population decoding analysis showed that visual stimuli could be decoded from V1 population firing patterns. Surprisingly, the attentional context (attend visual vs. attend auditory) could also be decoded from the neural activity in V1 even during the inter-trial intervals. These results show that there is robust and opposing attentional modulation of V1 excitatory neuron firing rates mainly in deep layers, and V1 inhibitory neurons mainly in superficial cortical layers. The ensemble neural activity carries rich information about not only the visual stimulus but also the task context. We

are currently optogenetically inhibiting inputs to V1 to determine the mechanisms of this attentional modulation.

Title: Investigating response behavior on added semantically specific auditory probe stimuli in motor-cognitive dual tasks

Authors: *J. MUELLER, C. LANGHANNS, H. MUELLER;
Justus-Liebig-University, Giessen, Germany

Abstract: Introduction
Probe-reaction time (PRT) techniques are used to infer the strength of cognitive involvement in a primary task based on reaction time delays in the PRT task (Posner&Boies, 1971). Specific insights into content and temporal dynamics of primary task related processing can be gained by manipulating the temporal locus of the probe (McLeod, 1978; Mattes, 2001). However, manipulating the semantic similarity between tasks and probe stimuli might also affect the processing (Wickens, 2002). Therefore, we use a motor-cognitive dual task (mcDT) in order to understand the dynamic shift of processing resources between the continuous motor task and the cognitive task. In the resulting triple-task, we analyze PRT to auditory probe stimuli at critical moments dependent on their semantic similarity to either the motor, or the cognitive task.
Methods
12 participants conducted a mcDT on three consecutive days. The cognitive task was a visually presented calculation task (subtracting two numbers). The motor task was a force tracking task on a leg press. The auditory probes were two spoken numbers (“4”&“6”, interference with calculation) and pairs of words expected to interfere with either the quantitative (“stronger”&“weaker”) or the spatial (“up”&“down”) aspect of the motor task. Reactions to the probes were given by pinching index finger and thumb. Participants were instructed to perform all tasks as good as possible. RT was recorded from the EMG-signal from M. interosseous dorsalis I.
Results and Discussion

Analyses based on performance differences in PRT (ΔPRT) show a main effect for multi- compared to single-tasking conditions, which is shown in higher RTs for all types of auditory probes during multi-tasking (χ^2=158.87, p<0.01*). Data also support the multiple resource theory (Wickens, 2002) by showing a significant interference of probe stimuli holding numbers with the performance in the calculus task (Z=-1.96, $p_{one\text{-}tailed}$=0.03, d=0.29*). Presented data will further quantify the effect of probe-type and -onset on performance to contribute to neuroscientific attention research.
* statistics based on preliminary data. Full data set will be presented at the conference.

Title: Coincident sound modulates visual processing in V1 and improve the mouse's ability to discriminate orientations

Authors: *J. CORBO, J. MCCLURE, JR, H. KHDOUR, P.-O. POLACK;
Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. Newark, Newark, NJ

Abstract: To create a coherent perception of its environment, the brain integrates information from multiple sensory modalities. In several species including rodents and humans, visual perception has been found to be modulated by the multisensory context. Previous researches have shown that multimodal integration can occur in the primary sensory cortices, putting into perspective the paradigm of a clear-cut parcellation of early unimodal processing into distinct channels. In V1, the co-presentation of pure tones with oriented drifting gratings were shown to improve the representation of orientation and direction in naïve mice by refining the distribution

of activity in the space of the individual neurons' preferred orientations. However, it is not known if this representational improvement is paired with an improvement of the perception of orientation. Yet, these results suggest that the presence of sound, by sharpening the representation of the orientation and direction of the visual stimuli in V1, could decrease the minimal angular distance that mice can discriminate. To test this hypothesis, we trained mice to discriminate between two gratings orientations in a 'go/no go' task, and gradually reduced the angular distance between the 'go' and 'no go' orientations by making the 'no go' stimulus closer to the 'go', from 45 to 15 degrees. The neural activity was recorded in behaving animals using two-photon calcium imaging in V1 layer 2/3. We find that the co-presentation of pure tones along with the visual stimuli enhances the difference between the neural representations of the visual stimuli and decrease the minimal angular distance between two orientated stimuli that mice can discriminate. This simultaneous sound-induced bias of the representation of orientations in V1 and of the perception of orientation by the mouse supports the emerging theory of V1 as an interface between bottom-up visual input and external or internal top-down influence.

Abstract: Although the primate visual system is one of the most intensively studied systems in neuroscience, there are still controversies regarding the organization of fiber tracts connecting visual areas. Whereas some investigators doubt the existence of the vertical occipital fascicle (VOF) and inferior longitudinal fascicle (ILF), others could demonstrate these fiber tracts using diffusion-weighted magnetic resonance imaging (dMRI)-based tractography (Tusa & Ungerleider, 1985; Catani et al., 2003; Yeatman et al., 2014; Takemura et al., 2017). Also, the distinction between ILF and the sagittal stratum (SS) has been controversially discussed (Schmahmann & Pandya, 2006). The reasons for these confusions are partly found in different methods used (i.e. Klinger's dissection, dMRI, or axonal tracing). While all these methods have own advantages and limitations, the measurement of the anatomical structures of fiber tract itself in the entire hemisphere with ultra-high resolution is essential to resolve existing controversies. Here we analyzed the data collected from fixed but unstained serial microtome sections of two vervet monkey brains (*Chlorocebus aethiops sabaeus*; 2.4 and 1 years old; both male; section thickness, 60 μm) using polarized light imaging (PLI; Axer et al., 2011). This method enables visualization of fiber orientations in each bundle at micrometer resolution (in-plane resolution: 1.3 μm). This resolution enables visualization of how fibers from lateral geniculate nucleus merge to the SS, and also demonstrate the existence of the callosal (tapetum) and association fibers (ILF, VOF, and dorsal occipital bundles) as independent units of white matter architecture in the visual system. VOF occurs between the dorsal and ventral extrastriate areas and has fiber orientations different from that of ILF. We also found that ILF fibers merge with SS at their posterior end, while the ILF is a distinct bundle from SS at inferior temporal gyrus. This organization of SS and ILF explains the historical confusions on distinction between them. The tapetum contains callosal fibers and can clearly be segregated from U-fiber layers of the calcarine sulcus (stratum calcarinum), supporting the idea that the tapetum is a part of callosal fibers from the splenium. In sum, PLI resolves a number of controversies regarding the existence and definition of visual white matter tracts, and provides essential information for integrating findings from axonal tracing and dMRI on primate visual system.

Title: Pattern of feedback connectivity from the frontal eye field of macaque to area lip

Authors: *B. AHMED, M. SMITH, A. J. PARKER, K. KRUG;
Univ. of Oxford, Oxford, United Kingdom

Abstract: Lateral intraparietal (LIP) cortex plays a central role in visuo-motor information processing, saccade-planning and decision-making, and has reciprocal cortico-cortical connections with the Frontal Eye Field (FEF), an area that is involved in planning and execution of eye movements (saccadic, smooth pursuit and vergence). Moreover, there is evidence that FEF neurons display sensitivity to binocular disparity. Here, we report on the distribution of retrogradely labelled cells within primate FEF that project to a single point in area LIP.
In 5 Rhesus macaques (Macacca mulatta), we placed a single injection (~80 nL) of the retrograde tracer Cholera Toxin subunit beta (CTb) into LIP.
Anatomically, LIP can be divided into dorsal (LIPd) and ventral (LIPv) regions based on myelination density. In two macaques, tracer was injected into LIPd, layers 3 to 5; in one macaque at the border of LIPd and LIPv, layers 1 to 3a; and in two others within LIPv. We defined area FEF as the region within the anterior arcuate sulcus, bounded ventrally by the tapering off of layer 4 (Nissl stained sections) and dorsally by a decrease in myelination density (Gallyas stained sections). It's medial and lateral boundaries were based on: Atlas of the Rhesus Monkey Brain (Saleem and Logothetis). In parasagittal sections (1:5 series, 50 um thickness), we marked the position of CTb labelled cell bodies within FEF and surrounding regions using Neurolucida (Microbrightfield Ltd). In general, CTb labelled cells were sparsely distributed throughout the dorso-ventral and medio-lateral extent of FEF, there were regions of higher density which formed one or more clusters. Although labelled cells were located in both supra- and infra-granular layers, there was a preponderance of labelled pyramidal cells within layers 2 and 3.
Attentional cues are known to enhance gamma-band oscillatory coupling between FEF and area V4, a property of FEF supragranular neurons. The large number of labelled supragranular cells suggests a similar linkage between FEF and LIP - a feedback coupling that may enhance a top-down attentional influence on LIP.

Title: Cortical magnification in human V1 and V2 predicts task performance around the visual field

Authors: *N. C. BENSON, M. CARRASCO, J. WINAWER;
Psychology, New York Univ., New York, NY

Abstract: Psychophysical performance varies across the visual field. Performance on most tasks drops precipitously with eccentricity. This pattern is reflected in visual cortex: the cortical magnification factor (CMF, cortical area per degree in the visual field) decreases with eccentricity, and population receptive field size (pRF) increases with eccentricity. Performance also varies systematically around the visual field at fixed eccentricity. For contrast sensitivity, acuity, and object recognition, performance is poorer on the upper than lower vertical meridian, and poorer on the vertical than horizontal meridian. These effects are most pronounced near the cardinal meridians [e.g., Carrasco et al 2000; Abrams & Carrasco 2012], rather than being general to hemifields or quarterfields. Silva et al. [2018 DOI:10.1016/j.neuroimage.2017.11.021] reported differences in CMF and pRF size between horizontal and vertical quadrants, and differences in CMF between upper and lower quadrants. Here, using a much larger dataset-181 subjects from the Human Connectome Project 7T Retinotopy Dataset [Benson et al. 2018, DOI:10.1167/18.13.23]-we asked whether there are differences in human V1 and V2 close to the cardinal meridians; horizontal vs. vertical and upper vs. lower vertical meridian. We measured the average width of the cortical representation of the vertical meridian, spanning ±15 degrees of polar angle from the V1/V2 boundary. This measure is robust to small errors in the localization of the V1/V2 border. We also compared pRF size for locations in V1 excluding regions near the vertical meridian to avoid possible blurring between V1 and V2. We found that the width of the upper (ventral) and lower (dorsal) vertical meridians were 5.0 mm and 8.8 mm, respectively, with only small differences in length. As a result, the surface area representing the lower vertical meridian, where performance is relatively good, is ~40% higher than the upper meridian, where performance is poorer. We also found that pRF size was smaller on the horizontal meridian, where performance is best, at all eccentricities than at oblique or vertical meridians. These polar angle patterns parallel the relationship among CMF, pRF size, and performance as a function of

eccentricity. We conclude that the representation of visual space on the surface of V1/V2 reflects task performance around the visual field.

Title: Uncovering network generation rules from large scale connectivity measurements

Authors: H. CHOI, B. H. HU, I. MAGRANS DE ABRIL, ***S. MIHALAS**;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Neural networks are marked by their complex connectivity at multiple scales, ranging from local cell-to-cell connectivity to large-scale networks of brain regions. Some of the key structural complexities of neural networks include modularity, hierarchical organization, spatial embedding, and sparse long-range connections. While such complexity is believed to underlie the computational flexibility of the brain, the generative principles that drive evolution of intricate connectivity among neuronal populations are not fully known. Here we propose methods to uncover network generative rules based on a single measurement of the state of the network in adulthood. To make this problem tractable, we assume: 1) stationarity of the plasticity rules in the period just before the measurement of the connectome, 2) exclusive dependence of changes in a connection on the activity relation of the nodes connecting it, and 3) dependence of the activity relation on chain graph motifs which begin or end on two nodes. With this set of assumptions, we can describe a family of plasticity rules. We use a Taylor expansion of these rules and search for coefficients of powers of the connection weight matrix and its transpose, to describe the effects of mono-synaptic interactions, di-synaptic interactions, and so on. In other words, these coefficients represent different effects on connection plasticity exerted by both direct and indirect interactions. To search for these coefficients, we implement two methods: a generative method based on generative adversarial networks (GANs) and an inference method based on distributions of connection weight powers. Our GAN method consists of a generator that iterates a fixed number of times over the generative rule defined on learnable parameters, and a discriminator that judges whether a given connectivity matrix is original or generated by the current generative function. On the other hand, our inference method searches for a set of matrix coefficients that minimizes an optimization function derived from Kullback-Leibler divergence between connection strength distributions of the true network and the learned network. To validate the feasibility of the generative rule, we first apply our two methods to artificial datasets generated by known generative rules and initial conditions. Then, we apply our

methods to a data-driven, mesoscopic mouse brain connectome (Knox et al. 2018), to uncover the generative rule for the mammalian cortical structure. We do observe that this method discovers plasticity rules which reproduce well the observed distribution of connection strength and network motifs in the mouse cortex.

Title: Does the cortex implement dropout?

Authors: *J. SHANG[1,2], B. HU[1], R. IYER[1], S. MIHALAS[1];
[1]Allen Inst. for Brain Sci., Seattle, WA; [2]Applied Mathematics, Univ. of Washington, Seattle, WA

Abstract: Neuronal responses to repeated stimuli are highly variable. This variability has been attributed to state fluctuations (Engel et al., 2016) or intrinsic lognormal distributions (Buzsáki et al., 2014). Several theories propose a role for this variability in neural coding, e.g. sampling-based probabilistic representations (Orbán et al., 2016). Here, we characterize the trial-to-trial variability in large-scale two-photon calcium imaging from the Allen Brain Observatory (de Vries et al., 2018) and electrophysiological recordings using Neuropixel probes across multiple brain areas in response to a wide range of visual stimuli (e.g. drifting gratings, natural images, natural movies), in both passive and active behavioral states, with the goal of linking the observed trial-to-trial variability to cortical computations.
In response to a repeated natural movie stimulus, many neurons show highly variable responses to their preferred movie frame, with response distributions better fit by two-component Gaussian or lognormal distribution compared to one-component Gaussian. We find visual thalamic neurons having a higher fraction fit by a one component gaussian, and small differences across cell types and cortical areas with the highest fraction of one component gaussian in the superficial layers. Additional analyses of two-photon calcium imaging data during a visual change detection task showed similar results. This result cannot be simply explained by correlations with simple behavioral covariates such as the animal's running speed. As an additional control, removing state-dependent fluctuations captured by regressing single neuron responses against the activities of all the other simultaneously recorded neurons and fitting the residuals revealed similar results.
One possible functional interpretation of the observed two-component Gaussian distributions is dropout, a neural network training technique, whereby units are randomly "dropped out", thereby

reducing feature co-adaptation and improving model generalization (Srivastava et al., 2014). We find that units in deep neural networks trained with dropout also show similar two-component Gaussian response distributions. Future work will include other response distribution types and investigate the potential functional role for this variability.

Title: Supervised classification of anatomical cell types in mouse visual cortex using arbor density and morphometric feature representations

Authors: *O. GLIKO, C. LEE, R. DALLEY, S. A. SORENSEN, U. SÜMBÜL;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: While the classical approach to anatomical classification of neurons has revealed numerous insights since the time of Cajal, it lacks objective criteria and requires an expert anatomist for identification. On the other hand, unsupervised clustering of anatomical features often conflicts with qualitative insights. Here, we seek to test the objective reproducibility of qualitative definitions of neuronal types. In particular, we propose a new 2d registered arbor density representation of neuroanatomy and compare its performance against morphometric and topological features by training neural network-based supervised classifiers. Our approach is to avoid the calculation of explicit features, and rather treat the arbor trace as an image registered to a common local coordinate axis using the pia/white matter boundaries. We represent apical and basal dendrites of excitatory neurons, and axons and dendrites of inhibitory neurons separately with 2d arrays of size 120x4. While many thousands of traces of neuronal arbors exist, datasets with local anatomical landmarks are much smaller. Therefore, we apply novel data augmentation strategies, including cell type dependent random shift of the arbor density representation in the laminar direction, modulation of the intensity values of the representations, and elastic deformation of the 2d arbor density images. We achieve >80% cross-validated classification accuracy (chance at ~4%) on a dataset with 487 excitatory and inhibitory neurons from mouse visual cortex with 26 expert assigned qualitative types.

Title: Inhibitory rTMS over the parietal cortex modulates functional connectivity

Authors: *S. SCHINTU[1,2], C. A. CUNNINGHAM[1], M. V. FREEDBERG[1], S. J. GOTTS[3], S. S. SHOMSTEIN[2], E. M. WASSERMANN[1];

Abstract: Hemispatial neglect of the right side of space is thought to result from hyper-activation of the left (intact) frontoparietal network, due to its release from inhibition by the right hemisphere. Nominally inhibitory rTMS over the left posterior parietal cortex (PPC) typically improves neglect and normalizes the hyper-active left frontoparietal functional connectivity (FC). Whereas if delivered over the right PPC in healthy participants shifts midline judgment rightward, mimicking neglect behavior, supposedly by changing frontoparietal FC. We investigated whether nominally inhibitory rTMS over the right PPC produces neglect like behavior and changes frontoparietal FC. In counterbalanced order, 17 participants received 40 sec of continuous theta-burst rTMS at 80% of active motor threshold, to the right PPC or vertex (control site) in sessions separated by ≥ 5 days. Before and after rTMS, participants underwent a 10-minute resting state fMRI scan and performed line bisection tasks. The PPC target was area 1 of the intraparietal sulcus (IPS1), where TMS has been shown to affect visuospatial behavior. The dorsal network was defined by intrinsic functional connectivity. As expected, participants exhibited a rightward shift in line bisection judgment after rTMS over the right PPC. However, the direction of FC change in the right hemisphere was highly variable and there was no overall effect of PPC vs. vertex rTMS. A whole brain, seed-based, analysis found an increase in FC between the PPC target and the left superior temporal gyrus (STG), which is a central node for visuotemporal attention. Follow up analysis showed that the left STG increased FC with the right medial frontal gyrus and right precuneus, both nodes of the frontoparietal network. Local inhibition of the right PPC shifts visuospatial behavior to the right through a mechanism that remains ill defined. Here we show that nominally inhibitory rTMS over the right PPC increases FC with STG (critical parts of the visual attention network) in the contralateral hemisphere,

which, in turn, becomes more connected with areas of the right frontoparietal network. These findings show that local inhibition of the right PPC reshapes the attentional network by recruiting regions of the contralateral hemisphere.

Title: 3d MRI-based marmoset brain atlas version 3: *In vivo* population-based MRI, dti and CT templates, and analysis tools

Authors: *C. LIU[1], C. C.-C. YEN[2], D. SZCZUPAK[3], X. TIAN[1], G. DANIEL[4], A. C. SILVA[5]; [1]NINDS/NIH, Bethesda, MD; [2]NINDS/LFMI/CMS, Natl. Institues of Hlth., Bethesda, MD; [3]Natl. Inst. of Hlth., North Bethesda, MD; [4]NIMH/NIH, Bethesda, MD; [5]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: By acquiring super-resolution MRI of ex-vivo brains, we had constructed a full 3D anatomical atlas of the marmoset brain. Version 1 contained the cortical parcellation, and version 2 the white matter pathways. However, these two previous versions were based on only a few brains of male marmosets, which imposes a limitation to their application in neuroimaging studies of large cohorts of animals. To address this problem, we collected in-vivo multi-modal MRI from 27 marmosets of both genders. The new in-vivo MRI dataset includes anatomical T1-weighted, T2-weighted, and multi-shell diffusion MRI, as well as functional resting-state fMRI. From the anatomical MRI, head profiles were created and compared to profiles based on CT images of the same subjects' heads. Analysis of the new MRI- and CT-based dataset revealed significant variations in head and brain shape and size, regional volumes of several brain structures, and brain connectivity, highlighting substantial individual variabilities in the marmoset population. We used the new dataset to create multimodal brain templates and co-registered them into a new and standard population-based template space, which was anatomically labeled using previous versions. We constructed population-based tissue types to facilitate volumetric analyses and built a population-based brain surface to facilitate 3D visualization and surface-based analyses. Combining information obtained from the MRI with

that of the CT dataset allows a more accurate frameless estimation of stereotaxic coordinates of different brain regions, which can be used, for example, for a more precise surgical planning. These templates and associated tools will comprise version 3 of our marmoset brain atlas project, which will significantly aid in a wide range of MRI and connectome studies.

Title: Strong correlation between extracellular spike waveform and spatial receptive field type in cat visual cortex

Authors: *S. SUN[1,2], H. MEFFIN[2,1], Y. WONG[3,4], S. L. CLOHERTY[3], A. ALMASI[2], M. YUNZAB[2], Y. JUNG[1,2], M. R. IBBOTSON[2,1];
[1]Optometry and Vision Sci., The Univ. of Melbourne, Parkville, Australia; [2]Natl. Vision Res. Inst., Melbourne, Australia; [3]Physiol., [4]Electrical & Computer Systems Engin., Monash Univ., Clayton, Australia

Abstract: Extracellular spike waveforms from recordings in the visual cortex have been classified into either regular spiking (RS) or fast spiking (FS) units, which are often associated with excitatory and inhibitory neurons, respectively. While both these types of spikes have waveforms with negative first phases, we show that there are also distinct classes with positive first phases, which are not regularly reported. The spatial receptive fields (RFs) of these different spike waveform types were estimated and we found that each spike type had distinctly different RF structures. 837 single units (SUs) in the cat visual cortex were classified into five categories by the shape of their spike waveforms: RS units (52%, 432/837) which are biphasic, have a dominant negative peak, and a slow inclining slope at the end of the waveform; FS units (22%, 185/837) which are biphasic, have a dominant negative peak, and a fast declining slope at the end of the waveform; triphasic spiking units (TS, 9%, 74/837) which have a positive first peak that is >10% of the negative peak, followed by a large negative peak and then a smaller positive peak; compound spiking units (CS, 3%, 27/837) which are also triphasic but with a significantly longer waveform; and positive spiking units (PS, 14%, 118/837) which have a positive peak greater than the negative peak. Of these 837 SUs, 231 had their spatial RFs estimated as the spatial filters in a general non-linear model of response to white-Gaussian noise (WGN) and

classified as either oriented and Gabor-like (orientation bandwidth < 90°) or non-oriented and blob-like (orientation bandwidth > 110°). RS and FS units had mostly oriented RFs (95%, 68/72; 99%, 71/72, respectively), while TS, CS and PS units had mostly non-oriented RFs (56%, 14/25; 75%, 6/8; 78%, 28/36, respectively). These non-oriented RFs are very similar to the centre-surround RFs reported in the lateral geniculate nucleus. We calculated several response properties that are statistically distinguishable between cortical and thalamic neural populations: spike-rate, burstiness, and response latency. On average, PS units had significantly higher spike-rate (t-test, $p < 0.05$), significantly higher proportion of burst spikes ($p < 0.001$), and significantly shorter response latency ($p < 0.05$) to RS and FS units. Thus, our results suggest that PS units, which have mostly non-oriented RFs and thalamic-like response properties, may correspond to recordings from thalamic axons projecting to the visual cortex, while RS and FS units correspond to cortical neurons, which have mostly oriented RFs. This would allow cortically implanted electrodes to record activity from thalamus and cortex simultaneously.

Title: Apparent cortical thinning in ventral temporal cortex from childhood to adulthood is associated with increased myelination

Authors: *V. S. NATU[1], J. GOMEZ[2], M. BARNETT[3], B. L. JESKA[1], Z. ZHEN[4], E. KIRILINA[5], C. JAEGER[5], S. COX[1], K. S. WEINER[6], N. WEISKOPF[5], K. GRILL-SPECTOR[1]; [1]Stanford Univ., Stanford, CA; [2]Univ. of California Berkeley, Berkeley, CA; [3]Univ. of Pennsylvania, Philadelphia,, PA; [4]Brain and Cognitive Sci. Sch., Beijing Normal Univ., Beijing, China; [5]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [6]Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: Human cortex appears to thin during childhood development. However, the underlying microstructural mechanisms are unknown. Using functional, quantitative, and diffusion magnetic resonance imaging (MRI) in children and adults, we tested three hypotheses

related to cortical thinning in the ventral temporal cortex (VTC) of 26 children (ages 5-12) and 27 adults using independent and complementary measurements of T_1 relaxation time from qMRI and mean diffusivity (MD) from dMRI. ***Pruning hypothesis:*** CT decreases from childhood to adulthood due to tissue reduction. Pruning predicts no changes or increases in T_1 relaxation time and MD across development. ***Growth hypothesis:*** white/gray boundary shifts deeper into cortex due to increased myelination, making the cortex appear whiter in adults. Myelin growth predicts lower T_1 and lower MD in adults than children. ***Cortical morphology:*** A third possibility is that changes in cortical morphology (cortical folding and surface area) during childhood development may result in thinning. Results show that from age 5 to adulthood T_1 and MD decreased in face- and character-selective regions within lateral VTC. These decreases occurred in mid and deep cortex, as well as in the adjacent white matter. T_1 reduction was also observed longitudinally in these brain regions in children. T_1 and MD decreases (i) were consistent with tissue growth and (ii) were correlated with the apparent cortical thinning. Tissue growth is consistent with increased myelination, which we validated using histological analyses in adult post-mortem brain tissue. In contrast, in a place-selective region located in medial VTC, we found no development of T_1 or MD after age 5 even as cortex thinned across development. Here, we found that cortical thickness was correlated with cortical morphology. These findings suggest that lateral VTC likely becomes more myelinated from childhood to adulthood, affecting the contrast of MR images, and in turn, the apparent gray-white boundary. Consequently, our data have broad ramifications for understanding both typical and atypical brain development, as well as for clinical conditions implicating myelin, including dyslexia, autism, and multiple sclerosis.

Title: Evidence of object-based warping in early visual cortex

Authors: G. GURARIY[1], T. J. VICKERY[2], *A. S. GREENBERG[1];
[1]Dept. of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Dept. of Psychology, Univ. of Delaware, Newark, DE

Abstract: In the visual domain, objects constitute high-level percepts that result from the spatial grouping of low-level sensory information. Interestingly, it has been demonstrated that the visual space within an object appears warped in a systematic manner. Specifically, when two items (i.e., dots) are placed within an object, they are perceived to be further apart relative to equidistant items that are not enclosed within an object. This distortion of space results in a robust visual illusion that has been observed under a variety of parameters and viewing conditions (Vickery & Chun, 2010). However, the neural mechanisms underlying this warping have not yet been explored. Here, we use fMRI to investigate the neural representation of object-based warping in different areas along the visual hierarchy. To measure behavioral effects (outside the scanner), human participants adjusted the perceived distance between two letters so as to perceptually match the distance between two reference letters (appearing either enclosed within an object or not). From this we computed the precise spatial locations at which the letters are perceived as a consequence of the object-based warping. During fMRI, participants performed a discrimination task (among four letters, one located in each screen quadrant) with the following three conditions: (1) all 4 letters were equidistant from one another, (2) two letters in one visual hemifield were enclosed within an object, and (3) two letters in one hemifield appeared without an object at the "warped" distances (from individual participant behavior). Additionally, we ran two separate localizers: (1) a spatial localizer to identify the retinotopic locations of the letters from conditions 1-3, and (2) a meridian localizer to identify early visual areas (V1-V3). The spatial localizer produced (a) two retinotopic ROIs for the letters enclosed by an object (conditions 1 & 2) and (b) two retinotopic regions corresponding to the "warped" spatial positions (condition 3). The mean BOLD response was extracted from each of the four ROIs for all three conditions. With no object present (condition 1), spatially localized ROIs in V1 showed the expected retinotopically-specific activation pattern of equidistant letters. Importantly, however, letters enclosed within an object (condition 2) elicited activity within retinotopic regions corresponding to the "warped" spatial locations (similar to condition 3). We interpret this as evidence of object-based warping in visual cortex, likely caused by feedback from higher level visual areas.

Title: Neural straightening of natural image sequences in macaque V1 and V2

Authors: *Y. BAI[1], O. HÉNAFF[2], C. ZIEMBA[1], E. P. SIMONCELLI[3], R. L. T. GORIS[1];
[1]Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX; [2]Gatsby Computat. Neurosci. Unit, Univ. Col. London, London, United Kingdom; [3]New York Univ. / HHMI, New York, NY

Abstract: A fundamental goal of sensory processing is predicting future states of the environment. Making visual predictions is challenging: under natural circumstances, visual input (the stream of images on the retina) follows complex temporal trajectories that are difficult to extrapolate. We've hypothesized that the visual system alleviates this problem by transforming its inputs into neural representations that follow "straighter" temporal trajectories (Hénaff et al., 2019), facilitating prediction. Previously, we provided psychophysical (Hénaff et al., 2019) and physiological (Bai & Hénaff et al., SfN 2018) support for this theory. Here, we investigate how temporal straightening emerges from the cascade of transformations performed by the visual system.

If temporal straightening is a fundamental goal of visual processing, we might expect that each stage in the visual hierarchy further straightens its inputs. To test this hypothesis, we compared the straightness of natural videos with the straightness of neural population activity elicited by these videos in the primary and secondary visual cortex (area V1 and V2, respectively). We presented random sequences of static frames taken from 16 short videos and used multi-electrode arrays to record population activity in the visual cortex of awake, fixating macaque monkeys (four V1 populations, ranging in size from 52-87 units; three V2 populations, 84-114 units). We obtained temporal trajectories of population activity by arranging neural responses in the videos' natural order.

We found that neural straightening of natural videos increases along the visual hierarchy. Both in V1 and V2, neural response trajectories were straighter than their pixel-domain inputs. This effect was more prominent in V2 than in V1. To test whether straightening is specific to natural videos, we also presented artificial videos that fade from an initial to a final frame. These movies, which follow straight paths in the pixel-domain, elicited the opposite effect in their neural response trajectories, which were significantly curved. Together, these results suggest that temporal straightening may be an objective that shapes the function of multiple stages of the primate visual system.

Title: The role of the primary visual cortex and the lateral occipital complex in scaling size information -- A TMS study

Authors: *H. ZENG[1], G. R. FINK[1,2], R. WEIDNER[1];
[1]Res. Ctr. Juelich, Juelich, Germany; [2]Dept. of Neurol., Univ. Hosp. Cologne, Cologne Univ., Cologne, Germany

Abstract: Neural activation in the primary visual cortex (V1) reflects perceived size rather than the retinal size of the stimulus, suggesting that feedback modulations possibly from extrastriate regions alter retinal size information. In particular, lateral occipital complex (LOC) may contribute to such feedback modulation as it is known to be highly involved in object size processing. To test for causal contributions of such feedback modulations from LOC on size representations in V1, we investigated the dynamics of relevant processes using transcranial magnetic stimulation (TMS). Specifically, we briefly disrupted the ongoing activity in V1 and LOC at early (100-150 ms SOA), intermediate (150-200 ms SOA), and late (200-250 ms SOA) time windows while participants performed size judgement tasks in either an illusory or a neutral context. Thus, TMS over V1 and LOC allowed determining whether these two brain regions are relevant for generating phenomenological size impressions. Furthermore, the temporal order of TMS effects allowed inferences on the dynamics of information exchange between the two areas. Notably, if feedback signals from LOC to V1 are crucial for generating altered size representations in V1, then TMS effects over V1 should be observed simultaneously or later than the effects following LOC stimulation.
Data from 20 healthy participants showed that TMS over both V1 and LOC impaired the illusion perception as compared to vertex stimulation. However, the strongest TMS effect of V1 occurred later than those of LOC supporting the view of a functionally relevant feedback modulation from LOC to V1 in scaling size information. The results suggest that perceived size representations are formed after feedback information from higher visual regions has been received. In sum, size perception emerges from the interaction between higher and low-level visual areas and feedback information flow plays an essential role.

Title: Neural correlates of target-background orientation similarity masking in primate V1

Authors: *S. C.-Y. CHEN, Y. CHEN, W. S. GEISLER, III, E. SEIDEMANN;
Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX

Abstract: Searching for and identifying targets in the natural environment is a primary function of our visual system. Backgrounds that look similar to the search target are well-known adversaries to visual search. However, there is no common agreement on the neural basis of

target-background similarity masking. Here, we examined how orientation similarity affects behavior sensitivity and neural-detection sensitivity in macaque V1.
Macaque monkeys (n=2) were trained to detect an additive Gabor target (4 cpd, 0.33° FWHM, 1.5-3° eccentricity) on grating backgrounds matched in spatial frequency, but of variable orientation. As the monkeys performed the task, we recorded V1 neural responses using voltage-sensitive-dye (VSD) imaging. As V1 is strongly selective to orientation, we hypothesized that V1 neural activity at the scale of orientation columns would correlate with behavioral detection performance.
As in human subjects, the monkeys' behavioral detection performance was worst when the orientation of the background was aligned to the target. Performance improved as the background rotated towards the orthogonal orientation. When the background was orthogonal to the target and background contrast was low, performance can reached nearly same level as for uniform (blank) background.
We next examined V1 responses at the orientation-columns scale. As expected, in the background-only and target-only trials, the population response peaked in the columns preferring the stimulus orientation. With the target added to the background, the target-evoked response (i.e., target + background response minus background response) displayed complex bi-phasic dynamics. In the first 50 ms, the response was strongest when the target and background orientations were aligned. This paradoxical response is anti-correlated with the behavioral masking effect.
After the first 50 ms, the target-evoked response was strongly suppressed by the aligned background, was less suppressed as the background rotated away, and approached the response level on uniform background when the background was orthogonal. V1 responses during this period are therefore positively correlated with the monkeys' detection performance. In addition, we found that the peak of the target-evoked population response deviated from target orientation, exhibiting a clear repulsion away from the background orientation.
A complete model of how target-background orientation similarity affects behavior may need to include the various components of the V1 neural population dynamics we have observed.

Title: Mechanisms of motion boundary perception in macaque V2

Authors: *H. MA, P. C. LI, J. M. HU, S. D. ZHU, X. Y. CAI, Q. L. SONG, Y. LI, C. FANG, K. YAN, H. D. LU;
State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China

Abstract: Our visual system can use multiple visual cues to detect the boundary of an object. Among these cues, motion cues are especially useful when luminance and color cues are unreliable (e.g. camouflage). A subset of orientation neurons in the ventral visual pathway have been found (Marcar et al.,2000; Mysore et al.,2006) that are sensitive to motion boundaries (MBs) created by relative motion. However, it is not clear about the neural circuits for such selectivity and whether these MB neurons in deed underlies the behavioral MB detection. To study these questions, we recorded neuronal activity in area V2 of macaque monkeys while they were performing a MB-orientation discrimination task. V2 regions selected for microelectrode array implant included both orientation domains and direction domains that were first identified with intrinsic signal optical imaging. MB stimuli were created by two adjacent patches of random dots in which dots were moving in opposite directions. We found ~30% orientation neurons in V2 exhibited MB-orientation selectivity, and their preferred MB orientations were consistent with their preferences for luminance gratings. When the difficulty of the MB-orientation discrimination task was adjusted by lowering the coherence or brightness of the moving dots, trial-to-trial variability of MB neurons' responses (choice probability, CP) was correlated with the monkeys` behavioral choices. For these MB neurons, their tuning to MB orientation emerged at ~85ms, which was ~50ms later than their visual latency (~35ms). This delay became even longer when the MB was moved away from neurons' RF centers, although their visual latency was not affected. This MB-orientation tuning latency was similar to the surround tuning latency of V2 direction-selective neurons when they responded to motion contrast between their RF center and surround. Pair-wise analysis also showed a general correlation of activity between neuron pairs, including direction-selective neuron and MB neuron pairs. Together, our preliminary results indicate that V2 is an important area for behavioral MB orientation discrimination, and intra-areal circuits in V2 may contribute substantially to this task.

Title: Network analysis of cortical dynamics implicates untuned neurons in visual stimulus coding

Authors: *M. LEVY[1], O. SPORNS[3,4], J. N. MACLEAN[2,1];
[1]Committee on Computat. Neurosci., [2]Neurobio., The Univ. of Chicago, Chicago, IL;
[3]Psychological and Brain Sci., [4]Network Sci. Inst., Indiana Univ., Bloomington, IN

Abstract: Unbiased and dense sampling of large populations of layer 2/3 pyramidal neurons in mouse primary visual cortex (V1) reveals two functional sub-populations: neurons tuned and untuned to drifting gratings. While tuned neurons have been thoroughly studied, untuned neurons remain poorly understood. Here we construct functional networks (FNs) of up to 350 neurons in V1 (20 datasets), summarizing the partial pairwise correlation structure as a directed and weighted graph, comprised of both tuned (60%) and untuned (40%) neurons. We then employ graph theoretic measures to evaluate the interrelationship between these functional classes of neurons. We find that FNs are stimulus-specific, as graphs of orthogonal directions are highly dissimilar and neighboring directions of drifting gratings are more similar than chance. The dissimilarity between FNs is primarily driven by the functional connectivity between untuned neurons since these connections are consistently different regardless of stimulus similarity. V1 FNs have a rich club topology that spans broad degree distributions and untuned neurons form a rich club of strong edge weights. Untuned neurons tend to be ranked higher than tuned neurons in random walks performed on these networks. Collectively these results suggest that untuned neurons occupy unique topological positions that render them ideal elements to facilitate read out of small differences in grating direction. To assess the potential of untuned neurons for decoding, we establish a two-phase decoding model of V1 and a downstream area, where 12 direction-specific FNs, inferred from data, are instantiated as recurrent neural networks. The spiking output of each model is then used as inputs to a shallow feed-forward neural network trained in a supervised learning manner. We are able to accurately decode the direction of drifting gratings. Permuting connections from either tuned or untuned neurons to the output layer produces a comparable degradation in decoding performance. Taken together, our results demonstrate that untuned neurons are integral to V1 FNs and suggest that tuning properties arise from network interactions involving tuned and untuned neurons in a way that facilitates decodability and separation between similar stimuli downstream.

Title: Functional network topology and computation in mouse visual cortex during stimulus presentation

Authors: *E. DE LAITTRE[1], J. MACLEAN[2];
[1]Committee on Computat. Neurosci., [2]Committee on Computat. Neuroscience, Dept. of Neurobio., Univ. of Chicago, Chicago, IL

Abstract: In the brain, information is computed and transmitted in the activities of networks of interconnected neurons. Analyzing the structure of functional interactions in these networks can provide insight into both processes. Functional networks summarize statistical dependencies in neural dynamics, creating a web of pairwise relationships where nodes correspond to individual neurons and edges correspond to functional (or effective) connections between neurons. Partial information decomposition is a recently developed tool that partitions the information passing from a number of sources (e.g. neurons) to a target (another neuron) into unique, redundant, and synergistic components. In this framework the synergistic component is interpreted as computation. Recent work in organotypic slice cultures has shown that the topological position of a neuron in the functional network relates to the amount of computation it performs (Timme et al., 2016; Faber et al., 2019). Here we explore whether functional networks that summarize *in vivo* cortical activity exhibit this same relationship between functional network topology and computation. Using two-photon calcium imaging, we recorded the activity of large populations of excitatory neurons in layer 2/3 of mouse primary visual cortex while mice viewed drifting gratings. From time series of somatic fluorescence we create functional networks where weighted, directed edges capture the functional relationships between pairs of neurons. At points where two directed edges converge on a single (target) neuron, we use partial information decomposition to quantify the amount of computation performed by the target neuron relative to the input of the two source neurons (i.e. amount of synergistic information present). Collecting data in vivo allows us to also consider how structured input to the circuit (in the form of visual stimulus) influences network topology, computation, and the relationship between the two. To do so we perform these analyses on data from each stimulus condition separately (one of twelve directions of drifting grating) and on data from the presentation of an unstructured visual stimulus (mean luminance matched gray). Partial information decomposition is a promising tool for dissecting functional relationships between multiple dynamic components, such as the activities of neurons in local cortical networks. Identifying components of network topology that support computation has the potential to reveal mechanisms of information processing at the neural circuit level.

Title: Prediction of single trial cortical neuronal dynamics through strong positive recurrent interactions

Authors: S. KOTEKAL[1], ***J. N. MACLEAN**[1,2];
[1]Neurobio., The Univ. of Chicago, Chicago, IL; [2]Computat. Neurosci., Univ. of Chicago, Chicago, IL

Abstract: To develop a complete description of sensory encoding, it is necessary to account for trial-to-trial variability in cortical neurons. Using a generalized linear model with terms corresponding to the visual stimulus, mouse running speed, and experimentally measured neuronal correlations, we modeled single trial dynamics of L2/3 murine visual cortical neurons to evaluate the relative importance of each of these factors to neuronal variability. We find single trial predictions improve most when conditioning on the experimentally measured local correlations in comparison to predictions based on the stimulus or running speed. Specifically, accurate predictions are driven by positively co-varying and synchronously active functional groups of neurons. Including functional groups in the model enhances decoding accuracy of sensory information compared to a model that assumes neuronal independence. Functional groups, in encoding and decoding frameworks,provide an operational definition of Hebbian assemblies in which local correlations can largely explain neuronal responses on individual trials.

