Abstract: Background: Frontotemporal lobar degeneration of the tau form (FTLD-tau) is a neurodegenerative disease that leads to different dementia syndromes. For example, primary progressive aphasia (PPA) is characterized by an isolated and progressive impairment of language, and focal atrophy of left-hemispheric regions. In contrast, behavioral variant of frontotemporal dementia (bvFTD) is characterized by progressive dysfunction in personality, and atrophy in bilateral frontal regions. Interestingly, both PPA and bvFTD can be causeed by th common 3R FTLD-tauopathy of Pick's disease (PiD). This stereological study investigated the cortical distribution of Pick bodies in bvFTD and PPA to establish clinicopathologic concordance between Pick's disease and the salience of the aphasic versus behavioral phenotype.
Methods: 12 right-handed cases with PiD as the sole pathologic diagnosis were identified from the Northwestern University Alzheimer's Disease Center brain bank (bvFTD, N=6; PPA, N=6). Paraffin-embedded sections were stained immunohistochemically with AT-8 to visualize Pick bodies. Unbiased stereological analysis (MicroBrightField, MBF Bioscience) was performed on all 12 cases in 3 regions bilaterally [middle frontal gyrus (MFG), inferior parietal lobule (IPL), superior temporal gyrus (STG)] and unilaterally in occipital cortex (OCC). Bilateral anterior temporal lobe (ATL) was analyzed in PPA cases only. Paired t-tests and one-way nonparametric ANOVAs were used to compare regional and hemispheric distribution within and between groups.
Results: Highest densities of Pick bodies were found in ATL (M=31,634; SD=10,502) in PPA, whereas peak densities were evident in the MFG (M=26,036; SD=8,719) in bvFTD. In PPA cases, there was leftward asymmetry of Pick bodies in MFG, IPL, and STG, the latter of which reached statistical significance ($p<0.05$; L>R). Interestingly, the ATL showed slight rightward predominance. Cortical distributions of Pick bodies in bvFTD were generally symmetric. As expected, the occipital cortex showed extremely sparse to no pathology in both groups.
Conclusions: Stereological quantitation confirms that the distribution of Pick body pathology is concordant with salient clinical features unique to PPA vs bvFTD. In bvFTD, Pick bodies were symmetric and highest in MFG, a region implicated in behavior/comportment, while in PPA, Pick bodies showed leftward asymmetry consistent with the aphasic phenotype. The vulnerability of the ATL to Pick's disease is remarkable, raising future questions about its functional significance within the human language network and the relationship of tau pathology to neuronal degeneration.

Title: Caspase-dependent tau cleavage as a pathogenic mechanism in Alzheimer's disease

Authors: *C. K. OPLAND[1], S. SINGH[2], Y. CHEN[3], X. TIAN[3], J.-H. TSENG[1], R. MEEKER[3], T. J. COHEN[3];

Abstract: With an estimated 5.8 million Americans affected and the sixth leading cause of death in the United States, Alzheimer’s disease (AD) is a neurodegenerative disease associated with extracellular amyloid beta plaques and intracellular accumulation of tau protein leading to pathological neurofibrillary tangles. Normally, in a healthy individual, tau is a microtubule-associated protein that stabilizes axonal microtubules in neurons. However, in an AD diseased neuron, tau collapses into twisted strands to form tangles correlated with neuronal degeneration. Tau undergoes many different post-translational modifications (PTMs), however, these modifications are still poorly understood on how they contribute to tau pathogenesis in AD. Tau cleavage by caspases, is believed to be an early toxic modification that precedes other later pathological modifications and drive neuronal degeneration found in human AD brain. Although the mechanism of tau cleavage and its role in Alzheimer’s disease is unclear, a current model suggests that tau is cleaved by caspase-3 at the C-terminus where it then changes tau’s conformation to generate a disease-associated species. With few reliable model systems with which to study this process, our lab has discovered that proteasome defects result in caspase-3 activation resulting in robust tau cleavage. In the absence of caspase-3 in neurons, tau cleavage is no longer produced suggesting that caspase-3 is the main component driving tau cleavage. As it is still unclear where and how tau is cleaved in the neuron, I observed both cleaved tau and caspase-3 enrichment at the post-synaptic density (PSD) where toxic tau species may be causing further damage resulting in neuronal network dysfunction. Forced expression of a cleaved tau species in neurons allowed us to further characterize the extent to which cleaved tau results in neuronal toxicity. Our study suggests that proteasome deficiency and subsequent accumulation of cleaved tau is a pathogenic mechanism that incites neurodegeneration in AD and likely other tauopathies as well.

Title: Locus coeruleus degeneration is related to pathologic stages of progressive supranuclear palsy and predicts laminar distributions of tau pathology

Authors: *D. T. OHM[1], C. PETERSON[1], S. AREZOUMANDAN[1], W. TROTMAN[1], E. XIE[1], C. MCMILLAN[1], D. WOLK[1], J. Q. TROJANOWSKI[2], E. B. LEE[2], M. GROSSMAN[1], D. IRWIN[1];

Abstract: The locus coeruleus (LC) sends widespread projections to the isocortex that result in a high density of noradrenergic fibers across cortical layers, especially infragranular layers in select regions. We recently demonstrated that LC degeneration is prominent among all tauopathies, including progressive supranuclear palsy (PSP). However, it is not clear whether LC degeneration increases with PSP stages and contributes to laminar distributions of pathology across heterogeneous isocortex. Here, we tested the hypothesis that LC degeneration worsens with increasing pathologic stages of PSP and is related to unique laminar distributions of tau pathology measured in up to ten isocortical regions. We digitally quantified neuromelanin content to measure the severity of LC degeneration in 19 cognitively unimpaired healthy controls (HC) and 44 PSP patients pathologically staged according to Kovacs et al. published criteria. In a subgroup of staged PSP patients (n=21) with available cortical tissue for laminar analyses, we measured the percent area occupied by AT8-immunoreactive tau pathology in supragranular (I-III) and infragranular (IV-VI) layers and calculated a ratio of supragranular-to-infragranular tau burden per region. Mann-Whitney U analyses compared LC degeneration between PSP stages and HC. Linear regressions adjusted for age and disease duration determined the association between LC degeneration and layer ratios of tau burden. We found severe LC degeneration in advanced stages of PSP that was greater than LC degeneration measured in HC ($Z=-4$, $p<0.001$) and early PSP stages ($Z=-2$, $p=0.04$). Less severe LC degeneration (found in early PSP stages) was associated with an infragranular-dominant profile of tau pathology, while more severe LC degeneration (found in later PSP stages) was associated with a more bilaminar to supragranular-dominant profile of tau pathology ($\beta=0.33$; $p<0.02$). Regional analyses showed that these relationships were evident among association regions ($\beta=0.53$; $p=0.004$) and temporo-occipital regions with mild pathology involved later in PSP progression ($\beta=0.54$; $p=0.007$). However, these relationships were not found in earlier-involved paralimbic and primary motor regions with severe pathology ($\beta=-0.07$; $p=0.76$). These findings suggest that the LC progressively degenerates with advancing pathologic stages of PSP. Furthermore, increasing LC degeneration was associated with more tau pathology accumulation in both infra- and supragranular layers. Therefore, LC degeneration may play a central role in trans-synaptic propagation of tau pathology into cortical regions and potentially between cortical layers in PSP.

Title: Characterization of distinct neuropsychiatric trajectories in FTLD-tauopathies

Authors: *R. KESZYCKI[1,2], A. KAWLES[1], G. MINOGUE[1], N. GILL[1,3], S. JUTHAPAN[1], C. NASSIF[1,2], M. RILEY[1], C. COVENTRY[1], H. ZHANG[1,3], E. ROGALSKI[1], S. WEINTRAUB[1,2], M. M. MESULAM[1], C. GEULA[1], T. GEFEN[1,2];
[1]Mesulam Ctr. for Cognitive Neurol. & Alzheimer's Dis., [2]Dept. of Psychiatry and Behavioral Sci., [3]Dept. of Preventative Med., Northwestern Univ., Chicago, IL

Abstract: Introduction: Frontotemporal lobar degeneration (FTLD) is a neurodegenerative disease commonly caused by 3R (Pick's disease, "PiD") or 4R tauopathies (corticobasal degeneration, "CBD" and progressive supranuclear palsy, "PSP"). FTLD-tauopathies can lead to language decline in primary progressive aphasia (PPA) or comportmental changes in behavioral variant frontotemporal dementia (bvFTD). Patients diagnosed with these distinct dementias often develop debilitating neuropsychiatric symptoms (NPS) over time. This study examined NPS in PiD, PSP, and CBD early and late in the disease course, as well as their change over time, in participants with PPA or bvFTD.
Methods: Fifty-one participants with clinical diagnoses of PPA (N=26) or bvFTD (N=25) and autopsy-confirmed PiD (N=17), PSP (N=14), or CBD (N=20) were identified from the Mesulam Center for Cognitive Neurology and Alzheimer's Disease research programs. NPS (total=12) were examined at initial and final visit (M=0.76 years before death; SD=0.72) with the Neuropsychiatric Inventory—Questionnaire (NPI-Q) and placed into 3 domains based on co-occurrence: 1) *Frontal/Comportmental* (apathy, disinhibition, motor disturbance, and appetite change), 2) *Affective* (depression, anxiety, elation, and irritability), and 3) *Disruptive/Psychotic* (delusions, hallucinations, agitation, and nighttime behaviors). Linear and logistic regressions controlling for disease duration and dementia severity (CDR global score) were used to compare group differences in average percentage of *total* and *domain-specific* symptoms endorsed at initial and final evaluation between PiD, PSP, and CBD with PPA or bvFTD.
Results: Across all participants with FTLD-tau, the most common symptom at initial presentation was irritability (47%) whereas apathy (67%) predominantly emerged at final evaluation. Psychosis (e.g., hallucinations) was nearly absent at both timepoints, ranging from 0-5%. Total NPS increased in CBD and PiD over time (by ~11%) and was driven by high endorsement of *Frontal/Comportmental* symptoms; compared to CBD and PiD, total symptom endorsement in PSP remained relatively stable ($p<0.01$). Regardless of pathology, *Frontal/Comportmental* symptoms increased in both bvFTD and PPA over time, but the magnitude of this was significantly higher in PPA (by ~25%; $p<0.05$).

Conclusions: FTLD-tauopathies can present with distinct neuropsychiatric phenotypes. PPA and bvFTD, though clinically distinct at onset, appear to converge in their neuropsychiatric presentations close to death. Findings highlight the prognostic value of identifying and monitoring NPS in non-amnestic neurodegenerative dementias.

Title: Differential Vulnerability of the Dentate Gyrus to Tauopathies in Aphasic Dementia

Authors: *A. KAWLES[1], G. MINOGUE[1], C. NASSIF[1], R. KESZYCKI[1,2], C. COVENTRY[1], E. ROGALSKI[1,2], M. E. FLANAGAN[1,3], M.-. M. MESULAM[1,4], C. GEULA[1,5], T. GEFEN[1,2]; [1]Mesulam Ctr. for Cognitive Neurol. & Alzheimer's Dis., [2]Dept. of Psychiatry and Behavioral Sci., [3]Dept. of Pathology, [4]Dept. of Neurol., [5]Dept. of Cell and Developmental Biol., Feinberg Sch. of Med. at Northwestern Univ., Chicago, IL

Abstract: Background. The dentate gyrus (DG) is a region of the hippocampal formation characterized by a single layer of densely packed granule cells, followed by an underlying polymorphic layer of the long-projecting hilus neurons. The granule cells receive input from the entorhinal cortex and send excitatory output to the hippocampal CA3 subfield via its mossy fibers. Prior work in Alzheimer's disease (AD) has shown that the dentate gyrus generally resists the development of tau tangles in the typical amnestic clinical syndrome. The susceptibility of the DG in non-AD tauopathies has not yet been investigated and can offer key insights into hippocampal function and selective vulnerability of the region to disease. Here, we report stereologic densities of tau inclusions in the DG across three conformationally distinct tauopathies, namely the FTLD 3R-tauopathy of Pick's disease (PiD); the FTLD 4R-tauopathy of corticobasal degeneration (CBD); and the 3/4R-tauopathy of Alzheimer's disease (AD), all of which manifested an aphasic dementia syndrome known as Primary Progressive Aphasia (PPA), in which language abilities are compromised and memory functions are spared.
Methods. Fifteen right-handed cases with clinical diagnoses of PPA and autopsy-confirmed tauopathy

diagnoses were obtained from the Northwestern Alzheimer Disease Center (PiD, N=5; CBD, N=5; AD, N=5). Specimens were stained immunohistochemically with AT-8 to visualize tau pathology of both the 3R and 4R type. Unbiased stereological analysis (MicroBrightField Bioscience) was performed on the left dentate gyrus to quantitate densities of tau-positive neurons. One-way nonparametric ANOVA was used to compare distributions.
Results. Highest densities of dentate gyrus tau pathology were found in PiD (~74,000 per mm^3), followed by CBD (~20,000 per mm^3), and then AD (~4,000 per mm^3); PiD showed significantly higher densities ($p<0.005$) compared to AD by an order of nearly 20-fold. While some tau pathology was found in PPA-AD cases in the hilus neurons, very few inclusions were present in the granule cells of the dentate gyrus. In contrast, the granule cells of the dentate gyrus contained a relatively dense collection of inclusions in CBD and particularly in PiD.
Conclusion. The dentate gyrus of the hippocampal complex is differentially vulnerable to tauopathies, with high selectivity to FTLD-tauopathies but not to Alzheimer-type neurofibrillary tau. These patterns of susceptibility in the non-amnestic, language-based clinical dementia syndrome known as PPA raise intriguing questions about the functional and structural integrity of hippocampal circuits in neurodegenerative dementias.