Title: Divisive normalization in the responses of V1 neurons in alert mice measured using calcium indicators

Authors: *Z. A. ZAYYAD[1,2,3], J. H. R. MAUNSELL[2,3,4,5], J. N. MACLEAN[2,3,4,5];

Abstract: Divisive normalization is a form of non-linear input summation found in diverse modalities and species. It has been described in systems ranging from the olfactory periphery in fruit flies to higher-order cognitive representations related to attention and decision-making in macaque monkeys. But while divisive normalization is widespread in the brain, the circuit mechanisms that underlie it are not well understood. We imaged hundreds of excitatory L2/3 neurons expressing GCaMP6s under the Thy1 promoter in mouse V1 at ~20-30 Hz in individual animals through a chronically implanted window. During imaging, we presented plaid cross-inhibitory stimuli made of two superimposed orthogonal drifting gratings, each presented at one of five contrasts (for a total of 25 stimuli). We imaged 10 fields of view in five awake, ambulating mice, recording calcium responses from 2949 cells. Of those, 668 preferred one of the orientations in the plaid stimulus. For this subset of neurons, we calculated a divisive normalization index by comparing the response evoked by a plaid stimulus to the sum of the responses to the plaid's component gratings. We observed a range of index values for divisive normalization, with some cells showing robust normalization and others giving responses that were closer to a linear sum of the responses to the individual gratings. The overall distribution was similar to that previously reported in monkey visual cortex. We are currently extending these results with electrophysiological measurements of V1 responses to the same stimuli. Our initial results suggest that the mouse will support combinations of genetic, electrophysiology, imaging, and psychophysics techniques to further elucidate the circuit mechanisms that produce divisive normalization.

Title: Specific topological features in functional networks contribute to the accuracy of a linear encoding model of single trial neocortical neuronal dynamics

Authors: *C. YU, M. LEVY, J. N. MACLEAN;
Univ. of Chicago, Chicago, IL

Abstract: The activity of neurons in sensory cortices covary on a moment to moment basis. We represent the co-activity of neurons as a directed and weighted functional network, constructed from somatic fluorescence changes from up to 350 neurons in mouse primary visual cortex (V1) in response to 12 directions of drifting gratings. Weights of functional connections, called edges, are assigned using partial pairwise correlation, and the directionality of each edge is assigned according to the lag that produces the maximal correlation, with lag 0 resulting in a reciprocal edge. We find that the resulting functional network is sparse and that reciprocal edges are more frequent than expected by chance, especially amongst the strongest edge weights. Moreover, reciprocal edges lead to enhanced clustering of a higher-order pattern, called motif, in which a neuron acts as a middle-man between two other correlated neurons. We employ functional networks in a simple linear encoding model of a single trial where each neuron's activity is predicted from the activity of its functionally connected counterparts. To determine which specific topological features are crucial for accurately modeling single neuron dynamics, we evaluated the interaction between topology and edge weights by computing the geometric mean of the edge weights in the motifs. We find that middle-man motifs tend to have, on average, large geometric means. In turn, the activity of neurons with high clustering scores of the middle-man motif are more accurately modeled using the activity of their functional neighbors compared to the rest of the population. By treating different directions of drifting gratings as the latent variables in a coupled hidden-markov-model (HMM), we further evaluate the role of reciprocal edges and higher-order motifs in accurate modeling of dynamics. Taken together, our results suggest that functional network topology has highly non-random features and that specific local circuit interactions support stimulus coding.

Title: Orientation and direction selectivity for neurons in V1 and V2 of the mouse

Authors: *D. RHEE[1], C. MCKINNON[2], J. N. MACLEAN[1], S. SHERMAN[1];
[1]Neurobio., [2]Computat. Neurosci., Univ. of Chicago, Chicago, IL

Abstract: Neurons in visual cortex are known to be highly selective to the orientation and direction of moving stimuli. Orientation and directional tuning have traditionally been assessed using simple geometric stimuli, such as drifting sinusoid gratings. How responses driven by these simplistic stimuli relate to responses to more complex naturalistic scenes is poorly understood. Here, we use 2-photon Ca^{2+} imaging to measure activity of single neurons in response to sinusoidal gratings, visual textures, and natural scenes moving in 12 directions in primary (V1) and secondary (area LM, V2) visual cortex in awake Thy-1 GCaMP6s mice. We then used the vector based approach to establish significant orientation selectivity and direction selectivity [Mazurek M, Kager M, Van Hooser SD (2014) Front Neural Circuits 8:92] to each of these three stimuli within the same neuron in these 2 areas. As expected, neurons in V1 and V2 were highly tuned to both orientation and direction of drifting sinusoidal gratings. Of neurons recorded in V1 >1/3 were tuned for direction and orientation. In contrast, <1/10 were tuned for direction and ~40% for orientation in V2. In comparisons between V1 and V2, grating and movie stimuli elicited different proportions of tuned cells; but texture stimuli elicited roughly equal proportions. Next we examined the differences in the preferred angle of orientation to each stimulus within single neurons. Surprisingly, we found both in V1 and V2 that the difference between preferred orientation for textures versus movies was relatively small, but for gratings versus either textures or movies was much larger. Finally, we examined the strength of tuning of individual neurons (based on normalized vector length) across stimuli and found this to be correlated for all three stimulus types in both V1 and V2. Our primary conclusion is that responses based on gratings serve as a poor predictor of how neurons respond to naturalistic stimuli. Perhaps the use of gratings, where orientation and direction is concatenated, poorly predicts the response to natural stimuli if cells have independent tuning vectors for direction vs orientation.

Title: Laminar functional connectivity in primary visual cortex

Authors: *J. NING[1], G. LI[2], C. BAKER[2];
[1]Dept. of Physiol., [2]Dept. of Ophthalmology, McGill Univ., Montreal, QC, Canada

Abstract: A laminar structure of 6 layers is conserved across different areas of mammalian cerebral cortex. In primary visual cortex, neurons in layer 4 receive direct input from the lateral geniculate nucleus and then project to layers 2, 3 and 5. However the laminar functional connectivity across laminae is not yet well understood. Here, we obtained recordings from linear array multi-electrodes (NeuroNexus, 32 channels, 100 micron spacing), inserted perpendicular to the surface of area 17 of anesthetized, paralyzed adult cats, for broadband recording (OpenEphys) across all 6 cortical layers. Correspondence of recording sites with cortical laminae was first established using current source density analysis (CSD) of low frequency responses to brief flashes of large-field luminance. Neuronal responses to binary sparse noise stimuli were then recorded. Multiunit activity (MUA) was extracted for each channel, as times of level-crossings at 3 SD of the bandpass digitally filtered (300 Hz - 3.0 kHz) signal. Two methods of transforming spike trains into continuous functions were evaluated: conventional binning, and convolution with a Gaussian. We estimated cross-correlations across all pairs of channels with respect to latency, and constructed a 32x32 MUA cross-correlation matrix, in which the diagonal corresponds to a channel paired with itself. The results showed MUA cross-correlation is related to the laminar structure measured by CSD, with greater laminar differentiation from convolution than binning. The pattern of pairwise correlation changes with latency, which provides indications of functional connectivity. Nearby channels usually gave higher cross-correlations than channels far apart, and intralaminar connectivity was dominant at nero-zero latencies. As time lag increases, the main pattern of cross-correlation moved away from the diagonal, suggesting interlaminar connections. In conclusion, MUA cross-correlation can provide a method to characterize vertical functional connectivity in the laminar structure of striate cortex. Interlaminar functional connectivity occurs at significant latencies, which might indicate how information flows between layers.

Title: Characterization of a mouse V1 model to inputs and perturbations using computational optogenetics

Authors: *B. CAI, Y. N. BILLEH, C. KOCH, A. ARKHIPOV, S. MIHALAS;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Large scale modeling is a very important tool to begin to tackle the vast complexity of the nervous system. Just in the visual cortex of the mouse we have characterized ~100 transcriptomic (Tasic et al. 2018) and 17 electrophysiological types and 38 morphological types (Gouwens et al 2018). Using this information as well as large collection of literature data, we have constructed a set of large scale models of the mouse primary visual system at multiple levels of resolution.
To investigate underlying characteristics of the V1 cortical area in mice, computational perturbation simulation experiments were conducted on a newly-built V1 column model using a novel point neuron model based on GLIF (Generalized Leaky Integrate-and-Fire) models. Point neuron models have two orders of magnitude speed benefit over biophysically detailed models, which allows us to more rapidly explore the space of inputs. In this study, we focus on the effects of three types of additional inputs on top of the visual inputs have on the simulated activity.
First, computational optogenetic perturbations were performed at the cell type population level to study the functional roles of different cell types in the inter-laminar interactions. Our results are consistent with mechanisms inhibition stabilized networks and inhibitory modulation of L6 on superficial layers (Olsen et al. 2012).
Second, single neuron perturbation simulations were conducted to explore how activity change of one cortical neuron could influence nearby cortical neurons and network activity. The simulation results are consistent with (Chettih & Harvey, 2019).
Finally, to simulate long range inputs we used the characterization of connectivity profiles between different cortical areas (Harris et al. 2018) and the characterization of dendritic profiles of V1 neurons, and we assumed cell-type specific connections being proportional to axo-dendritic overlap ("Peter's Rule"). When simulating additional top-down input we observe a broad increase in activity compared to bottom up input.
The vast array of additional in silico perturbation results from these simulations can establish potential hypothesis of optogenetic perturbative experiments for neuroscience experimentalists to advance our understanding of primary visual cortex.

Title: Systematic integration of structural and functional data into a multi-scale model of mouse primary visual cortex

Authors: *Y. N. BILLEH[1], B. CAI[3], S. L. GRATIY[3], K. B. DAI[4], R. IYER[4], R. ABBASI-ASL[3], X. JIA[2], J. H. SIEGLE[3], S. R. OLSEN[4], C. KOCH[3], S. MIHALAS[4], A. ARKHIPOV[4]; [2]Brain Sci., [1]Allen Inst., Seattle, WA; [3]Allen Inst. for Brain Sci., Seattle, WA; [4]Allen Inst. For Brain Sci., Seattle, WA

Abstract: Structural rules underlying functional properties of cortical circuits are poorly understood. To explore these rules systematically, we integrated information from extensive literature curation and large-scale experimental data collection efforts into data-driven, biologically realistic models of the mouse primary visual cortex. The models were constructed at two levels of granularity, using either biophysically-detailed or point-neuron models, and were tested against experimental recordings of neural activity during presentation of visual stimuli to awake mice. We demonstrate how in the process of building these models, specific predictions emerge about structure-function relationships in the cortical circuit. We discuss three such predictions regarding connectivity between excitatory and parvalbumin-negative inhibitory neurons; functional specialization of connections between excitatory neurons; and the impact of the cortical retinotopic map on structure-function relationships.
Our models use the Brain Modeling ToolKit (BMTK, github.com/AllenInstitute/bmtk) to integrate (Gratiy *et al.*, 2018) with NEURON (Hines and Carnevale, 1997) and NEST (Gewaltig and Diesmann, 2007) for parallel simulations. The model architecture and output are saved using the standardized SONATA format (github.com/AllenInstitute/sonata, Dai *et. al*, 2019). The models, code, and all meta-data resources will be publicly available via the Allen Institute Modeling Portal (brain-map.org/explore/models). As a free public resource, these models will be useful to the community for making direct predictions as well as complementing other experimental and modeling endeavors.

Title: Direction selectivity is strongly correlated with on/off response balance in primary visual cortex

Authors: *J. JIN[1], S. NAJAFIAN[1], R. MAZADE[1], C. PONS[1], E. KOCH[2], J. ALONSO[1]; [1]SUNY Col. of Optometry, New York, NY; [2]Caltech, Pasadena, CA

Abstract: Neurons in the primary visual cortex respond selectively to the direction of stimulus movement. Based on our previous results (Kremkow et al., 2016), we hypothesized that cortical direction selectivity should be related to the relative strength of ON and OFF cortical responses as is also the case for cortical orientation selectivity. Here, we tested this hypothesis by measuring the ON-OFF response balance and direction selectivity of a large number of cortical multiunit sites recorded with multielectrode arrays in cat visual cortex (n=24,660 recording sites). Because both direction selectivity and ON-OFF response dominance are clustered in cat cortex, a large number of multiunit recordings should allow us to measure any relation between these two stimulus parameters that was unnoticed in the past. The recordings were obtained with multielectrode probes of 16 or 32 recording sites that were linearly arranged (100 microns separation between sites). From all recordings, we selected for the analysis the 24,660 multiunit sites that responded most robustly to moving bars (signal/noise > 4, response per bar sweep > 7 spikes). Cortical multiunit was defined as spiking activity with a voltage larger than 60 microvolts to include only neurons in the immediate neighborhood of the electrode (estimated radius: ≤ 50 microns). We measured the direction selectivity (DS) of each cortical site as DS = (Rp - Rnp) / Rp, where Rp and Rnp are responses to preferred and opposite non-preferred directions (DS equals 1 when the direction selectivity is highest). We measured the dominant contrast polarity (CP) of each cortical site as CP = (ON - OFF) / (ON + OFF), where ON and OFF are the maximum responses to brief light or dark targets presented at the receptive field center of each cortical multiunit site (CP equals 0 when ON and OFF responses are equal in strength and the ON-OFF response balance is highest). Our results revealed a very strong correlation between cortical direction selectivity and ON-OFF response balance that could be accurately fit with a power function ($R = 0.995$, $p = 0.0004$, $CP = -0.2 + 0.2\ DS^{2.4}$). As expected, OFF responses were stronger than ON responses in most cortical sites; however, the OFF cortical dominance decreased with direction selectivity. The average OFF cortical dominance was strongest in cortical sites that were not direction selective (CP = - 0.2 for DS < 0.2) and became weaker as the direction selectivity increased (CP = -0.04 for DS > 0.8). These results demonstrate that, as for cortical orientation selectivity, direction selectivity is strongly related to ON-OFF response balance and increases when ON and OFF responses become similar in strength.

Title: Receptive field structures in ON and OFF domains of primary visual cortex

Authors: *R. MAZADE, J. JIN, C. PONS, J. ALONSO;
SUNY Col. of Optometry, New York, NY

Abstract: ON and OFF visual pathways signal the presence of light and dark stimuli in visual scenes and segregate in ON and OFF domains within primary visual cortex. We recently demonstrated that ON and OFF responses within a cortical domain have different spatiotemporal preferences: ON responses are strongest when the stimuli are large and slow while OFF responses are strongest when the stimuli are small and brief (Mazade et al., 2019). Here we demonstrate similar spatiotemporal differences between the responses from ON- and OFF-dominated cortical neurons and use these measurements to model their receptive field structures. We measured responses from ON- and OFF-dominated neurons to dark and light stimulus targets presented with different sizes, durations, and under different backgrounds. Cortical receptive fields were classified as ON- or OFF-dominated based on their contrast polarity, which was defined as the ratio (ON - OFF) / (ON + OFF), where ON and OFF are maximum responses to light and dark small brief targets (7 deg / 33 ms). ON- and OFF-dominated neurons showed pronounced differences in their spatiotemporal tuning that resembled the differences between ON and OFF responses from single cortical sites. OFF-dominated neurons responded 36% stronger than ON-dominated neurons when the stimuli were small and fast (e.g. 7 deg / 16 ms target; OFF: 116.8 ± 3.8 vs. ON: 85.7 ± 3.5 spk/s; $p<0.001$, Wilcoxon test). Instead, ON-dominated neurons responded 40% stronger than OFF-dominated neurons when the stimuli were large and slow (e.g. 23 deg / 133 ms target; ON: 75.7 ± 3.3 vs. OFF: 54.1 ± 1.7 spk/s; $p<0.001$, Wilcoxon test). OFF-dominated neurons showed stronger size suppression than ON-dominated neurons (e.g. 133 ms target duration, OFF: 48.1 ± 1.9 vs. ON: 26.3 ± 2.0% suppression, $p<0.001$, Wilcoxon test). However, the size suppression increased with background luminance only in ON-dominated neurons. OFF-dominated neurons also showed strong temporal suppression while ON-dominated neurons showed strong temporal facilitation (e.g. 17 deg target, OFF: 51.7 ± 1.8% suppression vs. ON: -13.9 ± 1.6% facilitation, $p<0.001$, Wilcoxon test). We used these measurements to model the receptive fields of ON- and OFF-dominated neurons with difference-of-Gaussians functions. Our model accurately replicates the experimental measures by assuming that OFF-dominated neurons show stronger spatial and temporal suppression than ON-dominated neurons but background luminance only suppresses ON-dominated neurons. We conclude that ON- and OFF-dominated neurons have different receptive field structures that match the different spatiotemporal properties of light and dark stimuli in visual scenes.

Title: Diversity of ocular dominance patterns in primary visual cortex originates from variations in local cortical retinotopy

Authors: *S. NAJAFIAN, J. JIN, J.-M. ALONSO;
State Univ. of New York Col. of Optometry, New York, NY

Abstract: The primary visual cortex contains a detailed map of retinal stimulus position (retinotopic map) and eye input (ocular dominance map) that results from the precise arrangement of thalamic afferents during cortical development. For reasons that remain unclear, ocular dominance maps are very diverse across species. They form patterns of highly organized stripes in humans and macaques, disorganized beads in cats and no pattern at all in rodents. Here, we used a new image-processing algorithm to measure published patterns of ocular dominance maps more accurately than in the past. These measurements revealed a tight relation between local patterns of ocular dominance and local changes in cortical retinotopy. This relation could be demonstrated in multiple regions of the primary visual cortex from an individual animal and in different species. For example, the median angle difference between the width axis of an ocular dominance stripe and the axis running along the slowest retinotopy gradient was 28.2 deg. in a human hemisphere, 23.8 deg. in a macaque hemisphere and 26 deg. in a cat hemisphere (26.6 deg. for the 3 hemispheres, n= 63 retinotopic sectors, p=0.02 that the similarity in angles is due to chance, Wilcoxon test). Because the retinotopic gradient increases with visual eccentricity, the relation that we described made us predict that visual eccentricity should be strongly correlated with stripe width, a prediction that we confirmed (e.g. ~10% reduction in ipsilateral-eye stripe width per every log2 degree unit of visual eccentricity, average $R^2 = 0.86$, n=8 hemispheres, example for one hemisphere shown in Figure 1a). Based on these results, we developed a computational model that sorts thalamic afferents by eye input and retinotopy to maximize the binocular retinotopic match at each cortical site. In our model, an increase in the cortical retinotopy gradient makes ocular dominance segregation and stripe width to decrease (Figure 1b). These results strongly suggest that the brain diversity of ocular dominance patterns emerges from variations in local cortical retinotopy.

Title: On and off visual pathways in human cortex have different spatial resolution

Authors: ***C. PONS**[1], J. JIN[1], R. MAZADE[1], J. KREMKOW[2], D. R. ARCHER[1], J. ALONSO[1]; [1]SUNY Col. of Optometry, New York, NY; [2]Neurosci. Res. Ctr., Charité-Universitätsmedizin Berlin, Berlin, Germany

Abstract: The visual system encodes light and dark stimuli through ON and OFF pathways that originate in the retina and remain segregated in visual cortex. Recent evidence in cats indicates that ON and OFF cortical pathways differ not only in their responses to light and dark stimuli but also in their stimulus spatiotemporal preferences. The ON pathway shows a preference for large slow stimuli and the OFF pathway for small fast stimuli (Mazade et al., 2019). Here we investigate whether these ON-OFF differences are also present in human cortex. We recorded visual evoked potentials with a customized dry electrode wireless EEG system (Wearable Sensing DSI-7-Flex) that had seven electrodes centered in visual cortex (Oz, O1, O2, POz, PO3, PO4, and Fpz, impedances < 1 MΩ). EEG signals were bandpass filtered between 5 and 100 Hz and response amplitude measured as the difference between maximum and minimum response within 30 to 200 ms. Human observers with normal visual acuity were asked to fixate on a central green dot monocularly (one eye covered with a patch), and refrain from blinking for the 6.6 second stimulus trial (25 to 75 trials). Eye movements were continuously monitored with an EyeLink 1000 Plus and a trial was aborted (and repeated) if the observer blinked or stopped fixating in the middle of the trial. During the fixation time, we presented a sequence of a checkerboard pattern (0.5 seconds) followed by a midgray blank (0.6 seconds), and repeated this sequence six times per trial. We measured OFF responses at the onset of dark-midgray checkerboards and ON responses at the onset of light-midgray checkerboards (VIEWPixx monitor, 120 Hz, luminance for light / dark: 96.48 / 0.46 cd/m^2). We used six different check sizes: 0.22, 0.45, 0.89, 1.78, 3.57 and 7.12 deg. Preliminary results (n=13 observers) revealed stronger responses to dark than light small checks (0.22 deg., 16.95 ± 1.97µV vs. 13.20 ± 1.29µV, p=0.008, Wilcoxon test), confirming the OFF dominance previously demonstrated in human visual cortex (Zemon et al., 1988). However, they also revealed weaker responses to dark than light checks when their size was eight times larger (1.78 deg., 10.58 ± 1.23µV vs. 12.02 ± 1.29µV, p=0.021, Wilcoxon test). Moreover, size suppression was stronger for dark than light checks (50.65 ± 4.51% for darks vs 39.53 ± 6.59% for lights, p=0.03, Wilcoxon test). The check size driving the strongest response also tended to be smaller when it was dark although the difference did not reach significance (0.63 ± 0.25 deg. vs. 1.25 ± 0.55 deg., p=0.12, Wilcoxon test). These preliminary results suggest that ON and OFF cortical pathways have different spatial resolution in humans, as previously demonstrated in carnivores.

Abstract: In recent years, large scale surveys of the physiological, transcriptomic, and skeletal morphological properties of neurons have expanded our understanding of the diversity of cell types within the mouse visual cortex. Data driven classifications based upon these surveys have in some cases reinforced classical views of neocortical cell types but have also revealed previously unappreciated diversity. However, this same approach has not been applied to the morphological and connectomics-based features that are observable with the ultrastructural resolution of electron microscopy (EM). Here we present the early stages of an EM data-driven approach to distinguish cortical cell types based on synaptic profiles and morphological features of varying cell compartments (e.g. cell body, nucleus, spines etc.). The current data set is comprised of 3D meshes from a densely segmented transmission electron microscopy image volume ($0.56x0.92x0.03mm^3$) taken from mouse primary visual cortex including Layer II/III through Layer VI. From this volume, nuclear, somatic, and synaptic features were collected from over 1300 cells selected across laminar layers. Our analysis presents quantifiable distinctions that reflect changes in laminar depth and broader cell-type differentiation. With a focus on Layer 5 pyramidal cells, nuclear features such as volume, level of invagination and relative orientation allow us to examine the degree to which nuclear morphology can distinguish cell classes such as IT, PT, and NP. While our analysis reveals some clear distinctions, it also presents a vast variability in cell morphology that will require more a comprehensive feature analysis to distinguish.

Abstract: Synaptic inhibition in the cortex is implemented by a group of cell types that shows a wide range of morphologic, physiological, transcriptomic and connectivity properties. They are widely acknowledged to play a crucial role in preventing run-away excitation while implementing sophisticated computations. While the mechanisms of their actions remain unknown they will be greatly dependent of which cells they target and where they target them. In order to quantify the pattern of connectivity of major inhibitory cell types onto their targets we have taken advantage of the fact that different inhibitory cell types target different cellular compartments in different proportions and that the fine morphology of their axons is different. Here we test if when analysed quantitatively, this differential targeting provides a robust bar-code to classify the axons of inhibitory cell types at scale and on densely segmented EM volumes. We analyzed the synaptic innervation patterns and morphology of over 1000 reconstructed inhibitory axonal segments in an EM volume from mouse V1 L2/3. We separated the targeted pyramidal cells into compartments (axon, dendritic shaft, spines) to assess the synaptic innervation patterns. For our morphological analysis, we developed a neural network autoencoder based on PointNet operating on meshes to encode the local morphology of axonal fragments. When comparing innervation patterns with our morphological encoding, we found agreements across these two domains. For instance, we found a putative basket cell type with large and flat boutons targeting only soma and dendrite but never spines whereas other putative

basket cell types distribute their synapses across these compartments. We present our structural analysis of inhibitory axons along with a comparison to described types in the literature.

Abstract: The structure of inhibition is a key factor shaping the activity of neuronal circuits. Diverse inhibitory cell types can exert their influence in different ways, due not only to characteristic specificity in which cell types they target, but even the precise locations onto which they make synapses. In mammalian cortex, GABAergic chandelier cells (ChC) show particularly exquisite specificity, exclusively targeting the axon initial segment (AIS) of excitatory pyramidal cells (PyC). While ChCs and AIS inhibition have been well-studied at the level of single ChCs or single PyCs, little is known about the structure of connectivity in a larger population context. We sought to address this by reconstructing PyC and ChCs in a 250x150x100 µm serial section electron microscopy volume covering L2/3 of mouse primary visual cortex. Neurons and synapses were computationally segmented and select cells were

manually proofread. We identified 145 PyC AISes fully contained within the volume and found 2091 synapses onto them, of which 1105 were from ChCs. The distribution of net ChC inhibition across PyCs was strikingly broad, ranging from 0-25 synapses (mean: 7.6). Thus in contrast to other forms of perisomatic inhibition, many PyCs escape significant AIS inhibition while other PyCs get many times more than average amounts. We found two correlates of this variability. First, net ChC inhibition positively correlated with the number of perisomatic synapses around the soma. Second, net ChC inhibition varied significantly with depth across L2/3, with upper L2/3 PyCs receiving significantly more ChC synapses than lower ones. Taken together, this suggests that inhibition is coordinated across distinct inhibitory cell types, but that AIS inhibition is distributed heterogeneously across L2/3 in visual cortex. In addition, detailed analysis of morphology found local coordination between distinct ChCs on a given AIS, for example ChC boutons often formed tightly apposed clusters instead of distributing themselves randomly across the AIS surface. This work shows ChCs to be a highly variable component in a coordinated pattern of perisomatic inhibition on PyCs in L2/3.

Title: Functional connectivity of excitatory inputs to excitatory cells in an EM-reconstructed volume of mouse V1

Authors: *.-. NINAI;
Princeton University, Princeton, NJ; Allen Inst. for Brain Science, Seattle, WA; Columbia University, New York, NY; Baylor Col. of Med., Houston, TX

Abstract: Although significant insight can be gleaned from analysis of neural activity or anatomy separately, answering many fundamental mechanistic questions in systems neuroscience requires information about both neural activity and connectivity in the same animal. Enormous strides have been made over the past decade in our ability to record activity from large populations of neurons distributed across multiple regions of the brain, and improvements in EM imaging techniques and the application of modern machine learning methods for segmentation of EM volumes have together enabled accurate reconstruction of increasingly large volumes of neural tissue. Here we describe an analysis of the connectivity of putative excitatory axons in a small volume of mouse primary visual cortex onto functionally-characterized excitatory cells. At Baylor College of Medicine, we recorded visual responses from neurons located in L2/3 of primary visual cortex of a 34 day-old male mouse expressing GCaMP6f in pyramidal cells under control of CamKII-Cre/tTA. The mouse was then shipped to the Allen Institute in Seattle where electron microscopy (EM) was performed on a ~200 x 150 x 100 micron volume, which was subsequently densely reconstructed at Princeton University. The EM data was subsequently used as ground-truth segmentation for a novel method to extract functional data developed at Columbia University. From this data we were able to analyze the projection patterns of tens of thousands of reconstructed axons onto hundreds of functionally-characterized neurons and isolated apical dendrites. Several methodologies have been used to find evidence for “like-to-like” connectivity (increased connectivity for cells with similar tuning preferences) via spine imaging (Iacaruso, et al 2017), combined *in vivo* imaging and *in vitro* multipatching (Ko et al. 2011; Cossell et al. 2015), and combined *in vivo* imaging with EM reconstruction (Bock et al. 2011; Lee et al. 2016). Here, we examine this question in this largest functionally-imaged and densely-reconstructed calcium imaging/EM data set collected to date in order to elucidate the principles of structure/function relationships including shared input and higher-order motifs.

Abstract: Finding sensory stimuli that drive neurons optimally is central to understanding information processing in the brain. However, optimizing sensory input is difficult due to the predominantly nonlinear nature of sensory processing and high dimensionality of the input space. Here, we developed *inception* loops, a closed-loop experimental paradigm combining *in vivo* recordings from thousands of neurons with *in silico* nonlinear response modeling. Our end-to-end trained, deep learning-based model predicted thousands of individual neurons' responses to arbitrary, new natural input with high accuracy, and was thus used to synthesize optimal stimuli - Most Exciting Images (MEIs). For mouse V1 these MEIs exhibited complex spatial features that deviated strikingly from the common notion that Gabor-like stimuli are optimal for V1. When presented back to the same neurons *in vivo*, these MEIs drove responses significantly better than control stimuli. Inception loops represent a widely applicable new technique for dissecting the neural mechanisms of sensation.

Abstract: A primary role of visual processing is the integration of information over retinotopic space. Visual integration is crucial for visual perception, and it has been studied most extensively in the primary visual cortex (V1). Neurons in V1 respond to stimuli in a confined spatial location, which defines the classical receptive field (CRF), yet visually driven neuronal responses are modulated by stimuli in the surrounding visual space. Characterizing its stimulus selectivity and determine its role in visual processing is a major milestone in understanding the visual system. In the past, researchers have typically assumed spatially uniform selectivity of the surround in V1 and many results have suggested that surround modulation reduces visual responses to repeating spatial patterns. At the same time, many theoretical studies argue that surround modulation reduces redundancy and enhances saliency in visual encoding. However, spatial-uniform tuning of the surround in V1 currently lacks empirical validation, and it is unclear how the theoretical models relate to the observed changes in neuronal responses to the surround. We characterize the spatial profile of one type of selectivity - orientation tuning in mouse V1 and assess changes in orientation coding by building a predictive model based on neuronal responses. We find that in the majority of recorded V1 neurons, orientation tuning changes as a function of stimulus location, violating the assumption that orientation selectivity of a single neuron in V1 is uniform across visual space. Because none of the existing parametric models of visual encoding were able to account for these findings, we trained a more versatile model, a neural network, to predict orientation in the stimuli from populational neuronal responses. Despite the fact that spatial orientation selectivity can vary for single cells, the model still reliably decoded the stimulus orientation. Our finding suggests that while the selectivity of neurons in mouse V1 can be complex, orientation is still robustly encoded in the cortical population response.

Title: Calcium-permeable AMPA receptors govern PV interneuron orientation selectivity

Authors: *I. HONG[1,2], J. KIM[3], R. C. JOHNSON[1,2], Z. YANG[4], D. CHEON[3], A. AGARWAL[5], D. E. BERGLES[1], S. P. BROWN[1], R. L. HUGANIR[1,2];

Abstract: AMPA receptors convey the majority of excitatory synaptic transmission throughout the mammalian cortex. A subset of AMPA receptors that lack the GluA2 subunit display distinct biophysical properties, including calcium permeability. Although these calcium-permeable AMPA receptors (CP-AMPARs) have been shown to trigger non-classical forms of synaptic plasticity, the computational role of these receptors and the wider impact on neuronal activity has not been explored. Here we find that PV and SOM interneurons express low levels of GluA2 protein and mRNA compared to other subunits, and the stoichiometry ratio is conserved from mice to humans, leading to abundant expression of CP-AMPARs. Using *in vivo* two-photon calcium imaging, we observed that replacing CP-AMPARs with calcium-impermeable AMPARs in PV interneurons substantially increased their orientation selectivity. This increase of orientation selectivity was cell-autonomous and could occur well beyond development. Paired patch-clamp recordings indicated that although excitatory-PV neuron connectivity and unitary synaptic strength was not changed, CP-AMPAR replacement led to substantial increases in neuronal excitability. These results demonstrate a novel role of CP-AMPARs in maintaining a low selectivity sensory representation in PV interneurons and suggest a conserved molecular mechanism that distinguishes the synaptic computations of certain inhibitory and excitatory neuron classes.

Title: Orientation maps in the primary visual cortex of an Australian marsupial, the Tammar Wallaby Macropus eugenii

Authors: *Y. JUNG[1,3], M. YUNZAB[3], A. ALMASI[3], S. SUN[1,3], S. CLOHERTY[4], S. BAUQUIER[2], M. RENFREE[2], H. MEFFIN[1,3], M. IBBOTSON[1,3];

Abstract: Orientation selectivity (OS) is a prominent feature of neurons in the mammalian primary visual cortex, but the spatial organization of these neurons varies across species. In carnivores and primates, orientation-selective neurons are organized into structured orientation columns, which are vertical arrays of neurons with the same orientation preference. These columns are organized into two-dimensional orientation maps in which the different orientations are arranged radially around singular, pinwheel centers. However, rodents and lagomorphs - despite having robust orientation selectivity in individual neurons - do not have orientation columns, but instead the neurons are randomly distributed throughout the cortex, in what is termed a salt-and-pepper organization. We do not know why some mammals have structured pinwheel maps while others have salt-and-pepper maps. We investigated whether the development of orientation maps is influenced by a genetic factor related to phylogeny. The entire mammalian line might have originated with the genetic capacity to develop orientation columns, but perhaps rodents and lagomorphs lost this organization due to a lack of environmental or behavioral drivers. We studied a highly visual marsupial, the Tammar wallaby (*Macropus Eugenii*), which represents a phylogenetically distinct branch of mammals for which the orientation map structure is unknown. If orientation columns are the mammalian norm, we should identify orientation columns in marsupial cortex. We used intrinsic optical imaging and multi-channel electrophysiology methods to examine the functional organization of the wallaby cortex. We found robust OS in a high proportion of cells in the primary visual cortex. Moreover, we found clear orientation columns similar to those found in primates and carnivores but with bias towards vertical and horizontal preferences, suggesting lifestyle-driven variations. The findings suggest that orientation columns are the norm and it might be that the rodents and lagomorphs are unusual in terms of mammalian cortical architecture.

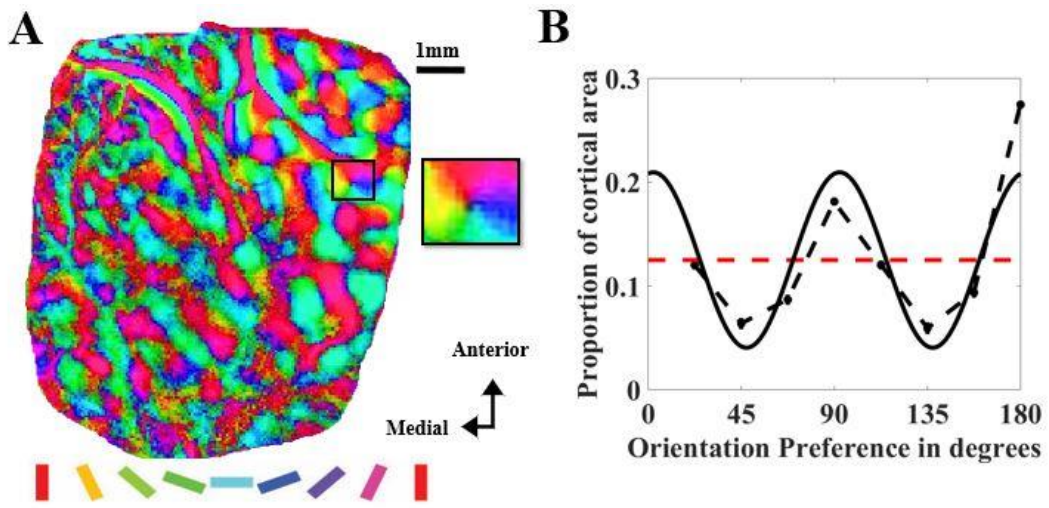

Figure 1. Orientation Preference map. (A) Orientation map showing the orientation preference for every region of the imaged wallaby visual cortex. The angle is color-coded according to the scheme at the bottom of the figure. We zoom in on a pinwheel location. (B) Distribution of orientation preferences. Proportion of cortical area representing different orientations from right eye stimulation (red line ± 1 SEM, thick line: least-squares sine curve fit). The best fitting sine curve with period 90° had peaks at 90° and 180°.

Title: Retinal origin of orientation column, clustered horizontal connections and patterned spontaneous activity in visual cortex

Authors: *M. SONG[1,2];
[1]Dept. of Bio and Brain Engin., [2]Program of Brain and Cognitive Engin., KAIST, Daejeon, Korea, Republic of

Abstract: In primary visual cortex (V1) of higher mammals, the orientation preference of neurons develops, organizing in a quasi-periodic pattern across the cortical space known as orientation maps CITATION Bla86 \l 1042 (Blasdel, 1986). In the same developmental period, it was reported that clustered horizontal connections develop to link iso-orientation column (Ruthazer,1996) and patterned spontaneous cortical activity in V1 matches the topology of

orientation map even before eye-opening (Smith, 2018), which suggests that orientation maps, clustered horizontal connections and patterned spontaneous activity might be closely related during their development. Thus, the study suggested that cortical interaction drives patterned spontaneous cortical activity and might form a backbone of clustered horizontal connections and orientation map self-organization, but underlying principle of development and developmental order among these three functional architectures are still unclear. Here, we propose another viewpoint that the inherent pattern of early retinal afferent mosaic instructs simultaneous emergence of clustered horizontal connections and orientation maps, and that patterned spontaneous activity is the result of such functional circuit formation. By assuming that the patterned afferents from retinal ganglion cell (RGC) seeds the layout of orientation map, (Paik and Ringach, 2011), we hypothesized that spatial pattern of retinal mosaic could be projected to cortex by the patterned retinal wave before eye-opening (Kershenstheiner, 2016), and may drive the emergence of orientation-selective horizontal connectivity in the cortex by Hebbian mechanism. Using a computer simulation, our model successfully showed (1) emergence of orientation-selective and horizontally clustered connections and (2) connectivity-driven cortical activity pattern which was refined over time to match the topography of orientation map (Smith, 2018). Our results suggest that early emergence of the functional network in the neocortex may be driven by projected structure and activity of retinal afferents, contrary to the previous notion of self-organization within cortical networks.

Title: Distinct functional networks of peripheral and central visual representations in primary visual cortex during rest and task

Authors: *B.-Y. PARK[1,4], K. BYEON[1,4], H. PARK[2,4], W. SHIM[3,4];
[1]Dept. of Electrical and Computer Engin., [2]Sch. of Electronic and Electrical Engin., [3]Dept. of Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of; [4]Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci., Suwon, Korea, Republic of

Abstract: The central and peripheral visual fields, which correspond to the posterior and anterior portions of the primary visual cortex (V1), respectively, are known to play distinct functional roles: The central visual field of V1 is specialized in processing fine-grained visual information whereas the peripheral visual field is involved in monitoring changes in the environment by integrating multisensory information. Although previous work reported distinct patterns of functional connectivity between subregions of V1 and other visual areas, associations of each V1 subregion with functional networks beyond visual areas remain to be known. In the current study, we examine the intrinsic patterns of functional connectivity between subregions of V1 and the whole brain during rest and their modulations during a task. FMRI data during resting state, a visual working memory task, and an auditorily presented language task were obtained from the Human Connectome Project database. Using the connectivity-based parcellation approach, V1 was parcellated into the anterior and posterior portions and the whole brain seed-based connectivity was performed between each subregion of V1 and the rest of the brain. The results showed distinct patterns of functional connectivity between each V1 subregion and auditory, somatosensory, extrastriate visual, and frontoparietal areas, as well as their differential modulation by task. During the resting state, strong functional associations between the anterior V1 and auditory and somatosensory cortex were found. The functional associations of the anterior V1 and other sensory cortices, however, were largely reduced during both tasks whereas the functional connectivity between the anterior V1 and frontoparietal areas increased. On the other hand, the posterior V1 increased its functional connectivity with the extrastriate visual areas when a visual working memory task was performed while the anterior V1 decreased its functional connectivity with other visual areas. Our findings suggest that distinct functional roles of peripheral and central visual field representations in V1 are supported by different functional networks in which each subregion of V1 is embedded: The posterior V1 forms the primary visual network with the extrastriate visual areas supporting the processing of focal visual information whereas the anterior V1 may form long-range functional connections with other sensory cortices for environmental monitoring via multisensory integration during rest but may be reconfigured to participate in the frontoparietal control network when cognitive task demand is high.

Title: Principles of columnar and salt-and-pepper organizations of orientation tuning in visual cortex

Authors: *J. JANG[1], M. SONG[1,2], S.-B. PAIK[1,2];
[1]Dept. of Bio and Brain Engin., [2]Program of Brain and Cognitive Engin., KAIST, Daejeon, Korea, Republic of

Abstract: In the mammalian visual cortex, spatial organization of orientation tuning in the primary visual cortex (V1) is arranged in different forms across species. For instance, columnar orientation maps are observed in primates while noisy salt-and-pepper organizations are found in rodents. However, it is unknown whether these disparate organizations indeed reflect species-specific developmental mechanisms of cortical circuits in evolution (Kaschube, 2014), or if any biological parameters (such as cortex size) determine it. To address this issue, we first analyzed neural parameter data in eight mammalian species, and found that the retina-to-cortex feedforward sampling ratio is a key factor that predicts the V1 organization of orientation tuning. We show that whether a species would have columnar maps or with salt-and-pepper organization, can be predicted solely by the retinocortical sampling ratio, as estimated from the size of the retina and V1 in each species. In particular, we show that the cortical organization of four species with V1 of similar size (columnar map in ferrets and tree shrews; salt-and-pepper organization in rabbits and gray squirrels) could be readily predicted by the ratio between the sizes of the retina and V1. This was impossible when considering only a single parameter such as V1 size. We confirmed that the sampling ratio between retinal and cortical neurons successfully predicts V1 organization of all eight species examined so far. Interestingly, we found that the results are mathematically consistent with a prediction by the Nyquist theorem in the Paik-Ringach model (Paik, 2011). Our results suggest a simple but fundamental principle of cortical organization: physical constraints in the periphery can initially contribute to the circuit design of the primary sensory cortex.

Title: A multiplicity of connectivity rules in higher-order visual circuits

Authors: *X. HAN[1,2,3], V. BONIN[1,2,3];
[1]Neuro-Electronics Res. Flanders, Leuven, Belgium; [2]KU Leuven, Leuven, Belgium; [3]VIB, Gent, Belgium

Abstract: Vision and visually-guided behaviors in mammals rely on multilateral neuronal pathways linking multiple higher visual areas (HVAs) that process distinct aspects of the visual scene in parallel. Computations and information flows in HVAs and higher-order visual circuits are still poorly understood. Here we developed an *in vivo* approach to map visual pathways anatomically and functionally in the mouse cortex. Combining retrograde and anterograde labeling with widefield, cellular and axonal calcium imaging, we characterized the flow of spatiotemporal information across eight visual cortical areas (V1, LM, AL, RL, AM, A, PM and LI) and a higher-order thalamic nucleus (LP, lateral posterior nucleus). Anatomical circuit tracing revealed HVAs specifically and selectively sample inputs from cortical and thalamic areas. Area AL, for example, receives inputs from a wide extent of cortical areas; PM avoids inputs from most anterior areas; while A selectively receives inputs from anterior areas. Functional cellular imaging revealed HVAs receive and send specific visual signals to distinct areas. For instance, while AL and PM show distinct tuning, they also innervate each other, layer2/3 corticocortical neurons show functional properties different from the general population and biased towards their projection targets. Importantly, the wiring rules are not uniform but strongly depend on source and target areas. For example, while AL sends distinct information to different areas, PM neurons send similar information across areas. Likewise, while AL sends highly specialized information to HVAs, it sends more diverse information to V1 and LM. Finally, projections from LP show the highest level of specificity even exceeding specificity of V1 and LM projections to HVAs. Together, these results provide a blueprint of the functional architecture of mouse higher-order visual circuits and suggest a multiplicity of rules of connectivity across the cortex.

Title: The distribution of norepinephrine transporter-immunoreactive axons in V1 and V2 of the macaque monkey

Authors: *C. ROACH[1], A. A. DISNEY[2];
[1]Duke, Durham, NC; [2]Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Norepinephrine is diffusely released into cortex from fibers originating in the locus coeruleus (LC), which synthesizes norepinephrine via the action of dopamine-beta hydroxylase (DBH). Once in cortex, norepinephrine is free to activate receptors until it is cleared from the extracellular space. Therefore, the presence of DBH and reuptake, via the norepinephrine transporter (NET), together define the extracellular concentration, and the temporal and spatial profile of the incoming noradrenergic signal in any given cortical area. It remains unknown if closely related cortical areas such as primary visual cortex (V1) and secondary visual cortex (V2) differentially use norepinephrine. Furthermore, it is unknown if differences in noradrenergic signaling could help account for differences in response properties between these two areas. Previous studies in primates have shown that V1 receives less dense innervation from the LC than does V2, as assayed by DBH immunoreactivity. None of these prior studies were quantitative and to our knowledge there have been no studies (quantitative or qualitative) of the other factor that defines noradrenergic signaling, the expression of NET. To address the lack of data on NET expression in primate cortex, and to begin building quantitative descriptions and models of cortical neuromodulatory systems, we immuno-labelled NET in tissue sections from 3 adult male rhesus macaques. We stereologically quantified the density of immunoreactive fibers in V1 and V2 and found that the density of NET-positive fibers in V1 is approximately 15% lower than the density in V2. We also dual-labeled sections for NET and DBH. Preliminary examination of these dual-labeled sections indicate that approximately 90% of DBH-positive axons also express NET. Because NET and DBH appear to co-localize on LC axons in both V1 and V2, the relative density of innervation (quantified here) and the laminar distribution of LC fibers emerge as the functionally relevant anatomical features of the noradrenergic system. Interestingly, previous studies have observed differences in the laminar distribution of DBH-positive fibers between primate V1 and V2.

Title: Functional stripes represent juxtaposed maps of central and peripheral space in tree shrew V2

Authors: *M. SEDIGH-SARVESTANI, K.-S. LEE, S. F. LIU, N. C. SHULTZ, R. SATTERFIELD, D. FITZPATRICK;
Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: The tree shrew primary visual cortex (V1) has long served as a model in vision due to its columnar-organized representation of multiple visual properties and resemblance to primate V1. However, the functional organization of the secondary visual cortex (V2) of the tree shrew remains unexplored. Whether tree shrew V2 exhibits an interleaved organization like that found in primate V2 (functional stripes) or a single visuotopic organization as in the mouse extrastriate areas, is unknown. In this study, we used functional imaging, and anatomical tracing, to examine the organization of V2 in the tree shrew.
To study functional responses of neurons in V2, we injected viral vectors expressing the calcium indicator GCaMP in V2, and performed chronic wide-field and two-photon imaging in awake, head-fixed animals viewing visual stimuli. To compare functional organization with anatomical organization, we injected viral tracers in the same or separate animals. Immunohistochemistry was performed on flattened brain sections to ease comparison of functional and anatomical data. Whereas the visuotopic map in tree shrew V1 is smooth and monotonic, the map in V2 is organized into interleaved stripes responsive to either central (-5-10°) or peripheral visual space (10-25°). This organization includes multiple smooth reversals in visuotopy, with continuity in visual space within the same stripe-type. In addition to differences in visuotopy, V2 stripes also differ in other functional properties. Central stripes, and not peripheral stripes, exhibited spatially organized orientation maps and sensitivity to horizontal disparity.
To understand the anatomical source of these functional differences, we studied the pattern of V1 axon projections in V2. As reported previously, single V1 injections produced multiple distinct patches in V2, forming an interleaved pattern of regions receiving inputs from central V1 and regions lacking input from central V1. Notably, the variations in stripe-type and thickness characterized on brain sections matched closely with those characterized via functional imaging. This suggests that the striped pattern in V2 largely stems from precisely organized and inter-leaved inputs from central and peripheral V1. We conclude that tree shrew V2 has a striped functional organization that is similar, although with notable differences in visuotopy, to primate V2.Therefore, the functional stripe organization of V2 is not a unique property of the primate brain and likely has earlier evolutionary origins. Our future studies aim to reveal the advantage of juxtaposed mapping of central and peripheral visual space in the cortex.

Title: Functional and anatomical alterations in V1 of asymmetric glaucoma patients

Authors: *L. BACHATENE, L. GAGNÉ-BROSSEAU, R. J. BUTLER, S. CÔTÉ, K. WHITTINGSTALL;
Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: Glaucoma alters vision in specific parts of the patient's visual field. Animal studies of glaucoma suggest that its degenerative effects extend from retina to the visual cortex, through trans-synaptic degeneration. However, such a mechanism and its relationship to visual deficits are poorly documented in humans. We sought to investigate the response of the primary visual cortex (V1) to monocular stimulation of either the glaucomatous or fellow eyes in a sample of asymmetric primary open-angle glaucoma (POAG) patients. For this, we used structural and functional magnetic resonance imaging to map the eye-specific retinotopic responses, population receptive field (pRF's) as well as corresponding cortical thickness.
First, we show that V1 responses of each eye were similar across all visual field locations of the stimuli. That is, stimulating within the scotoma (affected regions of the visual field) resulted in less V1 activation in both the glaucomatous and the fellow eyes. In addition, pRF's were similar during the stimulation of either eye.
Second, we found that, cortical areas corresponding to the scotoma (lesion projection zones or LPZ) were thinner than the healthy portions. Therefore, not only were the functional response profiles between both eyes similar, but the structural underpinnings were also identical, suggesting that despite clear differences in conscious vision, cortical alterations are indistinguishable between the diseased and the fellow eye. These findings support the trans-synaptic degeneration described in animal models, and demonstrate that cortical damages may occur while no visual loss is reported by the patient.
A better understanding of the relation between visual field defects and functional and structural changes in the brain may help understanding the neurodegenerative mechanisms of glaucoma and its progression.

Title: Electrophysiological investigation of posterior curvature-biased patches in monkeys

Authors: *S. R. ROBERT, X. YUE, M. YETTER, A. MESSINGER, L. G. UNGERLEIDER; Lab. of Brain and Cognition, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Curvature is one of many visual features shown to be important for visual processing. For instance, curved features provide sufficient information for categorizing animate vs. inanimate objects without top-down processing in both human (Zachariou et al., 2018) and nonhuman primates (Yue et al., 2018). Results from our fMRI study in rhesus monkeys (Yue et al. 2014) have shed light on some of the neural mechanisms underlying curvature processing. We described a network of visual cortical areas selective for curvature, one of which, the posterior curvature-selective patch (PCP), is located in dorsal V4. The fMRI responses in the PCP correlated significantly with curved Gabor filter values calculated from experimental images. The current study was designed to investigate whether the PCP contains a columnar organization for curvature, similar to the columnar organization for orientation in V1 and that for direction-of-motion in MT. We conducted electrophysiological recordings in awake, behaving macaques (n = 2) as they viewed curved Gabors manipulated along three feature dimensions: degree of curvature, orientation, and size. With electrode penetrations tangential to the surface of PCP, a correlation analysis between penetration distance and curvature revealed a marginally significant trend in one monkey ($p = 0.06$), suggesting that curvature preference increases as distance increases. Further, orientation preference correlated with penetration distance in a positive trend in one monkey and negative trend in the second ($p = 0.07$ and $p = 0.06$, respectively). Together, these data indicate that there may be curvature columns perpendicular to the surface, with orientation of curved surfaces varying across columns in the same layer. Additional data collection, with electrode penetrations both perpendicular and tangential to the surface of PCP, along with further data analysis will provide clearer and more direct evidence for whether columnar structure for the degree of curvature and orientation exists within PCP. The outcome of this study will advance our understanding of how middle-level visual features, such as curvature, are represented within macaque visual cortex.

Title: The relation between inter-areal functional and structural connectivity is frequency dependent

Authors: *J. VEZOLI[1], M. VINCK[1], A. M. BASTOS[1,2], C. LEWIS[1,3], C. A. BOSMAN[4,5], H. KENNEDY[6], P. FRIES[1,4];

Claude Bernard Lyon 1, Inserm, Stem Cell and Brain Res. Inst. U1208, Bron, France

Abstract: The relationship between on the one hand the strength of rhythmic neuronal synchronization and on the other hand sensory stimulation and cognitive factors is well established. Yet, the relationship between inter-areal synchronization and the strength of anatomical connectivity has remained elusive. In two macaque monkeys, we recorded with 252 channel electrocorticographic grids from the left hemisphere, while animals performed a visual attention task. For 91 pairs of cortical areas, we determined several frequency-resolved metrics of functional connectivity, namely coherence, Granger-causality and power-power correlations. For the same areas, and from an independent cohort of animals, we obtained quantitative measures of anatomical connection strength. Across the 91 area pairs, we directly related functional interactions to the corresponding anatomical connection strengths. First, inter-areal functional connectivity correlates with inter-areal anatomical connection strength. This correlation holds when partialized for distance, either physical distance, distance along the dural surface (relevant for potential volume conduction) or distance through the white matter. The strength of this correlation depends on the frequency and the metric of functional connectivity. Second, gamma band influences are more strongly correlated with the strength of the anatomical projections in the feedforward than the feedback direction; for the alpha-beta band, the opposite relationship holds. We have recently shown that gamma-band influences predominate in feedforward and alpha-beta influences predominate in feedback signaling. Hence, the above described relationship between functional and structural connectivity strength is mediated by frequency-specific directed influences and their corresponding anatomical projections. Finally, we calculated frequency-specific maps of network strength, displaying for each recording site the average strength of the functional connectivity with all other sites. These strength maps reveal distinct topographies: the gamma network dominates early and intermediate visual areas, the beta

network fronto-parietal areas, and the high-beta network pre-motor and motor areas. In summary, we show how stimulus- and task-related changes of inter-areal rhythmic synchronization are constrained by the underlying anatomical backbone in a frequency-specific manner.

Title: Assemblies of feature representation in a population of early visual neurons in the common marmoset

Authors: *M. M. FABISZAK[1], D. W. WEST[1], D. G. C. HILDEBRAND[1], S. R. SERENE[1], A. C. KOLSTAD[2], Z. WU[2], W. A. FREIWALD[1];

Abstract: Faces form a unique category of stimuli that bridge visual perception and social cognition. They are processed in dedicated areas of cortex, face patches, which are organized into an interconnected network. While insight into neurons within face patches has been explored through extracellular electrophysiology, the functional architecture of local ensembles of cells has remained elusive. Recently discovered face patches in the lissencephalic common marmoset brain provide the cortical access necessary in order to employ optical techniques to resolve both the functional properties as well as the spatial organization of these neural ensembles. Unique to marmoset face patches, the cortical boundaries of these patches overlap with areas usually attributed to early stage visual processing. In particular, the occipitally located face patch “O” overlaps with V2, an area usually thought to be composed of neurons with tuning properties to low-level visual stimuli such as, but not limited to, orientation and direction. Here, in the anesthetized marmoset, we demonstrate the areal parcelization of function along the dimensions of low-level visual stimuli and high-level visual stimuli including faces, objects, and bodies. The resultant tuning properties are further dissected along stimulus conditions that form an

intersection between high-level and low-level stimuli. Subsequently, we utilize two-photon microscopy to achieve single cell resolution of functional activity of neurons spanning V2 and "O" that are transduced with a viral calcium indicator. Finally, we perform volumetric immunohistochemistry on the entire region of cortex studied in this experiment to both measure the density of different cell types across this span of cortex and co-register the neurons functionally recorded with two-photon microscopy with their histologically identified cell types. Together, the population measurement of intrinsic optical imaging with the histologically identified cell types of single unit recordings of two-photon microscopy provide an unprecedented view into the dynamics underlying the encoding of early stage face perception in the common marmoset.

Title: Neurons exclusively sensitive to texture boundaries in early visual cortex

Authors: Z. LIANG[1,2], *G. LI[3], C. L. BAKER[2];
[1]Biomed. Engin., Anhui Med. Univ., Hefei, China; [2]Ophthalmology, McGill Univ., Montreal, QC, Canada; [3]The Res. Inst. of the McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Natural images from everyday scenes include a complex mixture of boundaries defined by differences of luminance (1st-order) or texture contrast (2nd-order). The majority of neurons found in early visual cortex respond to boundaries defined by luminance differences. However, many of these neurons in cat and macaque also respond to boundaries defined by texture cues (Mareschal & Baker, 1998; Li et al, 2014). Nearly all of the neurons that respond to 2nd-order boundaries, tend to respond more strongly to luminance boundaries. Neurons exclusively responsive to 2nd-order boundaries, which had been suggested by psychophysical and fMRI studies (Smith & Ledgeway, 1997; Nishida et al, 1997; Schofield & Georgeson, 1999; Ashida et al, 2007), have not been previously described in early visual cortex. Here we recorded responses of neurons in area 18 of anesthetized, paralyzed cats to ensembles of abruptly presented, static "flashed" luminance-modulated (LM) and contrast-modulated (CM) stimuli. Data were acquired from 32-channel probes (NeuroNexus, Open-Ephys). Single units were isolated from combined LM and CM datasets, using Kilosort2 and manual refinement with Phy.

Consistent with previous studies, we found neurons responsive only to luminance-defined stimulus attributes such as orientation and spatial frequency, as well as neurons responsive to both luminance- and contrast-defined boundaries. Besides these two common types of neurons, a new group of neurons were identified in our data-sets. These neurons exhibited significant response to contrast-defined boundaries, but produced little or no response to luminance-defined boundaries. Unlike neurons responsive to both luminance- and contrast-defined boundaries, which show clear tuning to carrier spatial frequency and weak tuning to carrier orientation, these neurons were not tuned to carrier properties. These results show that some area 18 neurons' response is specific to 2nd-order stimuli - they were not previously discovered due to methodology limitations. These neurons could serve as "2nd-order decoders" parsing texture contrast boundaries in the early visual system, invariant to the spatial properties of the textures.

Title: Neocortical interneuron subtype dynamics in mouse visual cortex: A potential cortical circuit motif for sensory detection

Authors: *A. I. MORE[1,2], C. A. DEISTER[1,2], A. R. TULETT[1,2], C. I. MOORE[1,2];
[1]Brown Univ., Providence, RI; [2]Carney Inst. for Brain Sci., Providence, RI

Abstract: Inhibitory interneurons are critical to neocortical computations, and diversity among them is thought to regulate the trial-by trial dynamics that shape perception. Specifically, parvalbumin-positive interneurons (PV) are key components of neocortical circuit motifs. Recent studies in several sensory modalities have tied PV, and their dynamics on single trials, to perceptual success. While PV have often previously been treated as a functionally homogenous populations, recent results from our lab in mouse primary somatosensory cortex (SI) demonstrate distinct dynamics in PV during threshold-level tactile detection. Specifically, two populations of PV exist that show either higher evoked firing rates for hits or for misses. These inhibitory dynamics suggest a specific wiring diagram that, when implemented in a computational model, can explain the rate and correlation dynamics in pyramidal neurons that carry perceptually-relevant signals. Based on additional preliminary evidence from our lab, there are multiple SOM subtypes as well that predict both hits and misses, with a bias toward hit-predictivity. These findings, in combination with our model circuit motif, implicate miss-predictive PV as the regulators of the pyramidal cells that carry the perceptually meaningful signal, and that these cells open a gate for successful sensory perception.

To test whether these distinct functional PV subtypes may be idiosyncratic to vibrissae processing in SI or could be a basic circuit motif for selectively prioritizing information flow through neocortex, we implemented a visual detection task in head-fixed mice during simultaneous two-photon calcium imaging. Under perceptually demanding task conditions, we recorded PV, SOM, and pyramidal cell activity in layers II/III of mouse primary visual cortex during threshold-level contrast detection. We imaged for twenty-five days throughout the acquisition of the task and also during high behavioral performance. The PV-Cre and SOM-Cre driver mouse lines were used to express GCaMP6s to assess basic detection of stimuli with different contrasts and probe PV, SOM, and pyramidal cell function, rate dynamics, and correlation structure (n = 7 mice). Data suggest distinct populations of PV in V1, with PV populations that predict hits and misses during perceptual performance.

Title: Augmenting deep neural networks with a recurrent model of grouping and border ownership

Authors: B. HU[1], ***S. KHAN**[2], B. P. TRIPP[2], E. NIEBUR[3];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Systems Design Engin., Univ. of Waterloo, Waterloo, ON, Canada; [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Figure-ground segmentation, or the organization of visual input into foreground and background regions, is an important component of scene understanding. Previous experimental work showed that neurons in primate extrastriate cortex can signal figure-ground relationships via differences in firing rates along object contours (border ownership coding). Computational models propose that recurrent interactions between populations of ``border ownership" and ``grouping" neurons, which integrate local feature information from border ownership neurons, provide a perceptual organization of the visual scene and can explain the observed border ownership coding. In these models, the connection weights between populations of neurons were manually specified. In the present work, we allow these connections to be learned in the context of different image segmentation tasks. We developed a convolutional network architecture with putative border ownership cells that were recurrently connected to grouping cells. For the first layer, we used the pretrained kernels from AlexNet, some of which resembled Gabor filters. Each cell in this first layer fed a pair of border ownership cells in the second layer. These pairs of cells were mutually inhibitory. The border ownership cells were also recurrently connected to

grouping cells. The kernels that connected border ownership and grouping cells in each direction were trained via backpropagation, with a regularizer that encouraged ring-shaped kernel structures. We included multiple scales of grouping cells via dilated convolutions.
The network branched out from this early-vision model into two directions, corresponding to outputs for different image segmentation tasks (object contour detection and figure-ground orientation labelling). Ablation experiments with different architectures showed that feedback from grouping cells improved performance by 2-4% on the contour detection task, and 20-27% on the figure-ground orientation task. Our results represent an important step towards incorporating border ownership into deep neural networks that are optimized for different visual tasks, and may provide further insight into its functional role.

Title: Retinotopic dependencies of receptive field properties in mouse V1

Authors: *I. M. NAUHAUS[1,2,3], I. RHIM[1,3];
[1]Dept. of Psychology, [2]Dept. of Neurosci., [3]Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX

Abstract: The mammalian retina distributes its resources across the visual field to more efficiently encode the most relevant statistics at each location of the natural environment. This is especially true in the mouse retina, which exhibits a spatially inhomogeneous distribution of photoreceptors and retinal ganglion cell-type. Retinal inhomogeneity has been linked to rodent behavioral output, yet the recapitulation of these maps at the level of visual cortex has not been thoroughly investigated. With two-photon imaging, we mapped each V1 neuron's retinotopy with a drifting bar stimulus, followed by characterization with a battery of gratings that varied in spatio-temporal frequency and color in cone-ospin (short 'S' & medium 'M') contrast space. First, we are assessing whether retinotopic dependencies of spatial frequency match local distortion in cortical magnification factor, as higher spatial frequencies require greater sampling density to maintain the same coverage. Next, we will show results on color tuning as a function of retinotopy. Color tuning is a particularly attractive avenue to study cortical transformations, as

previous studies in the retina have rigorously modeled S- and M-input to retinal ganglion cells as a function of the dorsoventral axis. We are using these front-end models of the anisotropy to model transformations between the retina and cortex. In addition to chromatically varying gratings, we are using sparse noise in both S- and M-opsin contrast to map the inputs of the cone opsins within each receptive field. We are testing for retinotopic dependence of cone opsin opponency that is predicted by either random or systematic wiring from the retina to V1.

Title: Contribution of intracortical inhibition to large-scale functional networks in early visual cortex

Authors: H. N. MULHOLLAND[1], B. HEIN[2], M. KASCHUBE[2], *G. B. SMITH[1];
[1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Frankfurt Inst. For Advanced Studies, Frankfurt Am Main, Germany

Abstract: In the visual cortex of carnivores and primates, large-scale functional networks span millimeters of cortical area. We have previously shown that in the ferret these large-scale networks are evident in the patterns of correlated spontaneous activity well before both eye-opening and the emergence of visually-evoked functional maps. This early correlated spontaneous activity arises from intracortical interactions and is predictive of future visually-evoked responses. Additionally, computational models suggest that propagating activity through purely short-range connections is sufficient to generate long-range correlated networks in the early cortex. These models require the coordinated interaction of intracortical excitation and inhibition, yet previous experiments have only measured the activity of excitatory cells in the early cortex.
Here, we use inhibitory-specific expression of genetically-encoded calcium sensors to monitor the spontaneous activity of inhibitory neurons in the early visual cortex. Inhibitory neurons show highly modular activity patterns, with a spatial scale similar to that observed previously for excitatory cells. Likewise, inhibitory neurons exhibit long-range correlations in their spontaneous activity, demonstrating their participation in millimeter-scale functional networks in the early cortex. Correlated spontaneous activity changed smoothly across cortical locations, punctuated by abrupt shifts in structure, previously termed ‘correlation fractures’, indicating that inhibitory

neurons also show precise fine-scale organization. When inhibitory and excitatory neurons were co-labeled, we found that the patterns of spontaneous activity were highly correlated between nearby excitatory and inhibitory cells, suggesting that inhibitory neurons participate in the same functional networks as excitatory cells. Lastly, we demonstrate that as early as P21 (~10 days before eye-opening), GABAergic signaling has a net inhibitory effect on cortical networks, consistent with our computational models. Taken together, our results show that intracortical inhibition is already highly organized into functional networks in the early visual cortex, and suggest that early inhibitory activity may play a role in shaping mature network organization.

Title: Implementation of human connectome low vision (HCLV) imaging protocol at University of Michigan

Authors: *N. NADVAR[1], J. CHOUPON[2], K. LITINAS[3], Y. SHI[2], L. HERNANDEZ-GARCIA[1,3], J. WEILAND[1];
[1]Biomed. Engin. Department, Univ. of Michigan, Ann Arbor, MI; [2]Lab. of Neural Imaging, Keck Sch. of Medicine, USC Stevens Neuroimaging and Informatics Institute, Univ. of Southern California, Los Angeles, CA; [3]fMRI Laboratory, Univ. of Michigan, Ann Arbor, MI

Abstract: One challenge in merging multicenter neuroimaging data is to derive standardized data features that best signify each center's performance in spite of the inevitable variation in acquisition due to scanners or adopted procedures. In the current work, we aimed to harmonize the acquisition of the magnetic resonance imaging (MRI) data involved in Human Connectome Low Vision (HCLV) project at two imaging centers: University of Southern California (USC) and University of Michigan (UM). To achieve this goal, we executed a case study in which we recruited a traveling subject, a normally-sighted male adult, at both locations. One T1-weighted (T1W) structural and six block-design task functional MRI runs were acquired with identical paradigms at each center. At USC, a 3T Siemens Prisma scanner was used with voxel size 2x2x2 mm (functional) and 0.8x0.8x0.8 mm (structural) and a multiband (MB) factor of 8 for functional runs. At UM, a 3T MR750 GE scanner was used with MB factor of 6, voxel size 2.4x2.4x2.4 mm (functional) and 0.5x0.5x0.8 mm (structural). Preprocessing consisted of

homogeneity, physiological noise, field map, motion and slice-timing corrections as well as smoothing, high-pass filtering, registration to T1 MNI152 template. One T1W and one fMRI run were also obtained from a spherical water-based fBIRN phantom filled with agar gel at each center. In order to quantify the performance of the different scanners, we calculated spatial SNR (Signal-to-Noise-Ratio), spatial CNR (Contrast-to-Noise-Ratio; for gray matter (GM) vs white matter (WM) vs CSF) and temporal SNR. In order to make an equitable assessment between the two centers, same repetition time (TR = 0.8 s) and number of volumes were used for each pair of functional runs; also the spatial and temporal SNR/CNR values were normalized per unit volume to account for differences in voxel sizes at two centers (nSNR/nCNR). Mean spatial nSNR was 42.9/317.1 (human/phantom) at UM and 25.8/54.6 (human/phantom) at USC. Mean spatial nCNR values for GM-WM, GM-CSF, WM-CSF contrasts were respectively 23.6, 15.6 and 39.3 at UM and 9.7, 11.7 and 21.4 at USC. Mean temporal nSNR across voxels of the subject at both locations yielded comparable results (mean of 3.5 vs 3.7 (UM vs USC) across all tasks), whereas this quantity for phantom data was 8.3 vs 16.8 (UM vs USC). Evidently, this study was able to narrow down the potential area of improvement for implementation of the HCLV protocol at UM to improvement in functional acquisitions. Difference in functional acquisition results between the two centers necessitates further investigation and should be accounted for in any combined group analyses of both centers.

Title: Serotonergic neuromodulation in the *Drosophila* visual system

Authors: *M. SAMPSON, K. MYERS GSCHWENG, B. HARDCASTLE, S. BONANNO, M. FRYE, D. KRANTZ;
UCLA, Los Angeles, CA

Abstract: Serotonergic neurons extensively innervate the visual system of the fruit fly *Drosophila melanogaster*, yet the role of serotonin signaling in visual processing is unknown. Identification of individual cells expressing serotonin receptors in visual system circuits will

allow us to determine the contribution of serotonergic modulation to visual processing computations. Five genetically distinct serotonin receptors are expressed throughout the optic lobe and we identified specific neurons and visual processing pathways targeted by serotonin neuromodulation. Single-cell labeling mapped serotonin receptors to specific visual processing neurons: L2, L4, L5, T1, Lawf1, and Lawf2. Lamina monopolar cell 2 (L2) receives direct input from photoreceptors and expresses the serotonin receptor 5-HT2B. Calcium imaging confirmed an increase in baseline calcium in response to bath-applied serotonin in L2 and its electrically coupled partner, L1. L1 and L2 are the first-order neurons in the light-ON and light-OFF pathways, respectively, and both information streams feed into motion detection circuits. L1 neurons do not express serotonin receptors, demonstrating that indirect mechanisms such as gap junctions enable neuromodulators to influence cells in the absence of receptors. We tested whether serotonin modulates visual responses in L2 neurons and found that serotonin increased the magnitude of visually induced calcium transients. This suggests that acute neuromodulation may regulate salience to specific visual stimuli in the light-OFF pathway. To examine long-term effects of serotonergic neuromodulation, we measured transcriptomic changes in L2 neurons following chronic increases in serotonin signaling. Together, these data allow us to compare serotonin modulation over multiple timescales. This work will reveal molecular pathways and transcriptional programs downstream of serotonin signaling cascades that are important for neuromodulation and will contribute to the understanding of how neuromodulatory signaling is integrated into sensory circuits.

Title: Predicting cortical thickness of primary visual cortex based on curvature and retinotopic eccentricity

Authors: *M. DEFENDERFER, K. M. VISSCHER;
Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Primary visual cortex (V1) has been one of the most heavily studied areas in the brain due to its role in processing vision, easily defined location at the calcarine sulcus, ease of stimulation, and its well-defined retinotopic organization. High resolution structural analysis of

V1 in humans has been made possible due to advances in MRI and surface reconstruction pipelines such as FreeSurfer (Dale et al., 1999). Measures of cortical thickness and curvature have been used in a variety of contexts, including healthy aging (Salat et al. 2004), cortical plasticity (Burge et al. 2016), and gyrification estimation (Luders et al. 2006). Anecdotal reports suggest that sulci may be associated with decreased cortical thickness compared to gyri, but we are not aware of explicit documentation of that trend. In retinotopic organization, areas of visual cortex associated with central vision (low eccentricity) have been found to have higher cortical thickness than areas associated with peripheral vision (high eccentricity) (Burge et al. 2016). However, to the best of our knowledge, no study has directly examined how eccentricity and curvature jointly predict cortical thickness. Our aim is to determine whether the effects of curvature and eccentricity on cortical thickness are independent and to identify the relationship among the three variables. In order to accomplish this, FreeSurfer outputs from the Human Connectome Project's Young Adult dataset were manually checked to exclude subjects with surface defects resulting in 786 quality subjects. We used a retinotopic atlas (Benson et al., 2018) to assign retinotopic coordinates to each vertex in V1. Curvature and cortical thickness values as defined by FreeSurfer and eccentricity values defined by the atlas were extracted and input to a linear model. Negative curvature values indicate convexity (including gyri) while positive values indicate concavity (including sulci). We found highly significant main effects on cortical thickness showing that thickness decreases with eccentricity ($p < 0.0001$, slope = -0.0025 mm/deg visual angle) and that thickness decreases with more concave curvature ($p < 0.0001$, slope = -.3484 mm/unit curv). We also observed a highly significant interaction of eccentricity and curvature ($p < 0.0001$, slope = 0.0207 mm/(deg*unit curv)). These results show that cortical thickness changes in a predictable manner across the cortical surface. This information is essential to future studies examining individual differences in cortical thickness, for example, determining how cortical thickness may have changed relative to what is expected in individual participants who have visual disorders.

Title: Could a neuroscientist understand a ConvNet?

Authors: *M. D. OLIVER[1], D. MILLMAN[2], S. E. DEVRIES[3], M. A. BUICE[3];
[1]Allen Inst. for Brain Sci., Seattle, WA; [2]Neural Coding Group, [3]Allen Inst. For Brain Sci., Seattle, WA

Abstract: Convolutional neural networks (ConvNets) are inspired by the hierarchical organization of the visual system as described by Hubel and Wiesel. When trained on visual object recognition tasks, ConvNets exhibit internal behavior that appears to resemble processing found in visual cortex. Because the entire architecture of a ConvNet is differentiable, it simple to characterize the artificial neurons within a trained ConvNet in terms of their optimal stimuli. Combined with the fact that the ConvNet provides a complete mechanistic description of unit responses, a trained ConvNet is thus a natural testing ground for the techniques used in visual neuroscience to characterize neurons. In this work we conduct in silico experiments on ConvNets analogous to those performed on animals in many electro physiology and optical-physiology labs. We analyze the responses of several pretrained ConvNets in response to a variety of standard stimuli (i.e. sparse noise, gratings, and natural images) to answer the following questions: Do traditional techniques such as the spike triggered average (STA) and spike triggered covariance (STC) reveal the fundamental tuning properties of the artificial neurons in a ConvNet? How do the features identified by STA and STC relate to the artificial neuron's optimal stimuli? Is spatial frequency tuning as measured with gratings meaningful for higher order artificial neurons? When do these techniques provide useful information and when are they misleading? Can more advanced nonlinear regression techniques provide more accurate characterizations of the selectivity of the artificial neurons? What stimuli work best for characterizing the responses of artificial neurons? How many stimulus-response pairs are necessary for fully characterizing an artificial neuron in the presence of biologically and experimentally realistic levels of noise? In answering these questions, we hope to provide the community with a better understanding of the virtues and drawbacks of current visual neuroscience techniques and provide guidance for effective neural characterization in future electrophysiology and optical-physiology experiments.

Title: Connectivity of the Tool Action Network: Lesion- and connectome-based symptom mapping of limb apraxic deficits after left hemisphere cerebrovascular accident

Authors: *F. GARCEA[1], C. A. GREENE[3], S. T. GRAFTON[4], L. J. BUXBAUM[2];
[1]Moss Rehabil. Res. Inst., Philadelphia, PA; [2]Moss Rehabil. Res. Inst., Elkins Park, PA; [3]UC Santa Barbara, Santa Barbara, CA; [4]Psychological & Brain Sci., UCSB, Santa Barbara, CA

Abstract: Recognizing, imitating, and producing skilled actions requires the integration of diverse computations supported by anatomically remote regions. Understanding how action systems in parietal cortex interface with semantic representations of action in the temporal lobe, and frontal lobe selection mechanisms remains a critical issue to address. Here we present two studies using support vector regression lesion symptom mapping (SVR-LSM) and connectome-based lesion symptom mapping to investigate where lesions perturb long-range connectivity among temporal, frontal, and parietal regions involved in action processing.

In the first study, we used SVR-LSM to investigate where lesion location predicted the severity of limb apraxia, a deficit in skilled action ability following left cerebrovascular accident (LCVA). Sixty-six LCVA participants took part in a battery of neuropsychological tests measuring tool use gesturing, novel gesture imitation, and gesture recognition. Impaired tool use gesturing was associated with lesions to the left inferior parietal lobule (LIPL), superior parietal lobule (LSPL), and left middle (LMFG) and inferior frontal (LIFG) gyri. Impaired novel gesture imitation was associated with lesions to peri-Sylvian regions, including the left superior temporal sulcus, LIPL, and LSPL. Gesture recognition ability was associated with lesions to the LMFG, LIFG, and left posterior middle temporal gyrus (LMTG). Importantly, these data replicate past studies, including findings from our lab.

In the second study, we correlated praxis deficits with the degree of structural connectivity among regions identified with SVR-LSM and remaining cortical and subcortical nodes in left and right hemispheres. Disconnection was estimated by projecting individual lesions into a Human Connectome Project derived structural connectome. The degree of impairment in tool use gesturing was associated with disconnection among right frontal and supramarginal gyri, LIFG, LIPL, LSPL, and LMTG adjacent to the lateral occipital cortex. Impairments in novel gesture imitation were associated with disconnection among left posterior intraparietal sulcus, LSPL, and right premotor and prefrontal cortex. Lastly, error-prone gesture recognition was associated with disconnection among the LMFG, LIFG, a white matter “bottleneck” medial to the insula, and the right MTG and right lateral occipital cortex.

Our findings suggest that praxis function is underpinned by a bilateral network of frontal, temporal, and parietal regions, with dissociable connectivity patterns determined by computations engaged in action recognition, imitation, and production.

Title: Multi-cell-type convolutional recurrent neural network models of visual cortex

Authors: M. SUN[1], J.-A. LI[2], M. DIPOPPA[1], *G. R. YANG[1];
[1]Columbia Univ., New York, NY; [2]Univ. of Sci. & Technol. of China, Hefei, China

Abstract: Deep convolutional neural networks (CNNs) are currently the leading models in explaining neural responses across the visual cortex of mice and monkeys. This success relies presumably on CNN's use of basic biological structural principles, including the hierarchical organization of visual areas. However, further comparisons with biological systems are hindered by CNNs' lack of structural motifs such as segregation of excitatory and inhibitory neurons. Here we ask whether CNNs endowed with multiple cell types and recurrent connections can succeed on the challenging ImageNet object classification task, and whether the network can recapitulate prominent cell-type specific findings regarding neural responses and connectivity from the visual cortex.More than half of the cortical inhibitory neurons express either parvalbumin (PV) or somatostatin (SST). PV and SST neurons are proposed to control the output and input of excitatory neurons, respectively, with local recurrent connections. Incorporating this structural motif, we built CNNs consisting of three model cell types: excitatory, input-controlling PV, and output-controlling SST neurons. Model excitatory neurons form recurrent connections locally and make long-range feedforward connections across areas.The network reached a performance on ImageNet close to that of recently proposed recurrent CNNs without the biological constraints. Experimental findings showed that excitatory and inhibitory neurons in the visual cortex have different response profiles and connectivity patterns. We tested whether these cell-type specific features can naturally emerge in our network through training. Similar to observations from mouse visual cortex, the connections from model inhibitory neurons to excitatory neurons after training were denser than those between excitatory neurons. Furthermore, the model reproduced the observed weaker orientation tuning in inhibitory neurons compared to excitatory neurons. This study demonstrates for the first time that artificial neural networks incorporating key biological constraints can match cell-type specific experimental findings while maintaining the ability to solve challenging tasks.

Title: Deep convolutional network model of macaque visual cortex

Authors: *B. P. TRIPP;
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Computational models can be useful for understanding how neural mechanisms relate to brain function. However, computational models are often capable of only simple behaviour. Deep networks, in contrast, make sophisticated decisions based on naturalistic stimuli, so they may be a good starting point for brain models with more realistic function. I developed a deep-network architecture that closely matches the architecture of primate visual cortex. The model has over 100 layers, corresponding to different cortical layers within 31 different visual areas. Various neuroanatomical properties from the macaque literature were approximated, including data from retrograde tracer studies, estimates of interlaminar connection densities and neuron counts, and receptive field sizes from electrophysiology. Each of these neuroanatomical measures was expressed as a function of convolutional network hyperparameters. An optimization approach was used to find hyperparameters that resulted in realistic neuroanatomical properties. The resulting architecture closely matches the data. Interestingly, the model has qualitatively different connection sparsity than past convolutional networks. Using a standard sparse-connection initialization scheme from the deep-learning literature, part of the ventral stream was trained on the CIFAR-10 dataset. This resulted in performance well below state of the art (79% accuracy on the validation data), suggesting that a somewhat non-standard approach may be needed to initialize and train biologically realistic architectures for high performance. Regardless, the model can process the same stimuli that are shown to humans in visual psychophysics tasks, it can be probed in detail to understand how it makes decisions, and its visual representations can be compared one-to-one with those of corresponding populations in the brain.

Title: Main cell types of the avian pallial visual DVR indeed express a mammalian cortical phenotype

Authors: C. NORAMBUENA, C. GONZALEZ-CABRERA, M. FERNÁNDEZ, G. MARÍN, *J. MPODOZIS;
Univ. de Chile, Santiago, Chile

Abstract: Despite seemingly differences in cytoarchitecture and early gene patterning, avian and mammalian pallial territories exhibit structural similarities that point to the existence of a common anatomical organization shared from early ancestry. The cell-type homology hypothesis, based on similarities in circuitry and neurochemistry, states that layer-specific cortical cell populations have equivalences with specific cell populations forming the nuclear masses of the avian pallial DVR. In the canonical neocortical circuit, layer 4 glutamatergic cells receive thalamic inputs and connect reciprocally, in a columnar fashion, with glutamatergic cells in the upper layers 2 and 3. Similarly, in the avian visual DVR, cells at the nucleus entopallium receive visually driven thalamic afferents and sustain "columnar-like" reciprocal connections with cells in the intermediate nidopallium and ventral mesopallium. Interestingly, layer 4 specific molecular markers such as EAG2 (ether-a-go-go2, a potassium channel gene) and RORβ (RAR-related orphan receptor beta, a transcription factor gene), as well as the vesicular glutamate transporter2 (VGLUT2), are also expressed massively at the entopallium. At present, it is unknown whether the entopallial neurons expressing EAG2, RORβ and VGLUT2 are involved in the columnar projection circuit. In addition, the molecular phenotype of the nidopallial and mesopallial cells involved in the columnar-like circuitry is also unknown. We investigated such issues in chicks (*Gallus gallus*) by combining injections of a fluorescent retrograde neural tracer (CTB-AF555) into the entopallial and nidopallial targets, with fluorescent "*in situ*" hybridization. We found that most "column-forming" entopallial cells were VGLUT2+ and also expressed EAG2 and RORβ. We also found that nidopallial and mesopallial cells involved in the columnar circuitry indeed expressed a glutamatergic phenotype, same as their mammalian hodological equivalents. These results further demonstrate that the avian forebrain contains cell types with connectional and molecular features proper of the cells of the mammalian sensory cortices. In particular, column-forming entopallial cells and cortical layer 4 senso-recipient cells appear to share several unique features, which lend a strong support to the cell-type homology hypothesis.