Title: Clinicopathologic correlates of psychiatric symptoms in chronic traumatic encephalopathy across brain regions

Authors: *I. MAHAR[1], S. CHANCELLOR[1], B. HUBER[1], T. STEIN[1], V. ALVAREZ[1], R. MATHIAS[2], J. CHERRY[1], A. MCKEE[1];
[1]Boston Univ., Boston, MA; [2]VA Boston Healthcare Syst., Boston, MA

Abstract: BACKGROUND
Chronic traumatic encephalopathy (CTE) is a neurodegenerative disease with cognitive, behavioral, and

psychiatric symptoms, with depression and suicidality present in a large proportion of CTE cases. Pathologically CTE is defined by a distinctive accumulation of hyperphophorylated tau (pTau) predominately involving the frontal and temporal cortices, medial temporal lobe, and brainstem. However, the association between pathology in particular brain regions and psychiatric CTE symptoms is unknown.
METHODS AND RESULTS
Human postmortem brains from CTE cases and controls were obtained from the VA-BU-CLF Brain Bank. Trained neuropathologists examined each brain for gross and microscopic pathology, and provided semi-quantitative assessments. Regions of interest (including frontal, temporal, limbic, and brainstem structures) were sectioned and stained for pathological markers of interest (e.g. pTau, β-amyloid, α-synuclein, pTDP43, etc). Stained slides were scanned and traced digitally, with staining quantified using a Leica Aperio system. Preliminary analyses suggest alterations in specific cortical, limbic, midbrain, and white matter structures may associate with depressive and suicidal features in CTE. In particular, cortical white matter loss as well as hippocampal and midbrain pathology were associated with psychiatric features. We have also found myelination and inflammation-associated changes in the anterior cingulate cortex of depressed CTE cases. Cytotoxic t-cells may be involved in depressed mood and disease progression in CTE.
CONCLUSIONS
This investigation is the first to explore associations between neuropathology in particular brain regions and psychiatric features in CTE. Preliminary results suggest increased neurodegenerative pathology, loss of white matter, neuroinflammation, and gliosis could underlie psychiatric phenotypes in CTE.

Title: Pathological tau species promotes maladaptive RNA translation

Authors: J. KOREN, III[1], S. GALVIS[1], **J. F. ABISAMBRA**[2];
[2]Ctr. for Translational Res. in Neurodegenerative Dis., [1]Univ. of Florida, Gainesville, FL

Abstract: A fundamental gap in the field is the incomplete identification of the mechanisms by which tau promotes cellular dysfunction. Several labs, including our own, established that pathological tau shifts the translatome yielding a maladaptive response. However, the molecular mechanisms driving this effect remain unknown. The overall objective of this study is to establish these mechanisms by defining 1) the impact of pathological tau on translation, 2) the components of RNA translation machinery that interact

with tau, 3) whether improving translation rescues brain function in models of tauopathy, and whether pathological tau impacts mRNA availability. We adapted surface-sensing of translation (SUnSET) for identification of newly-synthesized proteins in the brain. To this end, we used puromycin, a structural tRNA analog, and detected overall reduced levels of newly-synthesized (pumocyinylated) proteins in both in vitro and in vivo models of tauoapthy. We then coupled the puromycin assay with LC-MS/MS proteomics in the brains of TET-regulatable rTg4510 tau transgenic mice (+/- doxycycline) to identify proteins translationally altered by tauopathy. With microarrays, we confirmed that changes in the synthesis of translational machinery were not attributed to transcription. These results were further validated in Alzheimer's brains. Then, treating mice with a kinase inhibitor that inhibits the PERK pathway thereby restoring translation, we observed marked functional rescue in rTg4510 tau transgenic mice as evidenced by manganese-enhanced MRI and behavioral assays. Finally, to assess the extent to which tau impacts RNA availability for translation, we used enhanced-CLIP to determine tau-associated RNA sequences in human Alzheimer's brains, and we identified a discrete number of sequences that associate differentially with tau as a consequence of disease progression. These results suggest that pathological tau promotes a maladaptive response. A central group of proteins that are translationally reduced are those necessary for production of ribosome machinery. Overcoming deficits in their translation offers functional benefits. In addition, tau exerts unanticipated and potentially devastating effects on availability of RNAs for translation. Therefore, tau-mediated maladaptive translation may be a pathogenic event in tauopathies, and efforts to rescue these effects are currently underway.

Abstract: Triggering Receptor Expressed on Myeloid Cells-2 (TREM2) variants increase the risk of late-onset Alzheimer's Disease (AD). Recently, the interaction of TREM2 on tau pathology and inflammation has been investigated, but mainly in tau overexpression models. Here, we used an *in vivo* model of tau propagation using wild-type (WT) and TREM2$^{-/-}$ female and male mice. In this study, we aim to determine the role of TREM2 in tau propagation, and its cellular and molecular mechanisms. At 3 months of age, twelve mice per group were injected intracranially with PBS or tau isolated from an AD patient. Six months later, brain tissues were harvested for histological analysis and gene expression using NanoString. Histological analysis revealed a decrease on tau propagation in TREM2$^{-/-}$ mice observed by a reduction in tau AT8 immunoreactivity in different brain regions such as the mammillary area and the retrosplenial cortex contralateral. We also showed that in those brain areas, the number of microglia/macrophages by Iba1 staining in TREM2$^{-/-}$ mice does not increase compared to PBS injected animals, as it does in WT mice. We observed no change in the morphology of the microglia/macrophages in all groups. Furthermore, we determined that there are no changes in reactive astrocytes by GFAP immunofluorescence. Next, in order to identify a TREM2-related pathway or mechanism involved on tau propagation, we used the mouse neuroinflammation panel by NanoString and found that multiple pathway annotations were downregulated in the TREM2$^{-/-}$ mice injected with AD-tau compared to the WT, namely the microglia function score and the inflammatory signaling score. Our findings suggest that TREM2 modulates tau spreading *in vivo* by changing microglia/macrophages functionality. These findings provide more insight on the role of TREM2 in tauopathy models.

Title: Molecular activation of gliovascular signaling precedes blood-brain barrier disruption and neuronal loss in a mouse model of tauopathy

Authors: *Y. KOMURO[1], O. MINAEVA[2], J. A. MONCASTER[2], N. HUA[2], S. CARMICHAEL[1], L. E. GOLDSTEIN[2], J. D. HINMAN[1];
[1]Neurol., UCLA, Los Angeles, CA; [2]Radiology, Boston Univ., Boston, MA

Abstract: Increasing evidence points to disruption of the blood-brain barrier (BBB) as an inciting event in the pathogenesis of Alzheimer's disease. The contribution of tau-mediated pathways driving blood-brain dysfunction are comparatively understudied. Using the P301S mouse model of tauopathy, we employed dynamic contrast enhanced MRI (DCE-MRI) to demonstrate widespread BBB dysfunction in late stage tauopathy. Quantitative spatial analysis of BBB breakdown in the frontal cortex and

hippocampus of P301S transgenic mice was confirmed post-mortem using Gadolinium high-resolution metallomic imaging mass spectrometry (Gd-MIMS) to detect residual gadolinium in cerebral tissue. To identify molecular pathways regulating intercellular signaling between neurons and gliovascular support cells that are dysregulated in advance of BBB disruption, we developed a cell-specific viral approach for transcriptional profiling of novel pathways within the multicellular environment of the neurovascular unit (NVU) in tauopathy. Viral constructs using cell-type specific promoters (hSynapsin, GFAP, or PDGFRβ) to drive expression of antigen-tagged ribosomes (TRAP) were used to study variance in spatial and temporal gene expression patterns in NVU cell types in P301S transgenic mice prior to widespread BBB disruption. Coupling vTRAP with endothelial MACS-seq in P301S transgenic mice, we generated multiple cell-type specific transcriptomic databases of the neurovascular unit across several pathologically-relevant time points that precede BBB disruption seen by DCE-MRI. Gene ontology analysis indicates that multiple molecular programs driving neuronal differentiation, neurite outgrowth, and synaptogenesis are expressed in gliovascular cells in the prodromal stage. This specific and temporally regulated coordination of pathways in pericytes and astrocytes to support injured neurons may lessen with age and increased stress, leading to a failure in maintaining homeostasis and further neuronal injury. This suggests a paradigm for gliovascular rescue of neurodegeneration and implicates numerous novel perivascular molecular pathways in the pathogenesis of tauopathy and Alzheimer's disease.

Abstract: Hyperphosphorylation of the microtubule-associated protein tau under pathological conditions causes abnormal aggregation of tau, leading to the formation of neurofibrillary tangles (NFTs), an important hallmark of Alzheimer's Disease (AD) and other tauopathies. Increasing evidence supports the idea that the intermediate soluble tau aggregates propagate between synaptically connected neurons and induce "seeding" of non-pathogenic monomeric tau, thereby spreading tau pathology. Despite the knowledge acquired, the nature of the tau species involved in the propagation and seeding remains

unclear. In this study, we aim to identify the nature of the tau species responsible for seeding activity in order to use this species as a target or biomarker for disease progression. We profiled the temporal evolution of tau seeding activity in the brains of two mouse models of human tauopathies, hTau P301S (0N4R) and hTau P301S (1N4R), using a FRET-based biosensor cell line. Tau seeding was observed to be an early pathological indication and increased with age in both models. We then correlated seeding activity with the tau protein levels using a diverse set of antibodies against phospho- and conformational tau species in the same brain samples. Our results demonstrated that phosphorylation of tau at Serine 214 (pTauS214) was the only tau specie that correlates with seeding activity during disease progression in both tauopathy models. Interestingly, the deposition of pTauS214 was observed from an early stage and had a distinct histopathological pattern than the AT8-positive tau species, which is a common specie used to measure tau pathology. Furthermore, the pTauS214 species was enriched in synaptic fractions while AT8-positive tau species was absent in the synaptic fractions. Synaptic fractions displayed tau seeding activity at levels comparable to the cytosolic fractions, suggesting that the pTauS214 species is associated with the observed seeding activity at the synapse. Using AAV-based tauopathy mouse models we have also observed how the inhibition of tau phosphorylation at Ser214 decreases the overall tau levels at the synapse. Our results suggest that inhibition of phosphorylation at Serine 214 reduces the ability of the tau seed to migrate to the synapses and propagate trans-synaptically. Together, these results also set the stage for demonstrating the diversity of tau species present in the brain during the disease course and identify pTauS214 as an early target of therapeutic intervention for tauopathies.

Title: Super-resolution live cell microscopy of lysosomal organelle dynamics in health and neurodegeneration

Authors: E. LEISTEN, T. BELTON, ***Y. C. WONG**;
Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Lysosomes are critical organelles for regulating cellular degradation, metabolism, and crosstalk with other organelles. Interestingly, endolysosomal dysfunction has been implicated in many neurological disorders, highlighting their importance for maintaining neuronal homeostasis. Using advanced super-resolution imaging and live cell microscopy, we have investigated novel aspects of lysosomal network dynamics and function which are key for regulating cellular homeostasis. Moreover, lysosomal dynamics may be directly disrupted by specific disease mutations linked to neurodegenerative diseases, including various lysosomal storage disorders and Alzheimer's disease. Our findings further support a key role for properly regulated lysosomal dynamics in neuronal health, and the importance of investigating their

regulation using advanced imaging techniques and microscopy to elucidate new pathways contributing to neurodegeneration.

Title: Predicting conversion to Alzheimer's Disease from longitudinal changes in Hippocampal and Entorhinal Volume in Mild Cognitive Impairment

Authors: *S. K. RAJAGOPAL[1], T. A. POLK[2];
[1]Univ. of Michigan Psychology Grad. Program, Ann Arbor, MI; [2]Psychology, Univ. of Michigan Dept. of Psychology, Ann Arbor, MI

Abstract: Many patients with Mild Cognitive Impairment (MCI) progress to Alzheimer's disease (AD), but others do not, and understanding the factors that distinguish the two groups is a central challenge in the field. Here we applied multilevel growth curve modeling to data from 813 MCI subjects in the Alzheimer Disease Neuroimaging Initiative (ADNI) Database to examine whether longitudinal changes in hippocampal volume and/or entorhinal cortex (EC) volume were related to conversion. For both the Hippocampus and EC models, a two-level model (level 1 = timepoints nested within level 2 = subjects), which allowed for individual variation in both baseline volumes and slope (trajectories of change), fit better than one where slopes were fixed across subjects or in which both baseline volumes and slopes were fixed. Including a third level of nesting by grouping MCI individuals by their conversion to AD (age and sex matched groups, n(converters) = 329) yielded the best predictions of structural volumes with age. In particular, slopes of change in both Hippocampus and EC were more negative in converters than in non-converters. Model fits were compared using AIC measures, and both outcome volumes were divided by the whole brain volume to control for individual differences in brain size. We also tested whether the difference in rates of volume change before conversion would predict subsequent conversion. Specifically, we fit regression slopes to Hippocampus and EC volumes for each subject individually after excluding information from post-conversion visits. We saw that both the Hippocampus ($t(349.42) = 3.59$, $p<0.001$) and EC slopes ($t(395.54)=2.29$, $p=0.02$) significantly differed across cohorts with the slopes being significantly more negative in the converters than in the non-converters. A logistic regression model with cohort as outcome and ventricle volume as a nuisance covariate also revealed that both Hippocampus ($b_{Hippocampus}$ = -0.34(0.1), p = <0.001) and EC slopes (b_{EC} = -0.24(0.09), p = 0.012) were significant predictors of conversion. These results indicate that the rates of change in both hippocampal and entorhinal cortex volume in MCI patients are significant predictors of subsequent conversion to AD. They also demonstrate the promise of growth curve modeling in understanding the precursors of Alzheimer's disease.

Title: Varied ligand spacing as an approach for label-free phenotype-based screening of astrocytes in a mouse model of Alzheimer's disease

Authors: E. G. THOMPSON[1], ***P. J. CALHOUN**[2], M. C. ROBITAILLE[3], J. A. CHRISTODOULIDES[3], J. M. BYERS[3], M. P. RAPHAEL[3], J. D. ROTHSTEIN[1];

Abstract: Alzheimer's disease (AD) is a devastating neurodegenerative disease affecting more than 6 million Americans currently, expected to affect 12 million Americans by 2050. While there have been significant scientific advances in AD research, the causative agent of AD is still unknown. To date animal models of AD have primarily relied on aggregate protein mechanisms, namely tau and amyloid β, but have led to limited advancements therapeutically. To better understand AD disease pathology in a manner independent of identified key molecular players, we employed lithography and self-assembled monolayer surface chemistry to vary ligand spacing thereby challenging astrocytes during cellular attachment. In combination we utilized a novel self-supervised machine learning (SSL) algorithm to parameterize phenotypes of healthy- and AD model-derived astrocytes from mice. Importantly, the difference in phenotype parameters are not observable on completely coated or commercially available cultureware. Surfaces were characterized by surface plasmon resonance and high (not challenging) and low (challenging) density ligand spacing were identified for astrocyte adhesion. Key morphological biomarkers were identified including altered cell area, cell perimeter, and feret ratio allowing for quantification of "reactive" and healthy astrocyte populations *in vitro*. Utilizing Streptolysin O-mediated delivery of antibodies against amyloid oligomers, we demonstrate that this device could not only function as a drug-screening platform in AD, but also in various other neurodegenerative diseases. This approach represents a new tool for the cell biologist's toolkit that relies on the intimate relationship between cellular structure and function and is independent of prior knowledge of aberrant protein mechanisms or gene regulation.

Title: Plasma NfL is Associated with APOE e4 Allelic Dose, Hippocampal Atrophy and Alzheimer's-related Cerebral Hypometabolism in Cognitively Unimpaired Late-Middle-Aged and Older Adults

Authors: *M. MALEK-AHMADI[1], Y. SU[1], V. GHISAYS[1], V. DEVADAS[1], J. LUO[1], Y. CHEN[1], H. PROTAS[1], K. CHEN[1], K. BLENNOW[2], H. ZETTERBERG[2], R. J. CASELLI[3], E. M. REIMAN[1]; [1]Banner Alzheimer's Inst., Phoenix, AZ; [2]Univ. of Gothenburg, Gothenburg, Sweden; [3]Mayo Clin. Arizona, Scottsdale, AZ

Abstract: Background
Plasma neurofilament light (NfL) measurements appear to provide an indicator of neuronal neurodegeneration in persons with Alzheimer's disease (AD) and a wide range of other neurological disorders. Here, we used an ultra-sensitive assay to characterize plasma NfL measurements in cognitively unimpaired (CU) late-middle-aged and older adults to test our hypotheses that plasma NfL concentrations are associated with APOE e4 allelic dose, MRI measurements of hippocampal atrophy, and cerebral glucose hypometabolism. We also explored associations with PET measurements of cerebral amyloid plaque and tau tangle burden and MRI measurements of white matter hyperintensity (WMH) volume.
Methods
Plasma NfL concentration was measured using a Single molecule array (Simoa) assay on an HD-X Analyzer in 194 CU 69±9 year-old participants from the Arizona APOE Cohort Study, including 43 APOE4 homozygotes (HM), 51 heterozygotes (HT), and 100 non-carriers (NC). Generalized linear models were used to characterize associations with APOE4 allelic dose before and after adjustment for age, sex, and education to characterize associations with hippocampal volume, HCI, mean cortical PiB PET measurements of amyloid plaque burden, meta-region-of-interest (meta-ROI) flortaucipir PET measurements of tau tangle burden, and VMH volume before and after adjustment for age and APOE4 allelic dose. The association between NfL and the Delayed Recall portion of the Rey auditory verbal learning test (AVLT) was also explored.
Results
Plasma NfL levels were associated with APOE4 allelic dose after adjustment for age, sex and education ($p=0.006$, HM>HT>NC), and they were also associated with our brain imaging measurements of neurodegeneration after adjustment for age, sex, education, and APOE4 allelic dose ($p<0.001$ for hippocampal volume and $p = 0.003$ for HCI). A non-significant trend suggested a possible association between plasma NfL levels and tau tangle burden ($p=0.07$), which may be moderated through

measurements of neurodegeneration ($p = 0.008$). There were no significant associations with amyloid plaque burden or WMH volume. A weak, but statistically significant, correlation was noted for NfL and AVLT Total Learning ($r = -0.27$, $p<0.001$).

Conclusions

Plasma NfL measurement, a promising blood-based biomarker of neuronal degeneration, is associated with APOE4 allelic dose and brain imaging measurements of neuronal degeneration in CU adults, adding further support for its value as an indicator of neuronal degeneration in the preclinical study of AD.

Title: C5ar1 receptor antagonist pmx205 attenuates neuropathology-associated biomarkers in arctic mice

Authors: *A. MENDOZA ARVILLA, N. D. SCHARTZ, S.-H. CHU, A. J. TENNER;
Univ. of California, Irvine, Irvine, CA

Abstract: In the healthy brain, complement promotes synaptic pruning, clearance of neuronal blebs, recruitment of phagocytes, and protection from pathogens. However, in Alzheimer's disease (AD), aberrant complement activation may contribute to inflammatory pathways, neuronal dysfunction, and cognitive decline. Engagement of C5aR1 by the downstream complement activation fragment, C5a, can instigate a feed-forward loop of inflammation, injury, and neuronal death, thus providing a potential target for modulation in AD therapeutics. Therefore, we assessed the effects of C5aR1 antagonist PMX205 on plasma neurofilament light (NfL) as a biomarker for neurodegeneration in the Arctic mouse model of AD.PMX205 (20 µg/mL) was provided via drinking water. A group of WT and Arctic mice received milliQ water without drug. Treatment began at ages 4.5, 5.5, or 6.5 months and ended at 7 months of age. Blood was collected for plasma before treatment via submandibular face bleed. At 7 months, blood was collected and processed for assay of NfL with the MSD Neurofilament Light kit (MesoScale Diagnostics). We measured volume of PMX205/water consumed and body weight throughout our study. Mice consumed 4.5-5.5 mL of PMX205 or water per day with no effect of treatment. Similarly, PMX205 treatment did not alter body weight over treatment duration. Plasma NfL significantly increased in the Arctic mice between 4.5 and 7 months ($p<0.01$). However, after 12 or 2 weeks of PMX205, increase in NfL was suppressed, suggesting an attenuation of the neurodegeneration in the brain. Interestingly, after treating for 6 weeks, there was a strong trend for a reduction in plasma NfL ($p=0.06$). Finally, when we compared NfL levels between groups at 7 months, there was a significant

increase in plasma NfL in untreated Arctic compared to WT ($p<0.0001$). However, treatment with PMX205 for any duration resulted in lower NfL levels compared to untreated Arctic at 7 months ($p<0.05$). In summary, treatment with PMX205 can prevent increase of the blood biomarker NfL. This is consistent with our previous report in which genetic ablation of C5aR1 rescued loss of neuronal complexity in the Arctic mouse and provides support for the use of plasma NfL as a proxy for measuring neurodegeneration and treatment efficacy.

Title: Histone deacetylase expression in pre-clinical Alzheimer's disease: an ADNI study

Authors: *J. SHRIRAM[1], M. H. MALEK AHMADI[2], L. MAHADY[3];
[1]Col. of Med., Univ. of Arizona, Phoenix, AZ; [2]Banner Hlth., Phoenix, AZ; [3]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: ***Background*** Identifying serum biomarkers of prodromal Alzheimer's disease (AD) may have great clinical utility in facilitating early intervention against significant cognitive decline. Histone deacetylase (HDAC) proteins are major epigenetic modulators that represent a potential early-stage biomarker target with three human isoforms that have been previously implicated in AD pathogenesis. ***Objective*** We sought to determine whether HDAC 1, 2, and 6 expression differed based on APOE ε4 allele carrier status and AV-45 amyloid positivity status. ***Methods*** We extracted data for 114 cognitively unimpaired subjects from the Alzheimer's Disease Neuroimaging (ADNI) database. HDAC 1, 2, and 6 expression levels were compared between APOE ε4 carriers vs. non-carriers and AV-45 amyloid positive vs. negative subjects. ***Results*** We found that serum expression of HDAC6 was significantly higher in amyloid positive compared to amyloid negative subjects at two probes (11754957-A-AT, $p = 0.04$, Cohen's $d = 0.49$; 11756962-X-AT, $p = 0.03$, Cohen's $d = 0.56$). The remaining HDAC6 probes and all HDAC 1 and 2 probes did not significantly differ in expression levels across APOE ε4 carrier and amyloid status groups. ***Discussion*** We found that amyloid positive subjects had significantly higher HDAC6 expression relative to amyloid-negative subjects. Given the increasing interest in the use of blood-based biomarkers in AD, HDAC6 expression may be a potential biomarker of early AD. In particular, it may also serve as a potential treatment target for future AD therapies.

Title: The Influence of Age on Microglia Degeneration in the Human Brain

Authors: *R. SHAHIDEHPOUR[1], P. T. NELSON[2,3], A. D. BACHSTETTER[4];
[1]Neurosci., Univ. of Kentucky, lexington, KY; [2]Sanders-Brown Ctr. on Aging, [3]Dept. of Pathology and Lab. Med., [4]Spinal Cord & Brain Injury Res. Ctr., Univ. of Kentucky, Lexington, KY

Abstract: Microglia activation—typically described in terms of hypertrophic appearance—is a well-established feature of aging. However, recent studies have suggested that microglia dystrophy, not activation, that may lead to increased propagation of progressive neurodegenerative diseases such as Alzheimer's disease. Yet, a clear understanding of causes and consequences of dystrophic microglia is lacking. Although frequently observed in diseased brains, the appearance of dystrophic microglia in the hippocampus of individuals free of cognitive impairment suggests that microglia may be undergoing senescence with age, leading to dystrophy. Therefore, we hypothesized age could be a significant contributor to senescence and the presence of dystrophic microglia. To investigate this relationship, we employed stereological counts of total microglia, hypertrophic, and dystrophic microglia across the decades of the human lifespan. The microglia counts were completed in the CA1 subregion of the hippocampus in individuals without known neuropathology or neurodegenerative disease. We then compared these cases to previously generated data of individuals with confirmed neurodegenerative disease. We found a significant increase in the number of total microglia in the CA1 region related to age in disease-free individuals. However, further investigation showed that the bulk of this increased number of microglia was predominantly due to an increased population of hypertrophic cells but not dystrophic. In the presence of disease pathology, the percentage of microglia observed to be dystrophic was significantly greater than in normal aging individuals, while quantity of hypertrophic microglia did not change. These results challenge the current belief that microglial activation and hypertrophy are drivers of disease progression. Our findings provide evidence that normal aging is not associated with an increase in dystrophic microglia and suggest that dystrophic microglia may be a disease-associated microglia phenotype. Future work is required to understand the link between the increase in dystrophic microglia and neurodegenerative disorders.