Title: A two stage Bayesian observer predicts the effects of learning on perceptual decisions

Authors: ***S. PISUPATI**, S. MUSALL, A. E. URAI, A. K. CHURCHLAND;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Perceptual inference and reinforcement learning represent two specializations of Bayesian decision theory, describing optimal strategies in the face of perceptual or value uncertainty respectively (Dayan and Daw '08, Gershman and Daw '12). However, in real-life decisions, subjects may be simultaneously faced with both forms of uncertainty. This occurs, for instance, during early stages of training on perceptual decision-making tasks when subjects are learning stimulus-response-outcome associations from noisy observations. Here we describe a two-stage Bayesian learner that takes both forms of uncertainty into account. First, the observer uses noisy sensory observations on a given trial to update its beliefs about the state of the world. Second, the observer uses outcome observations across trials to update its beliefs about the value of different state-action pairs, taking into account the uncertainty in state estimation. The observer picks actions by sampling from these value beliefs and picking actions that maximize expected value with respect to the sample. This strategy, also known as Thompson sampling, promotes exploratory actions when value uncertainty is high, and automatically becomes more exploiting as this uncertainty decreases with training. The two-stage observer model makes predictions about how psychometric curves should evolve with learning of initial contingencies, reversals and changing priors (for different models of the world and different levels of perceptual and value uncertainty), in particular making strong predictions about changes in performance at the asymptotes of the curve or "lapses". The model also makes predictions about how the effects of sensory or value perturbations should change as animals learn. We compare these predictions to behavior of rats and mice under normal circumstances and following optogenetic perturbations of frontal and parietal cortices.

Title: Distributed neural signatures of evidence integration during prolonged deliberation

Authors: *M. L. WASKOM, L. SIDANI, R. KIANI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Decisions made under uncertainty can benefit when multiple pieces of relevant information, or evidence, are combined internally through a process of integration. Because evidence must often be accumulated over time, models of evidence integration highlight the close relationship between decision making and memory. Key to the development of such models has been the measurement of neuronal firing rate dynamics during decision formation. In rapid perceptual judgment tasks, ramping neuronal responses reflect a signature of integration, motivating efforts to understand the neural circuit mechanisms that provide a mnemonic basis for decision making. Recently, we reported that humans can produce behavior that approximates normative integration even when they must deliberate over much longer durations than encountered in standard tasks (Waskom & Kiani 2018, Current Biology). This invariance to timescale is inconsistent with the predictions of many existing circuit models, prompting us to seek a broader perspective on the neural substrates of evidence integration. To that end, we have conducted a human fMRI experiment aimed at characterizing the relationship between computational models of prolonged deliberation and measurements of neural activity across the whole brain. On each trial, subjects sequentially viewed 2-5 spatially localized Gabor patches with contrast intensities that had been sampled from one of two overlapping distributions. The subject's task was to make an inference about the generating distribution and, when prompted, signal their choice with an eye movement to one of two targets. The stimuli were briefly presented (200 ms) and separated by long, unpredictable gaps (2-8 s). This temporal control allowed us to model the dynamics of evidence integration at the timescale of the BOLD response. We have characterized these dynamics using intensive sampling of individual subjects (N=3, 240 min of task data per subject) and with respect to functional organization as determined by population receptive field modeling of visually-responsive voxels and resting-state mapping

of association cortex networks. Our results indicate that neural signatures of evidence integration are widespread and diverse, with the amplitude and temporal profile of responses in most visual and association regions exhibiting one of several distinct relationships to components of our evidence integration model. Together, these findings offer new quantitative insights about the interactions between sensory representations, working memory maintenance, and long-term memory storage that confer temporal flexibility on deliberative reasoning processes.

Title: Continuous decision-making as a lens into neural computation

Authors: *F. BAQAI[1], D. A. RUFF[2], B. D. DOIRON[3], M. R. COHEN[4];
[1]Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA; [2]Dept. of Neurosci., [3]Mathematics, [4]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Perceptual decision-making is a multi-faceted process. In natural behavior, decisions are affected by sensory thresholds, global cognitive processes like motivation or concentration, and selective cognitive processes like attention or prior beliefs. In the laboratory, these effects of these processes are typically studied in isolation or, rarely, in pairs. However, interactions between sensory, global, and selective processes might provide important insights into the computations and neural mechanisms underlying decision-making. In order to more sensitively probe these interactions we used a task with a continuous behavioral output in which subjects indicate the perceived direction of motion by looking at a point on a circle (Nichols and Newsome 2002; Cloherty et al 2019). We extended the task to include reaction times, global cognitive processes (by manipulating task difficulty), and selective cognitive processes (by changing the distribution of motion directions presented). Importantly, the changes in task difficulty and motion distributions were unsignaled. This setup allowed us to measure how, for example, concentration affects the ability of rhesus monkeys to notice changes in the distribution of motion directions, or whether there is an interaction between sensory thresholds and overall performance or sensitivity to the distribution of stimuli. To quantify these interactions and make

predictions about behavior and neural responses, we extended a standard accumulation to bound model (Gold and Shadlen 2007) to account for this continuous report by reshaping the bound into a ring. This model gives us interpretable parameters, but is still powerful enough to predict behavior. This model and task combination gives us sensitivity to changes in reaction times and choices associated with cognitive processes. This combination also provides a framework for understanding a subject's strategy, allowing us to investigate implications of the speed-accuracy tradeoff on reward. The model also makes predictions for neuronal mechanisms by determining whether cognitive processes affect the sensory representation (implicating visual cortex) or the starting point or dynamics of the decision (implicating premotor areas). Interactions between sensory and cognitive processes would imply interactions between the areas mediating each process. We will test these predictions in multineuron, multi-area recordings. More generally, combining a task with well-controlled stimuli and a rich behavioral output with a normative model will provide and important framework for designing experiments and interpreting behavioral and neuronal results.

Title: Adapting to an ever-changing world: How the brain makes decisions in the face of evolving behavioral rules

Authors: *C. XUE, L. E. KRAMER, M. R. COHEN;
Dept. of Neurosci. and Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: How do we flexibly adapt to a constantly changing world? While most of our senses are already developed during infancy, it is the capability of learning and updating the behavioral relevance of sensory information that makes animals and humans strong survivors in the wild or within a society. An abundance of psychophysical and electrophysiological studies on behaving animals have revealed how belief about the behavioral relevance of sensory information (often termed attention) modulates perception. On the other hand, it remains an open question how we flexibly change our beliefs based on perceptual evidence and what cognitive and neuronal factors

limit this flexibility.
We recorded simultaneously from groups of neurons in visual cortex (area V1) and parietal cortex (area 7a) while macaque monkeys performed perceptual decision-making tasks with rules evolving over time. The monkeys were required to: 1. discriminate different features of the same visual stimuli depending on the rule, and 2. flexibly update their beliefs about the current task rule (feature to be discriminated) based on what their history of stimuli, behavior, and rewards. Despite the fact that visual perception and task switching are thought to be mediated by different neural mechanisms and brain areas, we that there is a trade-off between the visual discrimination two: whenever the monkey does better at the perceptual task under a certain rule, he becomes less flexible in adapting to a new rule. We built models that predict both the monkey's choice and neuronal activity on a trial by trial basis. Overall, our results imply that there is a cognitive bottleneck that limits the brain's ability to perform well on a task while being flexible to take on other tasks. Models that describe behavior in this task may shed light on the neuronal underpinnings of cognitive flexibility in general.

Title: A multi-population, multi-task framework yields new insights about decision-making mechanisms

Authors: C. XUE[1], **L. E. KRAMER**[2], *M. R. COHEN[2];
[1]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [2]Dept. of Neurosci. and Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Perceptual decision-making, which is perhaps the premiere system for studying the relationship between neurons and behavior, has been dominated by two largely non-overlapping approaches. One approach aims to correlate the activity of sensory neurons with choices, typically in two-alternative forced-discrimination tasks. The other approach compares different task conditions to measure how cognitive processes like attention affect sensory responses. Some important conclusions from the two lines of work seem contradictory. Specifically, the former approach suggests that decision or feature attention mechanisms provide feedback to sensory

neurons, increasing correlated response variability (decision-feedback modulation) between choice-predicting neurons. However, the latter approach shows that attention decreases correlations among sensory-informative neurons in the same brain area but increases correlations between areas (attentional modulation).
We addressed this inconsistency by combining approaches. We recorded from areas V1 and V4 while the monkey performed two tasks: discriminating a subtly-changed location or spatial frequency of a Gabor patch. The monkey indicated the direction of perceived change by choosing the same left / right saccade targets in both tasks. This paradigm allows us to dissociate the two modulations by comparing noise-correlations based on the neurons' association with decisions or their feature preferences. Our analyses of noise correlations revealed both weak signatures of decision-feedback (increased correlation between neurons associated with the same choice) and strong signatures of attention-like selective modulation (lower noise correlations between sensory-informative neurons within areas and higher correlations between neurons in different areas). Future population measures of the animals' decision and task selection state on individual trials will further reveal how the two modulations work together to produce the cognitive flexibility that allows task-dependent mapping from vision to action.

Title: Using interactions between pharmaceutical stimulants and selective attention to test hypotheses about neuronal population activity in areas V4 and 7A

Authors: *A. M. NI, B. S. BOWES, D. A. RUFF, M. R. COHEN;
Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: We recently showed that cognitive processes like learning and attention, which improve performance on visually guided tasks, reduce shared trial-to-trial response variability (termed noise correlations or spike count correlations) between pairs of visual neurons, and that

there is a strong, quantitative relationship between performance and shared variability. This leads to the hypothesis that performance improves exactly when noise correlations change. A strong test of this hypothesis lies in the performance changes associated with artificial manipulations like the systemic administration of pharmaceutical stimulants. We investigated the effects of the most frequently used stimulant in the world, caffeine, and the most commonly prescribed pharmaceutical drugs used to treat Attention Deficit Hyperactivity Disorder (ADHD), methylphenidate and amphetamine, on the performance of rhesus monkeys performing a visual change detection task with an attention component. We found that even though these drugs are administered systemically, they have highly focused effects on performance, improving change detection at the attended but not the unattended locations. This result contrasts with naturally occurring global processes like the changes in arousal or motivation induced by a large unexpected reward, which did not interact with the selective effects of attention. Our behavioral results lead to specific, testable hypotheses about the neuronal population mechanisms underlying the effects of these drugs. For example, if the drugs selectively affect behavioral performance at attended versus unattended spatial locations, they should also differentially affect the shared variability of the neuronal populations with receptive fields that overlap the attended locations versus those with receptive fields that overlap the unattended locations. We are testing these hypotheses by recording the activity of neuronal populations in visual area V4 and simultaneously in area 7A, an area that may be related to the possible reward and decision-making effects of these stimulants. These results should shed new light on our understanding of the neuronal mechanisms that underlie selective processes such as attention and how such mechanisms are affected by both natural global cognitive processes and commonly used stimulants.

Title: Simultaneous population recordings from both superior colliculi do not support a limited resource theory of attention

Authors: *D. A. RUFF, M. R. COHEN;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Visual spatial attention has long been known to lead to faster and more accurate perceptual performance. Given these improvements, it is reasonable to wonder why subjects do not attend to everything all of the time. A leading hypothesis suggests that attention is a limited resource and that subjects can only focus their 'spotlight' of attention on a subset of possible locations because of those limits. Support for this hypothesis has been found using both behavioral and neurophysiological approaches. However, in a situation when stimuli are in opposite visual fields, we have previously found that the neuronal signatures of attention in each hemisphere of visual cortex are independent (Cohen and Maunsell, 2010). This result suggests that the resource bottleneck does not reside in the visual system, but it remains possible that the resource bottleneck is in the motor system. For example, the fact animals cannot simultaneously move their eyes to multiple locations might impose a limit on subjects' abilities to plan responses to multiple stimuli.

We tested this hypothesis by measuring the trial-to-trial fluctuations in attention to each hemifield that are reflected in the responses of populations of pre-oculomotor neurons. While monkeys performed a difficult visual task that required them to shift attention between hemifields, we recorded simultaneously from populations of neurons in both hemispheres of the superior colliculus (SC), which is involved in the planning and execution of eye movements. We used the responses of the simultaneously recorded neurons in each hemisphere to estimate the amount of attention allocated to the contralateral hemifield during each stimulus presentation (Cohen and Maunsell, 2010). The limited resource hypothesis predicts that attention to the two hemifields will be anti-correlated on a trial-to-trial basis. However, despite the fact that our neuronal estimates of attention robustly predicted behavioral performance, we found no relationship between the trial-to-trial estimates of attention based on SC neurons in the two hemispheres. This lack of correlation was in contrast to the large positive correlation that we observed between populations of simultaneously recorded neurons in visual cortex (the middle temporal area, or MT) and the SC in the same hemisphere, which shows that these methods can consistently detect fluctuations in attention that are consistent between areas. Our results suggest that the limited resource hypothesis cannot explain attention to opposite hemifields.

Title: Dissociating cognitive and sensory representations in posterior parietal cortex

Authors: *B. PEYSAKHOVICH, O. ZHU, G. IBOS, W. J. JOHNSTON, D. FREEDMAN; Univ. of Chicago, Chicago, IL

Abstract: Primates and other animals are remarkably skilled at visual categorization. Through experience, we can learn to treat visually dissimilar objects (e.g., a conifer and maple tree) as belonging to the same category (trees) and visually similar objects (e.g., a leafy oak tree and a stalk of broccoli) as belonging to different categories (tree and vegetable). In this study, we investigated how neurons in primate lateral intraparietal area (LIP) represent categories consisting of stimuli that differ in their sensory features. Previous studies have shown that LIP neurons encode category membership of motion stimuli. In these studies, monkeys were trained to group 360° of motion directions into categories based on a single arbitrary boundary. However, in this task, there is a strong correlation between category membership and motion direction: neighboring motion directions are more likely to belong to the same category than distant motion directions. In order to disambiguate cognitive (category) and sensory (motion direction) signals in LIP, we trained one monkey to perform a delayed match-to-category task in which he had to group twelve motion stimuli into two categories based on two orthogonal boundaries, such that motion directions that are 180° apart belong to the same category. Motion directions were separated into quadrants with 3 directions per quadrant, such that stimuli within one quadrant were 22.5° apart and near-boundary directions were 22.5° away from the boundary. We recorded from area LIP using single-channel electrodes (n = 8 sessions) and 16-channel Plexon V-probes (n = 41 sessions) while the monkey performed this categorization task. The monkey's accuracy was >80% for all conditions on included sessions. Preliminary analyses indicate that LIP neurons preferentially respond to all motion directions within one category, even when those motion directions are in opposite quadrants. These findings indicate that, through training, posterior parietal cortical circuits can reorganize to accommodate representations of categories that consist of visually dissimilar stimuli. Next, we will record in middle superior temporal area (MST) to better understand the transformation from sensory to categorical representations along the dorsal visual processing stream.

Title: Lateral prefrontal cortex (LPFC) is a likely contributor to task-related activity in area MT during the memory for motion task

Authors: *M. ISLAM[1], S. ZHU[1], K. WIMMER[2], T. PASTERNAK[1];
[1]Dept of Neurosci., Univ. of Rochester, Rochester, NY; [2]Campus de Bellaterra, Edifici C, Ctr. de Recerca Matemàtica, 08193 Bellaterra (Barcelona), Spain

Abstract: There is strong evidence that the circuitry sub-serving memory-guided comparisons of visual motion involves two reciprocally interconnected regions, the lateral prefrontal cortex (LPFC) and the motion processing area MT (e.g. Zaksas and Pasternak, 2006; Lui and Pasternak, 2011; Hussar and Pasternak, 2012). Specifically, when monkeys compare directions of two stimuli, S1 and S2, separated by a memory delay, both areas carry behaviorally relevant signals suggestive of active interactions between the two areas throughout the task. Thus, in response to motion in S1 and S2, LPFC neurons show direction selective (DS) activity, reminiscent of signals recorded in MT during the same task. During the memory delay, many neurons in the LPFC and to a lesser extent in MT, carry transient signals reflecting remembered direction in S1. In both areas, the activity during the delay increases in apparent anticipation of the comparison S2. During S2, neurons in both areas carry memory-related comparison effects (CE) reflecting remembered direction of S1, with some neurons showing stronger responses on trials when the preceding S1 moved in a different direction and some neurons showing stronger responses on trials when S1 direction was the same. In the LPFC, the majority of these signals weaken dramatically when the animals are rewarded without having to report their decision at the end of the trial (passive fixation task)(Hussar and Pasternak, 2009; 2012). To examine the top-down influences provided by the LPFC, we recorded from area MT during the passive fixation task, when many of the task-relevant signals in the LPFC, including DS, anticipatory and stimulus-selective delay activity and CE, are nearly absent. We found a significant reduction in the anticipatory delay activity, accompanied by increased trial-to-trial variability during the delay. On the other hand, in contrast to the near absence of the CE in the LPFC during the passive fixation, these effects appear to be preserved in MT, suggesting limited contribution of the LPFC to these signals. Similarly, responses to motion were equally DS during the active and passive tasks, suggesting that the influence of DS activity in the LPFC on processing of visual motion in MT is limited. These results show that during the motion comparison task, LPFC is a likely source of anticipatory delay activity in MT and contributes to the control of trial-to-trial variability of this activity. The preservation of CE in MT during the passive fixation task despite its absence in the LPFC, suggests either that these signals do not depend on the LPFC and are generated locally and/or rely on the influences contributed by other brain regions.

Title: Learning dependency of motion direction tuning in the lateral intraparietal area during a categorization task

Authors: *K. W. LATIMER, D. J. FREEDMAN;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Spiking responses in the lateral intraparietal (LIP) area in macaque cortex correlate with animals' perceptual and categorical visually-based decisions. Previous work has examined visual motion category encoding in LIP during a delayed match-to-category (DMC) task, as well as motion encoding during a similar motion direction discrimination task, the delayed match-to-sample (DMS) task. Here we examined LIP activity in monkeys at multiple stages of training on DMS and DMC tasks, and examined how neuronal responses during the DMC task varied according to the monkeys' prior training history. Specifically we examined neural activity during the DMC task in two groups of monkeys with different training histories. One group had been trained extensively on the DMS task (which required fine direction discrimination and comparison of motion directions) prior to learning the DMC task (Sarma et al., 2016). The second group had not been trained previously on the DMS task prior to the DMC task (Swaminathan & Freedman, 2012). Our analysis reveals that LIP neurons show motion direction tuning after both training conditions using a generalized linear model framework. Moreover, model-based dimensionality reduction reveals a distinct difference in motion direction tuning the DMS-trained monkeys: direction tuning in the DMC-only monkeys showed stronger transient tuning than the DMS-trained monkey. Training history can therefore impact the neural integration and representation of task-relevant sensory signals in LIP.

Title: Comparative decision-making in posterior parietal cortex: Proof of concept

Authors: H. LADRET[1,2,3], ***G. IBOS**[2,3];
[1]Visual Neurosci. Lab., Montreal, QC, Canada; [2]Inst. de Neurosci. de la Timone, CNRS, Marseille, France; [3]Aix-Marseille Univ., Marseille, France

Abstract: Deciding whether what we are looking at matches what we are looking for is a complicated task which requires to compare sensory and cognitive information. Recent publications (Ibos & Freedman, 2017; Freedman & Ibos 2018) proposed that neurons from lateral intraparietal area (LIP) are involved in such comparative process. These studies proposed that LIP neurons integrate bottom-up sensory signals and compare them to information related to the stimulus kept in working memory (presumably reflecting the integration of top-down signals originating in the prefrontal cortex). LIP neurons sequentially process and multiplex the information used by non-human primates performing a delay match to sample task: (i) selectivity to the identity of the stimulus kept in working memory; (ii) selectivity to the identity of the test stimuli; (iii) selectivity to the match/non-match status of the stimuli. This sequential processing suggests that LIP plays a specific role in the comparison of different sources of information. However, we still lack a computational framework which would validate LIP's putative role in such comparative decision-making. Here we present, as proof of concept, a spiking neural network (SNN) based on LIP neuronal activity during a delayed conjunction matching task (Ibos & Freedman, 2017). We demonstrate LIP's matching discrimination capacity based on the integration of both sensory and cognitive information. Specifically, we test that non-uniform distributions of synaptic weights and delays inside given groups of excitatory and inhibitory neurons create a spectrum of selectivity to the identity and the match status of the stimuli. We show that neurons from this SNN multiplex bottom-up sensory and top-down cognitive information as well as robustly encode the match status of the stimuli, reproducing previously presented experimental results.
This study demonstrates that biologically plausible organization could mimic LIP neuronal activity and confirms LIP's putative role in comparative decision-making. This model is encouraging further investigation, in order to test LIP's interaction with visual and prefrontal cortical areas in different behavioral framework.

Title: Two tradeoffs between local accuracy and catastrophic errors in a solution to the representation assignment problem

Authors: *W. J. JOHNSTON, D. J. FREEDMAN;
Dept. of Neurobio., Univ. of Chicago, Chicago, IL

Abstract: The brain has multiple distinct representations of the external world. In part, these distinct representations arise from different sensory modalities, like vision and touch, but they also arise within sensory modalities in cortex, in which different subsets of brain regions are thought to represent different features of the world (e.g., visual form and motion). Thus, information about a single set of stimuli is spread across many distinct sets of representations in different brain regions -- yet all of this information may potentially be relevant to behavior. In this work, we demonstrate a mechanism by which the brain can integrate information from these distinct representations. In particular, given a set of stimuli represented in two distinct brain regions, giving rise to two distinct sets of representations, we show how the brain can reliably discover the correct assignment between the two sets of representations. Importantly, an incorrect assignment (i.e., an assignment error) results in the representation of a non-existent stimulus, constructed from mismatched features across brain regions.
Here, we analyze a particular solution to this assignment problem: the representation of some of the same stimulus features in both brain regions. Using a statistical model, we derive the assignment error rate in terms of the number of stimuli, the number of overlapping features, and the distortion (i.e., the variance of an optimal estimator) of each of the features within each region. Using rate-distortion theory, we derive the amount of information in bits that an optimal system would need to implement this solution to the assignment problem, including an additional dependence on the total number of stimulus features and their distortion. Thus, we can fix the total amount of information used by the system and describe how changing the number of overlapping stimulus features, the relative distortion of those overlapping features across the two brain regions, and the number of stimuli affects both the assignment error rate and the achievable feature distortion. In this analysis, we demonstrate two tradeoffs: (1) increasing the number of overlapping features decreases the assignment error rate by almost an order of magnitude but

increases feature distortion by half an order of magnitude; (2) increasing the asymmetry of feature distortion across the two regions increases the assignment error rate as well as markedly slows its decay with additional bits but decreases overall feature distortion and speeds its decay. Finally, we explore how the brain may navigate this tradeoff within and across different sensory systems and link these theoretical results to experimental data.

Title: Common rules guide memory-guided comparisons of motion directions and locations in the lateral prefrontal cortex (LPFC)

Authors: H. SCOTT[1], K. WIMMER[3], ***T. PASTERNAK**[2], A. SNYDER[1];
[1]Brain and Cognitive Sci., [2]Dept of Neurosci., Univ. of Rochester, Rochester, NY; [3]Ctr. de Recerca Matemàtica, Campus de Bellaterra, Edifici C, 08193 Barcelona, Spain

Abstract: We previously showed that neurons in the lateral prefrontal cortex (LPFC) carry mnemonic signals for visual motion direction and speed during a working memory task (Hussar & Pasternak, 2012; 2013). During this task, monkeys compared the directions or speeds of two motion stimuli, S1 and S2, separated by a brief memory delay. We found that many LPFC neurons showed stimulus selective activity in response to S1 and S2 and transient signals during the memory delay. During the comparison S2, some LPFC neurons fired more vigorously when its direction/speed matches that of the earlier S1, while other neurons showed stronger responses when its direction/speed differed from that of S1. We asked whether these memory-related signals, termed “comparison effects”, are specific to the type of information being compared (i.e., visual motion), or are domain independent indicators of comparisons *per se* by recording from the same neurons during two matched tasks involving comparisons of either directions or locations of the same motion stimuli. We found that during S1 and S2, neurons were selective for motion direction during direction comparisons and for location during location comparisons. Delay activity showed similar transient signals reflecting remembered stimulus appropriate to the task. The comparison signals during S2 were also analogous for the two tasks, with some

neurons responding more to S2 when it matched the preceding S1, and some neurons responding more when the S1 was different. Importantly, often the same neurons showed comparison signals of the same sign for stimulus location and direction. These results reveal strong parallels between the way LPFC neurons represent motion and location information during memory-guided comparison tasks, suggesting a common, or analogous neural substrate for representing sensory information in LPFC during such tasks. They also demonstrate that prefrontal neurons flexibly alter their tuning properties to meet task demands.

Title: Cortical computations underlying categorization task switching

Authors: *K. MOHAN, O. ZHU, S. SWAMINATHAN, D. FREEDMAN;
Dept. of Neurobio., The Univ. of Chicago, Chicago, IL

Abstract: Primates exhibit exceptional flexibility in their behavior. Indeed, we can flexibly adapt to changes in task context with the same stimuli eliciting dramatically different behavioral responses. Yet, it remains unclear how neural circuits mediate such flexible behavior. To understand flexible decisions, we trained monkeys to alternate between motion categorization tasks in which they categorized the same random-dot motion stimulus in two different task contexts. The tasks differed both in the effector used for reporting the decision (eye vs. hand movement) and in the sequence of task events on which decisions were based. In the first task (one-interval categorization (OIC)), a single sample stimulus was presented and the monkeys rapidly reported its category membership by making a saccade to either a red or a green target to indicate “category 1” or “category 2” respectively. In the second task (delayed match-to-category task (DMC)), a sample stimulus was followed by a test stimulus after a 1 second delay and the monkeys reported whether the sample and test stimuli belonged to the same category by releasing a manual lever to indicate “category match”. While the monkeys performed the two tasks in alternating blocks of trials, we recorded neural responses from 102 neurons in the lateral intraparietal cortex. Single neuron responses were heterogeneous, non-linear and exhibited mixed tuning and dynamics for task-relevant variables - motion direction, category, and choice.

However, the neuronal population showed remarkably similar category selectivity in both tasks, despite differences in task demands like short-term memory and match/non-match judgments (accuracy of a linear category decoder: 85% OIC, 95% OIC with chance at 50%). By contrast, other task-relevant variables such as motion direction and choice varied between the two tasks. First, we found higher within-category direction information in the OIC, but not the DMC task (accuracy of a linear direction decoder: 74% OIC, 65% DMC with chance at 20%), suggesting that task demands differentially modulate neuronal responses. Second, we found that choice information was encoded independently in both tasks, thus revealing a transformation in information formats as "shared" category signals are routed to "distinct" action circuits. Our findings demonstrate that parietal neural circuits mediate flexible task-switching by differentially formatting relevant information in a task-dependent manner.

Title: Sensory evidence and expected reward are integrated beyond primary visual cortex

Authors: *L. E. WOOL, A. LAK, C. REDDY, K. D. HARRIS, M. CARANDINI;
Univ. Col. London, London, United Kingdom

Abstract: Choosing between alternatives requires integrating available sensory evidence with expected reward. This integration may be performed throughout sensory processing or occur at later stages. Given that primary visual cortex (V1) carries signals related to reward outcome (Shuler & Bear, 2006), we asked if it might combine visual evidence with information about expected reward value.
We used two-photon microscopy to measure neuronal activity while mice performed a visual decision-making task (Burgess et al., 2017). We used transgenic mice that expressed GCaMP6s in cortical excitatory neurons. When mice correctly detected the location of a grating in the left or right visual hemifield, they were given a water reward. The reward amount for correct-left and correct-right choices was unequal and changed over blocks of trials (Lak et al., 2018).
Changes in expected reward profoundly affected the animals' choices. Psychometric curves shifted between blocks, favoring choices promising larger rewards. This shift affected choices on

low-contrast trials (12%) and catch trials (0% contrast) more than on high-contrast (50%) trials. Therefore, behavior was informed by a combination of strength of sensory evidence and size of expected reward.
Changes in expected reward, however, had no significant effect on activity in V1. We measured V1 responses during the task, computed contrast-response functions at stimulus onset, and compared these between blocks. There was no difference between contrast-response functions between blocks. Some neurons also responded around the time of action, but these responses were again unchanged between blocks.
We are currently investigating whether expected reward has a neural correlate elsewhere in dorsal cortex. We are imaging neurons in secondary motor cortex (M2). Preliminary results suggest that some M2 neurons carry information about the upcoming reward during the response epoch, showing enhanced responses at the time of action during blocks with larger rewards.
We conclude that the integration of visual evidence and expected reward occurs only after primary visual cortex. This integration might occur when signals reach frontal cortex, where expected reward may modulate the activity of neurons that fire around the time of the action.

Title: Context determines the timescale of evidence evaluation for decision-making

Authors: R. HARUN, E. JUN, H. PARK, P. GANUPURU, A. B. GOLDRING, *T. D. HANKS;
Univ. of California-Davis, Davis, CA

Abstract: Decisions are based upon evidence and context, but how does context alter the timescale of evidence evaluation? To investigate this question, we examined how subjects utilized evidence in an auditory change detection task. 11 human subjects listened to streams of stochastic auditory clicks and were trained to respond when there was an increase in the generative click rate within a specified response window. Subjects performed this task in two contexts governed by the response window duration, a long response window (LRW:1000ms) or

a short response window (SRW: 500ms). To optimize performance, subjects had to adapt their timescale of evidence evaluation by evaluating evidence over a longer period when they had longer to respond and vice versa. We found that subjects adapted their timescale of evidence evaluation to match the task demands through *three* different analyses. 1) Reaction times were longer in the LRW compared to the SRW context, suggesting that subjects evaluated longer periods of evidence to form their responses in the LRW context. We next assessed the timescale of evidence utilization by examining the mean click rates that preceded false alarm (FA) responses. FAs were trials in which there were no changes in the generative click rate, but on average, FAs followed a period of increased click rates because subjects generally responded to local increases in the click rate that were present in the stochastic stimuli. 2) On average, longer periods of increased click rates preceded FA responses in the LRW compared to the SRW context (893 ± 7 ms vs 592 ± 4 ms, respectively), suggesting that longer periods of evidence were utilized in the LRW context. Lastly, we constructed a quantitative model to account for behavior in this task. We determined the model parameters that maximized the likelihood of observing the experimental trial outcomes (i.e. Hits, Misses, and FAs) given the auditory stimuli on each trial. 3) Behavior was best explained by a wider temporal evidence filter in the LRW compared to the SRW context, indicating that evidence had a longer influence on decisions in the LRW context. Our findings show that subjects contextually adapt their timescale of evidence evaluation to optimized decision-making behavior.

Title: Differences between rat and human decision making confirmed and attributed to different forms of behavioral variability

Authors: C. A. SHEVINSKY, Q. N. NGUYEN, ***P. REINAGEL**;
UCSD, La Jolla, CA

Abstract: In perceptual decision-making tasks, the unmodified drift diffusion model predicts that accuracy should be independent of a trial's reaction time. Humans and monkeys are widely reported to violate this prediction - their accuracy declines with reaction time. We have reported that rats also violate the prediction, but in the opposite direction- their accuracy improves with

reaction time (1,2). Here we replicate this result for N=18 rats in the random dot motion discrimination task. We also tested N=60 human subjects in the identical task and confirm that accuracy falls with reaction time, ruling out task differences as the cause of the discrepancy. Although we limit analysis to data that are apparently stationary, we argue that either the human or rat finding could be an artifact of undetectable and unavoidable non-stationarities on short timescales. To address this we introduce a new temporally-local analysis, which confirmed our findings in both humans and rats, and showed that the magnitude of the effect increases with stimulus strength in both species.
The behavioral data were fit with a hierarchical drift diffusion model (HDDM) (3) using free parameters for threshold (A), drift rate (V), non-decision-time (T), starting point variability (SZ), drift rate variability (SV), and non-decision-time variability (ST). Species-level hierarchical priors and individual parameters were fit simultaneously. Comparison of the species-level priors revealed that humans had higher drift rate variability SV than rats. Rats had lower threshold A, higher starting point variability SZ, longer and more variable non-decision time (T, ST). Together these differences account for the species-specific dependence of accuracy on reaction time, without postulating a decaying decision bound. Allowing the model parameters to depend on response side improved the model fit for each species, even after accounting for the increase in parameters (DIC). Allowing further dependence of parameters on the response and reward outcome of the previous trial improved the mode fit further. We conclude that much of the 'variability' is reducible to systematic and predictable effects of behavioral context. Such effects are equally prevalent, but differently manifested, in the two species. Perceptual decision making of rats and humans can thus be understood as fundamentally similar computations, with quantitative differences in exactly how behavioral context influences choice.

Title: Distinct roles for dopaminergic projections to dorsal and ventral striatum in sensory decisions

Authors: M. M. MOSS[1,2], K. D. HARRIS[1], M. CARANDINI[1], **A. LAK**[1,2];
[1]Univ. Col. London, London, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Dopaminergic (DA) projections to striatum have specialized roles in reward processing and movement regulation, depending on their anatomical targets within the striatum (Parker et al., 2016; Howe and Dombeck, 2016). However, the roles of striatal DA projections in sensory decision making are unknown.
We trained mice in a visual detection task in which the reward for correct choices to the left and right was unequal and switched across blocks of trials (Lak et al., 2018). Mice exhibited steep psychometric curves with negligible lapse rates, and shifted their psychometric curves between blocks to favor the side paired with larger reward.
To measure the activity of striatal DA projections during the task, we expressed GCaMP6 in midbrain dopamine neurons of DATCre mice, and implanted optic fibers above dorsal or ventral striatum.
DA projections to the ventral striatum encoded reward prediction error (RPE). Their activity in this task was similar to that of DA cell bodies in the ventral tegmental area (Lak et al., 2018). They were active at both stimulus onset and trial outcome. Their activity reflected sensory evidence and reward size, and differed between error and correct trials as predicted by RPEs of a reinforcement learning model that integrates sensory evidence and reward value (Lak et al., 2018).
In contrast, DA projections to the dorsal striatum encoded sensory information independent of choice accuracy and reward value. These projections responded at the stimulus onset, during which animals were instructed not to move, and also during choice execution. Their activity at the stimulus time reflected the strength of visual signals in a highly lateralized manner, appearing only in response to contralateral stimuli. This activity did not reflect the size of the upcoming reward, and was indistinguishable between correct and error trials. Their activity at the time of choice execution was also lateralized, appearing only during contralateral choices.
These findings indicate that the roles of DA projections during sensory decisions depend on their targets in striatum. The results suggest a novel role for DA projections to the dorsal striatum in encoding sensory information, independent of choice accuracy and expected reward size.

Title: Superior colliculus inactivation impairs perceptual decision-making in monkeys

Authors: *E. JUN[1], A. BAUTISTA[1], T. TAK[1], A. FABRO[1], N. WEBSTER[1], E. ALVAREZ[2], M. A. BASSO[1];
[1]Dept. of Psychiatry and Biobehavioral Sci. and Neurobio., Univ. of California Los Angeles, Los Angeles, CA; [2]UCLA, Los Angeles, CA

Abstract: Recent work in rodent posterior parietal cortex and reversible inactivation experiments in monkey area LIP calls into question the causal role of area LIP in perceptual decision-making. Therefore, we tested the hypothesis that the monkey superior colliculus (SC), another sensorimotor area involved in perceptual decision-making and attention, plays a causal role in perceptual decision-making. Two trained male rhesus monkeys performed a two alternative choice task in which they reported whether they perceived leftward or rightward orientation in a dynamic Glass pattern stimulus. We parameterized the difficulty of the decision by varying the coherence of the Glass pattern stimulus among 0, 3, 5, 10, 17, 24, 36, 50%. Monkeys reported their choices by making a saccade to a location corresponding to the orientation; to the right for rightward orientation and to the left for leftward orientation. We plotted psychometric functions and fitted the choice performance data with logistic functions to extract the choice bias and slope parameters. Monkeys also performed a simple saccade task in which a red and white target appeared in the same positions as those of the choice targets in the Glass pattern decision task. Monkeys made saccades to the white target and we measured the proportion of saccades made to the left and right hemifields. Using a custom-designed injectrode system, we infused muscimol (1μl, 0.5μg/μl at a rate of 0.1μl/min) into the intermediate layers of the SC at sites where we recorded delay-period and saccade-related neuronal activity. Results from five injections in two monkeys show that muscimol into the SC results in changes to monkeys' decisions. After muscimol, monkeys consistently showed a choice bias away from the target in the affected field and predominantly for lower coherence stimuli. Control injection of the vehicle saline did not change choice bias. Importantly, the distribution of left and right saccades in the simple saccade task did not change after muscimol injection, ruling out an interpretation based on purely a motor bias. Our results support the hypothesis that the SC of monkeys plays a causal role in perceptual decision-making independently of its role in saccade generation.

Title: Distinct representations of decision variable and task difficulty in the monkey lateral intraparietal cortex

Authors: *G. OKAZAWA, R. KIANI;
New York Univ., New York, NY

Abstract: The neural population of the monkey lateral intraparietal (LIP) cortex represents the formation of perceptual decisions communicated with saccadic eye movements. For example, in the direction discrimination task with random dots, the average PSTHs of LIP neural population ramp up at a rate proportional to the motion strength supporting a saccade toward the neurons' response field (Shadlen & Newsome 2001). These classic experimental results have motivated models in which neurons integrate sensory evidence into a decision variable (DV). In these models, the DV magnitude dictates the choice and confidence associated with the choice.
Here we show that LIP population responses also reflect stimulus difficulty distinct from DV in two perceptual tasks: direction discrimination with random dots (Shadlen & Newsome 2001) and a novel face categorization task (Okazawa et al 2018). We varied stimulus difficulty by changing motion coherence in the direction discrimination task and the distance of facial features to prototypes in the face categorization task. In both tasks, the LIP population simultaneously represented both the stimulus difficulty and the DV; population responses at each moment fell along a convex curve in the state space, where the location on the curve corresponded to the DV and depth from the base of the curve represented stimulus difficulty. The curves expanded over time, creating a 3D manifold that reflected the variety of neural trajectories in the state space during decision formation.
This simultaneous representation of the DV and stimulus difficulty suggests the possibility for choice-independent encoding of confidence, as opposed to a choice-dependent representation based on the DV (Kiani & Shadlen 2009; Beck et al 2008). However, by analyzing neural data while monkeys performed a post-decision wagering task to report their confidence, we show that the monkeys' confidence judgment did not correlate with fluctuation of population neural responses along the stimulus difficulty axis. We therefore suggest that the choice-independent representation of stimulus difficulty is most likely an implementational feature of the computations performed for integration of sensory evidence, but it is not read out by downstream areas for confidence reports or utilization of confidence for guiding behavior.

Title: The neural dynamics of deliberation and commitment during dynamic decision making in humans: A MEG study

Authors: *T. THIERY, P. RAINVILLE, P. E. CISEK, K. JERBI;
Univ. of Montreal, Montreal, QC, Canada

Abstract: Imagine you are driving to a new destination, deciding on the best route. As you drive, your decision is informed by road signs, advice from your passengers, your GPS, etc. Crucially, as you approach a potential turn, you are urged to make your decision even if you are not yet fully confident. In ecological settings, the available information for making a choice can change without warning, and the urgency to choose one way or another is among many factors influencing the decision process. Recently, neurophysiological studies in monkeys performing perceptual decision-making tasks, combined with computational models, have paved the way for theories about how the brain makes decisions in a constantly changing environment. However, the underlying mechanisms and whole-brain dynamics involved in processing sensory information and making a variety of trade-offs between the speed of a decision and its accuracy in humans are still poorly understood. Here, we recorded whole-brain rhythmic synchronization using magnetoencephalography in human participants (n=30) performing the “tokens task”, in which they must guess which of two targets receives the majority of tokens jumping from the center every 200ms, reporting their decision with a right or left button press. We show that while participants are deliberating about their choice, source-reconstructed local field potentials in the beta band [15-30 Hz]) build up in an evidence-related manner in sensorimotor regions, reflecting the competition between response options biased by sensory information provided by the tokens. In the same regions, theta oscillations ([4-8 Hz])] are involved in executing motor commands after participants have committed to a choice. Finally, we found increased high gamma oscillations ([60-90 Hz]) in the insula after participants made an error. This may indicate that high-frequency field potentials play a crucial role in our ability to evaluate choices by monitoring errors. Taken together, these results are congruent with previous studies looking at specific brain regions in monkeys, but they provide a more complete picture of how decisions evolve across a distributed network.

Title: The role of frontal cortex in multisensory decision-making

Authors: *P. COEN, M. J. WELLS, S. KACKAR, P. ZATKA-HAAS, M. CARANDINI, K. D. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: Several recent studies have shown that the mouse frontal cortex plays a key role in transforming sensory stimuli into appropriate motor actions during decision-making tasks. However, real-world decisions are invariably multisensory. Does frontal cortex combine information across sensory modalities when required for decision making, or does it represent separate modalities independently?
We trained head-fixed mice to perform an audiovisual spatial task where animals turn a steering wheel to indicate whether a stimulus appeared on the left or right. The stimuli can be auditory, visual, or a combination of the two, presented in coherent or conflicting locations. In one set of experiments, we optogenetically inactivated different spots across dorsal cortex on individual trials while mice performed this task. In a second set of experiments, we are currently inserting Neuropixels probes in frontal cortex while mice performed the task.
We found that auditory and visual primary sensory cortices were both required for the processing of modality-specific sensory information, and that the effect of inactivation in these regions was highly lateralized. The effects of inactivation on secondary motor cortex (M2) were also robust, but they were independent of modality. Inactivation of M2 in either hemisphere, irrespective of stimulus location, increased mouse reaction time, supporting a cooperative model of multimodal decision-making in M2.
To determine whether individual neurons in frontal cortex carry separate or merged representations of the two modalities, we are currently recording neural activity in M2 with Neuropixels probes. In initial experiments, we have observed neurons exhibiting a variety of response patterns: some neurons respond to both modalities, while others are selective for only one modality.