Title: Unique Molecular Signatures associated with Alzheimer's Disease in the Retina

Authors: *J. NGOLAB[1], A. MARK[3], J. BUCHANAN[4], S. KOROURI[2], A. WANG[4], S. PRIESSL[4], K. FISCH[3], R. A. RISSMAN[2];
[1]Neurosciences, [2]Neurosci., UCSD Sch. of Med., La Jolla, CA; [3]Ctr. for Computat. Biol. & Bioinformatics, [4]Ctr. for Epigenomics, UCSD, La Jolla, CA

Abstract: Background: Clinical studies of the retina in Alzheimer's Disease (AD) patients have reported alterations to the retinal structure and amyloid deposition. However, detection of amyloid-beta (Aβ) inclusions and retinal thinning have been inconsistent due to various protocols. Retinal Aβ deposition and phosphorylated tau also coincide in retinal diseases such as age-related macular degeneration and glaucoma, indicating that traditional pathological hallmarks of AD in the retina do not exclusively signify AD diagnosis. Microlevel assessment is needed to validate the retinal changes observed in AD. Next-generation sequencing technologies have revealed unique insights into the mechanisms involved in other retinal diseases such as age-related macular degeneration.
Methods: To gain molecular insight into the pathophysiology of retinal AD changes, we propose to conduct single-nuclei RNA-seq (snRNA-seq) analysis on retinal tissues extracted from severe AD cases indicated by clinical and pathological diagnosis. Postmortem tissues from the left eye of two autopsy-confirmed AD cases and two non-demented age-matched controls were processed for snRNA-seq analysis. Raw reads are to be processed to identify retinal cell types and differential gene expression within samples and between groups. Additionally, we will histologically process the right eye of each case to conduct morphological retinal assessments.
Results: We hypothesize that the molecular changes will localize to cells with thinning retinal layers. Both retinal measurements and snRNA-seq analysis are currently underway. By determining the transcriptional profile of the retinal cells and the corresponding architecture, we will potentially pinpoint the key players involved in AD-mediated retinal changes.
Conclusion: Structural changes to the retinal architecture may not be sufficient to signify AD, nor is the presence of retinal Aβ and phosphorylated tau restricted to AD retinopathy. Studying the transcriptional profile of the AD retina will provide biological context to retinal changes observed in AD.

Lee (leeyoung@skku.edu)
Identification of evolution of Aβ proteins from monomer to misfolding fibril and its pathophysiology associated with Aβ structural conformation are not clearly understood until now. The early diagnostic method to monitor the progressive Alzheimer's disease (AD) is a key for therapeutics. Here, we identified the Aβ aggregation states by a biophysical marker (dementia quotient, DQ) depending on light absorption with terahertz (THz) spectroscopy without any label. We developed the solution-based THz measurement system with specially designed solution chamber plate and identified the monomer, oligomer and, fibril states by DQ based on optical conductance change of Aβ structural conformation in real-time. The DQ is extracted the molecular localization constant by modified Drude-Smith model and DQ values are approximately 1 in fibrils, 0.64 in oligomers, and nearly zero in monomers, which is the limit of detection at nanomolar Aβ concentration. In addition, DQ index can measured in various Aβ polymerization medium during and long-term period up to 5 days. This suggests the new biophysical diagnostic method for AD since the DQ index is clearly identified the progressive stage of different Aβ protein structural states, which from monomer evolves to oligomer and reaches to fibrils, by using the label-free THz optical measurement.

Title: The role of brain networks in predicting time of progression to dementia in Primary Progressive Aphasia

Authors: M. QUIMBY[1,2], Y. KATSUMI[1,2], D. HOCHBERG[1,2], N. CARVALHO[1,2], M. BRICKHOUSE[1,2], B. DICKERSON[1,2], ***A. TOUROUTOGLOU**[1,2];
[1]Harvard Med. Sch., Boston, MA; [2]Frontotemporal Disorders Unit and Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: BACKGROUND. Patients with Primary Progressive Aphasia (PPA) have a prominent, isolated language deficit during the initial phase of the illness, with relative sparing of other cognitive and affective functions until later in the disease course as well as independent functioning consistent with Cognitive Functional Status of mild cognitive impairment (MCI). As their illness progresses, most PPA patients lose independent functioning due to worsening cognitive-behavioral symptoms and progress to dementia. However, the field does not yet have robust methods for prognostication. The development of quantitative neuroanatomical prognostic biomarkers for loss of independent functioning would be of value in research and clinically (e.g., treatment recommendations, family education). GOALS. The goals of the present study were to (1) examine the role of functional brain networks implicated in executive function, memory, and socioemotional processes in predicting progression to dementia from the MCI stage of PPA, and (2) examine the independent or synergistic contributions of atrophy in the language network compared to atrophy in other networks. METHODS. Fifty PPA patients (17 agrammatic, 14 semantic, and 19 logopenic variant), who underwent a clinical and MRI evaluation at baseline and had at least 6 months of follow-up, were included in this study. For each patient, we measured the time between the first visit and the progression to dementia or last observation. We estimated individual network atrophy using surface-based analyses based on a parcellation of the cerebral cortex into seven canonical functional networks. We performed Cox regression analyses to test the hypothesis that baseline atrophy in networks subserving non-language, cognitive or affective functions would predict progression to dementia. RESULTS. Univariate Cox regression analysis showed that patients with greater atrophy outside the language network, including the left frontoparietal, salience, default mode, and ventral frontotemporal networks, had the highest risk of progression to dementia within a shorter period. Atrophy in the language network was also a predictor, although slightly weaker. CONCLUSIONS. Taken together, these results suggest that baseline cortical atrophy outside the language network is an important predictor of more rapid progression to dementia in a heterogeneous sample of PPA patients. This measure should be included in precision medicine models of prognosis in PPA.

Abstract: Alzheimer’s disease (AD) is more prevalent in women, which is a critical concern as our aging population increases in number. This prevalence has yet to be characterized in people with Down Syndrome (DS), who are genetically predisposed to developing AD pathology. People with DS, who have full trisomy 21, inevitably develop AD neuropathology by the time they are 40 years of age. However, the initial signs of cognitive decline may not occur until almost a decade later. It is promising to note that up to 15% of elderly people who reach over 60 years of age with DS may not develop signs of dementia. Sex may play a significant role in the age of onset of cognitive decline, rate of progression and extent and type of neuropathology subsequently observed. Women with DS typically experience menopause between 44–46 years of age compared with an average of 51 years of age in the general population. Cognitive function in postmenopausal women with DS is worse than in men with DS at comparable ages, possibly owing to reduced bioavailability of estrogen in these women. Estrogens exhibit marked neuroprotective effects and disruption of its levels could have detrimental effects on the aging brain. Estrogens act on two primary receptors, ERα and ERβ,that are expressed throughout the hippocampus and frontal cortex, suggesting their role in regulating cognition and memory. I. Within the DS population, even fewer studies have investigated the role of estrogens and their receptors in the brain. Thus, lower levels of estrogen receptor expression could be associated with higher levels of AD pathology and neuroinflammation in women with DS compared to men. Our hypothesis is that AD pathology occurs at younger ages in women with DS, is more extensive in women as compared to men, and associated with down-regulation of ERα and ERβ. We acquired loads of estrogen receptors in the human frontal cortex, hippocampus, and posterior

cingulate cortex through immunohistochemical staining and quantification. Serial sections will be stained for tau neurofibrillary tangles and beta-amyloid plaques within a cohort of DS brains. Our study focuses on an area of research that is significantly understudied and critical for our understanding of risk factors for dementia in DS, and proposes a novel hypothesis that estrogen receptors are linked to AD pathology, cerebrovascular pathology and neuroinflammation.

Abstract: Neuromelanin (NMel) is a dark pigment characteristic of dopaminergic neurons in the human substantia nigra pars compacta (SNpc). Levels of NMel in humans are very high, thus enabling a direct macroscopical visualization of the SNpc. By contrast, most commonly used laboratory animals lack NMel. Although aged non-human primates (NHPs) also accumulate NMel over time, these levels are too low to be observed to the naked eye. Here we took advantage of AAVs coding for human tyrosinase (the enzyme mediating NMel synthesis) for driving a time-dependent NMel accumulation in dopaminergic neurons of the SNpc in NHPs up to similar levels as observed in elderly humans. Furthermore, NMel accumulation induced a synucleinopathy mimicking intracellular inclusions typically observed in patients suffering from Parkinson's disease (PD) known as Marinesco bodies (MBs; intranuclear aggregates) and Lewy bodies (LBs; intracytoplasmic inclusions). In parallel, a progressive nigrostriatal degeneration is observed in NMel-expressing dopaminergic neurons, together with a pro-inflammatory phenotype mediated by activated microglial cells and perivascular macrophages trying to digest extracellular NMel resulting from dopaminergic cell death. In summary, the conducted strategy resulted in the characterization and validation of a new NHP model of PD matching the known neuropathology of this disorder with unprecedented accuracy. Finally and most importantly, evidence was provided showing that intracellular aggregation of alpha-synuclein is triggered by NMel accumulation, therefore opening new interesting research avenues in the field of PD. In particular, any therapeutic approach intended to

decrease NMel levels may provide appealing choices for the successful implementation of disease-modifying therapeutics for PD.

Title: AAV-induced overexpression of E46K-like α-synuclein mutants in substantia nigra results in nigrostriatal degeneration and motor dysfunction: a new rat model for Parkinson's disease

Authors: *Y. PI[1], *Y. PI[1], R. DRISCOLL[1], C. EHRENFELS[1], R. MASSOL[1], M. LIU[2], F. DU[2], M. H. ARNOLD[1];
[1]Biogen Inc, Cambridge, MA; [2]FD NeuroTechnologies Inc, Columbia, MD

Abstract: α-synuclein (αSYN) is a synaptic protein generally acknowledged to be linked to the etiopathogenesis of Parkinson's disease (PD). Over-expression of human A53T αSYN (hαSYN A53T) with adeno-associated viral vectors (AAV) reproducibly resulted in degenerative changes in substantia nigra and neuromotor functional impairment in rodents and non-human primates (NHP)(Trends in Neurosciences, 2016, 39(11):751; PLOS ONE 2016; Nature Rev Neurosci 2017, 18: 515). Transgenic mice expressing human αSYN E46K also exhibited motor symptoms and moderate loss of nigrostriatal dopaminergic neurons at 6 months of age (Neuron 2018; 100 (1): 75-90.). Here we report a new rat model of PD by expression of human E46K αSYN mutation or amplified homologous E→K mutation (E35/46/61K) in unilateral substantia nigra (SN) via a chimeric AAV1/2 viral vector. Rats expressing hαSYN E46K showed virus dose-and time-dependent progressive neuromotor dysfunction, assessed weekly using cylinder test, while rats with sham surgery exhibited no change in neuromotor function. We also observed AAV-hαSYN E46K viral dose- and time-dependent loss of tyrosine hydroxylase positive (TH+) neurons in the SN of rats within 5 weeks post-stereotaxic surgery. Intracellular aggregated αSYN inclusions were observed and pS129 α-SYN was also stained positive in the TH+ neurons of SN in these rats. Total microglia and astrocytes were significantly increased in ipsilateral SN compared to the corresponding region in contralateral SN, suggesting activation and proliferation of microglia and astrocytes in response to aggregation of human mutant αSYN in TH+ neurons. TH+ terminals showed degenerative changes in the ipsilateral striatum, accompanied by inflammatory gliosis. These changes were not observed in the SN of sham control or AAV-mCherry rats. Rats injected with AAV E46K αSYN homologous E35/ 46/61K mutation exhibited similar neuromotor dysfunction and nigrostriatal neurodegeneration. We conclude that AAV-mediated-expression of hαSYN E46K or hαSYN E35/46/61K in the SN of rats can recapitulate the primary pathological hallmarks of PD accompanied by progressive

neuromotor deficits within a relatively short time. This AAV- hαSYN rat model provides advantages over transgenic models for assessing efficacy of novel drug candidates that may modify the progression of PD.

Title: Characterization of Striatal Dopamine Dynamics in the Rat Alpha-Synuclein Pre-Formed Fibril Model of Parkinson's Disease

Authors: *A. CENTNER[1], I. DEL PRIORE[1], M. COYLE[1], J. GLINSKI[1], S. COHEN[1], M. TERRY[1], N. E. CHAMBERS[1], J. PATTERSON[3], C. KEMP[4], A. STOLL[4], K. LUK[6], K. MILLER[5], C. E. SORTWELL[5], C. R. BISHOP[2];

Abstract: Parkinson's Disease (PD) is a movement disorder characterized by striatal terminal loss and progressive death of dopamine (DA) neurons within the substantia nigra. Abnormal, misfolded accumulation of the synaptic protein alpha-synuclein (α-syn) has been implicated in the cellular dysfunction that precedes neurodegeneration and is a hallmark pathological marker of PD. Given the role of endogenous α-syn in neurotransmission and reuptake mechanisms, these abnormal α-syn aggregates have potential to disrupt DA dynamics and accelerate neuronal death. A recent and unique rodent model utilizes recombinant α-syn proteins that form short fragments which, when introduced to brain, trigger the conversion of healthy endogenous α-syn to its pathological form. This pre-formed fibril (PFF) rat model of PD replicates the progressive accumulation of α-syn aggregation, neuronal loss and motor dysfunction observed in PD, however α-syn-aggregate-induced alterations in basal and evoked DA release remain to be described. In the present study, adult male Sprague Dawley rats received unilateral injection of mouse α-syn PFFs or PBS, as control, at 2 striatal sites. In a between subjects' design, at either 4- or 8-months post-surgery, animals underwent *in vivo* microdialysis to evaluate basal extracellular striatal DA and metabolite levels, DA turnover, local KCl-evoked striatal DA release, and systemic L-DOPA-induced DA release. Motor impairments were assessed with forepaw adjusting steps test (FAS) the days prior to microdialysis testing. Baseline DA levels in all age and brain treatment groups were stable and did not differ across time. Interestingly, PFF-treated animals displayed lower DA evoked responses, showing significant deficits in neurotransmission which worsened further with increasing post-infusion. Acute L-DOPA administration yielded an equivalent overall rise in DA in both PFF and control rats at the 4-month

time point; however, at the 8-month time point PFF rats displayed lower L-DOPA induced DA levels. In addition, motor impairment was not detected until the 8-month time point. Ongoing postmortem histological analysis will examine nigral dopamine neuron phenotype and survival at both the 4- and 8-month time point. Taken together, the present study provides evidence that synucleinopathy in the nigrostriatal system in the PFF model results in progressive changes in DA dynamics suggesting early deficits in DA release. The rat PFF model offers researchers a platform to examine mechanisms behind pathological α-syn associated degeneration and neurotransmission dysfunction and test novel therapies at early timepoints when deficits are emerging.

Title: Use of an infrared-monitored staircase device in analyzing symptom progression of preformed fibril- and virus vector-induced alpha-synuclein overexpression in the common marmoset

Authors: *L. R. UENO-NIGH, T. KANEKO, T. OISHI, K. INOUE, M. TAKADA;
Systems Neurosci., Kyoto Univ., Inuyama, Japan

Abstract: Previous research on Parkinson's disease (PD) common marmoset models has used the staircase task to quantify reaching and grasping ability. In the staircase task, marmosets are trained to reach with either hand to retrieve food rewards from a five-step staircase. Following induction of hemiparkinsonian symptoms, deterioration of marmosets' motor abilities can be measured based on the speed and accuracy of their retrievals. Advantages of this task include ease of training and dissociation of the spatial awareness from motor ability. However, manual recording and analysis of the task-related behavior is time-consuming and prone to human error, which makes it unsuited to frequent long-term use. As such, we newly developed a staircase device that automatically monitors the retrieval of reward from each step using infrared beams. Results are both easily obtained and accurate, with sensor data found to be consistent with retrievals recorded by high-speed video camera.
PD is known to be caused by aggregation of alpha-synuclein (α-syn) fibrils, which can be induced to create a PD model to test with the staircase device. However, injection of preformed α-syn fibrils alone, while promising for the study of synucleinopathy progression, does not seem to cause significant symptoms beyond moderate dopaminergic cell death. On the other hand, overexpression of α-syn using adeno-associated virus (AAV) vectors progresses slowly, making it inconvenient for research. A combined injection of AAV vector expressing α-syn and preformed α-syn fibril seeds into the substantia nigra pars compacta (SNc) has been found to exert synergistic effects, leading to more efficient and

drastic degeneration of dopaminergic cells.
Using advantages of the infrared-monitored staircase device, such as its ability to handle more frequent testing with finer resolution of retrieval times, we set out to precisely analyze the progression of symptoms manifested in marmosets exhibiting vector- and fibril-induced synucleinopathy. Results are currently pending and will be discussed in the presentation.

Title: Local overexpression of alpha-synuclein in the mouse prefrontal cortex leads to increased dendritic spine density and alters performance on cognitive behavioral tasks

Authors: P. J. BOSCH[1,3], G. DE CHOISY[2], R. C. COLE[2], S. NATHWANI[2], L. WAGNER[2], A. YOKIMISHYN[2], E. BAGNALL[2], Y. KIM[2], *G. M. ALDRIDGE[1,3];

Abstract: Lewy Body Dementias (LBD), including Parkinson's disease dementia and Dementia with Lewy Bodies, are characterized by widespread intracellular alpha-synuclein (alphaSyn) protein deposits, including in the cortex. LBDs cause cognitive changes, including abnormalities in executive function and cognitive fluctuations. The cause of these symptoms is still unclear, but it is known that genetic duplication of alphaSyn increases the risk of developing Lewy Body disease. One hypothesis posits that accumulation of alphaSyn in the cortex perturbs synaptic and cellular function. To investigate the effects of cortical alphaSyn, viral overexpression of human alphaSyn protein confined to the prefrontal cortex (PFC) was employed. We used *in vivo* 2-photon microscopy, in conjunction with intracranial viral injections, cranial window implantation and head-fixed behavioral paradigms to assess the cellular and behavioral consequences of alphaSyn overexpression for an extended period. Live-imaging studies focused on dendritic spine density of Layer V pyramidal neurons using *Thy1-YFP-H* transgenic mice and calcium imaging of Layer II/III neurons using *Thy1-GCaMP6s* transgenic mice. In addition, we developed a tactile head-fixed behavior where mice are required to locate a correct tactile cue to receive a liquid sucrose reward. After cranial window implant and initial imaging, male and female mice were randomized to injection with virus coding for alphaSyn or mCherry alone. Imaging was conducted in awake mice in one-week intervals for 2 months to observe dynamic changes in dendritic spines. We found an increase in the relative dendritic spine density in mice with local overexpression of alphaSyn, beginning at 4 weeks after injection. The density changes were secondary to transient changes in the formation rate of spines 3-4 weeks after injection, with no change in elimination rate. In contrast to alphaSyn overexpression in other brain regions, our results suggest that PFC local overexpression does

not cause spine loss over a two-month period. Using our head-fixed behavioral task, we found that mice with local alphaSyn overexpression tended to learn a simple tactile discrimination task faster than mCherry-injected control animals ($p = 0.054$); however, they perform more poorly than controls with increasing task complexity. To apply these techniques to an alternate animal model for LBD, our ongoing studies are investigating the injection of human preformed fibrils, with efforts to understand progression of LBD via alphaSyn aggregate spread throughout the brain and the subsequent neurological effects on our cellular and behavioral paradigms.

Title: Astrocytic Mitochondrial Calcium Dysregulation in the Striatum of an Alpha-synuclein Overexpression Model of Early-Stage Parkinson's Disease.

Authors: *T. HUNTINGTON, M. VALLE, R. SRINIVASAN;
Texas A&M Inst. for Neurosci., Texas A&M Univ., Bryan, TX

Abstract: Parkinson's disease (PD) is the second most prevalent neurodegenerative disorder affecting dopaminergic neurons in the nigrostriatal pathway. Recently, astrocyte dysfunction has been linked to early stages of neurodegeneration both in PD and other neurodegerative diseases; however, the underlying mechanisms linking astrocyte dysfunction with PD are not yet fully understood. Here, we study mitochondrial dysfunction in astrocytes of the dorsal lateral striatum (DLS) in a mouse model of early PD. To create this model, we performed a unilateral stereotaxic injection of adeno-associated virus (AAV) overexpressing alpha-synuclein (α-syn) in the substantia nigra pars compacta (SNc). When compared to mCherry-injected control mice, 4.5 months of AAV-mediated overexpression of α-syn was associated with a dysregulation of dopamine release and metabolism in the striatum. AAV-expressed human α-syn propagated from the SNc injection site to tyrosine hydroxylase (TH) positive terminals within the DLS, but induced minimal changes in TH content within the SNc. Using a previously characterized tool, we compared the kinetics of spontaneous Ca^{2+} influx between DLS astrocytic mitochondria from α-syn expressing mice and mCherry expressing control mice. We observed specific changes in spontaneous Ca^{2+} events between α-syn and mCherry overexpressing mice. Astrocytic mitochondrial Ca^{2+} influx also varied in response to dopamine receptor agonists. Together these data suggest that significant pathological alterations in spontaneous Ca^{2+} influx events occur in astrocytic mitochondria during early stages of PD.

Title: Keap1 accumulation-induced defects in mitochondria drive dopaminergic neuron loss in VPS35 D620N transgenic mice

Authors: *S. MA, H. KO;
Johns Hopkins Univ., Baltimore, MD

Abstract: Keap1 accumulation-induced defects in mitochondria drive dopaminergic neuron loss in VPS35 D620N transgenic mice Shi-Xun Ma[1,2,†,] Bo Am Seo[1,2], Seung-Hwan Kwon[1,2], Senthilkumar S. Karuppagounder[1,2], Han Seok Ko[1,2*] [1]Department of Neurology, The Johns Hopkins University School of Medicine, Baltimore, Maryland, United States of America [2]Neurodegeneration and Stem Cell Programs, Institute for Cell Engineering, The Johns Hopkins University School of Medicine, Baltimore, Maryland, United States of America The vacuolar protein sorting 35 (VPS35) D620N mutation is known to be the major genetic cause of the late-onset, autosomal dominant familial Parkinson's disease (PD). However, the effects of VPS35 D620N on the function and survival of dopamine (DA) neurons still remains unclear. To address this, we developed tyrosine hydroxylase (TH) promoter-controlled tetracycline VPS35 D620N transgenic (Tg) mice expressing human VPS35 D620N mutation selectively in DA neurons. Behavioral, pathological, and biochemical analyses revealed that the VPS35 Tg mice recapitulated cardinal features of PD, which included an age-dependent substantial loss of DA neurons in the substantia nigra compacta and locus coeruleus and significant reductions in the levels of DA and its metabolites in the striatum. The loss of DA neurons in the VPS35 D620N Tg mice was accompanied by motor deficits, neuroinflammation, accumulation of pS129 α-synuclein and α-synuclein aggregates, and increased Tau phosphorylation in the midbrain. VPS35 D620N expression led to mitochondrial dysfunction, which included reduced mitochondria size and complex I activity, and increased reactive oxygen species (ROS) production, which was prevented by a short hairpin RNA knockdown of Kelch-like ECH-associated protein 1 (Keap1), leading to the restoration of the nuclear factor erythroid 2-related factor 2 (Nrf2) activity in SH-SY5Y cells . We are currently determining the neuroprotective effect of Keap1 knockdown in the DA neurodegeneration in the VPS35 D620N Tg mice. Taken together, this VSP35 D620N mouse model provides a valuable platform in deciphering the molecular mechanisms underlying VPS35-associated PD and for testing neuroprotective therapies. Additionally, the identification of Keap1 provides a molecular mechanism for DA neurodegeneration due to VPS35 D620N mutation in PD.