Overall, our results suggest a key role for secondary motor cortex in the processing of audiovisual information for multisensory decisions.

Title: Cortical states during sensory decision making

Authors: *E. A. K. JACOBS[1], N. A. STEINMETZ[4], A. J. PETERS[2], M. CARANDINI[3], K. D. HARRIS[2];
[1]Sainsbury Wellcome Ctr. for Neural Circuits and Behaviour, [2]Inst. of Neurol., [3]Inst. of Ophtalmology, UCL, London, United Kingdom; [4]Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Cortical desynchronization is associated with improved performance in sensory detection tasks. A current view holds this improvement occurs because desynchronization enhances cortical sensory coding. We tested this hypothesis in mice, by asking whether cortical desynchronization is specific to the cortical areas of the sensory stimuli being processed, and whether it leads to increased selection of correct stimuli in multiple-alternative choice tasks. We monitored cortical activity using widefield imaging of genetically encoded calcium indicators, while mice performed variations of a visual alternative choice task (Burgess et al. 2017), as well as auditory and audio-visual alternative choice tasks. We quantified movement by monitoring the motion of the steering wheel the animals were using during the task to make choices, and acquired simultaneous pupil measurements to assess overall arousal level. We validated that synchronized and desynchronized states could be detected in widefield data by comparing it to simultaneously-recorded electrophysiology.
In a 3-alternative task (where subjects had the option to choose left, right, or nogo), cortical desynchronization was associated with increased probability of making an action (choosing left

or right), but was uncorrelated with accuracy: the probability that animals would select the correct vs. incorrect side was independent of desynchronization. Action probability was more strongly correlated with desynchronization of somatomotor cortex than of visual or auditory cortex, in both visual and auditory versions of the task. The correlation of desynchronization with action probability could not be fully explained by a measure of arousal as inferred from pupil size.
We conclude that, at least in this task, cortical state relates more to behavioral engagement than to sensory accuracy, and that this state is global rather than localized to cortical regions where the stimuli are processed.

Title: Different influences of explicit and implicit Bayesian priors on perceptual decision-making

Authors: V. THAKUR[1], J. DITTERICH[3], M. A. BASSO[2], ***B. J. KNOWLTON**[1];
[1]Psychology, [2]Psychiatry and Biobehavioral Sci. and Neurobio., UCLA, Los Angeles, CA; [3]Ctr. for Neurosci. & Dept. of Neurobiology, Physiol. & Behavior, Univ. of California, Davis, CA

Abstract: Previous experience can lead to biases in decision-making. We assessed whether Bayesian priors could be learned implicitly in a perceptual decision making task and attempted to characterize differences in the implementation of biases between subjects who were aware of the priors and those who remained unaware using the Drift Diffusion Model (DDM) of decision-making. Participants observed a dynamic Glass pattern (Glass, 1969) and had to determine the orientation direction of the stimulus. The difficulty of the decision was varied across trials by varying stimulus coherence. The stimuli appeared in two different colors (red or green) and we varied the priors in two experimental conditions across groups of participants. In the first experiment (75-25), Glass patterns of one color were presented with a direction prior of 75% left, 25% right, and Glass patterns of the other color had the opposite direction prior (25% left, 75% right). In the second experiment, Glass patterns of one color were presented with a direction prior of 75% left, 50% right, and Glass patterns of the other color had equal priors (50% left,

50% right). In both experiments, one group of participants was told about the priors (the Explicit group) and another group was not (Implicit group). At the end of the session, participants were asked if they thought the colors were equally distributed in both directions and, if not, which direction was dominant for each color. Based on their responses, participants in the Implicit groups were excluded if they reported that they became aware that the different colors were associated with different priors. For each experiment there were 20-25 participants in each condition and they completed 1200 trials. In both experiments, both Explicit and Implicit subjects were able to incorporate the stimulus-specific priors into their decisions according to their psychometric functions, but Explicit subjects did to a larger extent. Using the DDM, we observed that in both experiments, drift rate was different for each color in both Explicit and Implicit groups. This effect was stronger in the Explicit groups than in the Implicit groups. Participants in the Explicit groups also showed changes in the starting point of evidence accumulation, while this effect on start point was much less pronounced in the Implicit groups. These results suggest that implicit learning of Bayesian priors in perceptual decision-making is supported by changes in drift rate in the direction of the more frequent orientation. Awareness of the priors increases these changes in drift rate but also leads to changes in start point consistent with the priors.

Title: Representation of an evolving decision spanning eye movements in area LIP

Authors: ***N. SO**[1], M. N. SHADLEN[2];
[1]Zuckerman Institute, Columbia Univ., New York, NY; [2]Neurosci., Howard Hughes Med. Inst. - Columbia Univ., New York, NY

Abstract: Many decisions are based on evidence gathered before and after unrelated activities. Hence, the decision process may need to pause, store the accumulated evidence and resume acquisition of new evidence later. Intervening actions may affect the context or reference frame in which evidence is acquired, necessitating invariance with respect to such action-induced changes. It is not known how the representation of an incipient decision is maintained across intervening actions. To address this, we recorded from a population of neurons in the lateral intraparietal area (LIP) that are known to represent neural computations over flexible timescales

but in a fixed oculocentric frame of reference. Two monkeys reported the direction of motion in a dynamic random dot display comprising two 80 ms pulses (D1 and D2) separated by ~2s, during which the monkey made intervening eye movements (IEMs). In the *main version* of the task, a set of IEMs ultimately brought the monkey's gaze back to the initial fixation point (FP), such that the eye-centered positions of the choice targets remained the same during the two decision epochs. In the *allocentric variant*, the IEM brought the monkey's gaze to a new FP, such that the eye-centered positions of the choice targets differed during the two decision epochs. In both variants of the task, monkeys made their choices based on both D1 and D2 pulses. During the initial decision, neurons with response fields (RFs) aligned to one of the choice targets (N1 neurons) responded in a graded manner to D1 despite the fact that the choice target was never the object of the next eye movement. During the IEM, these N1 neurons lost their decision-related information, but other neurons represented the information as the choice target entered their RFs (N2 neurons). When the monkey returned its gaze to the initial FP, the N1 neurons recovered their initial decision information and then updated this activity with new evidence from D2. In contrast, when D2 was presented at the new FP (allocentric variant), the N2 neurons responded to D2 by updating their newly acquired representation of D1. These results suggest that LIP neurons, as a population, can represent the evolving decision across IEMs in a way that achieves invariance to gaze, despite individual neural RFs defined in an oculocentric frame of reference. We also present evidence from mulitneuron recordings that the mechanism involves passing information between subpopulations, like N1 and N2, within LIP. The finding extends neural mechanisms thought to support the stability of space across eye movements to the generalization of a decision in which evidence accumulation is tied to specific action plans.

Title: Posterior parietal cortex plays a causal role in perceptual and categorical decisions

Authors: *Y. ZHOU[1], D. J. FREEDMAN[2];
[1]Dept. of Neurobio., [2]Neurobio. and Computat. Neurosci., Univ. of Chicago, Chicago, IL

Abstract: Decision making requires evaluating incoming sensory stimuli in order to select task-appropriate motor responses. The primate posterior parietal cortex (PPC) is well suited to

mediate decision making because of its anatomical position at a midpoint in the sensorimotor cortical hierarchy. Indeed, neurophysiological recordings have demonstrated a correlation between PPC activity and monkeys' decisions during visually-based discrimination and categorization tasks, with much of this work focusing on the lateral intraparietal (LIP) area of PPC. Yet, PPC's causal role in visual decisions has been debated, with recent work showing that PPC inactivation had no discernable impact on task performance during a widely studied visual motion discrimination task. However, that study focused on PPC's contribution to motor aspects of decisions (deciding where to move), but not sensory aspects (deciding what you are looking at). Thus, we tested whether LIP plays a causal role in visual decisions, and directly compared its role in sensory evaluation and motor planning functions, by reversibly inactivating LIP during visual discrimination and categorical decision tasks. Here we show that LIP inactivation affected both sensory and motor aspects of behavior, but preferentially impaired decisions when visual stimuli, rather than motor response targets, were in the inactivated visual field (IVF). To further test LIP's role in sensory evaluation during perceptual decisions, we recorded neuronal activity in the same LIP regions targeted for inactivation. We recorded from 194 LIP neurons in the same two monkeys used in the inactivation experiment, during the performance of the motion direction discrimination task. In these experiments, motion stimuli were shown at multiple levels of coherence and were always placed within LIP neurons' receptive fields. This revealed neuronal activity that was highly correlated with monkeys' trial-by-trial decisions about the stimuli shown within neurons' RFs, including for stimuli with zero motion coherence. Taken together, this work demonstrates that the primate PPC plays a significant role in mediating visual decisions, with a preferential role in sensory evaluation compared to motor planning during visual perceptual and categorical decision-making tasks.

Title: Neural processing of somatosensory feedback and pre-motor planning in children with childhood apraxia of speech

Authors: *A. ENGELHART[1], A. MCILRAITH[2], J. IUZZINI-SEIGEL[3], J. R. GREEN[4], T. P. HOGAN[4], T. M. CENTANNI[1];
[1]Psychology, Texas Christian Univ., Fort Worth, TX; [2]Univ. of Houston, Houston, TX; [3]Marquette Univ., Milwaukee, WI; [4]MGH Inst. of Hlth. Professions, Boston, MA

Abstract: Childhood apraxia of speech (CAS) is a neurological pediatric speech disorder characterized by poor planning of speech sound sequences in the absence of neuromuscular deficits. Children with CAS evidence a constellation of symptoms including, but not limited to, inconsistent speech sound production, vowel errors, difficulty with coarticulatory transitions, and prosodic disturbances; in addition, poor response to intervention is common and many will participate in speech treatment throughout childhood and into adolescence. The underlying neural mechanisms of CAS are still largely unknown, which leads to inconsistencies in both diagnosis and response to intervention. According to the Directions Into Velocities of Articulators model (DIVA) of speech motor acquisition, two main deficits may be present in CAS. One of these is a weakness in feedforward control, hereafter referred to as motor planning. Under this hypothesis, neural encoding of somatosensory information is intact but the pre-motor planning area for speech (Broca's area) fails to develop an accurate motor sequence for the intended utterance. The other is an overreliance on afferent feedback mechanisms including auditory or somatosensory. The latter system processes somatosensory information regarding the articulators (e.g. the lips, cheeks, and tongue), which is needed to properly plan and produce speech as well as evaluate the accuracy of the executed movement. In the current study, children with or without CAS and typically developing adults were assessed and then completed two tasks while magnetoencephalography (MEG) recordings were acquired. These tasks were designed to evaluate the neural markers of CAS and determine whether deficits in somatosensory processing and pre-motor planning exist in isolation or in tandem. The first task aimed to evaluate somatosensory feedforward processes by lightly stimulating participants at two articulator locations: the lip and the tongue, while MEG data were acquired. The second task aimed to evaluate the motor planning deficit. Participants completed a non-word repetition task to allow for imaging of the pre-motor planning process in Broca's area. We evaluated neural activation in two regions of interest: primary somatosensory and Broca's area. We present our findings in the context of these two deficits and evaluate whether these deficits occur in tandem or separately. Implications for diagnosis and treatment will also be discussed.

Title: Previous exposure to sensory feedback noise causes a decrease in online compensation for sensory perturbations

Authors: *B. PARRELL, C. NIZIOLEK;
Communication Sci. and Disorders, Univ. of Wisconsin-Madison, Madison, WI

Abstract: In motor control, sensory afferent information is combined with forward model predictions into a single estimate of the current state of the motor plant, which is then used by the controller to generate motor commands. The integration of sensory and predictive signals is typically understood as a (quasi-)Bayesian process, where the weight assigned to each signal is proportional to its reliability. Consistent with this, previous work has shown that increased noise (decreased reliability) in the visual signal leads to a decrease in the use of visual feedback for hand position estimation. However, how long-term exposure to unreliable feedback affects the sensory integration process remains unclear. Here, we leverage the unique characteristics of the speech motor control system to test the hypothesis that persistent exposure to unpredictable noise in sensory feedback changes the relative weighting of sensory and predictive signals. In speech, online compensation for sensory perturbations is typically incomplete (10-25%); this partial response allows us to test for potential increases, as well as decreases, in the reliance on sensory afferent information during motor performance. In a within-subjects experiment, we first manipulated the reliability of the auditory feedback received during speaking, then assessed the compensatory response to large auditory perturbations. In two separate sessions, participants first produced a baseline block of under one of two conditions: 1) a veridical baseline in which speech feedback was unperturbed, or 2) a noisy baseline in which small alterations to auditory feedback of vowel formant frequencies were drawn from a normal distribution with a standard deviation of 15 mels. In each session, this baseline block was followed by a test block where vowel feedback was shifted by +/- 125 mels on a random third of trials. We test two competing hypotheses. H1: If the feedback mismatch during the noisy baseline block is attributed to inaccuracies in forward model prediction, reliance on sensory feedback should increase, leading to a larger compensatory response to test-block feedback perturbations in the noisy compared to the veridical session. H2: If the mismatch is attributed to errors in the sensory system, reliance on sensory feedback should decrease, leading to a smaller compensatory response in the noisy session. Results show that participants produce smaller responses to auditory perturbations during the test block in the noisy session compared to the veridical session. This suggests that exposure to random sensory prediction errors causes a downweighting of sensory feedback and increased reliance on forward predictions.

Title: Naturalness of transformed auditory feedback sounds changes the patterns of compensatory articulatory responses and self-agency ratings in speech production

Authors: *Y. UEZU, S. HIROYA, T. MOCHIDA;
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: Speech conveys linguistic information and speaker's individuality somewhat irrespective of the naturalness of sounds. On the other hand, from the viewpoint of speech motor control, the sound quality of auditory feedback might affect the speaker's own articulatory movement due to sensorimotor error correction mechanisms. To investigate whether the naturalness of feedback speech sound contributes to articulatory motor control, we have performed formant transformed auditory feedback (TAF) experiments where a low-pass filter (LPF) controlled high-frequency component of feedback speech sound. Results have shown that the lower the LPF's cutoff frequency (Fc), the larger the compensatory response error, indicating that stable articulatory control requires speech information in high-frequency component. However, few studies have been conducted on the relationship between articulatory motor control and sound naturalness by adding noise to feedback sound. In this study, formant TAF experiments were performed where the naturalness of feedback speech sound was controlled by LPF, and adding high-pass or broadband noises. Self-agency ratings for feedback speech sound were also conducted during TAF experiments. Native Japanese speakers were participated in the experiments. They were instructed to repeat 100 Japanese syllable /he/. Formant frequencies of speech sound are gradually shifted and the maximum (F1, F2) perturbations were (+150, - 300) Hz. They were also asked to answer, "Do you feel like you're speaking to the feedback sound?" in 5-Likert scale for every 5 utterances. The condition of the Fc was 3, 4 and 8 kHz. We had three noise conditions: no noise, high-pass and broadband noises. In the high-pass noise condition, speech-shape noise over Fc was added to the LPF speech of Fc. In the broadband noise condition, pink noise under Fc and speech-shape noise over Fc were added to the LPF speech. Results showed that the compensatory response of F2 under high-pass noise condition at Fc = 4 kHz was equal to that for no noise condition at Fc = 8 kHz, indicating that high-pass noise may recover the naturalness of feedback speech sound. Compensatory responses of F2 under the noise conditions were larger than those of no noise condition at Fc = 3 and 4 kHz. However, self-agency ratings increased for broadband noise but decreased for high-pass noise compared to no noise. This means that a relationship between compensatory responses and self-agency ratings cannot be explained by a simple mechanism. Therefore, we speculate that articulatory motor

control strategy may change depending on characteristics of naturalness of feedback speech sound.

Title: Differences between the cortical substrate for vocalization and grasping in the marmoset

Authors: *C. M. CERKEVICH[1,2], J.-A. RATHELOT[4], P. L. STRICK[1,2,3];
[1]Neurobio., [2]Ctr. for the Neural Basis of Cognition, [3]Univ. of Pittsburgh Brain Inst., Univ. Pittsburgh Sch. Med., Pittsburgh, PA; [4]Inst. des Neurosciences de la TImone (UMR 7289), Aix-Marseille Univ., Marseille, France

Abstract: Marmosets exhibit a high degree of vocal communication and remarkable capacity for precise control over their vocalizations. We have undertaken a series of studies to explore the neural substrate that supports these unique abilities. To gain further insights into this issue, we compared the distribution of output neurons in the cerebral cortex that are concerned with the control of a laryngeal muscle to that of output neurons involved in the control of a hand muscle. In several marmosets, we injected rabies virus, a retrograde trans-synaptic tracer, into the right extensor digitorum communis (EDC) of the hand (n = 2) or the right cricothyroid (CT) muscle of the larynx (n = 2). We set the survival time to label the output neurons in layer V of the cerebral cortex with disynaptic inputs to motoneurons of the injected muscle.
Our results indicate that the primary motor cortex (M1) is the main origin (96%) of the layer V neurons with disynaptic input to EDC motoneurons. Much less substantial outputs originate from two premotor areas on the medial wall of the hemisphere: the supplementary motor area (SMA: 3%), and the ventral cingulate motor area (CMAv: 1%). Overall, the ratio of M1 to premotor output for descending control of a hand muscle in the marmoset is 24:1.
In contrast, M1 is the origin of less than one third (32%) of the layer V neurons with disynaptic input to CT motoneurons. Smaller, but substantial outputs also originate from four premotor areas: the SMA (20%), the CMAv (19%), the rostral cingulate motor area (CMAr: 19%), all on the medial wall of the hemisphere, as well as the ventral area 6 (6V: 19%) on the lateral surface.

Overall, the ratio of M1 to premotor output for descending control of a laryngeal muscle in the marmoset is ~0.47:1.
These results suggest that the marmoset's exquisite control of vocalization is accompanied by a major expansion of descending outputs from premotor areas in the frontal lobe. Thus, the enhanced control of vocalization may depend on parallel pathways from multiple cortical motor areas to brainstem vocal control centers. The increase in output from two premotor areas in particular, the SMA and 6V, may be especially critical to marmoset vocal abilities (Cerkevich & Strick, 2018).

Title: Ultrasound visual feedback of the tongue influences speech adaptation to a palatal perturbation

Authors: G. BARBIER[1], M. BAL[1], R. MERZOUKI[1], S. BAUM[2], ***D. SHILLER**[1];
[1]Univ. de Montréal, Montreal, QC, Canada; [2]McGill Univ., Montreal, QC, Canada

Abstract: Clinical studies have suggested that ultrasound feedback of the tongue during speech — providing real-time visualization of the tongue surface in the mid-sagittal or coronal plane — may be beneficial in the treatment of speech errors. Visual feedback of intra-oral movement is not a typical condition of speech production, however, and it remains unclear how it might interact with existing mechanisms of speech motor learning and control. In the present study, we experimentally altered the vocal tract of healthy adult talkers using a palatal prosthesis to perturb the production of the alveolar fricative "s". This physical manipulation was combined with the controlled application of ultrasound visual feedback during a 20-minute practice phase with the prosthesis in place. Acoustic changes in speech output related to the perturbation and subsequent adaptation were examined in three separate groups of talkers (n=15): two receiving visual ultrasound feedback of the tongue during speech practice (in either the mid-sagittal or coronal plane), and a control group receiving no visual feedback. The availability of visual feedback of the tongue, as well as the axis of feedback, was found to influence the pattern of compensation to

the palatal perturbation as well as the learning after-effect. The results indicate that talkers will readily integrate real-time visual feedback of the tongue into the sensorimotor processes driving speech adaptation, with the nature of that feedback (e.g., the visualized axis of tongue movement) further playing a role.

Title: Local cooling reveals brain stem pattern generator mechanisms for vocalizations

Authors: *K. HARTMANN, M. BRECHT;
Humboldt University/ BCCN Berlin, Berlin, Germany

Abstract: Vocalizations in mammals require precise timing and control over a multitude of muscles. While there is agreement that the vocal pattern generator (VPG) is situated in the brain stem, the exact identity of these circuits and their functionality are debated. Specifically, three alternatives have been suggested to form the VPG based on [i] electrophysiological evidence the reticular formation (RF), right above the superior olivary complex (Hage and Jürgens 2006), [ii] anatomical and lesion studies in the nucleus retroambiguus (NRA) (Holstege 1989), or [iii] a delocalized VPG that involves the reticular formation, the NRA and other circuits in between these two nuclei (Hage 2009). Here we evaluate these alternatives in rats. To this end we applied microstimulation in the periaqueductal gray of anesthetized rats, and induced natural calls. To perform a functional mapping of brain stem circuits, we adopted the local cooling strategy of Long and Fee (2008), which has revealed much about the functionality of bird song circuits. Specifically, we used localized cooling by placing a gold pin, attached to a peltier-element along with multiple thermistors, on the exposed brainstem. Both local temperature measurements and moving of the cooling probe suggested a specificity of cooling effects in the sub-millimeter range. We made six observations: [1] Call production was strongly affected and often totally aborted by cooling an anterior position above the RF. [2] Call production was strongly affected and often totally aborted by cooling a posterior position above the NRA. [3] Call production was only weakly affected by cooling intermediate positions between the RF and the NRA. [4] In a fraction of cases, cooling the position anterior to the RF resulted in a selective loss of high-frequency call components ($\geq$ 40 kHz). [5] In a fraction of cases, cooling the posterior position above the NRA resulted in a selective loss of low-frequency call components ($\leq$ 40 kHz). [6] Cooling often led to abbreviated calls and almost never led to a consistent call prolongation. We

conclude the rat VPG likely consists of both the RF and the NRA without a major contribution of circuits in between these structures. Finally, the cooling induced call abbreviation and the absence of call prolongation suggest that these nuclei do not control call production in a clock-like fashion as the bird HVC does, but that they act more like steam engines for call production.

Title: Cortical dynamics of the speech motor control network in the non-fluent variant of primary progressive aphasia

Authors: *H. KOTHARE, K. RANASINGHE, L. B. HINKLEY, D. MIZUIRI, M. LAURICELLA, S. HONMA, V. BORGHESANI, C. L. DALE, W. SHWE, A. WELCH, Z. MILLER, M. GORNO-TEMPINI, J. F. HOUDE, S. S. NAGARAJAN;
Univ. of California, San Francisco, San Francisco, CA

Abstract: Primary Progressive Aphasia (PPA) is a clinical syndrome in which patients progressively lose speech and language abilities. The nonfluent variant of PPA (nfvPPA) is characterised by impaired motor speech and agrammatism. These speech and language deficits are often associated with left fronto-insular-striatal atrophy in nfvPPA patients. Functional magnetic resonance imaging as well as diffusion tensor imaging studies further suggest impaired connectivity of neural circuitry involved in speech motor control. However, none of these studies provide sufficient temporal resolution to document the dynamics of the recruitment of the speech motor control network during vocal production.
In this study, we employed magnetoencephalographic (MEG) imaging to investigate sensorimotor integration during an altered auditory feedback paradigm in 18 nfvPPA patients and 17 healthy controls. Participants were prompted to phonate the vowel /ɑ/ for ~2.4s. Unbeknownst to them, following a randomly jittered delay of 200 to 500 ms after voice onset, the pitch of their feedback was shifted either up or down by 100 cents (1/12th of an octave) for a period of 400ms. Vocal pitch responses were examined as the participants responded to this pitch perturbation. Task-induced neural oscillations relative to a pre-perturbation baseline were examined in the theta-alpha (4-13 Hz) and the beta bands (13-30 Hz) associated with attention

and sensorimotor integration respectively. Nonparametric statistical tests were performed to look at neural activity differences in patients compared to healthy controls with cluster-threshold corrections for multiple comparisons.
Behaviourally, nfvPPA patients showed a smaller compensation response to pitch perturbation than controls. Baseline pre-perturbation pitch variability did not differ significantly between the two groups, indicating that reduced vocal compensation cannot simply be attributed to insufficient vocal control range in patients. Patients also exhibited reduced task-induced theta-alpha neural activity in the right superior temporal gyrus, right superior temporal sulcus, right middle temporal gyrus and the right temporoparietal junction. Patients also showed increased task-induced beta-band activity in the left dorsal sensorimotor cortex, left premotor cortex and the left supplementary motor area.
Collectively, these results suggest significant impairments in processing of auditory feedback during vocal production in nfvPPA patients.

Title: Intent matters - Laryngeal mechanosensory evidence of efference copy with voice and intent to voice

Authors: T. FRODEL[1], H. SAKE[1], S. ZORN[1], S. WILSON[1], M. SMARZINSKI[1], S. A. PALM[1], ***M. J. HAMMER**[2];
[2]Airway Sensory Physiol. Lab., [1]Univ. of Wisconsin-Whitewater, Whitewater, WI

Abstract: Laryngeal mechanoreceptors provide perceptual and proprioceptive afference for a variety of essential human functions including airway protection, breathing, deglutition, speech, and voice. It is interesting that mechanosensory information that yields a defensive airway response when a healthy individual breathes may go largely unnoticed when the individual voices. Modulation of laryngeal mechanosensory detection may be critical to maintain an uninterrupted speech/voice pattern in the presence of potentially distracting self-generated sensory input. However, it remains unknown whether the intent to voice itself may result in

sensory modulation, even in the absence of actual phonation. We used an endoscopic technique to measure laryngeal mechanosensory detection thresholds in healthy participants during tidal breathing, during a voice task, and during an interrupted voice task. We found that mechanosensory detection thresholds were similarly elevated for all participants during the voice and interrupted voice task. However, we found that during the voice tasks women maintained more sensitivity (smaller increases in detection thresholds) than men. Based on our recent findings, we would suggest: (a) Efference copy and laryngeal mechanosensory modulation are important for healthy speech/voice sensorimotor control. (b) Motor intent itself may result in laryngeal mechanosensory modulation. (c) Voice-related laryngeal mechanosensory modulation appears to be a sex-dependent phenomenon. (d) Mechanosensory modulation, motor intent, and efference copy each have important implications for clinical manifestations of speech/voice disorders such as Parkinson's disease and Spasmodic Dysphonia.

Title: Auditory-vocal control systems are affected by predictive processing within extended time ranges

Authors: *O. KORZYUKOV[1], T. FRODEL[2], Y. LEE[3], A. BRONDER[3], M. WAGNER[4], V. GUMENYUK[2], C. R. LARSON[3], M. J. HAMMER[2];
[1]Univ. of Wisconsin - Whitewater, Whitewater, WI; [2]Univ. of Wisconsin-Whitewater, Whitewater, WI; [3]Northwestern Univ., Evanston, IL; [4]Compumedics, Hamburg, Germany

Abstract: The human brain generates implicit expectation about the future, representing one of the fundamental principles of neural computations for driving neural/cognitive processes and behavior. Aberrent neuronal mechanisms of predictive processing are linked to brain pathology. Although the auditory-motor control system relies on neural processes that predict the sensory consequences of self-generated actions within milliseconds, our previous study shows that this system can be involved in predictive processing in a time range of seconds. Theoretical frameworks suggest that prediction error minimization is one of the fundamental principles of brain organization. We tested this hypothesizes with Event Related Potentials (ERP) for auditory-motor control system in the time range of seconds. The non-parametric permutation test

of differences in ERP scalp topography identified 2 sequential stages of predictive processing associated with (i) prediction error monitoring of incoming sensory information for detection of potential prediction errors, and (ii) evaluation of error monitoring output in order to optimize top-down predictions until prediction error is minimized. Our results suggest that reflexive brain mechanisms that control accuracy of vocalizations can be affected by inputs from brain levels associated with predictive coding in more extended time scales. Results provide empirical support that temporal hierarchy is recapitulated in the macroscopic organization of the cortex. The brain models slower environmental changes providing a context for more rapid reflexive corrections.

Title: Speech auditory-motor adaptation is driven by implicit learning

Authors: K. S. KIM[1], ***L. MAX**[2];
[1]Univ. of Washington, Seattle, WA; [2]Univ. Washington, Seattle, WA

Abstract: Recent work on sensorimotor learning has dissociated explicit and implicit contributions. The explicit component involves intentional strategy use and is driven by target error. The implicit component involves the updating of an internal forward model without awareness of the learner and is driven by sensory prediction error. In studies of reaching in a perturbed visual environment, it has been possible to estimate the explicit contribution by asking subjects to report intended aiming direction before each trial. The strength of the implicit contribution can then be estimated by subtracting this explicit aiming direction from the actual movement direction.
Sensorimotor adaptation also occurs in speech production (e.g., with shifts of vowel-specific resonance frequencies in the auditory feedback). For speech, however, it is not clear how to dissociate the contributions of explicit and implicit learning components, or even to determine if there indeed are contributions from both components: naïve subjects have no explicit knowledge of the mapping between speech articulator positions and resonance frequencies in the auditory feedback, and efforts to ask subjects about intended auditory “aiming” have been unsuccessful.

Approaches such as constraining planning duration or examining interference from a second task could be considered, but would negatively impact speech execution or leave open alternative interpretations. We report an initial attempt at determining the existence of an explicit component in speech auditory-motor learning while also examining changes in auditory targets. Typical adults and adults who stutter (a population with limited adaptation) produced words in baseline, perturbation, and post-perturbation phases. The perturbation consisted of shifting the first resonance frequency of the produced words "bed" and "pet" such they perceptually moved toward "bad" and "pat." After each trial, subjects used a scale on a touch-screen monitor to indicate how much they had intentionally changed their speech. Every 10 trials, they used a similar scale to listen to unaltered and altered versions of their own production of the target word and to select the best match for what the word "should sound like" (estimating the current target). Stuttering adults showed substantially less learning than nonstuttering adults. Neither group showed a systematic target shift in parallel with learning. With very few individual exceptions, neither group reported any intentional (explicit) adjustments in their speech. Speech auditory-motor adaptation may be an entirely implicit learning process, but improved experimental paradigms should be explored.

Title: Simultaneous decoding of attentional and reward modulations in human EEG

Authors: *M. RAKHSHAN[1], M. MAECHLER[1], T. LYTCHENKO[2], N. HELLER[1], A. SOLTANI[1], G. CAPLOVITZ[2];
[1]Dartmouth Col., Hanover, NH; [2]Univ. of Nevada Reno, Reno, NV

Abstract: Reward expectation can modulate different aspects of behavior and cognitive processes including the deployment of attention. In addition, it has been proposed that the subjective sense of certainty (confidence) is influenced by what is attended and can modify how reward feedback is incorporated. However, it is currently unclear how expected reward and attention interact to determine confidence. To study this interaction, we developed a novel detection paradigm with two RSVP streams while simultaneously recording EEG signals. Human subjects (N=20) were instructed to covertly attend to one of the two streams and respond once they detected a target stimulus (if present) in the attended stream. Target in the unattended

stream required no response. Importantly, each trial was associated with different amounts of reward expected upon a correct response. In addition, the subjects also had to report their confidence in their choice on each trial before receiving reward feedback. Analyses of choice and reaction time data revealed significant effects of expected reward on reaction time such that subjects were faster with larger expected reward. In addition, reaction time was shorter and accuracy was higher on trials in which the confidence was higher. At the neural level, we used a combination of frequency-tagging, MVPA and independent component analyses to identify neural correlates of the location of covert attention and the fate of the target in the attended and unattended streams. In addition, we examined how these neural correlates were modulated by expected rewards, and level of confidence. Together, these findings indicate the feasibility of our approach in decoding reward and attentional signals in EEG data and exploring how their interaction determines confidence.

Title: Distinct auditory neural populations track vocalization feedback delays

Authors: *M. OZKER SERTEL[1], Z. HUANG[1], Q. ZHU[1], B. MAHMOOD[1], D. MAKSUMOV[1], W. DOYLE[2], O. DEVINSKY[1], A. FLINKER[1];
[1]Neurol., [2]Neurosurg., NYU Sch. of Med., New York, NY

Abstract: Neural responses in the auditory cortex are suppressed during self-generated vocal sounds. This auditory suppression mechanism has been hypothesized to facilitate the detection of vocalization errors. Nevertheless, while such a link has been demonstrated in the primate vocalization literature, it remains unclear in humans. To test this hypothesis, we conducted an auditory repetition task and a delayed auditory feedback task with neurosurgical human subjects using electrocorticography (ECoG) recordings. Neural responses in the high-gamma broadband frequencies (70-150 Hz) were used as the primary measure of neural activity. In the auditory repetition task, subjects listened to a word and repeated it afterwards. In line with previous findings, auditory responses were suppressed during speaking compared to listening, but to a different extent in different electrodes. In the altered feedback task, subjects read aloud visually presented words, while their voice was recorded by a microphone and played back to them

through earphones in real time with 0, 50, 100 or 200 millisecond delays. Behaviorally, articulation duration increased with increasing amount of delays. Recordings from auditory cortex exhibited different types of responses to delayed feedback. Some electrodes showed a response profile sensitive to articulation duration, exhibiting longer response durations for increasing delays. While other electrodes showed sensitivity to the amount of feedback perturbation, exhibiting larger response amplitudes for increasing delays. Moreover, the degree to which electrodes were sensitive to feedback delays was significantly correlated with the amount of suppression in each electrode. These results suggest that distinct neural populations of the auditory cortex are sensitive to articulation duration and alterations in the auditory feedback during speech production and these responses are linked to vocalization-induced suppression in the auditory cortex. These findings constitute one of the first reports from neural recordings in humans, providing direct evidence that auditory suppression is linked to a mechanism for vocalization error detection.

Title: Sensitivity to natural and altered auditory feedback in L1 and L2

Authors: ***S. BAKST**, C. A. NIZIOLEK;
Communication Sci. and Disorders, Univ. of Wisconsin–Madison, Madison, WI

Abstract: We listen to ourselves while talking, comparing our acoustic output to an internal auditory representation of how our speech should sound. Because these representations of speech targets may be less robust in a second language (L2), self-monitoring may be less successful, resulting in less native-like speech. Here, we investigate language learners' responses to both natural variability in their own speech as well as experimentally-induced errors in order to measure speakers' sensitivity to internally- and externally-generated errors.
In the first study, participants who had studied French in adulthood were recorded producing monosyllabic words in L1 (English) and L2 (French) during a magnetoencephalography (MEG) scan. The vowels tested were English {i, ɛ, æ} ("Eve", "eff", "add") and French {i, ɛ, œ} ("Yves", "hais", "oeuf"). We investigated functional differences while speaking and listening to

acoustically-matched productions played over headphones in L1 and L2. Neuroimaging studies have previously shown that the auditory cortical response to hearing one's own speech during L1 production is suppressed in comparison with silent listening to those same productions (Houde et al. 2002; Niziolek et al. 2013). MEG data show left auditory cortical suppression in both L1 and L2, providing evidence for similar predictive success in both languages.
Furthermore, this suppression has been correlated with a behavioral response in L1, where speakers steer deviant productions towards their auditory targets while speaking (Niziolek et al. 2013). This corrective behavior is evident in the magnitude and direction of vowel formant trajectories throughout an utterance. In the first study, speakers showed such corrective behavior while speaking L1, but in L2, utterances were both more acoustically variable and showed less self-correction. In L1, acoustic variability is positively correlated with self-correction, but the increased acoustic variability in L2 vowels did not trigger commensurate self-correction, indicating a weakened ability to self-correct in L2. In a second study, speakers produced English and French monosyllables under conditions of altered auditory feedback. On one-third of trials, the vowel formants of produced words were shifted up or down, creating the perception of an error. We will compare correction of internally- and externally-generated error to understand speakers' sensitivity to auditory feedback in native and learned languages.

Title: Characterization of movements evoked from electrical stimulation of motor cortex in awake marmoset

Authors: *S. C. STERRETT, L. ZHAO, X. WANG;
Johns Hopkins Univ., Baltimore, MD

Abstract: Understanding the neurobiology of vocal control in non-human primates is important as an evolutionary and physiological basis of understanding human speech control. The common marmoset (Callithrix jacchus) exhibits highly active and diverse vocal behavior in captivity, which makes it an interesting model of study in this area. Anatomic evidence in marmoset suggests that motor cortical areas in the frontal lobe could modulate vocal articulators and possibly aspects of vocal production. Recent neural recording studies have showed that neural activities in motor, premotor, and prefrontal cortical regions of marmoset are associated with

certain aspects of vocal production. It remains an open question how these cortical regions are functionally related to particular aspects of vocal production. Previous studies in marmoset have shown that facial muscle twitches can be evoked by intracortical microstimulation from various regions in cortex in an anesthetized preparation. Additionally, studies using long-train stimulation in non-human primates have shown evoked complex motor movements. In the present study, we used intracortical microstimulation to map simple and complex movements in an awake marmoset preparation. We showed that simple movements of vocal articulators, including the jaw and tongue, can be evoked by short train electrical stimulation. Additionally, we showed that complex orofacial movements can be evoked by long-train stimulation. Finally, we investigated modifications of vocal output by electrical stimulation of motor and premotor cortical regions while a marmoset engaged in natural vocal behaviors.

Title: Learning a novel motor skill reshapes the temporal organisation of activity in the rat brain

Authors: *P. SALVAN, A. LAZARI, C. SAMPAIO BAPTISTA, H. JOHANSEN-BERG; WIN, FMRIB, Univ. of Oxford, Oxford, United Kingdom

Abstract: Motor skill learning results in synaptogenesis and long-term potentiation in the rat motor cortex. Such functional and structural plasticity at the synapse might be expected to alter the temporal organisation of brain activity at larger spatial scales but this has not yet been tested. Here we used longitudinal resting-state fMRI to compare rats who underwent skill reaching (SR) training with (active and passive) controls and asked whether longitudinal changes in time-varying brain activity 1) could discriminate SR animals from controls; and 2) could predict SR learning rates. We studied time-varying patterns of BOLD fluctuations in whole-brain resting state networks (RSNs) through hidden Markov models, describing RSNs' time-series as a sequence of transient, repeating states of activity (Fig A); and describing RSNs' temporal organisation as the state-to-state transition probabilities (TPs) (Fig B). Based on longitudinal changes in brain states' TPs (Fig C), we found that a classifier was able to reliably and significantly discriminate SR animals from controls (median over 10 separate runs: accuracy =

71%; p-value = 0.0470). SR animals compared to controls exhibited greater *attractiveness* for the motor state: brain activity transitioned more frequently towards rather than away from the motor network (Fig D). Crucially, a classifier based on changes in functional connectivity was not able to significantly discriminate between SR animals and controls (p-value = 0.2920). In SR animals we then studied SR performance over time and extracted individual learning rates (Fig E). We then tested whether changes in brain states' TPs (Fig F) were related to motor learning performance. We found that increased attractiveness for the motor states was significantly correlated with individual learning rates (Spearman's rho = 0.69; p-value = 0.01) (Fig 1.G). Together, these results show that the temporal organisation of brain activity changes during motor learning in rats, and that it does so in a behaviour-relevant manner.

Title: NMDA receptor-mediated motor cortex plasticity after 20 Hz transcranial alternating current stimulation

Authors: *M. A. NITSCHE[1], A. SALEHINEJAD[2], M.-F. KUO[2], D. SCHUTTER[3], M. WISCHNEWSKI[3];
[1]Psychology and Neurosciences, Leibniz Res. Ctr. for Working Envrn., Dortmund, Germany; [2]Leibniz Reaearch Ctr. for Working Envrn., Dortmund, Germany; [3]Radboud Univ., Nijmegen, Netherlands

Abstract: Background: Transcranial alternating current stimulation (tACS) has been shown to modulate neural oscillations and excitability levels in the primary motor cortex (M1). These effects can last for more than an hour and an involvement of N-methyl-D-aspartate receptor (NMDAR) mediated synaptic plasticity has been suggested. However, to date the cortical mechanisms underlying tACS after-effects have not been explored. Methods: 11 participants completed the study and were included in all analyses (mean age ±standard deviation, 23.1 ±3.4; 9 Female). We applied 20 Hz beta tACS to M1 for 20 min with an intensity of 2 mA peak to peak while participants received either the NMDAR antagonist dextromethorphan (150 mg) or a placebo. The effects of the intervention on cortical beta oscillations were explored via EEG, and on motor cortical excitability alterations via transcranial magnetic stimulation single pulse-elicited motor evoked potential amplitudes. Results: When a placebo medication was administered, beta tACS was found to increase cortical excitability and beta oscillations for at least 60 minutes, whereas when dextromethorphan was administered, these effects were completely abolished. Conclusions: These results provide the first direct evidence that tACS can induce NMDAR-mediated plasticity in the motor cortex, which contributes to our understanding of tACS-induced influences on human motor cortex physiology.

Title: Effects of electrode orientation on the impact of transcranial direct current stimulation on motor cortex excitability

Authors: *M.-F. KUO[1], A. FOERSTER[1], F. YAVARI[1], L. FARNAD[1], A. JAMIL[1], W. PAULUS[2], M. A. NITSCHE[1,3];
[1]Leibniz Res. Ctr. for Working Envrn. and Human Factors, Dortmund, Germany; [2]Georg-August-University Göttingen, Göttingen, Germany; [3]Neurol., Univ. Med. Hosp. Bergmannsheil, Bochum, Germany

Abstract: Background: For effects of transcranial direct current stimulation (tDCS), electrical field distribution and coverage of the target areas play a decisive role. **Methods:** We explored the effect of different angle-orientations of tDCS electrodes applied over the upper limb motor cortex (M1) on motor cortex excitability in healthy volunteers. Sixteen individuals received 1 mA anodal or cathodal tDCS through 35cm² electrodes over M1 for 15 minutes. Transcranial magnetic stimulation was used to examine tDCS-generated cortical excitability effects. The M1 electrode-orientation was following the right-left longitudinal plane, or positioned with 45° deviation from the midsagittal plane. Coverage of underlying brain and electrical field orientation were also investigated. **Results:** Cortical excitability modulation was observed only when the electrode was aligned with 45° angle, which covered a larger area of the motor cortex. **Conclusion:** an electrode angle-orientation of 45° induces superior neuroplastic effects of M1 due to a better alignment with the motor cortex.

Title: Long-term changes in the neural coding of primate finger movements induced by paired nerve stimulation

Authors: *M. GERMANN, B. HABEKOST, S. N. BAKER;
Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Non-invasive methods relying on stimulating pairs of afferent nerves have been shown to induce plastic changes in the sensorimotor cortex. Associative (AS) and non-associative (NAS) peripheral nerve stimulation might be of therapeutic use for the treatment of a number of neurological conditions associated with a dysfunction of afferent processing leading to maladaptive cortical and sub-cortical plasticity including stroke, spinal cord injury, neuropathic pain, and dystonias. Despite promising results and applications in human subjects using these methods, little is understood about the underlying basis for the observed changes. This study aimed to investigate the underlying cortical mechanisms induced by AS and NAS nerve stimulation. To this end, two female macaque monkeys were trained to execute selective finger movements with the thumb and index finger. The task performance was compared before and after one hour of paired AS and NAS median and ulnar nerve stimulation. Additionally, multi-unit (MU) activity of stable neurons from the primary motor cortex and single-unit activity of identified pyramidal tract neurons (PTNs) were recorded during task performance.
Our results indicate that the monkeys were able to move their thumb and index finger less selectively after one hour of AS, measured by an increased number of errors and decreased performance measures. NAS however decreased error numbers and led to increased performances. The difference of the performance change between the AS and NAS intervention was significant for both monkeys. A linear discriminant analysis of MU activity revealed a reduced ability to decode which digit moved from cell activity after AS. This effect was seen in the majority of recorded MUs. By contrast, coding of finger movement was largely unchanged after NAS. The same trends could be seen in the linear discriminant analysis of PTN activity. Our analysis suggests that cortical representations of thumb and index finger became less distinguishable after AS. This diminished ability of the cortex to code movement of the two digits may have led to behavioural consequences, as indicated by the decreased performance measures. Our results are in line with previous findings which demonstrated that motor-cortical representations of the synchronously stimulated muscles extend and overlap after AS. Paired nerve stimulation can thus be used to induce long-term changes in cortical representations, which could have potential in rehabilitation and treatment of neurological disorders with maladaptive neuroplasticity like focal hand dystonia.

Title: Cortical excitability and tSMS-induced plasticity in a large sample of patients with Parkinson's disease

Authors: *C. AMMANN[1], M. DILEONE[1,2], C. PAGGE[1], A. OLIVIERO[3], J. A. OBESO[1,4], G. FOFFANI[1,3];
[1]CINAC, Univ. Hosp. HM Puerta del Sur, CEU-San Pablo Univ., Móstoles, Spain; [2]Advanced Neuro-rehabilitation Unit, Hosp. Los Madroños, Brunete, Spain; [3]Sescam, Hosp. Nacional de Parapléjicos, Toledo, Spain; [4]Ciberned, Inst. Carlos III, Madrid, Spain

Abstract: Cortical excitability and plasticity changes measured by transcranial magnetic stimulation (TMS) have been defined in patients with Parkinson's disease (PD). After 30 years of TMS research in PD results are still mixed and most studies present reduced numbers of subjects. Moreover, studies on evolution of cortical changes with disease progression are scarce. Here we aim to dissolve ambiguity of existing results studying a large sample of patients with a wide range of disease stages. We assessed corticospinal and intracortical excitability recording TMS-induced motor evoked potentials (MEP) from a hand muscle in 130 patients. We classified 4 groups: *de novo* levodopa-naïve (n=47), on levodopa medication without (n=36), and with (n=47) levodopa-induced dyskinesias (LIDs), and healthy controls (n=40). A sub-sample of each group (*de novo*/n=21; non-dysk/n=22; dysk/n=22; control/n=20) received 10 min of transcranial static magnetic field stimulation (tSMS) over the motor cortex, which decreases cortical excitability in healthy subjects (Oliviero et al, 2011). Thus, we assessed cortical plasticity through MEP amplitude changes recorded before and after tSMS. All patients were studied off medication. We confirmed a reduction of intracortical inhibition first observed for the more affected side in *de novo* patients and bilaterally impaired once the disease progresses. No significant alterations were found for intracortical facilitation. PD resting motor threshold values showed a decreasing trend compared to controls. Surprisingly, a significant increase from early on (also less affected side) of MEP variability compared to controls has been observed with a high area under the receiver operating characteristic curve (ROC) comparing less and more affected side of *de novo* patients with healthy subjects. Regarding plasticity changes, we observed a loss of tSMS-induced plasticity in *de novo* and non-dyskinetic patients turning into a

paradoxical MEP potentiation in dyskinetic patients compared to decreased MEP amplitude in healthy subjects. We conclude that cortical excitability is altered in PD expressed early on by changes in corticospinal excitability and intracortical inhibition as the disease progresses. Once altered, excitability abnormalities remain unchanged with PD evolution. We suggest that the decreased inhibition is not due to increased intracortical facilitation. Moreover, MEP variability could present a valuable diagnostic measure for PD in early stages. Finally, we propose that the motor cortex plays an active role in LID pathophysiology rather than being just a 'passive integrator' of subcortical and corticocortical abnormalities.

Title: Cerebellar tDCS improves performance of a timing-based video game more than M1 tDCS or practice alone

Authors: M. E. WOLFE[1], J. PEREZ[1], A. W. MEEK[2], B. J. POSTON[3], ***Z. A. RILEY**[4]; [1]IUPUI, Indianapolis, IN; [2]Dept. of Kinesiology, Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [3]Kinesiology and Nutr. Sci., Univ. of Nevada Las Vegas, Las Vegas, NV; [4]Indiana Univ. Purdue Univ. at Indianapolis, Indianapolis, IN

Abstract: Transcranial direct current stimulation (tDCS) is a brain stimulation technique that has been applied to the motor cortex (M1) to facilitate learning of skilled, dexterous hand tasks. However, when there is a timing component to the motor skill, tDCS is usually applied to the cerebellum (CB). The purpose of this study was to compare M1 tDCS and CB tDCS to determine which resulted in better performance and timing accuracy of a video game involving dexterous finger movements and timing. 100 healthy adults (age: 18-33 yrs ± 3.1) were randomized into M1 anodal (n=25), CB anodal (n=25), CB cathodal (n=25), or CB sham (n=25) stimulation groups. The task used the Step Mania video game that is timing-based and involves pressing the correct arrow keys on a keyboard at specific times when scrolling icons overlapped on a computer screen. Each subject practiced the task at least two times to obtain a pre-practice score. Each key press corresponded to a time relative to the optimal key pressing time. Scores for each trial were an average these numbers. Each subject completed ~2 minutes of practice

followed by ~2 minutes of rest and repeated this 5 times for 20 total minutes of practice. Post-test scores were obtained 5 and 10 minutes following practice. During practice, tDCS was delivered at 2mA in accordance to the condition the subject was randomized to (M1 anodal, CB anodal, CB cathodal, sham). There was a significant main effect for time ($p<0.001$) for changes in timing accuracy but no interaction for time*condition ($p=0.270$). Improvements in timing accuracy occurred faster (trial 1—5 minute post-test) for the M1 anodal ($p=0.004$) and CB cathodal ($p=0.001$) conditions. Timing accuracy did not significantly improve until the 10-minute post-test for the CB anodal ($p=0.003$) and sham ($p=0.009$). Error scores resulted in a significant effect of time ($P<0.001$) but not a significant effect for time*condition ($p=0.173$). Both the M1 anodal ($p=0.008$) and CB cathodal ($p=0.013$) had significant improvements error scores at the 10-minute posttest. In the context of motor learning, these results show that M1 anodal and CB cathodal stimulation conditions both accelerate the learning of a timing-based video game faster than either CB anodal stimulation, or simply practice alone.

Title: Variant target effects on motor learning through tDCS

Authors: *J. PEREZ, C. L. LASHER, K. J. HARBISON, Z. A. RILEY;
Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Transcranial direct current stimulation (tDCS) is a form of non-invasive brain stimulation that has been utilized to stimulate the motor cortex (M1) to accelerate motor learning. The tasks most commonly studied with tDCS of M1 are sequential finger tapping and visual isometric pinch force tasks, though these tasks do not require changing endpoints based on the target. Other tasks with changing endpoints, such as reaching and pointing, require motor adaptive responses from error signals to continually update and improve the movements, usually driven by the cerebellum (Orban de Xivry and Shadmehr, 2014). The purpose of the present study was to determine if tDCS to M1 would still be effective at accelerating motor learning when throwing darts at different targets, even if motor adaptation is primarily mediated through a different brain region. To examine this, participants were randomized into a sham (n=32) or anodal (n=34) tDCS conditions and completed a dart throwing task in which they performed one

pre-test, five practice rounds, and one post-test. In the pre-test, participants aimed to hit the bull's eye. During practice, participants threw at 8-bull eye's sized targets evenly positioned around the dartboard (each 16.5cm from center bull's eye) while receiving either anodal or sham stimulation. Those in the anodal tDCS group received 2mA of stimulation over M1 for 20 minutes. Those in the sham condition only received 30 seconds of stimulation before the machine shut off; but completed the same number of throws as those in the anodal group. Participants repeated the pretest procedures directly after practice, 1-hour after practice, and 24-hours after practice. Results indicated that both groups improved on the task significantly over time ($p \leq 0.001$) and that the variability in their throws decreased significantly ($p \leq 0.001$), though there was no interaction ($p = 0.34$), indicating the stimulation did not have an overall effect on performance. Stimulation of M1 did not appear to be effective at accelerating learning of throwing darts at variable targets beyond what normal practice provides. It is certainly possible that this is due to the learning changes being mediated through the cerebellum, where motor adaptation occurs, and not M1 where movements are simply carried out.

Title: Changes in dorsolateral striatum neural dynamics during recovery after motor cortical stroke

Authors: *L. GUO[1], S. KONDAPAVULUR[1], S.-J. WON[2], K. GANGULY[1];
[1]Neurol., UCSF, San Francisco, CA; [2]Neurol., San Francisco VA Med. Ctr., San Francisco, CA

Abstract: Even with present state of the art rehabilitation methods, a substantial number of stroke patients continue to experience chronic upper-limb motor deficits. Current rehabilitation and neuromodulation methods are hampered by a limited understanding of brain reorganization after stroke, especially at the network and neural dynamics level. Past research has focused on the role of the perilesional cortex (PLC), the area of cortex directly adjacent of the stroke site, in motor recovery. However, executing a skilled motor action requires coordinated activity of both

cortical and subcortical motor areas. Particularly, the dorsal lateral striatum (DLS) is involved in motor learning and execution in healthy individuals and loses input projections after a motor cortical stroke. However, its role in motor recovery after stroke remains unknown.
To understand the dynamic changes in the brain during the stroke recovery process, we first trained Long Evans rats on a single-pellet reach-to-grasp task that assesses skilled forelimb motor function. Next, we induced a photothrombotic stroke over the forelimb motor cortex, and then implanted electrodes in both the PLC and DLS. We then recorded single unit and local field potential data while rats underwent physical rehabilitation using the same task.
On average, accuracy (i.e. pellet retrieval success) and speed of movements significantly decreased after stroke. There was a partial restoration of motor performance with rehabilitation training, reaching a plateau that was generally lower than pre-stroke levels. Interestingly, pharmacological inactivation of DLS post-stroke further decreased the accuracy, speed and amplitude of movements, indicating that DLS was still involved in motor performance after stroke recovery. Although the average movement-locked unit firing pattern in DLS did not change during recovery, there was an expansion in the proportion of movement-modulated units in DLS. Strikingly, DLS population neural activity on a trial by trial level became more consistent and coordinated after rehabilitation. These results demonstrated that the DLS, a previously understudied area in the context of stroke, is also functionally affected by a motor cortical stroke and that patterns of neural activity in DLS during motor actions are reorganized with recovery.

Title: Pain induced metaplasticity interferes with motor learning in intact rats

Authors: M. HUOT-LAVOIE[1], W. K. TING[1], M. DEMERS[1], C. MERCIER[2], *C. ETHIER[1]; [1]Univ. Laval - CERVO, Quebec City, QC, Canada; [2]CIRRIS - Laval Univ., Quebec, QC, Canada

Abstract: Motor learning and pain are two key components of rehabilitation. Despite being mostly studied independently from each other, important interactions exist between them in the context of spinal cord injury. Ongoing nociceptive activity or recent pain episodes can reduce the

malleability of the spinal motor circuits and prevent motor learning in spinalized rats. In the neurologically intact system, it has been proposed that descending serotoninergic fibers could counter the repressive effect of pain on motor system plasticity. The aim of our study is to verify whether a recent pain episode affects locomotor pattern learning in intact rats.
For this purpose, we trained Long Evans rats to walk on a custom-made horizontal ladder. After a series of initial training sessions, the rats underwent a week-long rest, during which they were randomly assigned to a control group or one out of two pain conditions. Nociceptive stimuli of different duration were induced by capsaicin or Complete Freund's Adjuvant injections, and timed so that the mechanical hypersensitivity had entirely subsided by the end of the resting period. Training then resumed on a modified version of the horizontal ladder. We evaluated the animals' ability to adapt to the modified task by measuring their transit time and paw misplacements for two 30-minutes daily sessions.
Our results show that prior pain episodes do affect motor learning in neurologically intact rats. The motor learning deficits also seem to be influenced by the duration of the pain episode. Rats displayed learning deficits 24h after receiving a subcutaneous injection of capsaicin, even though they did not show signs of mechanical hypersensitivity. Rats previously subjected to a week of inflammatory pain caused by a Complete Freund's Adjuvant injection displayed even more prolonged motor learning deficits. Our results suggest that prior pain episodes can negatively influence motor learning, and that the duration of the impairment relates to the duration of the pain episode. Our results highlight the importance of addressing pain together with motor training. They may have important implications not only for rehabilitation after neurological lesions, but also for performance athletes returning to sports after injury.

Title: The influence of glucose on intracortical and corticospinal excitability as assessed using transcranial magnetic stimulation

Authors: *S. L. TOEPP[1], C. V. TURCO[1], C. NICOLINI[1], A. J. NELSON[2];
[2]Dept Kinesiol, [1]McMaster Univ., Hamilton, ON, Canada

Abstract: Experiments using transcranial magnetic stimulation (TMS) to measure corticospinal and intracortical excitability are commonly used in neuroscience research in clinical and basic applications. However, the effect of dietary factors such as glucose consumption on TMS-based measures has received minimal attention despite the potential influence on precision and reliability. The present double-blinded, placebo-controlled study tested the effects of glucose on two standard TMS measures. Short-interval intracortical inhibition (SICI) is a paired-pulse measure thought to reflect $GABA_A$-mediated neurotransmission, while single-pulse motor evoked potential (MEP) recruitment curve is a frequently used indicator of corticospinal excitability and may reflect cortical glutamate levels. For both measures, TMS was delivered over the left motor cortex and MEP responses were recorded using surface EMG over the muscle belly of the first dorsal interosseous muscle of the right hand. Healthy males (n = 17; age = 22.47 +/- 1.29 y) each participated in 4 sessions. Session 1 involved familiarization to TMS, followed by acquisition of an individualized blood glucose response curve. During sessions 2, 3 and 4, dependent measures were taken before (T0), and at two timepoints following (T1 and T2), ingestion of an experimental treatment solution. The solutions contained glucose (75 g), sucralose-sweetened placebo (control for sweetness) or plain water (control for time). The T1 post-drink assessments were started 5 minutes prior to the blood glucose peak observed during Session 1. T2 assessments were started 35 minutes after T1 to coincide with the delayed arrival of glucose in the cerebrospinal fluid. One-way repeated measures ANOVA found a significant time effect on MEP recruitment curve area for sucralose-sweetened placebo ($p < 0.05$) but not plain water or glucose. Post-hoc paired-sample t tests revealed that MEP recruitment curve area was significantly greater than baseline at T1 and T2 ($p < 0.05$ for both timepoints). No effect was detected with respect to SICI for any treatment. This investigation provides important insight concerning the influence of glucose and will strengthen the interpretation and utility of TMS studies in the future.

Title: Dexterous timing-based video game performance with complementary transcranial direct current stimulation of the primary motor cortex and cerebellum

Authors: *A. W. MEEK[1], J. PEREZ[1], M. WOLFE[1], A. BOCKELMAN[1], K. HARBISON[1], C. LASHER[1], B. J. POSTON[2], Z. A. RILEY[1];

[1]Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [2]Kinesiology and Nutr. Sci., Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Transcranial direct current stimulation (tDCS) applied to the primary motor cortex (M1) and cerebellum (CB), can facilitate learning of dexterous motor skills. Although the motor cortex and cerebellum work together to execute movements, stimulation of each site independently can influence motor learning through different mechanisms. It is unknown whether complementary stimulation of both sites simultaneously will influence motor learning. The purpose of this study was to determine if complementary stimulation of M1 and CB would facilitate learning of a video game requiring well timed dexterous finger movements compared to practice without stimulation. Forty-nine adults were randomized into an active stimulation (n=25) or sham (n=24) control group. Step Mania is a timing-based video game that involves pressing arrow keys on a keyboard at specific times when scrolling icons overlap stationary targets on a computer screen. Each key stroke corresponded to a time relative to the optimal key pressing time, putting key strokes into bins corresponding to an accuracy score. Optimal keystrokes received a score of 1, and this score decreased as they were further away from the target (0.8, 0.6, 0.4, 0.2 or 0 points for misses) Subject performance was assessed by timing accuracy (i.e. optimal keystroke timing) and movement errors (i.e. incorrect key strikes). Each subject practiced the task twice to obtain a pre-practice score. Subjects completed 5 practice trials with ~2 minutes of rest after each trial for 20 total minutes of practice. Post-test scores were obtained 5 and 10 minutes after practice. During practice, separate stimulators applied 2 mA anodal tDCS to M1 and 2mA cathodal tDCS to CB. Timing and error data were analyzed with 8 (time) x 2 (condition) mixed ANOVAs. Non-normal movement error data were transformed with a square root transformation. The stimulation group had significantly higher timing scores for each practice trial ($p < 0.001$ to $p = 0.008$) and both the 5 ($p = 0.002$) and 10 minute ($p = 0.001$) post-tests ($p = 0.04$). The stimulation group had significantly fewer movement errors in the first 3 practice trials ($p = 0.036$ to $p = 0.044$) and the 5 minute post-test ($p = 0.044$) compared to sham. These results suggest that complementary M1 and CB tDCS can lead to greater performance gains after 20 minutes of practice compared to normal practice alone. This appears to primarily be due to an effect on timing accuracy which persists after practice. The improved timing accuracy after practicing with stimulation may be facilitated, at least in part, by more practice with correct keystrokes during early practice trials.

Title: Transcranial direct current stimulation promotes motor recovery in a mouse model of stroke by affecting key molecular players of neuroplasticity

Authors: V. LONGO[1], A. RE[1], S. A. BARBATI[1], M. G. DI DONNA[1], *L. LEONE[1], C. GRASSI[2], M. V. PODDA[2];

Abstract: No effective treatments have been identified so far to restore motor function after stroke. The most recent approaches aim to promote brain cortex plasticity and, in this context, transcranial direct current stimulation (tDCS) has become one of the most promising tools, although the mechanisms underlying its effect are not fully understood yet. The purpose of this study is to examine tDCS effects on functional recovery of the paretic limb in a mouse model of stroke and to identify the underlying molecular mechanisms. Focal infarct of forelimb motor cortex area was induced by phototrombosis in 5/6-week-old C57BL/6 mice using the photochemical dye, Rose Bengal, and after 72 hours mice were subjected to tDCS or sham stimulation. TDCS (35.4 A/m^2 for 20 min) was applied once per day for 3 consecutive days (3×tDCS) using a bipolar montage (anode over stroked motor cortex and cathode over the undamaged one). Motor recovery was assessed by grip strength test and single pellet reaching task. Molecular analyses were performed by Western immunoblotting, qRT-PCR, dot blot and ELISA. Results showed that 3×tDCS enhanced forelimb motor recovery after stroke. Indeed, 24 hours after tDCS, mice showed a significant enhancement of neuromuscular strength (+40.0±8.7%; n=11; p=0.0001) and of the success rate in the single pellet reaching task (0.18±0.05; n=12; p=0.04) compared to post-stroke values assessed before stimulation. In contrast, sham stimulated stroked-mice exhibited no significant improvement in strength and success rate (strength: n=8, p=0.7; success rate: n=11, p=0.15).Of note, epigenetic analysis showed that functional improvement in 3×tDCS mice was associated with reduced levels of 5-hydroxymethylcytosine (5hmC), which could be considered a novel outcome measure of functional recovery. Interestingly, our molecular analyses revealed that 3×tDCS modulated key players of neuroplasticity in the motor cortex. Specifically, 3×tDCS mice displayed enhanced levels of Bdnf mRNA (4.55±0.08 fold increase *vs.* sham; p=0.004) and the activated forms of proteins ERK1/2 ($pERK^{Thr204}$; 1.81±0.13 fold increase *vs.* sham; p=0.001) and MEF2C ($pMEF2C^{Ser387}$; 3.09±0.24 fold increase *vs.* sham; p=0.0004). Altogether, our data unveil molecular determinants of neuroplasticity that are affected by tDCS and support the use of this non-invasive brain stimulation technique in clinical settings to promote recovery of motor function after stroke.

Title: Inducing associative plasticity in a premotor-motor circuit in humans: A randomised-controlled evaluation

Authors: *A. LAZARI[1], L. VERHAGEN[2], P. SALVAN[1], D. PAPP[1], O. VAN DER WERF[1], B. GAVINE[1], M. COTTAAR[1], C. STAGG[1], M. F. RUSHWORTH[3], H. JOHANSEN-BERG[4]; [2]WIN, Dept. of Exptl. Psychology, [1]Univ. of Oxford, Oxford, United Kingdom; [3]Univ. Oxford, Oxford, United Kingdom; [4]Univ. Oxford, Oxford, United Kingdom

Abstract: Methods to induce plasticity in the human brain *in vivo* are still in their infancy. Much of the literature has focussed on targeting individual brain regions, but there is an increasing understanding that connectivity between areas, rather than activity of single regions, may be a key driver of brain function and behaviour.
In recent years, paired associative TMS (paTMS) has emerged as a brain stimulation protocol to potentiate the pathways connecting distant brain areas by activating them in conjunction. Previous evidence suggests paTMS can be used flexibly in many different neuroanatomical domains to induce physiological and behavioural effects. However, this has not been tested in a randomised controlled fashion yet. Moreover, it is unclear how long the paTMS effects last for, and whether they lead to structural reorganisation in the stimulated pathways.
Here, we carry out a randomised-controlled assessment of paTMS where 32 subjects are allocated to paTMS or a control protocol consisting of an equal amount of pulses, but delivered at an interval known not to induce plasticity effects. To characterise paTMS-induced plasticity, effects of paTMS on a set of behavioural, physiological, and MR-based structural and functional markers were assessed. Behavioural testing consisted of an action reprogramming task, while physiological testing consisted of TMS-based metrics of connectivity and overall cortical excitability. DWI, qMRI and rs-fMRI scans were collected before and 24h after paTMS or control.
Preliminary results show that participants receiving paTMS become faster at action execution compared to controls (mixed ANOVA significant group by time interaction, $F(6,14)=23$, $p < 0.0001$). Moreover, changes in cortical excitability across time were also different between paTMS and control (mixed ANOVA significant group by time interaction, $F(1,7)=53$, $p = 0.0002$).
These results corroborate previous findings on the efficacy of paTMS and show that paTMS can

be used to potentiate long-range circuits in humans *in vivo*, and can do so more lastingly than previously thought.

Title: Investigating the interaction of vagus nerve stimulation intensity and interval on motor cortex plasticity

Authors: ***R. A. MORRISON**[1], T. DANAPHONGSE[2], S. T. ABE[3], M. STEVENS[3], K. S. ADCOCK[1], M. P. KILGARD[1], S. A. HAYS[4];

[1]Sch. of Behavioral and Brain Sci., [2]Texas Biomed. Device Ctr., [3]Sch. of Natural Sci. and Mathematics, [4]Erik Jonsson Sch. of Engin. and Computer Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Vagus nerve stimulation (VNS) has recently emerged as a method of enhancing rehabilitation for a wide range of neurological disorders including stroke, traumatic brain injury, and spinal cord injury. Recovery is associated with plasticity in central networks after injury, and VNS promotes recovery by inducing plasticity in networks activated during rehabilitation. Thus, increasing the amount of VNS-mediated plasticity could lead to enhanced recovery.
A number of stimulation parameters influence the magnitude of plasticity driven by VNS. Increasing the current intensity of VNS yields an inverted-U effect on plasticity, where moderate intensities drive the most plasticity while low and high intensities have little effect. The interval between stimulations also affects the magnitude of plasticity. However, it is unknown whether these parameters interact to affect the degree of VNS-mediated plasticity.
Here, we sought to investigate the interaction between interstimulation interval (ISI) and VNS intensity and their effects on plasticity. Rats performed a motor task in which VNS was paired with rhythmic jaw movement during chewing with an ISI of 8 or 32 seconds and an intensity of either 0.4 or 1.2 mA. After five days of VNS pairing during behavioral training, intracortical microstimulation (ICMS) was used to document movement representations in the motor cortex, and motor cortex area eliciting jaw movement was compared between groups.

Title: Daily activity composition is associated with c-TBS induced neuroplasticity in the human motor cortex in older adults

Authors: *A. E. SMITH[1], M. R. GOLDSWORTHY[2], L. GRAETZ[2], N. THORNTON[2], N. HODYL[2], M. C. RIDDING[2];
[1]Univ. of South Australia, Adelaide, Australia; [2]Univ. of Adelaide, Adelaide, Australia

Abstract: Aging is associated with a reduced capacity of the human brain to re-organise the strength of its connections (called neuroplasticity). Regular engagement in physical activities may enhance this capacity. Surprisingly, however, little is known about the relationship between daily activity compositions (incorporating physical activity, sedentary behaviour and sleep) and neuroplasticity in older adults. The purpose of this study was to determine the association between habitual activity and motor cortical neuroplasticity by measuring motor evoked potential amplitudes (MEPs) elicited after a single, and paired continuous theta burst stimulation (cTBS) paradigm, targeting the primary motor cortex. Twenty-seven (66.5 ±4.6 yrs, 13 women) older adults participated in the study. MEPs were recorded from the right first dorsal interosseous muscle before, between and at 0, 10, 20, 40 and 60 min after paired cTBS separated by 10 min. Habitual activity was assessed objectively for 24 h/day over 7-days. Average time spent in sleep, sedentary behaviour, light physical activity and moderate-to-vigorous physical activity were calculated using pre-defined cut-points (COBRA software, UniSA). When accounting for age and sex, time spent in light physical activity was correlated with a greater neuroplasticity response after paired cTBS (r=-.507, P= 0.007). There was also a trend for greater engagement in sedentary behaviour to be correlated with a reduced neuroplasticity response. Compositional data analysis revealed more time spent in light physical activity at the equal expense of sleep, sedentary behaviour and moderate-to-vigorous physical activity was associated with greater motor cortical neuroplasticity (P= 0.02). These findings provide the first evidence that engaging in light physical activity promotes motor cortical neuroplasticity in older adults.

Abstract: Operant conditioning of the largely monosynaptic H-reflex is a targeted and non-invasive therapeutic intervention for people with motor dysfunction after spinal cord injury and possibly stroke. It can be used in conjunction with other therapies and has no known adverse side effects (Norton and Wolpaw, COBS, 2018). Here, we report on continued work to extend H-reflex conditioning to the upper extremity (i.e., flexor carpi radialis [FCR]). The conditioning protocol is similar to the one of Thompson, Chen, and Wolpaw (2009): 30 (six baseline and 24 conditioning) sessions over 10 weeks with 245 (20 control and 225 baseline/training) trials/session. In conditioning trials, the participant is asked to either increase (up-condition [UC]) or decrease (down-condition [DC]) H-reflex size. In each trial: the participant maintains a fixed level of background electromyography (EMG); the H-reflex is elicited by a stimulus that produces an M-wave of fixed size; H-reflex size is measured; and, in the conditioning trials only, immediate visual feedback shows the person whether H-reflex size satisfied a criterion. In previous studies of soleus H-reflex conditioning, the H-reflex of most participants gradually changed in the instructed direction over the 24 conditioning sessions. To date, 5 participants have completed the FCR H-reflex conditioning protocol. Four (3 UC and 1 DC) changed FCR H-reflex size in the instructed direction (average change from baseline was 24%). This average H-reflex change is slightly less than previously reported for the soleus H-reflex (~31%; Thompson, Chen, and Wolpaw, J Neurosci, 2009) for reflex conditioning of the lower extremity. The difference may reflect the challenges of working with the upper extremity (e.g., smaller muscle size, maintaining participant posture across sessions). To address these issues, we are working to minimize intra- and/or inter-session variations in key factors (e.g., Mmax, Hmax, Mtarget error). As a result, the coefficient of variation of the H-reflex for the control trials of the baseline sessions is less for the 3 participants currently completing the protocol (0.24) than it was for the first 3 participants (0.35). Finally, because the corticospinal tract is essential for H-reflex conditioning, we have begun to collect electroencephalography (EEG) data every 6th session. Analysis of EEG features (e.g., sensorimotor rhythms) immediately prior to H-reflex elicitation should provide insight into the neural mechanisms responsible for the reflex changes and may lead to protocol modifications that enhance the reliability, rapidity, and magnitude of reflex conditioning.

Title: Spinal reflex conditioning system for enhancing motor function recovery after incomplete spinal cord injury

Authors: J. NORTON[1], T. M. VAUGHAN[1], *A. EFTEKHAR[1], A. K. THOMPSON[2], A. HARRISON[3], M. SONNTAG[3], A. M. MELEHAN[3], E. BROWN[3], K. LUU[1], S. DEVETZOGLOU-TOLIOU[1], I. P. CLEMENTS[3], J. R. WOLPAW[1];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY; [2]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC; [3]BioCircuit Technologies, Atlanta, GA

Abstract: Spinal Cord Injury (SCI) affects ~300,000 people in the US, with 11,000 new cases per year. After SCI, spinal reflex function becomes abnormal, contributing to motor impairments and spasticity that affects 65-78% of people with SCI. Current therapies are only moderately successful; motor function often does not return to useful, let alone pre-injury levels. Prior research resulted in a novel, non-invasive therapy that targets beneficial change to specific spinal reflex pathways. The patient learns, through operant conditioning, to modify the brain's control over the reflex pathway. In animals and people with SCI, spinal reflex conditioning reduces spasticity, eliminates limping, and increases walking speed. Clinical translation of spinal reflex conditioning techniques would be facilitated by improved technology for robust, precise, and turnkey implementation. Towards this end, we describe the development and validation of a non-invasive multielectrode array-based platform for spinal reflex conditioning. The system facilitates precise, array-based measurement of H-reflex via integrated hardware and software able to detect and interpret EMG signals, optimize neural stimulation, and provide real-time patient feedback. Practical implementation of spinal reflex conditioning therapies will improve recovery for patients who have reflex-mediated spasticity arising from conditions such as spinal cord injury and stroke.

Title: Impact of globus pallidus or sensorimotor cortex ablation on spinal motoneuron GAD67 and KCC2 and on ventral horn interneuron GLUR2/3: Implications for the mechanisms of spinal reflex operant conditioning

Authors: *Y. WANG[1], L. CHEN[1], J. R. WOLPAW[1,2], X. Y. CHEN[1];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NYS Dept. of Hlth., Albany, NY; [2]Stratton VA Med. Ctr., Albany, NY

Abstract: Operant conditioning of the H-reflex (HR) produces a hierarchy of plasticity in brain and spinal cord (Neuroscientist 16:532-49, 2010). HR down-conditioning increases GABAergic input to spinal motoneurons (MNs) that may account for the HR decrease (Eur J Neurosci 23: 141-150, 2006; J Neurophysiol 108: 2668-2678, 2012). Down-conditioning is prevented by corticospinal tract transection, sensorimotor cortex (SMC) ablation, or bilateral globus pallidus (GP) ablation. This study explored the impact of SMC or GP ablation on: GABAergic input to the MNs; potassium-chloride cotransporter (KCC2) in the MNs; and glutamate receptors in ventral horn spinal interneurons (INs). BY affecting chloride balance, KCC2 down regulation impairs GABAergic inhibition and may produce GABAergic excitation (Nat Med 16:302-308, 2010; J Neurosci 33:15488-503, 2013).
Ten anesthetized Sprague-Dawley rats were implanted with EMG electrodes in right soleus (SOL) and a stimulating cuff on right posterior tibial nerve; the left SMC hindlimb area (SMC rats, n=4) or the GP bilaterally (GP rats, n=6) was ablated. Thirty days later, each was exposed to SOL HR down-conditioning. The rat was then injected in right SOL with CTB-Fluor 647, and perfused 3 days later. Five weight-matched naïve control (NC) rats were similarly injected and perfused. Lumbar 4-5 spinal cord was blocked and cut into 16-μm sections for anti-GAD67, anti-KCC2, or anti-GluR2/3 immunohistochemistry labeling. Three-D image stacks were analyzed in

a blinded manner with the Fiji-image J program. Immunoreactivity (IR) in GP and SMC rats was expressed in % of NC values and assessed with one-way ANOVA.
In SMC and GP rats, GAD_{67}-IR on SOL MNs was 81(±6 SEM)% and 92(±3)%, respectively, of the NC value (p=0.03 & 0.08 vs. NC; LSMeans contrast). Number of GABAergic terminals/MN in SMC and GP rats was 13(±1) and 15(±1), respectively; both were decreased ($p<0.01$) vs NC (17(±1)). MN KCC2-IR in SMC and GP rats was 85(±4)% and 89(±3)%, respectively (p=0.001 & 0.03 vs. NC). MN GluR2/3-IR of SMC and GP rats was 109(±6)% and 96(±2)%, respectively, in MNs (p=0.104 & 0.28); it was 122(±2)% and 106(±1)% in ventral horn INs ($p<0.001$ for both).
These initial results indicate that SMC or GP ablation decreases spinal MN GABAergic input and may impair GABAergic inhibition, and increases glutamate in ventral horn INs. Because SMC or GP ablation prevents HR down-conditioning, the GABA and KCC2 effects are consistent with the hypothesis that the spinal GABAergic impact of down-conditioning underlies the HR decrease. The relevance of the increased IN glutamate to the impact of SMC or GP ablation on down-conditioning is at present unclear.

Title: Tracking of whisking into target zones using a closed-loop, real-time feedback system

Authors: *K. SEHARA[1], V. BAHR[2], B. MITCHINSON[3], M. STAAB[1], S. E. DOMINIAK[1], M. J. PEARSON[4], M. E. LARKUM[1], R. N. S. SACHDEV[1];

Abstract: One of the principal functions of the brain is to control movement and rapidly adapt behavior to a changing external environment. Over the last decades our ability to monitor activity in the brain, manipulate it while also manipulating the environment the animal moves through, has been tackled with increasing sophistication. Yet, our ability to track the movement of the animal in real time has not kept pace. Here we use a Dynamic Vision Sensor (DVS) based event-driven neuromorphic camera system to implement real-time tracking of a single whisker that mice can move at ~ 25 Hz. The customized DVS-system used here converts whisker motion into a series of events that can be used to estimate the position of the whisker and to trigger a position-based output within 2 milliseconds. Here we interactively set a virtual target region in front of the mouse and generated fast sensory feedback when mice moved their whisker into the target zone. Mice were trained to move a whisker to a target zone, a location varied in the course of a session. We show that mice learn to position their whiskers to the target zones, and change their whisking to match the changing location of the target. The methods developed here are being used to examine the phase and context dependent effects of sensory and motor cortical activation and inactivation on changes in set point / whisking into and out of the target zone.

Abstract: The Air-track is a floating “real-world” environment that mice propel around themselves. It has walls that mice contact as they navigate the plus maze shaped platform for reward. Our previous work shows that as mice navigate the maze, they move their whiskers in a stereotyped manner: every trial shows the same pattern of whisking even though the duration of the trials varies widely. Our work has also shown that side to side asymmetry in whisker position, set point of whiskers and whisking frequency are behavioral state dependent and that together these parameters of whisker motion are sufficient to determine “where” the mouse is in the maze and “what” the mouse is doing in the maze. While whiskers are informative about mouse behavior in the maze, mice have little difficulty performing the task even when whiskers have been trimmed. Here we considered the possibility that mice use vision, perhaps they even move their eyes as they navigate the maze. Indeed, while mice push and pull a maze around themselves, they do move their eyes bilaterally, in concert with the movement of the platform. We find that mice first indicate their intent to move the platform by moving their whiskers, then they begin to move the platform, and finally once the platform begins to move, mice move their eyes conjointly. We are examining in particular how and when the eyes move in relationship to the looming and diminishing appearance of objects, i.e. as walls appear and disappear from the animal’s view. We are also examining the role of cortical control in eye movement and whisker positioning.

Title: Combining H-reflex conditioning and locomotor training enhances locomotor recovery in rates with incomplete spinal cord injury

Authors: *J. R. WOLPAW[1,2], L. CHEN[1], X. YANG[1], Y. CHEN[1], X. Y. CHEN[1];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY; [2]Stratton VA Med. Ctr., Albany, NY

Abstract: Operant conditioning of the spinal stretch reflex or its electrical analog, the H-reflex (HR), changes brain and spinal cord (Curr Opin Behav Sci 20:138-144, 2018 for review). In rats and humans with incomplete spinal cord injury (SCI), appropriate reflex conditioning improves locomotion (J Neurosci 26:12537-12543, 2006 & 33:2365-2375, 2013). We are exploring in rats the impact of combining H-reflex conditioning with locomotor training (an established therapy) after SCI.

Under anesthesia, Sprague-Dawley rats were implanted with EMG recording and nerve stimulating electrodes, and received a right SCI at T9. Twenty days later, each rat was exposed to a 60-day intervention of either right soleus HR up-conditioning combined with 5 days/wk locomotor training (CB rats, n=9), or locomotor training alone (LT rats, n=7). Locomotor EMG and HRs, and horizontal ladder crossing were assessed before and after SCI, and at the end of the 60-day treatment.

In rats with SCI, CB treatment increased the protocol HR (the HR during the conditioning protocol) ($p<0.001$, paired t-test); LT treatment did not affect the protocol HR ($p=0.54$). Final HR averaged 210(±19 SE)% of pre-treatment value in the 9 CB rats and 97(±5)% in the 7 LT rats ($p<0.001$ CB vs LT by t-test). In CB rats, the protocol HR appeared to increase more quickly and more than in normal rats exposed to up-conditioning alone. CB, but not LT, treatment also increased the locomotor HR (the HR during locomotion) ($p=0.02$ & 0.31, respectively). Final soleus locomotor HR averaged 273(±57)% of pre-treatment value in CB rats and 106(±5)% in LT rats ($p=0.024$). Both CB and LT treatments were associated with moderate increases in the soleus locomotor burst (120(±5)% and 115(±9)% of pre-treatment value, respectively).

Before SCI, footfalls (i.e., misses) in horizontal ladder crossing were 0.11(±0.08SE)/crossing for CB rats and 0.24(±0.10)/crossing for LT rats ($p=0.32$ CB vs LT by t-test). After SCI and before treatment, they were 6.24(±0.82)/crossing for CB rats and 5.34(±0.58)/crossing for LT rats ($p=0.41$). After treatment, they were 1.80(±0.51)/crossing in CB rats and 5.14(±0.57)/crossing in LT rats ($p<0.001$).

These initial results indicate that, in rats with right SCI, the combination of right soleus H-reflex up-conditioning and locomotor training produces locomotor recovery in SCI rats superior to that produced by locomotor training alone. Further assessment of locomotor kinematics and of the persistence of the superior recovery is underway. If confirmed, these results should lead to human studies exploring the ability of this combined therapy to enhance recovery after SCI beyond that achieved by either therapy alone.

Title: Coordination of whiskers and nose in a go-cue task and the role of motor cortex

Authors: *M. STAAB[1], K. SEHARA[2], S. DOMINIAK[1], M. E. LARKUM[1], R. N. SACHDEV[1]; [2]Inst. of Biol., [1]Humboldt Univ. zu Berlin, Berlin, Germany

Abstract: Rodents move their whiskers to map the external space around their face, and they move their nose to sample the odor field. The motion of these two active sensing elements is often coordinated, to the extent that whisker motion and breathing / sniffing have been linked to the same CPG in the brainstem. Here, in a simple go-cue triggered-whisking to touch task, we monitored the movement of C1 and C2 whiskers bilaterally, while also monitoring the movement of the nose. In preliminary experiments we also performed optogenetic inactivation of the motor cortex to examine whether coordination of whisker movement on one side of the face, coordination of whisker movement bilaterally, or whisker-nose motion coordination were altered. We find that: 1) Each mouse has distinct patterns of whisker motion, with distinct pattern of coordination between whiskers and coordination of whisker-nose motion; 2) Whiskers on one side of the face don't move together: the spread between adjacent whiskers changes, and the speed of adjacent whiskers varies in the course of each trial; 3) the nose moves on every trial, with large movement just before or just after whiskers hit the contact sensor; 4) Inactivation of motor cortex in Vgat-cre;FLEX-Chr2 mice affects performance - success rate decreases, and affects the coordination between whiskers, between whiskers and nose motion, and alters the frequency components in whisking.