Title: Tissue plasminogen activator promotes dopaminergic neuron degeneration in an α-synuclein based mouse model of PD via a non-proteolytic interaction with the N-methyl-D-aspartate receptor

Authors: *D. TORRENTE[1], D. A. LAWRENCE[2];
[1]Dept. of Mol. and Integrative Physiol., Univ. of Michigan, Ann Arbor, MI; [2]Dept. of Intrnl. Medicine, Div. of Cardiovasc. Med., Univ. of Michigan, Ann Arbor, Ann Arbor, MI

Abstract: Parkinson's disease (PD) is characterized by the progressive loss of dopaminergic (DA) neurons in the substantia nigra (SN). The causes of PD are unknown, however, there is evidence supporting the involvement of the immune response and excitotoxicity in the degeneration of DA neurons. Recently, we found that the protease, tissue plasminogen activator (tPA), is highly expressed in the SN. In the central nervous system, tPA is considered a neuromodulator, regulating events, such as excitotoxicity and microglia activation; events associated with DA neuron degeneration in PD. We found that in the SN of naïve WT mice, tPA colocalizes with the vesicular GABA transporter, a presynaptic marker of GABAergic axons. Retrograde tracing of axons innervating the SN using Cholera Toxin B in combination with a tPA-β-galactosidase reporter mouse showed that tPA-expressing neurons innervating the SN were mostly located in the striatum. This suggests that striatal neurons expressing tPA could affect DA neuron survival in the SN. To test this, we use an α-synuclein-based mouse model of PD, where a recombinant adeno-associated virus expressing human α-synuclein (AAV2-hα-syn) was injected into the SN. Mice lacking tPA ($tPA^{-/-}$) showed significant protection of DA neurons and recovery of lateralized sensory-motor integration in a corridor task compared to WT mice after AAV2-hα-syn injection. RNA-seq analysis in WT and $tPA^{-/-}$ mice after AAV2-hα-syn injection showed that overexpression of hα-syn in WT mice significantly upregulates the expression of genes involved in antigen processing and presentation such as *Ctss*, *b2m* and *FcgRIII*. In contrast, in $tPA^{-/-}$ mice expression of these genes was downregulated. RNA-seq data was validated by qPCR and immunohistochemistry. Mechanistically, injection of AAV2-hα-syn into mice overexpressing proteolytically-inactive tPA (tPA Ala) resulted in a significant increase in the degeneration of DA neurons compared to WT or $tPA^{-/-}$ mice. Using a neutralizing antibody that blocks the interaction of tPA with the N-methyl-D-aspartate receptor (NMDAR; Glunomab, a generous gift from Denis Vivien, Université de Caen Basse-Normandie), we found that Glunomab delivered directly into the SN protected DA neurons and significantly reduced the expression of MHC class I in the SN of tPA Ala mice compared to tPA Ala vehicle-treated mice. Overall, we discover a new population of tPA-expressing neurons in the striatum that innervates the SN and showed that tPA may play a direct role in DA neuron survival in the context of α-synuclein neurotoxicity via a non-proteolytical interaction involving the NMDAR and the upregulation of the MHC I-mediated immune response.

Abstract: Alpha-synuclein is a presynaptic protein that abnormally aggregates in Parkinson's disease and other neurodegenerative diseases. Both the precise mechanisms that trigger alpha-synuclein aggregation and the role of synuclein pathology in disease progression are largely unknown. Using an in vivo zebrafish model to transiently express different forms of human alpha-synuclein, we show that alpha-synuclein localizes to presynaptic terminals and is phosphorylated at serine-129 by an endogenous polo-like kinase, as in mammals. By optimizing the fluorescence recovery after photobleaching (FRAP) technique and exploiting the visual advantages of transparency during zebrafish development, we were able to measure the levels of aggregation at presynaptic terminals. Mutations at serine-129 suggest that phosphorylation at this site alone does not directly alter alpha-synuclein mobility. Our results demonstrate that human alpha-synuclein can be expressed successfully in zebrafish and that disease-relevant post-translational modifications occur within neurons. Zebrafish provide a powerful model organism to study in vivo alpha-synuclein function and aggregation, and may help lead to therapeutic advances for neurodegenerative diseases.

Title: Soluble lymphocyte activation gene-3 Contributes to α-Synucleinopathy in the early Parkinson's Disease

Authors: *N. WANG[1,2], Y. KIMURA[1,2], S. BRAHMACHARI[1,2], L. ROSENTHAL[1], T. DAWSON[1,2], V. DAWSON[1,2], X. MAO[1,2];

Abstract: The pathologic accumulation and aggregation of α-Synuclein (α-Syn) underlies Parkinson's disease (PD). We have recently identified lymphocyte activation gene-3 (LAG3) as a receptor that mediates pathologic α-Syn cell-to-cell transmission (Mao et al., 2016). Serum and cerebrospinal fluid (CSF) soluble LAG3 (sLAG3) levels have been demonstrated to be potentially associated with PD development and clinical phenotype. However, little is known about the mechanism of sLAG3 on the development of α-Synucleinopathy in PD. Here, we detected sLAG3 in the CSF of PD patients from the Johns Hopkins PDBP cohort by using ELISA. We found sLAG3 is significantly lower in the CSF of PD patients than that in control, which is consistent with previous study. Then, we purified the sLAG3 protein and determined the effect of sLAG3 on the endocytosis of α-Syn-biotin PFF in cultured cortical neurons. The results showed that sLAG3 can promote the endocytosis of α-Syn-biotin PFF in neurons. Given that a low dose of sLAG3 (α-Syn-biotin PFF / sLAG3 ratio > 10) is enough for facilitating α-Syn PFF transmission in neurons, sLAG3 may play an important regulatory role in PD progression. Accumulating evidence indicates that LAG-3 is an inhibitory co-receptor and plays pivotal roles in autoimmunity, sLAG3 may also be involved in inflammation caused by α-Syn PFF in the brain. To determine whether sLAG3 mediates PFF-induced activation of microglia, in the presence or absence of purified sLAG3, we examined mRNA levels of pro-inflammatory cytokines by Quantitative PCR and examined secreted cytokines in microglial conditional medium from PFF- or PBS- treated microglia with commercial protein multiplex arrays. We found that in the presence of sLAG3, PFF-treated microglia showed higher levels of cytokines relative to the PFF only group, while sLAG3 had no significant effect on PBS-treated microglia. The results indicate that the enhancement of PFF-induced microglia activation by sLAG3 may cause excessive immunity of microglia and promote the deterioration of α-Synucleinopathy. We also assessed α-Syn-induced pathology by monitoring the pS129 level in cultured neurons with sLAG3. We found that sLAG3 can also promote PFF-induced pS129 pathology, and showed an enhanced effect with increasing sLAG3 concentration. We propose that not only membrane-bound receptor LAG3, sLAG3 is also involved in α-Synucleinopathy and non-motor symptoms (e.g. sleep disorders) in PD. These microglial and neuronal response in the presence of sLAG3 may further interpret that sLAG3 may serve as a biomarker and enhancer of α-Synucleinopathy early during PD development.

Title: Role of NACore threonines in the aggregation and toxicity of human alpha-synuclein

Authors: *N. NATHAN KOCHEN, D. SEANEY, V. VASANDANI, E. E. LIAO, A. R. BRAUN, J. SACHS;
Biomed. Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: Understanding the key molecular interactions that lead to alpha-synuclein (aSyn) oligomer and fibril formation are critical for bridging the knowledge gap between conformation and toxicity. Our previous work demonstrated that crystallographic waters within the aSyn NACore stabilize the fibrillar structure, with water-Thr75 interactions forming a water-wire that spans throughout the Tuttle et al. Greek Key aSyn fibril. We hypothesize that these water-threonine interactions are important in the fibrillogenesis cascade of aSyn.
Recent publications, totaling more than 10 new aSyn fibril structures, have allowed us to explore this water-stabilization phenomenon in an array of aSyn conformations. In this study, we show that Thr75, located in the amyloid-prone NAC core, interacts with water molecules to form a water-threonine network in the 2018 Li et al. Rod and 2020 Schweighauser et al. Multiple System Atrophy solved structures via all atom molecular dynamics simulations. Using recombinant protein, we show that mutating Thr75 to an alanine residue (T75A) - and thus eliminating its side-chain hydrogen bonding ability - leads to decreased monomer-only and pre-formed fibril seeded aggregation monitored via Thioflavin T.
Future experiments will assess the effect of the T75A mutation on *in cell* aggregation as measured by Förster Resonance Energy Transfer (FRET) measurements of our GFP-aSyn/RFP-aSyn fusion constructs. Finally, we will determine whether the decrease in aggregation of the T75A mutant leads to an increase in cytotoxicity relative to WT aSyn via overexpression in neuronal cell lines.

Abstract: Lewy body disorders are characterized by proteostatic and redox disequilibrium, leading to deposition of α-synuclein in hallmark inclusions and oxidative damage to DNA. One common pathway for repair of oxidative DNA damage is base excision repair (BER), which involves the coordinated activity of several enzymes, including apurinic/apyrimidinic endonuclease 1 (APE1). Here, we report that knockdown of APE1 with two independent shRNA sequences or inhibition of APE1 DNA repair activity increased inclusions bearing pathologically-phosphorylated α-synuclein (pSer129) in preformed fibril-treated primary hippocampal cultures. Second, we examined APE1 expression in a mouse model of limbic-predominant α-synucleinopathy, in which α-synuclein fibrils are infused into the olfactory bulb/anterior olfactory nucleus (OB/AON). Six months later, we observed a fibril-induced decrease in APE1 expression in the brains of male mice and an increase in females. Similar patterns were noted for APE1 mRNA expression. Third, we demonstrated that the loss of APE1 in fibril-infused male mice *in vivo* is mediated by oxidative stress, as APE1 loss was abolished by dietary administration of the antioxidant N-acetylcysteine. Fourth, OB/AON tissues harvested from fibril-infused male mice displayed higher cleavage of synthetic DNA lesions on a novel biochip than tissues collected in parallel from fibril-infused female mice. However, OB/AON tissues harvested from fibril-infused female mice had higher DNA repair activity on the biochip compared to males. Assessments of open field activity measures and sucrose preference revealed a negative behavioral impact of α-synuclein fibril infusions in male but not female mice. Finally, APE1 expression was quantified in the human olfactory bulb and amygdala harvested from control subjects or patients with Lewy body disorders. Similar to fibril-infused male mice, men with Lewy body disorders displayed lower APE1 expression compared to women with Lewy body disorders. These findings reveal a sex-biased impact of limbic α-synucleinopathy on APE1 expression and function.

Title: Impact of post-translational modifications on membrane-induced alpha-synuclein aggregation in synucleinopathy disorders

Authors: *M. GUZMAN SOSA[1], O. ALI[1], S. DUTTA[1], A. SADEK[2], M. M. K. SYED[2], H. LASHUEL[2], J.-C. ROCHET[1];

Abstract: Alpha-synuclein (aSyn) is a presynaptic protein that forms aggregates in the brains of individuals with Parkinson's disease (PD) and other synucleinopathy disorders. aSyn is thought to exist as a natively unfolded protein in the cytosol, but upon interacting with anionic lipids on cellular membranes it adopts an amphipathic helical structure that is likely critical for the protein's function in modulating synaptic vesicle release. Data from our group and others suggest that the aggregation of membrane-bound aSyn plays a central role in the protein's neurotoxicity in PD via a mechanism involving vesicle disruption. Increasing evidence suggests that the mechanism of membrane-induced aggregation is distinct from the more extensively studied process of aSyn aggregation in the absence of membranes. Although various post-translational modifications (PTMs) of aSyn identified in cell culture, animal models, or human brain have been shown to modulate aSyn aggregation in the absence of lipids, little is known about the effects of PTMs on membrane-induced aSyn self-assembly. We hypothesize that certain PTMs promote the protein's aggregation at the surface of phospholipid membranes, resulting in enhanced aSyn neurotoxicity, based on evidence that some PTMs alter the conformation of membrane-bound aSyn and/or perturb aSyn-membrane interactions. To address this hypothesis, aSyn variants with N- and C-terminal truncations previously identified in human brain were characterized in terms of their relative propensities to undergo membrane-induced self-assembly and elicit vesicle disruption. We found that aSyn variants with C-terminal truncations underwent more extensive oligomerization and accelerated fibrillization (yielding fibrils with altered morphologies visualized by EM) compared to WT aSyn when incubated with phospholipid vesicles at a low pH mimicking the acidic conditions of endocytic compartments. Moreover, the rate of aSyn-mediated vesicle disruption at pH 7 (relevant to cytosolic conditions) increased with the extent of the C-terminal truncation. N-terminal aSyn truncation mutants also formed fibrils more rapidly than WT aSyn in the presence of vesicles at low pH but had a reduced ability to elicit membrane permeabilization at pH 7. Current efforts are focused on characterizing our panel of aSyn truncation variants in terms of aggregation propensity and toxicity in neuronal cell culture models. The results of these studies will provide new insights into the role of aSyn PTMs and membrane-induced aggregation in the pathology of synucleinopathy disorders, setting the stage for developing therapies targeting aSyn in the brains of patients.

Title: Effect of lysine-directed PTMs on KTKEGV motifs in α-synuclein protein.