Title: An epidermal electronic system (EES) grid electrode for measuring electromyography (EMG) during operant conditioning of human flexor carpi radialis H-reflex

Authors: J. J. S. NORTON[1,2], Y. T. KWON[3], A. EFTEKHAR[1], **T. FAKE**[1,4], *A. M. CUTRONE[1,2], J. R. WOLPAW[1,2], W. YEO[3];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY; [2]Stratton VA Med. Ctr., Albany, NY; [3]George W. Woodruff Sch. of Mechanical Engin., Georgia Inst. of Technol., Atlanta, GA; [4]Univ. at Albany, Albany, NY

Abstract: Operant conditioning of the flexor carpi radialis (FCR) H-reflex may provide a non-invasive and targeted therapeutic intervention for people with motor dysfunction in the upper extremity following stroke (Norton and Wolpaw, COBS, 2018). In the conditioning protocol, an FCR H-reflex is elicited with surface electrical stimulation and measured with electromyography (EMG). After collection of baseline data, participants are asked to either increase or decrease their H-reflex size. Guided by visual feedback, the participants learn to change H-reflex size after multiple sessions. Here, we report initial development of a flexible and conformal grid of EMG electrodes using an epidermal electronic system (EES; Herbert et al., Materials, 2018). In contrast to traditional EMG electrodes, the EES device conforms to the skin and does not require electrolytic gel. The initial design of the EES device consists of a 4 x 4 grid of electrodes; each electrode measures 0.4 x 0.6 cm with an inter-electrode distance of 1.0 x 1.4 cm. The individual electrodes are made of circular pads connected by serpentine mesh. In two pilot experiments, we are collecting data to demonstrate that the newly designed EES device can measure reflex responses from the FCR. Experiment 1 is comparing the H/M ratios measured (during recruitment curves [RCs]) with a traditional electrode to those measured with an EES device. Initial results show small differences between the H/M ratios recorded from the two devices which may be due to minor differences in the recording conditions (e.g., electrode size and time of day). Experiment 2 is evaluating inter-session variability in reflex measurements using RCs; the EES device provides stable Hmax and Mmax values despite variations in placement between sessions. With further evaluation and refinement of methods, the EES device may increase the stability and comprehensiveness of EMG recording during H-reflex conditioning sessions, and may thereby enhance the consistency and effectiveness of reflex conditioning protocols.

Title: The effect of perturbation-based training on the soleus H-reflex

Authors: ***J. H. BARNES**[1,2], E. W. GREENBERG[1], S. M. HECKMAN[1], J. R. CRENSHAW[2], J. R. WOLPAW[1,3];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY; [2]Univ. of Delaware, Newark, DE; [3]Stratton VA Med. Ctr., Albany, NY

Abstract: Perturbation-based training (PBT) protocols, in which participants repeatedly attempt to recover from rapid surface translations, seek to improve the reactive response needed to maintain upright balance during external disturbances. While this type of training has been shown to reduce the likelihood of falls in some at-risk populations, the neuroplasticity underlying it is unknown. To begin addressing this gap in knowledge we investigated the effect of PBT on the soleus H-reflex, bilaterally. Six participants (3 men) aged 28-48 years completed a six-session PBT protocol. Perturbations, consisting of brief (600-700ms) rapid posterior surface translations, were delivered during standing via a computer-controlled treadmill and custom software. Each participant experienced ~75 perturbations/session; perturbation difficulty level, defined by the acceleration/deceleration rate of the treadmill belts, was adjusted on a trial by trial basis according to a progressive practice training model. Before each trial, the participant was instructed to “try not to step.” To determine the effect of this training on the soleus H-reflex, soleus H-reflex/M-wave recruitment curves and soleus H-reflex control trials (i.e., H-reflex responses elicited while background EMG and M-wave size are constant) were recorded bilaterally during standing before training began and after completion of the six training sessions. Over the course of training, all participants improved in their reactive abilities, successfully responding to faster and larger perturbations without stepping. For four participants, this improvement was associated with an increase in soleus H-reflex size in the leg used most often for stepping during unsuccessful trials; the H-reflex in the other leg did not change. For two participants, soleus H-reflex size decreased approximately equally in their stepping leg and their stance leg. Study of additional individuals is being conducted and analyses of electromyographic activity, kinematics, and ground reaction forces are ongoing to explore their functional relevance.

Title: The relationship between sensorimotor cortex activity and H-reflex size in human flexor carpi radialis: Toward enhancing the therapeutic efficacy of spinal reflex operant conditioning

Authors: *L. M. MCCANE[1], J. R. WOLPAW[1], A. EFTEKHAR[1], A. K. THOMPSON[2], D. J. MCFARLAND[1], W. G. BESIO[3];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY; [2]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC; [3]Electrical Computer and Biomed. Engin. Dept., Univ. of Rhode Island, West Kingston, RI

Abstract: Operant conditioning of the H-reflex (electrical analog of the spinal stretch reflex) in the soleus muscle can trigger wider beneficial plasticity that improves walking in animals or people with incomplete spinal cord injury (Thompson & Wolpaw 2014). Animal studies show that H-reflex conditioning requires sensorimotor cortex (SMC). Furthermore, in both animals and people, H-reflex size correlates with SMC sensorimotor rhythm (SMR) amplitudes immediately before H-reflex elicitation (Boulay CB et. al. 2015, Thompson AK et. al. 2018). Taken together, these findings suggest that brain-computer interface (BCI)-based SMR training could improve the consistency, rapidity, and magnitude of H-reflex conditioning and thereby enhance its clinical efficacy and practicality. To evaluate this possibility, we are recording EEG from the scalp over SMC during flexor carpi radialis (FCR) H-reflex elicitation. The goal is to define the normal relationship of H-reflex size to preceding SMR activity and to the concurrent somatosensory evoked potential (SEP). We hypothesize that H-reflex size will correlate with preceding SMR amplitudes in β and γ frequency bands and with amplitudes of components of the SEP produced by the stimulus that elicits the H-reflex. The relatively large and EEG-accessible arm region of human SMC should facilitate this analysis. The study is approved by the New York State Dept Health IRB. Neurologically healthy people are seated with the right arm extended in a neutral position. EMG is collected from 8 arm muscles (bipolar, 2 kHz) while the person keeps FCR EMG at ~10% maximum voluntary contraction (guided by visual feedback). Median nerve stimulation (1-ms biphasic) is delivered in 6 blocks of 50 trials each (1 trial every

4-6 sec). Stimulus amplitude (initially selected from the ascending limb of the person's H-reflex recruitment curve) is continually adjusted to maintain a small stable M-wave. Sixteen channels of scalp EEG and tEEG (Koka K et.al., 2007) are recorded (1200 Hz) over left SMC. BCI2000 software records EEG and EMG, controls the stimulus, and provides visual feedback. Ten people have been studied to date. Data analysis is: assessing the degree to which SMR β and γ band amplitudes predict H-reflex size; delineating SEP components and their correlations with H-reflex size and SMR amplitudes; comparing results for EEG and tEEG data; and defining inter-person variations in EMG across the 8 muscles. The results should guide future studies seeking to improve the clinical efficacy and practicality of spinal reflex conditioning (e.g., by training SMR amplitude and/or using SMR amplitude to trigger H-reflex elicitation).

Title: Neural correlates of graded movement for brain-computer interfaces

Authors: *C. HADDIX, A. AL-BAKRI, S. SUNDERAM;
Univ. of Kentucky, Lexington, KY

Abstract: Brain-computer interfaces (BCI) are often designed to detect and act on changes in brain signals, termed event-related potentials (ERP), associated with attempted or imagined movement for instance. The number of commands available for BCI operation is limited by the number of distinct mental tasks the user can perform (e.g. right hand, left hand, foot movement, etc.). As an alternative, we propose to predict and use, from the electroencephalogram (EEG), the degree of effort in a specific movement task to generate multiple command signals out of one. In an IRB-approved study, ten healthy subjects participated in a handgrip task in which they were required to control the force applied on a hand dynamometer to match a target value based on visual feedback provided by means of a digital display. Target forces were specified as a percentage of the subject's maximum voluntary contraction force (MVC) - 20%, 35%, 50%, 65% -- and used as a measure of their effort in the task. A neural network was trained to classify the EEG associated with these force targets and tested using 4-fold cross validation on each subject

individually. Preliminary results indicate that EEG features related to modulation of the sensorimotor rhythm (SMR) are separable for different degrees of effort. Pooled accuracies for the four classes, with a baseline resting condition and pre-movement preparation also considered as classes, ranged from 64-69%, well above the level expected from chance of 16%. The results of this study highlight the potential for expanding the degrees of freedom associated with simple control signals intended for use with a BCI. Further development of the effort prediction model, with dynamic feedback to the subject on their intended level of effort as predicted from the EEG, may find utility in rehabilitative protocols for those afflicted with neuromuscular impairments.

Title: Resting state functional connectivity alterations associated with chronic stroke recovery via a brain-computer interface

Authors: *J. B. HUMPHRIES[1], A. SCOTT[2], M. OLUFAWO[2], K. Y. PARK[3], A. G. S. DANIEL[1], K. RYBCZYNSKI[2], T. NOTESTINE[2], A. R. CARTER[4], E. C. LEUTHARDT[2]; [1]Biomed. Engin., [2]Neurosurg., [3]Radiology, [4]Neurol., Washington Univ. in St. Louis, St. Louis, MO

Abstract: *Background:* Stroke is a leading cause of adult disability. Approximately 77% of stroke survivors experience a loss or reduction of upper extremity motor function known as hemiparesis, and 65% of hemiparetic stroke patients do not regain motor function 6 months after stroke. Recently, upper motor therapy for chronic stroke survivors with a brain-computer interface (BCI) controlled with motor cortical signals from the non-lesioned hemisphere was found to be effective for restoring motor function in the chronic stage of stroke. However, the effects of this therapy method on the function and organization of the brain are not yet well understood. *Methods:* To understand how the functional organization of the brain changes during chronic stroke recovery with a contralesional BCI, a cohort of chronic stroke patients underwent resting-state functional MRI (rs-fMRI) scans and motor function evaluations before and after receiving 12 weeks of contralesional BCI therapy at home. Patients were asked to perform a cued motor imagery task for an hour per day, 5 days per week by using an BCI hand orthosis controlled with noninvasive EEG signals. EEG signals were processed in real time. Motor imagery detection was translated into a command for motors to open the hand orthosis. Functional connectivity was calculated from rs-fMRI data by computing the pairwise correlations among regions of interest in preprocessed data. Preprocessing included image coregistration and alignment, normalization to atlas space, smoothing, and nuisance regression. *Results:* This study is still ongoing; however, preliminary analysis of rs-fMRI data has revealed interesting trends. The change in functional connectivity over the course of therapy was calculated for 3 patients, 2 of which achieved clinically significant recovery defined as an increase of greater than 6 points on the Upper Extremity portion of the Fugl-Meyer Assessment. Intra-region and interhemispheric functional connectivity of cortical somatomotor network (SMN) voxels increased in the patients who achieved clinically significant recovery and

decreased in the patient who did not. Examples of these cortical areas include Primary Motor and Sensory Cortex and Premotor Area. *Conclusions:* A longitudinal change in SMN connectivity corresponding to motor recovery may indicate a reorganization of motor-related function induced by contralesional BCI therapy. This result also informs the role of the contralesional hemisphere in stroke recovery by showing that bilateral motor function changes can benefit motor recovery in a chronic stroke population. We expect these results to become more robust as we recruit and analyze more patients.

Title: Bispectral feature extraction improves brain-computer interface performance

Authors: *D. SYED[1], C. K. KOVACH[2], P. E. GANDER[2], C. G. REDDY[3], B. F. SNOAD[2], M. A. HOWARD, III[2];
[1]Carver Col. of Med., Iowa City, IA; [2]Dept. of Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [3]Neurosurg., Univ. of Florida-Gainesville, Gainesville, FL

Abstract: Brain-computer interfaces (BCIs) allow a computer to interpret and act on its user's intentions, without need of the peripheral nervous system. BCIs classify brain states by extracting relevant features from electrode data through the application of machine learning techniques. Time-varying signal power recovered by bandpass filtering within pre-selected frequency bands, or by more comprehensive time-frequency decompositions, often provide the input to such classifiers. But because the power spectrum discards phase information, these techniques are insensitive to properties of the signal related to spectral phase, such as any information encoded in cross-frequency interactions, notably phase-amplitude coupling. This information is preserved in so-called higher-order spectra, which are related to time-shift invariant higher moments (Nikias and Raghuveer 1987, Kovach et al. 2018). We have recently developed a novel approach to recovering information from higher-order spectra using an application of the bispectrum (Kovach et al. 2018, Kovach and Howard, preprint), in the form of

filters optimized for the detection of characteristic recurring features within a signal. Here, we investigated whether this bispectral approach to feature extraction could improve the performance of an electrocorticographic (ECoG) BCI. We trained a support vector machine classifier to discriminate two mental task conditions (in which a human subject was instructed to "imagine the tune of 'Jingle Bells'" or "imagine feeling very angry"), using both bandpass power in standard EEG frequency divisions and the output of bispectral feature extraction. The trained classifier was used offline to simulate driving a robot in real time. Our bispectral/bandpass classifier performed with higher accuracy than either technique alone. Additionally, the combined classifier performed comparably to band power alone using fewer channels. Our findings suggest that feature identification with higher-order spectra may improve ECoG BCI performance while minimizing implant size.

Title: Resting and pre-stimulus EEG spectra predict SNR of EEG and BCI performance

Authors: *L.-W. KO[1], H.-Y. CHANG[1], T.-P. JUNG[2];
[1]Inst. of Bioinformatics and Systems Biol., Natl. Chiao Tung Univ., Hsinchu, Taiwan; [2]Swartz Ctr. for Computat. Neuroscience, Inst. for Neural Computation, Univ. of California San Diego, La Jolla, CA

Abstract: Most research in Brain-Computer-Interfaces (BCI) focuses on technologies to improve accuracy and speed. Little has been done on the effects of user state changes on BCI performance. For example, stress, arousal, motivation, and fatigue can all affect the EEG signals used by a BCI, which in turn impacts performance. To systematically explore the factors affecting BCI performance, this study embeds a Steady State Visually Evoked Potential (SSVEP) based BCI into a "game with a purpose" (GWAP) to obtain data over significant lengths of time under both high and low stress conditions. Ten healthy volunteers played a GWAP that resembles popular match-three games, such as Jewel game, Zoo, or Candy Crush. We recorded the target search time, target search accuracy, and EEG signals during gameplay to

investigate the impacts of stress on EEG signals and BCI performance. We used Canonical Correlation Analysis (CCA) to determine whether the subject had found and attended to the correct target.The experimental results show that SSVEP accuracy is reduced by stress. We also found a negative correlation between EEG spectra and the SNR of EEG in the frontal and occipital regions during gameplay, with a larger negative correlation for the high-stress conditions. Furthermore, CCA also showed that when the EEG alpha and theta power increased, the target search accuracy decreased, and the spectral amplitude drop was more evident under the high-stress situation. These results provide new, valuable insights into research on how to improve the robustness of BCIs in real-world applications.

Abstract: Neuroprosthetics hold tremendous promise to advance our understanding of the nervous system through basic research, and to restore lost sensory inputs and motor outputs through brain-computer interfaced (BCI) devices. Maintaining high quality neuronal signals for long periods of time are key challenges that must be thoroughly addressed to develop clinical applications for neuroprosthetics. Previous studies have shown that acute and chronic inflammation, oxidative stress, and BBB disruption are likely factors that contribute towards inconsistent chronic electrode performance. Methods to reduce the host response is essential to the development of clinically effective BCI devices and may be achieved with mild therapeutic hypothermia (mTH). The therapeutic benefits of mild hypothermia for some neurological conditions include a reduction in inflammatory processes and restoration of the blood brain barrier (BBB). To examine the benefits of mTH during electrode implantation, our laboratory has designed a custom device to deliver controlled mTH to the implant site without requiring any modifications to the current surgical approach. In vivo cortical temperature measurements were compared to theoretical 3D modeling to determine a cooling profile and protocol. Once developed, male Sprague-Dawley rats (250-300g; n=20) were implanted with custom-made, non-functional Utah Microelectrodes Array (UMEA) consisting of 4 x 4 grid of 1.5mm long parylene-coated silicon shanks. mTH was applied to the implant site (n=10) prior to surgical implantation. The temperature of the implant site was slowly lowered by 3-4 degrees (cooling phase: 10 mins), the UMEA was inserted, and cooling continued for 120 minutes (maintenance phase) followed by a slow rewarming phase (10 mins). We compared mRNA expression levels for genes associated with apoptosis, inflammation and the blood brain barrier (BBB) at 48 hours, 72 hours, 7 days and 14 days post implantation between normothermic and hypothermic groups. We show significant beneficial molecular responses to therapeutic hypothermia and demonstrates the efficacy of hypothermia in reducing inflammation and altering molecular activity that may benefit restoration of the functional properties of the BBB following UMEA implantation.

Title: Decoding of arm movements from electroencephalogram using convolutional neural network

Authors: *M. KATO, S. SHIMADA;
Meiji Univ., Kawasaki, Japan

Abstract: In the present study, we measured electroencephalogram (EEG) when an individual performed reaching movements with his right arm. We made a CNN model that can decode four directions of reaching motion of the right arm from EEG data. Two healthy right-handed male subjects (aged 23) with written informed consent took part in this study. The trials of experiment were conducted by operating the avatar's right arm displayed on the screen using a joystick. Trials began by placing the avatar arm on the base position, which was shown as a 12×12 cm^2 square located at the center of the screen. The avatar arm had to keep inside of a base position for a random interval of 0.4 to 1 s. After this hold, a target appeared on the screen. The target was a circle with a diameter of 12 cm appeared at the distance of 20 cm either front, back, left, or right of the base position. When the avatar arm reached to the target and 1 s passed, the base position re-appeared. The experiment consisted of 2 sessions. The session included 8 blocks and one block included 150 trials. EEG signals were sampled at 1200 Hz from 60 channels. EEG data from 0.5 s before the target onset to 3.25 s (3.2 s for Subject2) after the onset was defined as a trial. Each trial was classified into 4 classes (front, back, left, right). The input data was created by extracting the EEG data with a time window of 2 s and a slide width of 0.04 s in each trial. The input data was divided into training data, validation data, and test data at 8: 1: 1. We constructed a CNN model to classify arm movements from EEG with four convolutional layers and one softmax classification layer. The result showed that the CNN model can classify the four types of movements of the right arm with accuracy of 78% (front: 77%, back: 54%, left: 90%, right: 90%) for Subject1 and 57% (front: 85%, back: 38%, left: 60%, right: 44%) for Subject2. The classification accuracy of Subject 2 was lower than Subject 1, mainly due to measurement noise. Also, the accuracy of the back was the lowest for both subjects, though still higher than the chance level, possibly because the movement to pull back the arm is rather small. The result demonstrated that the CNN model is possible to classify four types of movements of the right arm from EEG data.

Title: Novel electrodes for reliable EEG recordings on coarse and curly hair

Authors: *A. ETIENNE[1], H. WEIGLE[1], T. LAROIA[1], A. AFELIN[2], A. KRISHNAN[1], S. KELLY[1], P. GROVER[1];
[1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Wesleyan Univ., Middletown, CT

Abstract: EEG is a powerful and affordable brain imaging tool used for the diagnosis of neurological disorders (e.g. epilepsy), brain computer interfacing, and understanding how the brain functions. Unfortunately, existing EEG electrodes and systems are not designed to accommodate a large fraction of the population. Specifically, existing EEG systems work best with individuals with short, straight hair. That leaves most of the population (including a large fraction of women) at a disadvantage, and leaves a smaller subset of people (those with long and curly or kinky hair) with an experience that can range from uncomfortable to emotionally taxing, and in the worst case, still does not yield high-quality measurements. Bringing human-centered design to EEG, we design EEG recording systems, "goEEG systems," including hair preparation and electrodes, specifically aimed at accommodating coarse and curly hair.

The study applied our goEEG system to individuals with coarse and curly hair, comparing the results with classical approaches used in the field. We performed experiments for quantifying advantages of our electrodes over classical ones with braided hair, as well as classical electrodes on unbraided hair. On the left side of the head, we cornrowed hair according to the 10-20 system. Next, we placed two industry standard gold cup electrodes and two of our electrodes on the braided side. We repeated the placement on the right hemisphere where the hair was left free and not cornrowed. The proposed electrodes, in conjunction with our recently proposed EEG-compatible braiding techniques [Etienne et al., EBMC'17], were observed to have an order of magnitude lower impedance than conventional systems.

Our novel electrodes and braiding goEEG solution provides a lower impedance than traditional systems used clinically and neuroscientifically for EEG recordings. Lower impedance not only provides higher SNR recordings, it also implies improved electrodes-skin contact. Thus, it is likely that goEEG electrodes will offer longer term recordings because they will maintain contact longer.

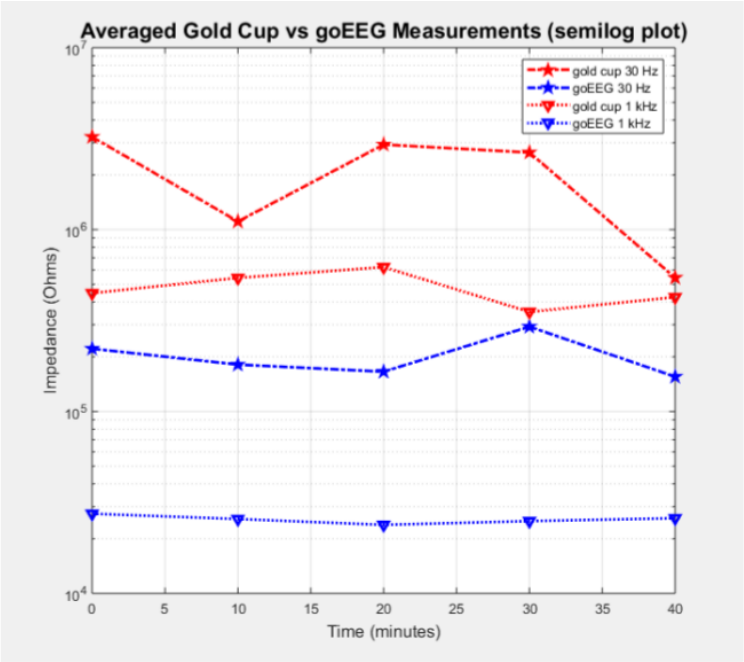

Figure 1: Shown above are the average measured impedances over time of the Gold Cup (industry standard) electrodes and the goEEG electrodes, depicted at both 30 Hz and 1 kHz, with the y axis on a logarithmic scale. We can see that the impedances for the goEEG electrodes are, on average, an order of magnitude lower than the Gold Cup electrodes for each respective frequency.

Title: Effects of training on electroencephalogram about motor imaginary tasks pertaining to the lower limbs

Authors: ***M. S. SHIBATA**[1], K. HOSHINO[1], A. ISHIYAMA[1], Y. ONO[2];
[1]Electrical Engin. and Biosci., Waseda Univ., Tokyo, Japan; [2]Meiji Univ., Kanagawa, Japan

Abstract: We measured electroencephalography (EEG) activity related to motor imaginary of the lower limbs. The purpose of this study is to confirm if training strengthens event-related

desynchronization (ERD) or event-related synchronization (ERS) in motor area for the lower limbs. Four healthy young adult (all men) participated in the study. First, the participants performed the motor imaginary tasks pertaining bending movements of both knees for two seconds before training while their EEG responses were measured. After that, the participants were trained. In the training, the participants watched the video of the person moving the leg in the first-person view and performed the motor imaginary as directed by the video. The training was conducted three times on different days, and the motor imagery EEG was measured after the training. Also, the participants actually bend both knees and their EEG responses were measured at this time. The experiment is conducted to compare the EEG when they actually move the legs with the EEG that appeared by training of motor imaginary of both knees bending. The EEG of pre-training and that of post-training were compared. The electrical signals were acquired from the Cz electrodes according to the International 10-20 system which corresponds to the motor field of the legs. Blink-related artifacts were removed and the power spectrum intensity was calculated by time-frequency analysis. Spectrum powers for the alpha wave band (7 - 14 [Hz]) and the beta wave band (15-30 [Hz]) were determined. Training-related change in alpha wave region showed two different tendencies of enhanced ERD or ERS. That in beta wave region showed no remarkable change in ERD and ERS. The power spectrum intensity of both of the EEG frequency was examined in the same manner as before. The participant who could enhance ERD approximately by 50% by training showed ERD approximately 50% during actually moving. Similarly, those who could enhance ERS showed ERS during actually moving. These results suggest that motor imagery training could strengthen motor-related activity and there is the possibility that the motor imagery EEG after training and the actually moving EEG are similar.

Title: A computational model and brain-computer interface technology that uses virtual reality to measure anxiety induced disruption to motor function in biological systems

Authors: *R. MEACHAM, M. E. HERNANDEZ, S. M. LAVALLE, R. B. SOWERS, A. YERSHOVA;
Univ. of Illinois Urbana-Champaign, Urbana-Champaign, IL

Abstract: We propose a new approach that unites both machine learning and experimental methods to measure and predict cognitive states such as anxiety, based on physiological signals and computer vision, with regard to biological systems at the neuronal level. Our study examines the effect of virtual reality scenes with differing levels of anxiety-inducing stimuli to persons with or without a fear of falling. The experiments used the HTC Vive to show subjects custom-built animated virtual reality (VR) simulations of a local neighborhood park using Unity. Different versions of the VR simulation were generated, each with a varying level of anxiety-inducing stimuli, in order to show the walking paths with high, low, and moderate levels of risk for falling. EEG, EOG, and heart rate were measured as subjects participated in these virtual experiences. Using a machine learning model for emotional expressions, we also measured emotional engagement with specific anxiety inducing segments of the stimuli. Our results suggest that frontal alpha and beta frequencies may provide salient neural features for detection of anxiety, in high versus low anxiety trials. There are no noticeable desynchronous characteristics in these datasets, however this may simply be due to the limited sample size or differences in stimuli between VR conditions. The results from our preliminary research suggest promise for VR and brain-computer interface technology as a promising rehabilitation tool and behavioral training technique. VR provides the sensation of presence in an imaginary world, which opens up the possibility of rehabilitation from anxiety disorders such as fear of falling, fear of flying, and post-traumatic stress disorder. Given prior findings that suggest that individuals who have high emotional engagement (high anxiety) at the beginning of exposure and gradual habituation (decrease in anxiety) have the most successful recoveries, future work will examine individual changes in anxiety during the exposure to anxiety-inducing VR simulations.

Title: Electrocortical activity while standing, walking, and recovery after unpredictable trip perturbations

Authors: *J. AN, D. YOO, B.-C. LEE;
Univ. of Houston, Houston, TX

Abstract: Although the balance-recovery reactions from unexpected gait perturbations (e.g., trips and slips) are relatively well-understood in musculoskeletal and biomechanical perspectives, little is known about how the brain's electrophysiological activities are dynamically changed during balance recovery after unpredictable gait perturbations. In this study, 128-channel non-invasive electroencephalography (EEG) signals were collected from healthy young adults during quiet standing, normal walking, and recovery following trip perturbations induced by a programmable split-belt treadmill. The programmable split-belt treadmill produced an unpredictable trip perturbation by quickly stopping the treadmill's left belt. The stopped left belt returned to the pre-perturbation walking speed after the first heel strike of the compensatory limb (i.e., non-tripped limb). We analyzed electrocortical activity during three different periods (i.e., standing, walking, and recovery following the trip perturbation). Power spectral analysis was computed using Welch's method from two different clusters of electrodes in the primary sensorimotor cortex (SMC) and posterior parietal cortex (PPC). The results showed that alpha (8-13 Hz) spectral power was significantly decreased during the recovery period compared to the walking and standing periods in both SMC and PPC. These findings may inform improvements of gait perturbation paradigms intended for fall reduction and prevention.

Title: Brain computer interface based communication for individuals in locked-in state without gaze fixation

Authors: *A. TONIN[1], A. JARAMILLO-GONZALEZ[1], A. RANA[1], M. KHALILI ARDALI[1], N. BIRBAUMER[2,1], U. CHAUDHARY[1,2];
[1]Univ. of Tübingen, Tübingen, Germany; [2]Wyss Ctr. for Bio and Neuroengineering, Geneve, Switzerland

Abstract: Several neuronal disorders, such as amyotrophic lateral sclerosis (ALS), severely impairs the communication capacity of an individual. Commercial eye tracker-based communication devices along with several other brain computer interfaces (BCIs) have been developed to provide a means of communication to individuals in locked-in state (LIS), i.e., individuals who can reliably move their eyes and fixate their gaze. Once the individuals lose the gaze fixation ability none of the available devices function. Therefore, patients who can still open and close their eyes albeit with difficulties but cannot fixate their gaze and without intact eye movement control are left without any means of communication. To provide such individuals with a means of communication an electroencephalogram (EEG)- and electrooculogram (EOG)-based auditory BCI communication system was developed, which enabled such individuals to auditorily form sentences.
The BCI communication system is based on a binary yes/no classification that allows individuals to select letter. This study was performed with four individuals with ALS in transition from the locked-in state to completely locked-in state but unable to use eye trackers for communication. The signal was recorded using both EEG and EOG electrodes and the individuals were asked to auditorily select or discard a word, a letter or a group of letters by thinking yes/no and moving or not-moving their eyes.
The developed system has been tested in total 45 times and all the four individuals successfully performed at least one copy spelling session, selecting a test sentence, and one free spelling session, freely selecting a sentence. The speller worked with an information transfer rate of 5.664±0.25 bits/min and attained a typing speed of 0.551±0.049 char/min. The signal analyses show that the developed system can even work using only two EOG electrodes, which needs to be tested by performing more BCI sessions with these individuals.
The developed auditory speller system has the potential to provide a means of communication to individuals without gaze fixation ability and with invisible but miniature eye-movements. The complete auditory implementation implies a slow typing speed but assure the usability of the system by patients with non-intact sight.

Title: Differences in event related desynchronization of mu rhythms between three types of motor imagery during action observation of leg movement

Authors: *K. HOSHINO[1], M. SHIBATA[1], A. ISHIYAMA[1], Y. ONO[2];
[1]Electrical engineering and Biosci., Waseda Univ., Tokyo, Japan; [2]Meiji Univ., Kanagawa, Japan

Abstract: Brain-machine interface based on Electroencephalography (EEG-BMI) can be used to recover motor function by re-establishing motor pathway, and this method has been increasingly applied to the rehabilitation of stroke patients in recent years. However, the analysis of EEG for legs movements is less advanced than it is for hands, making it more difficult to apply to rehabilitation at present. In this study, we analyzed event-related desynchronization (ERD) of mu rhythms in EEG of motor imagery during action observation of three types of lower limb movement, with the aim of suggesting an effective rehabilitation system. Six healthy men participated in the study, which comprised two experiments: (1) motor imagery of foot movement (MI experiment), and (2) motor imagery during action observation of three types of foot movements (MI-AO experiment). During both experiments, all participants were seated in front of a computer screen with their legs stretched out, parallel to the floor, on footrests. In the MI experiment, they were instructed to perform motor imagery of both knees bending for two seconds according to a cue presented on the screen, for 10 times. In the MI-AO experiment, they were asked to perform motor imagery of both knees, the right knee, and the left knee while watching a leg-action video on the screen, with 20 trials performed for each of the types of movement. ERD power and occurrence rate were evaluated in both experiments. The MI-AO experiment shows that the ERD power was significantly increased for the MI-AO of both legs compared to the right and the left individually. There was no significant difference in the occurrence rate of ERD between the three types of leg movement with the rate being approximately 50% in all cases. No differences in the power and occurrence rate of ERD were observed between MI and MI-AO. These results suggest that movement of both legs is desirable for patients with difficulty in detecting ERD power when they start their motor imagery training. There was no difference in ERD power and occurrence between MI and MI-AO, suggesting that observation of movements that are unfamiliar to the participants might not contribute to enhance ERD strength. Therefore, visual and proprioceptive neurofeedback on top of MI or MI-AO might be better rehabilitation method.

Title: Decoding movement intentions from posterior parietal cortex using functional ultrasound neuroimaging

Authors: *S. L. NORMAN[1], V. N. CHRISTOPOULOS[1], D. MARESCA[1], C. DEMENÉ[2], T. DEFFIEUX[3], M. TANTER[4], M. G. SHAPIRO[1], R. A. ANDERSEN[5];
[1]Caltech, Pasadena, CA; [2]CNRS UMR 7587, INSERM U979, ESPCI Paris, PSL Res. Univ., Inst. Langevin, Paris, France; [3]Physmed / Inserm U1273, Paris, France; [4]INSERM, Paris, France; [5]BBE, Calif Inst. of Technol., Pasadena, CA

Abstract: Advanced neural interfaces have the potential to impact neuroscience from bench to bedside. Recently, functional ultrasound (fUS) was introduced as a revolutionary hemodynamic imaging technique with excellent spatiotemporal resolution (e.g. 100 μm,10 ms), field of view (e.g. 15mm) and sensitivity [Mace et al, Nature Methods, 2011]. In addition, it is portable and potentially noninvasive. As a result, fUS is rapidly gaining popularity in neuroscience methodology for its ability to record high-quality neurovascular function in awake, behaving animals. Brain-machine interfaces (BMIs) are devices that use neurophysiological signals from the brain to control external devices. In addition to their clinical applications, BMIs are powerful tools for investigating brain function [Zhang et al., Neuron, 2017]. Here, we utilize fUS as a recording technique in an offline brain-machine interface (BMI) paradigm to investigate movement intention in the posterior parietal cortex of a non-human primate (NHP).Specifically, we trained the NHP to perform memory-guided saccades and reaches (acquired via joystick) to targets presented in left or right visual fields. During the task, we acquired fUS images at 1 Hz over the intraparietal sulcus (IPS) to capture the lateral intraparietal area (LIP) - an area associated with planning eye movements - and the parietal reach region (PRR) - an area associated with planning reaching movements. Using hemodynamic fUS signal during movement planning, we classified left-cued vs. right-cued eye and hand movements. Cross-validated decode accuracies ranged from 61.5% (binomial test vs. chance level, $p=0.012$) to 100% ($p<0.001$) on a given day (average across days: 80%, $p<0.001$).Finally, we leveraged the BMI decoders to elucidate spatiotemporal patterns of information content and propagation through posterior parietal brain regions. Specifically, we found highly localized patches of

activity tuned to contralateral movement intention in LIP, VIP, and PRR. We also identified patches of activity in medial parietal area (PM), located within PGm, consistent with electrophysiological (Thier et al., Journal of Neurophysiology, 1998) and histological (Passarelli et al., Cerebral Cortex, 2018) findings, but not previously reported in studies using noninvasive techniques such as MRI.These findings suggest that 1) fUS is capable of decoding single-trial movement intention and is therefore a viable neural interface for online BMI control, and 2) multiple brain areas within PPC, previously only detectable by more invasive methods, play critical roles in planning eye and hand movements.

Title: Longitudinal observation of event-related potentials commonly used in brain-computer interfaces

Authors: *J. R. ESTEPP[1,3], A. M. PIASECKI[4], K. E. ALEXANDER[1], C. L. WINTERMUTE[1], S. M. ELBASIOUNY[2,1];
[1]Dept. of Biomedical, Industrial, and Human Factors Engin., [2]Dept. of Neuroscience, Cell Biology, and Physiol., Wright State Univ., Dayton, OH; [3]US Air Force Res. Lab., Wright-Patterson AFB, OH; [4]Ball Aerospace, Fairborn, OH

Abstract: Electroencephalography (EEG) data are often referred to as being non-stationary, but it is rarely ever the case that this non-stationarity is explicitly defined, and its effect in use cases such as brain-computer interfaces (BCIs) is not well understood. BCIs often make use of the brain's phase-locked response to stimuli, as measured by EEG, as an alternate control pathway to infer and actuate motor intent when the primary motor pathway is unavailable. These so-called event-related potentials (ERPs) can be decoded in either single- or multiple-trial (e.g., averaged) paradigms such that a specific selection in a fixed-choice problem can be decoded from the cortical response. While there are many examples of test-retest reliability of ERPs in literature, it is also often reported that these decoders need to be retrained to the fixed-choice problem due to an observed decay in performance, which has sometimes been attributed to the non-stationarity

effect in EEG without direct evidence. There seems to be dissonance between these two findings; if the ERPs can be reliably evoked, then why do the decoders ever need to be retrained? The goal of this work is to observe test-retest reliability of common ERPs used in BCIs in a longitudinal study consisting of weekly sessions spanning approximately 3 months' time. To achieve this, dense-array EEG was recorded from participants while they observed open-loop versions of common ERP-inducing stimuli (both active and reactive) in a within-subjects, repeated measures design. The hypothesis is that that other factors affecting single-trial response data that are not observable in average ERPs over a large number of trials must be affecting the generalization of the decoder, thereby unifying test-retest reliability of ERPs and decoder instability claims. Regarding non-stationary, this hypothesis can be restated by saying that the ERP itself is parametrically stationary, whereas other processes influencing the recorded voltage waveform are driving non-stationarity in the single-trial response. While these factors could be numerous and difficult to control for in well-designed experiments, it is expected that an initial observation of high test-retest reliability for the average ERP is important knowledge with which to begin to realize the possibility of decoder generalization. These findings will significantly contribute to our understanding of the dynamics of the cortical signals being mapped by these decoders and allow for decoder training and validation strategies to be developed from these data in future work.

Title: Deep learning time-resolves fNIRS cortical activation asymmetries during a force tracking task evoking non-stationary haemodynamic responses

Authors: *P. ORTEGA, A. FAISAL;
Computing, Imperial Col., London, United Kingdom

Abstract: Functional near-infrared spectroscopy (fNIRS) is a wearable, non-invasive brain imaging technique that offers a new window for the brain's motor control study in less constrained environments. However, the slow dynamics of the hemodynamic response (HR) and the interference of pulse, breathing and sensor movement artifacts limit our ability to time-

resolve cortical activation differences for different motor behaviors. While standard methods require simplifying assumptions on the HR model and systemic noise interference that do not hold for all experimental conditions, we address the cortical response decoding problem from a data-driven perspective. We propose a convolutional neural network architecture, hemCNN, that learns easy-to-interpret filters in three fNIRS dimensions: oxy/deoxy-hemoglobin, channel and hemisphere. Our architecture is trained to classify fNIRS signals as belonging to left or right-hand use during a 1 Hz paced hand-grip force-tracking task performed by 12 people. Our method resolves per-trial and intra-stimuli hemispheric differences in time under non-stationary conditions for both hands. All tests are conducted in unseen subjects confirming the inter-subject stability of the models. Additionally, recorded systemic signals (breath and pulse) are discarded as sources of information for the classification task, further supporting the functionality of the features. In the oxy/deoxy-hemoglobin dimension, the convolutional filters learn features mostly related to oxy/deoxy-hemoglobin over-crossing points. In the channel and hemisphere dimensions, the convolutional filters reveal an early contralateral activation followed by an ipsilateral activation around central channels. Our approach reduces some unrealistic strong assumptions on the nature of the signal and extracts more suitable features based on the raw data, enabling new findings that support previous evidence from similar but less dynamic tasks that could not be resolved using standard methods. The absence of baseline correction and the invariance of the convolution operation to time translations of our method could help to unlock fNIRS for a variety of real-time and continuous fNIRS streaming tasks with applications from mobile brain imaging to brain-machine interfacing.

Title: A web-based BCI application with interactive customizing tool for severe paralysis patients and their caregivers

Authors: *T. KOMATSU, K. TAKANO, K. NAKAMURA;
Systems Neurosci. Section, Dept. of Rehabil. for Brain Functions, Res. Inst. of Natl. Rehabil. Ctr. for Persons with Disabilities, Tokorozawa, Saitama, Japan

Abstract: We have developed the efficacious brain-computer interface (BCI) system for late-stage amyotrophic lateral sclerosis (ALS) patients including completely locked-in state. The system recorded steady-state visual evoked potentials (SSVEPs) induced by flickering green/blue LEDs using non-invasive solid-gel electrodes. To downsize this, we introduce a web-application approach to the BCI system. This has similar advantages to the traditional modularly configured BCI platform connected by TCP/UDP, except that its GUI is rendered by WebGL on the modern browser rather than the native application. The BCI application server constantly pushes EEG or its classified signals to the browser through WebSocket. Though the original system has kept applicative accuracy for over 27 months, we had to learn a lot through the operation. The optimal content and resolution for the user (ALS patient) and operator (nurse, occupational therapist, home-care worker, etc.) GUIs differed in most cases. Also, the researcher wanted to observe the raw or processed EEG. If a BCI-GUI is provided as a web application, they can use the terminal, even though their personal iOS/Android tablet, without having to install any GUI processes. So our BCI web server provides different URIs to render GUIs for users, operators, researchers and developers. Severe paralysis users were able to call the on-screen functional icons, or large buttons, corresponding to each of the green/blue flickering LEDs as a Yes/No communication board or a remote control switch to kick something APIs. In a progressive paralysis, the number of LEDs that effectively induced SSVEPs tended to decrease with paralysis progresses. For practical use, it is necessary to customize the function and number of LEDs and their state transitions, such as a simple loop or a hierarchical tree structure, in the field. The BCI web server also provides URIs for GUI edit tools that allow general caregivers to resolve these problems as easily as drag and drop. To update and downsize our efficacious SSVEP-based BCI system for late-stage ALS patients, we replace its native GUI application with the web application using WebSocket and WebGL. Severe paralysis users are able to control this with the same input accuracy as the original. Caregivers operate and customize the BCI-GUI for daily communication and kicking environmental APIs well. This source code and architecture will release under a suitable open-license.