Authors: *J. GADHAVI, S. SHAH, S. GUPTA;
IIT Gandhinagar, Gandhinagar, India

Abstract: Parkinson's disease (PD) is one of the critical neuro-degenerative diseases. PD causes loss of dopaminergic neurons in the substantia nigra. The two major pathological hallmarks of PD include Lewy bodies and Lewy neurites in which the aggregated α-synuclein protein is found to be of major constituent. The α-synuclein protein is a 140 amino acid long natively unfolded protein and has 7 consensus imperfect repeats (KTKEGV) present in its sequence. In literature, it has been reported that the KEKEGV motif plays a crucial role in maintaining the native structure of α-synuclein. Also, the various post-translational modifications (PTMs) such as methylation, glycation, ubiquitination, sumoylation, acetylation, and carbamylation on the lysine site have been found to have a role in α-synuclein protein aggregation in PD. In the current work, we wanted to identify the role of a charge neutralizing PTMs (acetylation and carbamylation) on KTKEGV motif derived peptides present in α-synuclein protein and α-synuclein itself. Therefore, we performed in-situ acetylation and carbamylation modification on various KTKEGV motif-derived peptides are present in α-synuclein protein and α-synuclein. These peptides were synthesized by Fmoc based solid-phase peptide synthesis chemistry and further characterized by LC-MS. After synthesis, their aggregation kinetics behavior was studied by inducing PTMs (acetylation and carbamylation). Here, we observed the distinct aggregation kinetics pattern in various peptides of α-synuclein which was confirmed by biophysical assays such as ThT assay, ANS assay, congo-red birefringence microscopy, AFM, and SEM. We further identified that the carbamylation and acetylation played a site-specific role and induced amyloidogenesis in specific sites, while in other sites; it did not show aggregation. Our findings suggest that these site-specific charge neutralization by post-translational modification act as a seed for modulating α-syn protein aggregation. These findings could help to identify the site-specific role of PTMs in inducing the PD.

Abstract: Parkinson's Disease (PD) is a human fatal and incurable neurodegenerative disorder linked to the loss of dopaminergic neurons in the midbrain. A key pathological marker of PD is the presence of Lewy bodies, which are composed of misfolded α-synuclein protein. α-Synuclein is a highly post-translationally modified protein in both healthy and diseased states. Modifications on it include phosphorylation, nitration, SUMOylation, acetylation, and glycation. Regulation by lipids is also suggested to modify its toxicity. The toxicity of wildtype α-synuclein and six well-known mutant versions linked with familial PD (A30P, E46K, H50Q, G51D, A53T, A53E) is well-modeled in budding yeast systems. In contrast, the toxicity mechanisms of three newer PD-linked α-synuclein mutants (A18T, A29S, and A53V) is poorly understood; particularly, the impact of post-translational modifications and lipid homeostasis on their toxicity is unknown. Using our lab's budding yeast model of PD, we investigated the toxicity potential of these three new mutants by assessing the impact of the mutations on yeast growth, protein localization, and expression in various yeasts strains. We report that: 1) All three mutants are toxic to yeast, but to different degrees and, surprisingly, less than wild-type α-synuclein; 2) Yeast strains with altered triglycerides reduce α-synuclein toxicity; 3) Yeasts strains with enhanced acetylation or reduced glycation environments rescue α-synuclein toxicity; 4) and, finally, enhanced SUMOylation is protective against α-synuclein toxicity. This study expands the evaluation of genetic α-synuclein mutants linked with PD in yeast models and supports the relevance of covalent modifications and lipid homeostasis on α-synuclein toxicity.

Abstract: Progressive loss of dopaminergic neurons within the substantia nigra as well as misfolded and aggregated α-synuclein (α-syn) within neurons throughout different regions of the brain, including cortex, are hallmarks in Parkinson's disease (PD). Several studies indicate that misfolded α-syn is released by neurons and taken up by recipient neurons where it acts as seeds to cause misfolding and aggregation of endogenous α-syn. To better understand processes involved in α-syn neuron-to-neuron spreading, we used a high-capacity microfluidic co-culture platform and high-content imaging on compartmentalized neuronal cultures to assess cellular uptake, axonal transport, somatic accumulation of α-syn seeds and aggregation of endogenous α-syn in transgenic mouse cortical neurons, overexpressing human α-syn. In detail, embryonic transgenic F28 mice cortical neurons were plated in the microfluidic co-culture plates allowing axons to grow into a cell-free interconnecting well. At 6 days *in vitro* (DIV), fluorescently labelled α-syn preformed fibrils (PFFs) or other preparations of α-syn seeds were applied to the cell-free axonal side. Cultures were maintained for up to 34 DIV and neuron-to-neuron spreading of α-syn were assessed using immunocytochemistry and high content analysis. We demonstrate that fluorescently labelled α-syn PFFs are taken up by the axons, are retrogradely transported, accumulate and remain within neurons close to the entrance area of the interconnected well. Axonal uptake of PFFs cause endogenous α-syn aggregation, appearing as perinuclear Lewy-body like accumulations and axonal speckles, in a concentration- and time-dependent manner. In addition, there were clear differences in seeding potency between the different PFFs tested resulting in varying degrees of aggregation that could be detected throughout the interconnected well. Since the microfluidic co-culture platform, containing an array of 96 experimental units, allows for local intervention of neuropathological processes, this assay platform can contribute to an increased understanding of processes leading to progressive α-syn aggregation in neurons. In addition, it allows for profiling of larger compound sets, in the search for molecules preventing progressive synucleinopathy with the potential to halt or delay the progression of PD.

Title: Potential Role of Alpha Synuclein Oligomeric Polymorphisms in Synucleinopathy Pathogenesis

Authors: *K. MOORE[1], U. SENGUPTA[2], M. KIDD[3], C. JEREZ[3], S. GAIKWAD[3], R. KAYED[2];
[1]Univ. of Texas Med. Br., Webster, TX; [2]Neurol., [3]Univ. of Texas Med. Br., Galveston, TX

Abstract: Neurodegenerative disorders are characterized by unique combinations of symptoms and pathological hallmarks of proteinaceous aggregates. Parkinson's disease (PD) and Dementia with Lewy bodies (DLB) are the two major synucleinopathies characterized by α-Synuclein (α-Syn) protein aggregates. Tauopathies, such as Alzheimer's disease (AD) and Progressive Supranuclear Palsy (PSP), also exhibit α-Syn pathology. Accumulating evidence suggests that an intermediate state of aggregates, oligomers, are the most potent neurotoxic species. Although multiple neurodegenerative diseases exhibit α-Syn aggregates, the behavioral phenotypes and neuropathology associated with each disease is distinct. Several studies have shown that amyloid aggregates, specifically fibrils of many amyloidogenic proteins such as α-Syn, amyloid β and tau represent considerable polymorphism at their molecular level. Our lab has demonstrated α-Syn can form distinct inclusions/conformations with distinct properties in the presence of different physiological inducers. Recombinant α-Syn oligomers modified by physiological inducers, dopamine or docosahexaenoic acid each exhibit distinct properties such as seeding propensity, aggregate size, and toxicity. By utilizing our lab generated α-Syn Toxic Conformation Monoclonal Antibodies (SynTCs) in a combination of biochemical and cellular assays, we provide evidence of distinct immunoreactivities as well as inflammatory responses associated with each oligomeric polymorphism. We also evaluate the effects of α-Syn oligomer immunodepletion in different cell types using cell-based assays and immunocytochemistry. These experiments provide cellular modeling of the effects of α-Syn oligomeric polymorphisms as well as if the therapeutic targeting of stable α-Syn oligomers can halt or reduce the neuropathological implications observed in synucleinopathies. We hypothesize amyloidogenic polymorphs may reflect the greater variability of disease phenotypes evident in synucleinopathies. With evidence showing oligomers as the most toxic species, neuroprotective intervention strategies targeting stable, toxic oligomers could be disease-modifying. Following in vitro analysis, our next step is to conduct an immunotherapy study with the SynTCs in a synucleinopathy mouse model. This immunotherapy study would evaluate the in vivo physiological effects of α-Syn oligomeric polymorphisms and if their therapeutic targeting can reduce or halt pathological implications and behavioral phenotypes associated with synucleinopathies.

Title: Novel Stabilizers of the Cytoskeleton in Lewy Body Disorders

Authors: *A. S. JAMENIS, T. N. BHATIA, K. M. MINER, K. KAKU, Y. SHAH, B. A. DEMARCO, R. N. CLARK, A. GANGJEE, R. K. LEAK;
Duquesne Univ., Pittsburgh, PA

Abstract: Lewy body disorders are associated with hallmark inclusions containing aggregated forms of the normally presynaptic protein α-synuclein. When α-synuclein aggregates in the synapse, it may be transported along axonal microtubular tracts to the soma for degradation or deposition into insoluble inclusions. However, during this transportation, α-synuclein aggregates may also adhere to the microtubules and impede the axonal transport of other cellular constituents. Axonal transport is known to depend upon the stability of the microtubule tracks, but the specific impact of α-synucleinopathy on microtubular dynamicity is not known. Here, we assessed markers of microtubule stabilization in olfactory bulb and amygdala samples harvested postmortem from men and women with Lewy body disorders and age-matched control subjects. Unexpectedly, we observed that women showed higher levels of detyrosinated α-tubulin (marker of microtubule stability) as well as higher levels of tyrosinated α-tubulin (marker of non-stabilized microtubules) compared to men. In order to test the impact of microtubule stabilization on the functional properties of α-tubulin, we measured inclusion formation in primary hippocampal cultures treated with novel heterocyclic microtubule stabilizers and challenged with preformed α-synuclein fibrils. As expected, the microtubule destabilizer nocodazole prevented the reduction in pathological inclusions that was observed with two of the novel microtubule stabilizers. Preliminary data assessing the influence of the biological sex on microtubule stability in validated male versus female primary neuron cultures suggest that the two microtubule stabilizers reduced the pathological inclusions—particularly in male neurons. These collective data suggest that biological sex affects microtubule stability, including in the context of Lewy body disorders.

Title: Effect of cannabis on motor and non - motor symptoms of Parkinson's disease: a behavioral and pharmacological study

Authors: *E. GIORLA[1], C. BAUNEZ[2];
[1]Inst. De Neurosciences De La Timone, Marseille, France; [2]INT CNRS & Aix-Marseille Univ., Marseille, France

Abstract: Interest in cannabis and cannabinoid research for treatment of neurological disorders have received growing attention over the past years. Although there is evidence from animal and human studies that cannabis has some symptomatic effects, many therapeutic challenges remain. Cannabis and

cannabinoid treatments require further evidence to refine the therapeutic applicability of cannabis-based medicines. Since the endocannabinoid system is largely expressed within the basal ganglia, most studies regarding Parkinson's disease (PD) and cannabis have focused on the cellular and molecular interactions between cannabinoids and dopamine. However, if cannabinoids have the potential to be beneficial for motor symptoms in various animal models of PD, the optimal treatment remains to be identified. The present study thus aims at highlighting the role of cannabis on motor and non-motor symptoms of PD. Despite the fact that there are evidences to suggest that cannabis could be beneficial for parkinsonian patients, the available data are inconsistent. One critical question remaining to be addressed is whether CBD alone could be sufficient or whether THC is required to obtain a therapeutic effect. Here we have addressed it using behavioural measures assessing motor and non- motor functions. We have run 2 different experiments. First, in our model of haloperidol-induced catalepsy, we found that the combination of THC + CBD seems to be efficient to alleviate motor symptoms. THC alone, but not CBD alone, also seemed to be beneficial on this measure. Then, in a rat model of Parkinson disease, induced by a bilateral 6-OHDA injection in the dorso-lateral striatum, we assessed both motor, attentional, impulsive and motivational processes in the 5 choice serial reaction time task. As for the catalepsy experiment, we here tested CBD alone, THC alone and CBD/THC mix. The preliminary results suggest that injections of THC+CBD seem to be the best treatment to reduce the deficits induced by the DA depletion, since it decreased impulsivity and improved attentional deficit, common deficits in our PD model, it shows no detrimental effect. In conclusion, although it is currently trendy to consider therapeutical use of cannabis, the exact composition of what is available on the market is critical for efficiency. Our results suggest that CBD alone will not be efficient enough and it is important to have THC in the mixture. This is thus still illegal in our country, but may be soon accessible.

Title: The relevance of EEG biomarker in evaluating the anti-dyskinetic effect of drugs in Parkinson's disease.