Abstract: Persons in the completely locked in state (CLIS) suffering from amyotrophic lateral sclerosis (ALS) are deprived of many Zeitgebers of the circadian rhythm: While cognitively intact, they are completely paralyzed, eyes mostly closed, with artificial ventilation and artificial nutrition, and social communication extremely restricted or absent. Polysomnographic recordings in 8 patients in CLIS however revealed the presence of regular episodes of deep sleep during night time in all patients. It was also possible to distinguish an alpha-like state and a wake-like state. Classification of REM sleep is difficult because of absent eye movements and absent muscular activity. 4 out of 8 patients did not show any sleep spindles. Those who have spindles also show K-complexes and thus regular phases of sleep stage 2. Thus, despite some irregularities we found a surprisingly healthy sleep pattern in these patients concordant with positive quality of life reports.

Title: Hydrophilic conductive sponge electrodes for EEG monitoring

Authors: *A. KRISHNAN, K. ROZYLOWICZ, H. WEIGLE, S. K. KELLY, P. GROVER; Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Objective and Rationale: Despite being almost 100 years old and being widely used clinically, there are several limitations in today's EEG technology, including: (i) a large setup time, about 45 minutes per patient for 16-32 electrodes; (ii) drying of gels which increases electrode-skin impedance, lowering quality of recordings; (iii) sticky gels and electrodes that do not sit well with hair on the scalp. These issues are addressed in this work, where we have developed a novel hydrophilic conductive sponge-based electrode. Current clinical techniques

use a gold cup that holds an electrolytic gel against the scalp to create a low-impedance electrode. A key factor that makes a low impedance bio-signal sensor is the ionic interface between the metal connector and the skin. Sponge electrodes are useful in this regard, and those have been used in neuroscience experiments thus far are non-conductive, and are ineffective when they dry. Clinical settings require long periods of monitoring. Our earlier work [Krishnan et al., EMBC'17] considered the use of conductive polymer materials made of biocompatible polydimethylsiloxane (PDMS), however, these polymers are hydrophobic and do not support an ionic medium for an extended amount of time. To ensure easy application and retention of saline solution in the electrode-interface, we developed a methodology to use a hydrophilic polymer material to create a conductive sponge that ensures that the electrode remains conductive even as it is drying, providing a graceful degradation of impedance which can be rehydrated when required.
Methods and Results: Our conductive sponge material was developed by using a commercial pre-polymer compound of diisocyanate and a polyol. A surfactant was added to allow for water absorption and carbon nanofibers were used for conductivity. On mixing the pre-polymer with water, the curing process results in a foam due to the generation of carbon dioxide. Once cured, the samples were tested for impedance and hydrophilicity. Dry electrode impedance was under 30kΩ (@1kHz) with the time for water absorption at about 20 seconds. On the other hand, damp electrode impedances were under 10kΩ and showed instantaneous water absorption. Usability of the electrodes was tested by performing EEG experiments on humans and we were able to observe alpha wave activity in the brain.
Conclusion: Our hydrophilic conductive sponges provide a low-cost, low-impedance and fast-installation solution for EEG recordings. Additionally, they are non-magnetic and can be used in conjunction with MRIs enabling measurement of brain activity at a high spatial as well as high temporal resolution.

Title: Evidence of latency variation in the P3 speller brain computer interface

Authors: *D. E. THOMPSON[1], M. MOWLA[1], J. E. HUGGINS[2];
[1]Electrical and Computer Engin., Kansas State Univ., Manhattan, KS; [2]Physical Med. and Rehabilitation; Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: The P3 event-related potential is a notoriously variable brain response, yet it has been used successfully for brain-computer interfaces (BCIs) for over thirty years. Our prior investigations [1] indicated a possible causative link between P3 latency jitter and poor BCI performance. That relationship has been investigated by other groups, e.g. [2]. However, some have argued [3] that latency jitter in people with amyotrophic lateral sclerosis (ALS) has yet to be demonstrated.

We approached this question through an offline analysis of an existing dataset of 40 people operating a BCI, 25 men (age: 45±21 years, mean±std.) and 15 women (age: 42±20 years). Of these, 12 had ALS and 6 had muscular dystrophy. We used the first visit by each person, with N>=69 characters.

We added normally-distributed latency jitter to the brain responses. Our method [1] gave an estimate for the endogenous latency. We compared two models for BCI performance, one based on added jitter and one based on the sum of added and endogenous jitter.

As seen in the figure, total estimated jitter has a clear relationship between jitter and performance. Further, the slope from the artificial jitter is nearly equivalent to the slope calculated from between-sentence comparisons of endogenous latency jitter. Taken together, these two pieces of evidence support the claim that our method is measuring endogenous latency jitter.

Title: Assessment of high-frequency and multi-color visual stimulus using dry electrodes for BCI applications

Authors: ***Y.-T. WANG**, S. JENNINGS, R. VIAJAR, M. A. CHEVILLET;
Facebook, Menlo Park, CA

Abstract: Steady-state visual evoked potential (SSVEP) brain-computer interface (BCI) has attracted much attention as it requires less training time and provides a high information transfer rate. However, the use of wet (gel) electrodes and flashing visual stimuli severely limit its relevance to real-world applications. We assessed the feasibility of combining (1) wireless EEG system with dry electrodes, (2) over-critical-fusion-frequency visual stimuli, and (3) training-free decoding algorithms. A customized headband provided partial coverage of the occipital cortex using 6 dry electrodes, and SSVEPs were induced using an iso-luminance visual stimulus consisted of red and green colors flashing at 50 Hz. Finally, two training-free decoding algorithms - canonical correlation analysis (CCA) and filter bank CCA (FBCCA) - were applied to evaluate decoding accuracy.
The study was approved by an external Institutional Review Board, and 20 participants were

provided written informed consent form before the participating. Six dry “Flex” electrodes (Cognionics, Inc.) were positioned over region Oz and data were collected at 500 Hz sampling rate. Ground and reference electrodes were attached on the forehead. Participants were presented with two different visual stimuli: a circle alternating between black and white at 10 Hz, and a circle alternating between red and green at 50 Hz. Both visual stimuli covered ~5 degree field of view, and data were recorded during 2 one-minute sessions for each visual stimulus. Data were epoched into 3-second trials after applying a band-stop filter (59-61 Hz).
Trials with blinks and an absolute value over 25 micro-volts were rejected.
The mean decoding accuracy of black-white stimulus using 3-seconds of SSVEP response time was 0.9739±0.0811 for CCA and 0.9524±0.1129 for FBCCA. In contrast, the mean decoding accuracy of the red-green stimulus using 3-second data was 0.4454±0.1627 for CCA and 0.7507 ± 0.2276 for FBCCA. The difference between CCA and FBCCA was not significant for the black-white 10 Hz stimulus (p= 0.1729), but was significant for the red-green 50 Hz stimulus (p<0.01).
Notably, the decoding accuracy using FBCCA was better than CCA when using more than 1.8 seconds of the SSVEP response. These results suggest that it is feasible to detect SSVEPs using dry electrodes and over-critical-fusion-frequency stimulus, and that FBCCA can improve decoding accuracy in high-frequency SSVEP-based BCI.

Title: Bimodal electroencephalography (EEG) and functional near-infrared spectroscopy (fNIRS) brain-computer interface (BCI) for communication by individuals in completed locked-in state (CLIS)

Authors: *A. JARAMILLO-GONZALEZ[1], A. TONIN[1], M. KHALILI ARDALI[1], A. RANA[1], N. BIRBAUMER[1,2], U. CHAUDHARY[1,2];
[1]Inst. for Med. Psychology and Behavioural Neurobio., Univ. of Tuebingen, Tuebingen, Germany; [2]Wyss-Center for Bio- and Neuro-Engineering, Geneva, Switzerland

Abstract: Individuals in completely locked-in state (CLIS), due to amyotrophic lateral sclerosis (ALS), are left without a means of communication. A recent functional near-infrared spectroscopy (fNIRS) based brain-computer interface (BCI) demonstrated classification of "yes" and "no" answer by individuals in CLIS with up to 70% accuracy. Such a low classification accuracy and high error rate limit the performance of the BCI system. Hence there is a need to explore other approaches to improve the classification and thereby the performance of the BCI system. Several multimodal Brain-Computer Interfaces (BCI) have proven successful in recent years, therefore multimodal BCI that exploit the complementary information from multiple data sources is a potential path for improvement. Here we propose the use of a bimodal EEG-fNIRS hybrid BCI (hBCI), taking advantage of the synergistic effect of both signals, improving the spatiotemporal resolution and increasing the reliability of the engineered features. Available data set of different days and sessions from six individuals in CLIS, recorded with simultaneous 7 EEG and a set of 8 fNIRS source-detectors (20 channels), acquired during a "yes" and "no" questions' paradigm, will be analyzed. A supervised modality integration using 1) General Linear Model (GLM) obtained from extracting EEG features and correlating them with the fNIRS data, and 2) a symmetric approach by analyzing both EEG and fNIRS data series with Mutual Information will be performed. Along with this, an unsupervised approach by means of Principal Component Analysis (PCA) will also be performed. The results obtained from these analyses will be compared to determine the methodology to be implemented to improve the classification of "yes" and "no" answer by individuals in CLIS, thereby improving the performance of the BCI-based communication.

Title: Towards non-invasive decoding of cortical patterns: Goal directed movements, movement trajectories, error potentials, hand movement attempts and artificial sensory feedback in humans

Authors: *G. R. MUELLER-PUTZ, J. PEREIRA, R. KOBLER, C. LOPES DIAS, L. HEHENBERGER, A. SCHWARZ, P. OFNER, A. I. SBURLEA;
Graz Univ. of Technol., Graz, Austria

Abstract: In Europe estimated 300,000 people are suffering from a spinal cord injury (SCI) where 40% are tetraplegics. With the help of motor neuroprostheses (NP), grasping and elbow function can be substantially improved. A natural solution for controlling a robotic arm or a NP would be to record motor commands from the corresponding cortical areas and convert them into control signals with the help of brain-computer interface (BCI) technology [1]. We showed the control of a motor neuroprosthesis in individuals with SCI using electroencephalography (EEG) [2, 3]; however, the control strategy is not yet intuitive enough. The objective of FeelYourReach project is to develop a novel EEG-based control framework that incorporates goal-directed movement intention, movement decoding, error processing and delivery of sensory feedback for a more intuitive control of a robotic arm. Our findings in these areas show that goal-directed movements have different neural correlates than movements that are not directed towards a target [4]. Moreover, we found differences between the neural correlates of externally and internally-driven target selection [5]. Progress was made in the decoding of 2D/3D arm movement trajectories [6]. We also explored the relation between neural, muscle and kinematic correlates of a large variety of hand movements [7]. Next, we showed the asynchronous detection of erroneous potentials in a task that involved continuous control and feedback [8]. During the MoreGrasp project [9], we developed a novel NP which allows an end-user to regain control of the lost hand-function by either using a shoulder position sensor, instrumented objects, the neural correlates of movement attempt, or a combination of them. Currently, a clinical study is ongoing and preliminary results on 15 end users will be shown. Our current findings suggest that with these approaches an end-user will be able to intuitively control a NP with his/her mind only. [1] Müller-Putz et al. Prog in Brain Res 2016 [2] Rupp et al. Title: Relating neural, muscle and kinematic grasping correlates during movement observation and execution

Authors: *A. I. SBURLEA[1], N. BUTTURINI[2], G. R. MUELLER-PUTZ[1];
[1]Inst. of Neural Engineering, TUGraz, Graz, Austria; [2]Univ. of Padova, Padova, Italy

Abstract: Electromyographic and kinematic information have been proposed as candidates for the neural representation of hand control. However, it remains unclear how these movement covariates are reflected in electroencephalographic (EEG) activity during different stages of grasping movements, such as hand-preshaping, reaching the final grasping posture and holding. In this exploratory study, we simultaneously acquired EEG, kinematic and electromyographic signals in 31 human subjects while observing 33 different pictures of hand-object interaction and executing the different types of grasps previously observed. Our study aims were three-fold. First, we investigated the relation between EEG movement covariates and the behavioral covariates associated with the movement execution phase. Using representational similarity analysis, we found that EEG activity reflected different movement covariates in different stages of grasping. During the pre-shaping stage, centro-parietal EEG in the lower beta frequency band reflected the object's shape and size, whereas during the finalization and holding stages, contralateral parietal EEG in the mu frequency band reflected muscle activity. Second, we asked how the EEG patterns of static grasping observation relate with the behavioral covariates of movement execution. We found that the EEG representation of the observation phase in the mu and low beta frequency bands was correlated with the muscle representation during the execution, most strongly in the movement holding phase. This similarity indicates that when visually processing the hand-object interaction, we focus on the final grasping posture. Furthermore, we found that contralateral and central parietal and occipital regions in the mu and beta frequency bands of the EEG representation of movement observation reflected the object's shape and size. Third, we investigated whether the muscle envelope of different grasping movements can be continuously predicted from low frequency EEG amplitudes using a filtering approach. We achieved higher prediction accuracy for intermediate grasps compared to power or precision grasps. These findings contribute to the understanding of the temporal organization of neural grasping patterns, and could inform the design of noninvasive neuroprosthetics and brain-computer interfaces. Moreover, these findings allow us to gain a joint understanding of the relation between movement observation and execution and a mean to facilitate an intuitive control of neuroprostheses in motor impaired individuals.

Title: Using ErrPs to improve continuous BCIs

Authors: *C. LOPES-DIAS, A. I. SBURLEA, G. R. MUELLER-PUTZ;
Inst. of Neural Engin., Graz Univ. of Technol., Graz, Austria

Abstract: Brain-computer interfaces (BCIs) convert brain activity of a user into actions of an external device and are a valuable tool for people with severe motor disabilities. However, BCIs' performance is not optimal and, sometimes, unintended actions are executed.
The recognition that a mistake has been committed is associated with a neural pattern named error-related potential (ErrP). The use of ErrPs is an intuitive strategy to improve BCIs by allowing to identify (and correct) unintended commands.
The existence and detection of ErrPs in discrete BCIs (in which actions occur in a discrete manner) is well established, but BCIs are developing to provide users continuous control. In this situation, the user's awareness that the BCI performed an unintended action can occur at any moment. Therefore, such BCIs require an asynchronous decoding of ErrPs. We try to address the asynchronous decoding of ErrPs during continuous control and feedback.
In our first experiment, the EEG of 15 able-bodied participants was measured while they controlled a cursor on a screen towards a target using a joystick. In 30% of the trials, the participants lost control over the cursor and this deviated into an unintended direction. Evaluating the data offline, in a simulated online scenario, we obtained an average TNR (percentage of correct trials in which no ErrP detection occurred) of 84% and an average TPR (percentage of error trials in which no ErrP detection occurred before the error onset and at least one ErrP detection occurred after the error onset) of 65%.
In our second experiment, we measured the EEG of 15 able-bodied participants while they controlled a robotic arm towards a target using their right hand. In 30% of the calibration trials, the robot made an 'error' during the trajectory and participants lost control over the robot. The experiment was divided in calibration and testing phases. The calibration phase was used to train an ErrP classifier. In the testing (online) phase, participants could regain the robot's control if an ErrP was detected after the error occurred. In the testing phase, we obtained an average TNR of 87% and an average TPR of 70%.
We also investigated the use of generic ErrP classifiers. For that, we used the calibration data from our second experiment and tested the performance of generic classifiers (trained with the data of 14 participants and tested in the remaining participant). We obtained an average TNR of 82% and an average TPR of 54%.
These results indicate that asynchronous detection of ErrPs is reliable even in an online scenario and that a generic classifier could be used as a strategy to eliminate calibration, serving as a starting point for an adaptive classifier.

Title: Visuo-spatial complexity and object-relatedness impact brain activity during motor imagery

Authors: *S. C. WRIESSNEGGER, J. PEREIRA, A. SCHWARZ, G. MUELLER-PUTZ; Inst. of Neural Engin., Graz Univ. of Technol., Graz, Austria

Abstract: Motor Imagery (MI) is a task which has been used for driving brain plasticity and motor learning in several fields including sports, motor rehabilitation and brain-computer interface (BCI) research. In the past, many studies have shown that changes in brain activity associated with MI can serve as useful control signals for BCIs. Most studies focus on improving signal processing feature extraction and classification methods, but the performance of a BCI can also be improved by optimizing the user's control strategies. That is, using more vivid and engaging mental tasks for control instead of simple hand/finger tapping tasks. We performed several neuroimaging studies measuring electrical and hemodynamic brain activity during different types of MI. We investigated imagining a more complex action, such as playing tennis or football, which incorporates not only motor-related processing but also visuo-spatial imagery which is refelected in fronto-parietal network activation [1]. In another study using functional near infrared spectroscopy (fNIRS) we investigated MI including emotion-laden objects. Twenty right-handed healthy participants performed motor imagery of squeezing different types of affective objects, like a sticky ball, a cactus or a rotten apple. The results showed that affective MI compared to neutral MI lead to increased oxy-hemoglobin [oxy-Hb] concentration changes. Brain regions located contralateral frontal and also parietal show higher [oxy-Hb] increases [2]. A follow up study with the same paradigm but by means of electroencephalography (EEG) was performed with 15 right-handed healthy participants. We found a stronger left parietal event related desynchronization [ERD] during the imagery of squeezing a cactus in the beta frequency band. Summarizing, our studies indicated a more distinctive brain activity in a broader network of brain areas during the performance of more complex MI tasks when compared to simple tasks. Therefore we surmise that visuo-spatial cognition and action affordances play a significant role in MI eliciting distinctive brain patterns suggested to improve the performance of future BCI systems.

Title: Investigating goal-directed movement planning and intention using electroencephalography

Authors: *J. PEREIRA, A. I. SBURLEA, P. OFNER, A. SCHWARZ, G. MÜLLER-PUTZ; Graz Univ. of Technol., Graz, Austria

Abstract: Investigating the neural correlates of goal-directed actions, including the movement planning phase, is of interest for the development of brain-computer interfaces (BCIs) for control. We use electroencephalography (EEG) to study several aspects of movement planning in execution (ME) and imagination (MI) tasks in subjects without motor disabilities, as first steps towards intuitive BCIs for people with upper-limb motor impairments. In a first study (n=10), we investigated whether the presence of a motor goal could influence the classification performance (of ME vs. rest) during a reach-and-touch task [1]. We show that movement-related cortical potentials (MRCPs) on the goal-directed condition differ from those of the non-goal-directed condition. Moreover, we show that low-frequency time-domain EEG features are suitable for classification of movement intention, and that the classification performance is affected by the goal-directedness of the movement. Highest accuracies are achieved on the goal-directed condition (accuracy=79%), rising above chance-level before movement onset for all subjects (and for 6 subjects on the non-goal-directed condition). The classifier patterns attributed these differences to premotor and primary motor areas, as well as to the posterior parietal cortex. On a second study (n=15), we focused on the goal-directed MI of a grasp, to study the differences between externally-cued or internally-driven target selection processes - which are related to the definition of the motor goal itself [2]. For that purpose, we developed a paradigm that allowed the separation between target selection and the actual MI. We found out that the late event-related cortical potentials encode differences between both conditions - which reflect the perceptual and cognitive processes prior to the MI. Additionally, we could estimate a reliable MI

onset that enabled us to train for the first time a classifier of self-paced MI vs. rest, leading to an offline performance significantly higher than chance-level for both time-locked and asynchronous classification scenarios. We believe that these findings contribute to the development of intuitive BCIs in which movement targets are defined internally and the goal-directed movements are self-paced.

Abstract: Electroencephalographic (EEG) and magnetoencephalographic (MEG) signals carry information about upper-limb kinematics. Their expression in M/EEG signals is potentially influenced by many factors. We believe that vision and movement type (i.e., discrete vs continuous) are key factors. To identify their effects, we investigated visuomotor tasks in several studies.
In a first EEG study (15 healthy subjects), we investigated the influence of vision during goal-directed upper-limb movements [1]. Our paradigm implemented a center-out task (COT) followed by a pursuit tracking task (PTT). It involved two visual stimuli (target and cursor) in two conditions. In one condition (exe), subjects controlled the cursor with their right hand. In the second condition (obs), subjects observed a computer controlled cursor. Regarding the PTT, our findings indicate that premotor and primary sensorimotor areas carried significant information

about cursor velocity in the exe condition, whereas parieto-occipital areas carried significant directional information in either condition. Regarding the COT, we could classify condition (exe vs obs) and direction (left, up, right and down) above significance level. The two classifiers relied on different cortical areas. Contra-lateral pre- and primary motor areas predicted condition, while parieto-occipital areas predicted direction in both conditions.
In a second EEG study (10 healthy subjects), we investigated how the results of the PTT translate to an online control scenario. In both conditions (hand movement based control, EEG based control) the kinematics could be decoded above the significance level, with parieto-occipital areas carrying significant information about end-effector velocity. We observed an amplitude-scaling mismatch between the decoded and actual kinematics, which resulted in declined tracking quality in the EEG based control condition.
To address the amplitude-scaling mismatch, we conducted an MEG study (20 healthy subjects), where we investigated a similar PTT as in the first EEG study. In this study, the subjects controlled the cursor with their right index finger [2]. We found that the MEG signals carried not only significant information about velocity, but also about speed in primary-sensorimotor areas. We believe that our findings can aid to a new generation of non-invasive brain-computer interfaces.

Title: Low impedance, low cost electrodes for long-term electroencephalography and non-invasive electrical brain stimulation

Authors: *N. VYSOKOV[1], I. TARASENKO[1], A. TARASENKO[2], M. OGANESYAN[1]; [1]BrainPatch, London, United Kingdom; [2]Univ. Col. London, London, United Kingdom

Abstract: Combining non-invasive recording of electrical brain activity (electroencephalography or EEG) with non-invasive electrical brain stimulation (NIBS) is a challenge in many aspects. Currently electrodes suitable for EEG and NIBS require cumbersome procedures of gel or special paste application prior to the electrode set up; saline-soaked sponges may also be used but their EEG performance may be inconsistent.
We have developed electrodes that can be used for EEG recordings as well as for NIBS; below we present the results of the tests performed. The electrode assembly consists of a layer of

medical-grade highly absorbent foam saturated with saline solution, and a thin interface of conductive material, all held together by soft non-conductive polymer that prevents leakage and evaporation (A). Thus, when the electrodes come in contact with the scalp or hair, the liquid interface is created which in turn results in the electrode impedance in the sub 5 kOhm range over the forehead (Fp1-Fp2) and over the hair (T3-T4). Due such low impedance we could obtain high signal-to-noise ratio for EEG recordings over a period of at least 2 hours (C). The data acquired is of sufficient quality to detect changes in conventional parameters (e.g. see alpha waves in panel C), but also for processing by more sophisticated machine learning algorithms. The observed change in impedance was in the range of +/- 10%, the quality of the recorded signal was comparable and voltage (4.5-6 V) required to reach the same current (1 mA) for tDCS/tACS didn't differ significantly.

Most importantly, these electrodes can be used in a headband so that they are easy to apply (B), do not cause discomfort and are relatively inexpensive. This makes them potentially suitable for a wide variety of clinical and medical applications as well as home use. The ability to record EEG and deliver the stimulation without the need to change the electrode set up opens up the potential avenues for further research on closed-loop electrical NIBS.

Title: Open Phantom: A freely available phantom device for use in EEG testing and validation

Authors: A. B. YU[1], S. E. BOTTOMLEY[1], C. G. SINKS[2], M. W. NONTE[3,1], ***W. HAIRSTON**[4];

Abstract: Despite electroencephalography (EEG) being commonly used for decades in medicine and as the basis for a myriad of neuroimaging research, the EEG community as a whole has yet to adopt a single device or approach for calibrating and validating EEG data acquisition equipment or related algorithms. While so-called phantom devices are used in MRI, CT, PET, and other imaging devices for testing and calibration, to date no such device has been widely adopted for EEG. To be useful, such a device would need to be (1) electrically conductive in a manner roughly analogous to the human scalp, (2) consistent and predictable, and (3) relatively cost-effective in order to be accessible across the community. A major challenge to all three of these has been finding a suitable material which can satisfy all of these needs. We propose that a suitable phantom head device can be easily fabricated using ballistics or similar gelatins, in order to meet all of the above criteria (inexpensive, easy to mold, and has conductively tunable). Here, we discuss an ongoing project developing such phantoms, their general design, and suitability for different applications, with designs that are freely available. An MRI was used to create a realistic size/shape head model, which was then used to design an inverse mold based on pouring gelatinous fluid in from the top. In one design, the internal brain capsule contains multiple internal dipole sources, while another uses a rigid skull formation to simulate the rigidity and poor conductivity of skull. Designs can be 3-D printed and easily fabricated within a day, and researchers are invited to modify designs and provide their own modifications back to the community. Once fabricated, phantoms can be used for a variety of applications, with differing designs specific to each. For example, models can be used for characterizing the size and origin of motion-related artifacts in EEG, testing the efficacy of different noise removal techniques, evaluating the SNR of different electrodes or other DAQ approaches, or even predicting the noise associated with a particular environment.

Title: Fabrication of tunable electrical skull phantom from carbon nanofiber-doped PDMS

Authors: T. X. CAI[1], ***M. FORSSELL**[2], A. KRISHNAN[2], J. W. REDDY[2], P. GROVER[2], M. CHAMANZAR[2];
[1]Biomed. Engin., [2]Electrical and Computer Engin., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Objective:
Novel neural stimulation and recording techniques can be better developed and validated on tissue phantoms that mimic specific properties of brain tissue, scalp and skull. The properties of these artificial samples can sometimes more accurately match live tissue, and offer better control, than excised biological samples, enabling calibration of stimulation and recording techniques under different conditions. The electrical properties of the brain are often approximated by saline solutions and agar gels. However, investigations on transcranial brain interfacing also benefit from the use of skull phantoms, for which no standard exists. The study presented here reports a versatile method to fabricate skull-like electrical phantoms using carbon nanofiber (CNF)-doped polydimethylsiloxane (PDMS).

Methods and results:
The skull phantom must have low conductivity matching that of the skull, which ranges from 10 to 100 mS/m. In order to be used in electrophysiological experiments, e.g. to test or study noninvasive techniques, the skull phantom must also be biocompatible as well as stable in contact with cerebrospinal fluid (CSF). Agar-based tissue phantoms absorb water and ions, resulting in variable conductivities that change over time.
Conductive PDMS phantoms can be fabricated by mixing conductive particles with the monomer before curing. However, clustering leads to an inhomogeneous material in which the overall conductivity is dominated by low conductivity regions, in particular for samples in which the overall conductivity is low. Our method consists of incorporating CNFs (PR-24-XT-HHT, Pyrograph) into the PDMS matrix before curing. The CNF is first dispersed in isopropyl alcohol (IPA), then mixed with methyl-terminated PDMS monomer before mixing with a regular PDMS monomer (Sylgard 184, Dow Corning). The methyl-termination aligns the CNFs and results in a greater homogeneity of the CNF dispersion, and therefore a greater homogeneity of the conductivity in the sample. After sonication, the solvent is evaporated and then the CNF-PDMS sample is cured.
Conclusion:
The resistivity of the samples is characterized as a function of the mixing ratio of CNF in PDMS, displaying an inverse relationship. A resistivity of 12Ωm is obtained at 1.7% CNF in weight. The degree of homogeneity of the phantoms is characterized by fabricating 1 cm-thick samples and measuring the conductivity of individual 1 mm-thick slices. Edge effects result in lower conductivity along the top and bottom of the sample, as expected. At depths between 3 mm and 9 mm, the conductivity is measured to be 12.3±3.5 Ωm (n=17 slices over 3 samples).

Title: A computational framework for the Argus II implant: Factors influencing neural activation volume

Authors: *K. E. FINN[1], H. J. ZANDER[1], S. F. LEMPKA[2], J. D. WEILAND[3];
[1]Biomed. Engin., [2]Biomed. Engineering, Anesthesiol., [3]Biomed. Engineering, Ophthalmology and Visual Sci., Univ. of Michigan, Ann Arbor, MI

Abstract: Electrical stimulation of retinal tissue via the Argus II implant induces visual percepts in blind people. Percepts are consistent trial to trial for single electrodes but vary across subjects and electrodes (Luo 2016). We hypothesize that computational models can predict variation caused by device placement and disease progression. Previous models have neglected these effects, simplifying the retina as a slab of homogenous tissue and using an idealized microelectrode array (MEA) at uniform distance from the retina (Loizos 2018, Esler 2018, Abramian 2015). The purpose of this exploratory research was to quantify the benefit of an anatomically accurate eye model with realistic implant placement.
We created a 3D COMSOL model to integrate eye shape, electrode array curvature and device position in and around the eye. Based on the physical model of device and eye, we generated finite element electric field solutions. For comparison, we implemented a simple literature-based model with an idealized ground and MEA, using the same tissue thicknesses, conductivities, and electrode size. Neural activation volume was defined as retinal tissue exceeding a certain voltage during an applied stimulus. The voltage threshold (13 mV) was found using a biophysical retinal ganglion cell model and standard pulse (biphasic, 0.45 msec, 20 Hz) (Fohlmeister 1997). We applied current in the clinical range (0-100 µA) to single electrodes and quantified neural activation volume in mm^3. Higher activation volume implies larger visual percepts.
Results for both models are shown below. All electrodes in the simple model activated equal volume, which increased linearly with current. The new model had great activation volume at currents above 70 µA and up to 24% variation between electrodes. Our results suggest that curvature dependent electrode-retina distance, implant details, and ground position have substantial effects on electric field shape. Including these factors represents an improvement over previous retinal stimulation models.

Title: Studying the effect of order and duration ratio of pulse polarities on perception thresholds with Argus II retinal prosthesis

Authors: *D. HAJI GHAFFARI[1], K. E. FINN[1], V. E. JEGANATHAN[1], J. D. WEILAND[1,2]; [1]Biomed. Engin., [2]Ophthalmology, Univ. of Michigan, Ann Arbor, MI

Abstract: Retinal prosthetic implants have helped improve vision in blind patients with retinitis pigmentosa (RP) and age-related macular degeneration (AMD), two of the common retinal diseases that lead to loss of photoreceptors and eventual blindness. Although patients with retinal implants have reported improvement in light perception and performing visual tasks, their ability to perceive shapes and letters is currently limited due to the low precision of retinal activation. A clinical trial reported that among 30 implanted patients, about half of the electrodes have thresholds above the acute stimulation safety limit. To allow safe stimulation, such electrodes are used in unison with neighboring electrodes, effectively creating a larger electrode, which further decreases the resolution. Thus, threshold reduction remains an important topic.
A previous *in vitro* mouse retina study in our lab (Chang et al. 2018) used calcium imaging to measure responses to electrical stimulation. Based on this study, we hypothesize that asymmetric anodic-first stimulation with duration ratios greater than 10 reduces the retinal ganglion cell (RGC) activation threshold, versus a standard cathodic-first biphasic pulse. Patch clamp recordings of RGCs verified this result. We are currently performing human subjects testing to further examine the effect of asymmetric anodic-first pulses on perception thresholds. In one Argus II retinal prosthesis subject, we measured responses to asymmetric anodic-first (AAF), symmetric cathodic-first (CF), symmetric anodic-first (AF), and symmetric cathodic-first stimulation with an interphase gap (ICF).
Subject 1 demonstrated a significant increase in perception probability with AAF pulses of 0.07, 0.1, and 0.2 ms duration compared to CF and AF, with an average increase of 94.07 % and 94.17 % respectively. Perception probability for the AAF decreased after adding a ICF with an interphase gap of 1.01 ms to the trial. ICF resulted in a perception probability 35% greater than that of the AAF, indicating that the ICF is either more effective than the AAF in decreasing perception thresholds or it results in brighter phosphenes. Post-test interview revealed that this

subject's criteria for perception was to only report the brightest percepts. The subject had few false positives, but likely underreported dim percepts. Thus, the percentages above are interpreted as indicating relative brightness amongst different stimulus types. The qualitative results from this subject are consistent with measurements from *in vitro* mouse retina.

Abstract: Electrical stimulation of visual cortex produces perception of small flashes of light known as phosphenes. It has long been recognized that this could provide the basis for a visual cortical prosthesis, a device that could restore partial vision to blind subjects. Currently, an early feasibility trial is underway for the Orion Visual Cortical Prosthesis produced by Second Sight Medical Products. The device includes a camera, a visual processing unit, a transmitter, wireless transmission of signals to an implanted receiving coil, and an array of 60 cortical surface electrodes. The array is placed over the primary visual cortex and surrounding areas. This device has been implanted in four subjects at UCLA and two at BCM. In this abstract, we report on initial results from the two subjects at BCM. Subject 1 (M; age 34; age at onset of blindness 9) was implanted ~1 year ago. Initial testing was conducted by using a laptop computer rather than the camera to drive electrical stimulation (direct mode). After implantation, 58 electrodes were available for electrical stimulation, and 58 produced phosphenes when stimulated with currents <7.5 mA at 20 Hz (threshold = 4.95 +/- 1.14 mA, mean +/- stdev). Following this initial testing phase, the system was then connected to the camera (video mode). Using the system in video mode, the subject could perform a square localization task on a computer touchscreen with high

accuracy (mean error with system on = 3.2 cm, mean error with system off = 12.3 cm). In addition, the subject could locate items placed on a table in front of him, and could use the system for basic navigation tasks, for example to find hallways within buildings, or to identify sidewalks. Subject 2 (M; age 57; age at onset of blindness 45) has been implanted for ~4 months. After surgery 59 electrodes were available for electrical stimulation, and 55 produced phosphenes when stimulated with <7.5 mA (mean threshold 3.71 +/- 1.19 mA). We obtained highly reliable phosphene mapping in this subject, and he is in the process of video mode testing at this time. At the meeting we will present quantitative data from visual function testing of both subjects, and videos demonstrating the performance of the subjects in visually guided behaviors.

Title: Early feasibility study for the Orion cortical visual cortical prosthesis: From thresholds to visual function

Authors: ***U. K. PATEL**[1], M. ARMENTA SALAS[1], S. NIKETEGHAD[2], W. H. BOSKING[3], V. WUYYURU[1], M. P. BARRY[1], D. YOSHOR[3], J. D. DORN[1], N. POURATIAN[2]; [1]Second Sight Med. Products, Inc., Sylmar, CA; [2]Dept. of Neurosurg., UCLA, Los Angeles, CA; [3]Dept. of Neurosurg., Baylor Col. of Med., Houston, TX

Abstract: Stimulation of human visual cortex is known to elicit visual perceptions that could potentially be used for creating artificial vision for individuals who have lost their vision due to non-cortical etiologies. Although there have been attempts to build brain stimulators for the

visual cortex in the past, fully implanted, chronic cortical visual prostheses have remained theoretical until recently. The Orion Visual Cortical Prosthesis System, which is currently being tested in a five-year early feasibility study (NCT03344848), is a new device that is intended to restore some functional vision to blind patients. There are currently six subjects enrolled between two study centers. Average age at time of implant was 50.3 years. All subjects had bare or no light perception due to non-cortical etiology at the time of implant, but were previously sighted. The Orion System comprises an implant (consisting of an electronics package, receiving antenna, and an electrode array with 60 non-penetrating electrodes with 2mm diameter); glasses with a video camera; headwear containing a transmitting antenna; and a video processing unit (VPU). The video camera collects real-time visual information, which is then processed by the VPU and converted to stimulation patterns on the electrode array. The Orion implant drives each electrode with current-controlled, charge-balanced square waves. A radio frequency link between the transmitting and receiving antenna sends data and power to the implant.
Phosphene thresholds are a primary input to the individualized program that converts visual information into stimulation patterns. Bounded by device capability and safety limits, thresholds were found for over 97% of electrodes. Average thresholds ranged from 1.6 mA - 3.7 mA across subjects at first measurement and were mostly stable over time. The interplay among threshold results, waveform parameters, and safety and performance constraints of the implant will be discussed with regards to strategies for stimulation of real-time visual information. As of May 1, 2019, average implant duration was 11.1 months (range 3.4 - 15.0 months). One serious adverse device event (seizure) has been reported. At six months post-implant, 3 of 5 subjects performed significantly better with the system on than off on a light localization task; 2 subjects performed better on a direction of motion task, and no subjects had measurable visual acuity. All 5 subjects were rated as receiving “positive” or “mild positive” benefit on a functional vision assessment.

Title: Reliable shifts in phosphene location achieved using current steering in human visual cortex

Authors: *D. OSWALT[1], W. H. BOSKING[2], P. SUN[2], U. K. PATEL[4], M. ARMENTA SALAS[5], J. D. DORN[6], B. L. FOSTER[2], M. BEAUCHAMP[3], D. YOSHOR[7];

Abstract: Electrical stimulation of early visual cortex is known to elicit visual percepts called phosphenes that can be localized in visual field space to the corresponding part of the retinotopic map. Cortical visual prosthetic devices (CVPs) attempt to use the reliability of spatial relationships between many phosphenes to evoke visual patterns, with more complex patterns theoretically feasible as the number of electrodes increases. While novel phosphene locations have traditionally been limited to the number of electrodes present in cortex, this study proposes creation of virtual electrodes through current steering paradigms to evoke phosphenes in locations distinct from the physical electrode. Current steering uses parallel stimulation on nearby electrodes; the location of a virtual electrode is modulated by the ratio of current applied to each electrode in the pair. This technique has been used in cochlear and retinal implants to improve resolution, but has previously not been evaluated in cortex.Static current steering paradigms were evaluated in one sighted subject (sub1) undergoing clinical epilepsy monitoring and one blind subject (sub2) enrolled in an early feasibility study for a CVP system (NCT03344848). Subjects were asked to fixate during stimulation then indicate phosphene location on a touch screen monitor. Sets of trials with randomized presentation of fixed and virtual electrodes were conducted. In a condition with two fixed and one virtual electrode, each subject reported three phosphene locations. Sub1 reported phosphenes in an intermediary location an average 2.77 deg from either fixed electrode (4.9 deg separation). Sub2 reported an intermediary phosphene location 3.3 deg from fixed electrodes 5.4 deg apart. In a condition with two virtual electrodes, sub2 responded with four phosphene clusters, with an average shift of 2.7 deg between cluster centers, fixed electrodes spaced 6.9 deg.Current steering was also tested with a dynamic stimulation protocol, whereby current was applied in rapid succession at varied ratios to create three virtual locations in addition to the two fixed. Sub2 reported five

phosphenes, with cluster centers shifting an average 1.5±0.4 deg, fixed electrodes spaced 5.5 deg.In each condition phosphene locations reliably shifted with the ratio of applied current. These experiments demonstrate current steering as an effective means to introduce phosphene locations distinct from those generated with physical electrodes. The use of virtual electrode may improve device resolution in a step towards creating more coherent visual sensations and directly translate to improved functional outcomes of CVPs and other BCIs.

Abstract: Pioneering work by Dobelle et al (1974) provided key evidence for restoring some artificial vision through cortically-implanted prosthetic devices. Regardless of recent advancements with human BMI systems (Hochberg, 2012; Aflalo, 2015), few have involved sensory areas, specifically cortical areas related to primary visual function (Artificial Vision, 2017). We are interested in developing a cortical prosthetic system that restores a level of artificial functional vision to people living with blindness. To this end, Second Sight is

conducting an Early Feasibility Study with the Orion™ System, a cortical vision prosthesis, at two different clinical sites. The study's primary goal is to demonstrate the safety of the device, and one of its research objectives is to characterize the phosphenes generated with the system. As part of the study, we recruited six subjects who are bilaterally blind with bare or no light perception, due to a non-cortical etiology. A pre-implantation MRI and a post-implantation CT were collected for all subjects. The MRI and CT images were co-registered using tools from FSL (FMRIB Analysis Group, 2019), the electrode locations were determined using image thresholding with MRICron software (NITRC, 2019) and tools from iElectrodes software (Blenkmann et al, 2017). Using the estimated electrode locations, and a recent area and map location template from sighted subjects (Benson et al, 2014), we estimated where the phosphenes would be perceived in each subject's visual field. After initial threshold assessment across the array, we collected empirical spatial map (i.e. phosphene location) data from single electrode stimulation. The spatial data were captured for five of the subjects, across different sessions. When compared against the predicted locations, the subject's responses differed on average 40° (s.d. 6°) in polar angle, and 17° (s.d. 5.7°) in eccentricity, across all tested electrodes. Moreover, we observed that for several electrodes the reported empirical locations followed well the predicted distributions. We have also conducted an initial exploration of shape and size of the phosphenes, finding that for most of the subjects the larger size phosphenes correlate to more eccentric locations. These first assessments provide key insights to understanding the quality and reliability of the visual information we can provide with the current system, and its future functionality.