Authors: *V. DUVEAU, A. EVRARD, J. VOLLE, C. ROUCARD, Y. ROCHE;
Synapcell SAS, St Ismier, France

Abstract: State-of-the-art clinical literature shows that motor symptoms of Parkinson's disease (PD) result from a dysfunction of the cortico-basal ganglia circuits. A hyper synchronization of beta rhythms in this circuit, positively correlated to motor symptoms, has been characterized in both parkinsonian patients and animal models. This aberrant excessive beta oscillation is suppressed by dopaminergic treatments, which simultaneously improve motor deficits. However, a chronic L-DOPA treatment induces abnormal involuntary movements (AIMs) and a prominent resonant gamma oscillation. This project aimed at investigating the effect of the antidyskinetic drug amantadine, which is routinely used in the clinic, on L-

DOPA-induced gamma oscillations in the 6-OHDA rat model of PD. In this poster, we will show that chronic administration of L-DOPA low dose (6mg/kg) induces specific gamma oscillations and AIMs which gradually increase with repeated treatments. We will demonstrate that a pre-treatment with amantadine dose-dependently reduces L-DOPA-induced gamma oscillations and AIMs score. Our data will illustrate how the preclinical study of cortical beta and gamma oscillations offers relevant and translatable EEG biomarkers that add significant value to drug development as stable, quantitative, and objective endpoints for the development of new antiparkinsonian and antidyskinetic neurotherapeutics.

Title: Differential effects of directional deep brain stimulation on parkinsonian gait in the parkinsonian non-human primate

Authors: *D. SULLIVAN[1], A. M. DOYLE[2], D. L. BAUER[3], Z. LAO[3], J. D. KRIEG[1], L. K. WILMERDING[1], M. BLUMENFELD[1], E. E. LECY[1], C. SPENCER[1], S. BEST[1], C. M. HENDRIX[3], J. WANG[3], J. L. VITEK[3], M. D. JOHNSON[1];
[1]Biomed. Engin., [2]Neurosci., [3]Neurol., Univ. of Minnesota, Minneapolis, MN

Abstract: Background: Deep brain stimulation (DBS) in the subthalamic nucleus (STN) is a proven therapy to treat many of the motor signs of Parkinson's disease. Parkinsonian gait dysfunction, however, can be difficult to manage with conventional, quadripolar STN-DBS leads.
Objective: In this study, we compare changes in gait speed with targeted stimulation within and slightly dorsal to the STN in a non-human primate.
Methods: A directional DBS lead containing two vertically segmented rows with three radially segmented contacts per row was chronically implanted such that the top vertical row of contacts was slightly dorsal to the STN and within the lenticular fasciculus. The subject voluntarily navigated over a pressure walkway system. Data was collected before and after rendering the subject parkinsonian with systemic MPTP as well as during a monopolar review of DBS configurations.
Results: Gait speed was significantly decreased following MPTP treatment. DBS delivered at 0.2 mA through one of the three contacts investigated was found to significantly increase gait speed. This was not observed at higher stimulation amplitudes (0.3mA) that were closer to the internal capsule side effect

threshold.
Significance: Parkinsonian gait deficits, including gait speed, may be differentially affected with directional DBS lead technology and thus requires careful titration of stimulation amplitude to avoid confounding therapeutic effects.

Abstract: Parkinson's disease (PD) is a prevalent motor disease caused by the accumulation of mutated α-synuclein (α-Syn); however, its early stages are also characterized by non-motor symptoms, such as olfactory loss, cognitive decline, depression, and anxiety. The therapeutic effects of environmental enrichment (EE) on motor recovery have been reported, but its effects on non-motor symptoms remain unclear. Herein, we reveal the beneficial effects of EE on PD-related non-motor symptoms and changes in synaptic plasticity in the nucleus accumbens. To investigate its therapeutic effects in the early phase of PD, we randomly assigned eight-month-old mice overexpressing human A53T (hA53T) α-Syn to either the EE or standard condition groups for two months. Next, we performed behavioral tests and biochemical and histological analyses at 10 months of age. EE significantly alleviated locomotor hyperactivity and anxiety during the early stages of PD. It normalized the levels of tyrosine hydroxylase, phosphorylated and oligomeric α-Syn, and soluble N-ethylmaleimide-sensitive factor attachment protein receptor complex-forming proteins, including synaptosomal-associated protein, 25 kDa, syntaxin1, and vesicle-associated membrane protein 2 (VAMP2). Moreover, the interactions between VAMP2 and

pSer129 α-Syn were markedly reduced following EE. The restoration of synaptic vesicle transportation status may underlie the neuroprotective effects of EE in hA53T α-Syn mice.

Title: Detecting excessive daytime sleep in Parkinsonian non-human primates via local field potentials from deep brain stimulation leads

Authors: *A. K. VERMA, S. ACOSTA-LENIS, Y. YU, T. HAVEL, A. DENICOLA, H. YAO, E. MARSHALL, M. STOLLER, D. ESCOBAR SANABRIA, M. HOWELL, C. MACKINNON, J. L. VITEK, L. A. JOHNSON;
Univ. of Minnesota, Minneapolis, MN

Abstract: The propensity to become drowsy or fall asleep while conducting daily routines is common in people with Parkinson's disease (PD) and adversely impacts their quality of life. Deep brain stimulation (DBS) of the subthalamic nucleus (STN) and internal globus-pallidus (GPi) is an established treatment for motor symptoms of PD, however, the utility of local field potential (LFPs) recorded from DBS lead implanted in the STN and GPi for characterizing daytime sleep remains unclear. Physiological understanding of neural activity in the STN and GPi corresponding to daytime sleep can provide a rationale for engineering closed-loop DBS paradigm for detection and disruption of sleep-related neural activity. To this end, we recorded LFPs from STN and GPi via DBS lead implanted in two nonhuman primates (*macaca mulatta*) rendered parkinsonian by administrating neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Power in δ (1-4 Hz), θ (4-8 Hz), α (8-12 Hz), β (12-35 Hz), ϒ (35-90 Hz), and high-frequency (HF, 200-400 Hz) bands of STN and GPi LFPs (1-sec long for continuous detection) were extracted to test whether these features can discriminate awake and sleep states. Holdout cross-validation (70% training and 30% testing) technique was used to train a support vector machines classifier. The classifier yielded >85% sensitivity, specificity, and accuracy for discriminating awake and sleep states. Results suggest that LFPs recorded from both STN and GPi via DBS lead contain reliable neural signatures for discriminating awake and sleep states continuously. The findings could have implications in the development of personalized closed-loop DBS strategies for detecting and disrupting sleep-related neural activity in PD patients to promote wakefulness supplemental to providing aid to motor impairment.

Title: Involvement of autophagy in levodopa-induced dyskinesia

Authors: *C. PLEWNIA[1], M. FEYDER[1], O. J. LIEBERMAN[2], G. SPIGOLON[1], A. PICCIN[1], L. URBINA[1], B. DEHAY[3], Q. LI[4], P. NILSSON[1], M. ALTUN[1], E. SANTINI[1], D. L. SULZER[2], E. BEZARD[3], A. BORGKVIST[1], G. FISONE[1];

Abstract: Autophagy is one of the major degradation pathways in eukaryotic cells and plays an essential role in maintaining effective turnover of proteins and damaged organelles. It is intensively studied in cancer, metabolic and neurodegenerative diseases, but little is known about its role in pathological conditions linked to altered neurotransmission. In this study, we examined the involvement of autophagy in levodopa (l-dopa)-induced dyskinesia, a frequent motor complication developed by Parkinson's disease patients in response to dopamine replacement therapy. In Parkinson's disease, the loss of dopaminergic input to the dorsal striatum leads to the sensitization of dopamine D1 receptors (D1R) which confers on l-dopa the ability to activate the mammalian target of rapamycin complex 1 (mTORC1) in the striatal projection neurons of the direct pathway. The ability of rapamycin, an inhibitor of mTORC1, to counteract dyskinesia has been previously related to its action on mTORC1 downstream targets involved in the control of protein synthesis. However, virtually nothing is known about the impact on l-dopa-induced dyskinesia of dysregulated autophagy, which is another important downstream target of mTORC1. In this study, we used a mouse and a non-human primate model of Parkinson's disease to examine changes in autophagy associated with chronic l-dopa administration and to establish a causative link between mTORC1 inhibition of autophagy and dyskinesia. We found that l-dopa-induced dyskinesia is associated with accumulation of the autophagy-specific substrate p62, a marker of autophagy deficiency. Increased p62 was observed in striatal projection neurons of the direct pathway and depended on D1R-mediated activation of mTORC1. Inhibition of mTORC1 with rapamycin counteracted the impairment of autophagy produced by l-dopa and reduced dyskinesia. Importantly, the anti-dyskinetic effect of rapamycin was lost when autophagy was constitutively suppressed in D1R-expressing striatal neurons, through inactivation of the autophagy-related gene protein 7. These findings indicate that, in Parkinson's disease, augmented responsiveness at D1 receptors leads to dysregulated autophagy, and results in the emergence of l-dopa-induced dyskinesia. They further suggest the enhancement of autophagy as a therapeutic strategy against dyskinesia.

Title: Identification of caspase and pro-inflammatory cytokines in a murine model for preterm hypoxic ischemic encephalopathy.

Authors: *T. C. HILLMAN, M. M. GHALY, C. G. WILSON;
Ctr. for Perinatal Biol., Loma Linda Univ., Loma Linda, CA

Abstract: Preterm hypoxic ischemic encephalopathy (pHIE) is a condition where blood and oxygen are prevented from reaching a fetus's brain resulting in neural inflammation and a spectrum of neurological conditions. Causes for pHIE vary creating a challenge for clinicians to diagnose the severity of an insult until after the damage is irreparable. Because most preterm HIE insults occur while the fetus is inside the mother, the signs, symptoms, and exact time of insults are often not clear. Current clinical interventions like therapeutic hypothermia and erythropoietin have decreased the severity of damage in full term infants; however, preterm infants do not respond to these treatments. Studying pHIE in a model where the insult started in utero has so far only been possible in large mammal models. Recently, however, use of a murine model which includes maternal factors has become available. The murine groups were divided into pHIE, three surgical control groups and a naïve group with tissue being harvested on the same post-gestational day for all groups. Using unbiased stereology, coronal brain slices were stained with caspase-9 and then counted to compare expression levels. The cortex of the right and left cerebral hemispheres were counted separately to identify if insult was bilateral or unilateral. Following caspase-9 staining 1.5 mm coronal brain sections were isolated and processed to investigate expression of pro-inflammatory cytokines IL-1B and TNF-α using an ELISA. The inflammatory pathway result for caspase-9, IL-1β and TNFα showed higher expression in pHIE than all controls. Caspase-9 expression in pHIE animals had higher positive cell counts per area in the cortex than the control animals. Expression of IL-1β and TNF-α had higher expression in 1.5 mm coronal cerebral hemisphere slices than the control animals. Expression of both the caspase marker and cytokines shows similarities to those seen in clinical reviews of human preterm infants. Additional analysis into the expression caspase-1 and other pro-inflammatory and anti-inflammatory cytokines needs to be conducted. Comparison between sex, sidedness, and target brain structure is underway. Looking at how murine pHIE pups in comparison to a murine full-term model in both inflammatory pathway proteins and miRNA will help direct more targeted therapies for preterm infants suffering from pHIE.

Abstract: Severe traumatic brain injury (TBI) usually leads to intracerebral hemorrhages which result in iron accumulation. Iron deposits are risk factors of post-traumatic epilepsy (PTE) after TBI. In the EpiBioS4Rx Project 2 study, we investigated the temporospatial patterns of post-hemorrhagic iron deposits after lateral fluid percussion injury (LFPI) induced severe TBI. We used adult male 11-weeks old Sprague-Dawley rats: lateral fluid percussion injury (LFPI) (n=12), LFPI and deferiprone (DEF) (LFPI+DEF; n=9), sham (n=12) and naïve (n=4). Sham rats underwent a left parietal 5mm craniotomy only, whereas LFPI were also subjected to ~3.2atm pressure pulse. The LFPI+DEF group received DEF, an iron chelator, DEF 100mg/kg ip followed by 7.6mg/kg/day via a minipump infusion sc right after TBI and for 7 days (d). Rats were perfused at 2d, and 1, 2, 4, or 8 weeks (wk) after LFPI. Perfused brains were sectioned and stained with Perl's Prussian blue stain for iron using qualitative (distribution in the brain) and quantitative analyses, to determine the iron-stained areas (pixels/mm^2) of corpus callosum/external capsule (CC/EC). Additional rats underwent LFPI or sham surgeries (n=10/group) and subsequently MRI at 9d and 5 months (mo) post-surgery. Multi-echo gradient echo (MGE) 3D sequences, with outer volume suppression and fat suppression, were used. MGE data was used to calculate T2* maps, anatomical mixed contrast images and field maps. CC/EC, parasagittal and lateral cortices, hippocampus, striatum and thalamus of LFPI rats ipsilaterally to the lesion had high quantity of iron deposit. Iron deposits were rarely seen in sham, and never in naïve rats. LFPI group had more total iron pixels compared to control ($p=0.023$) or sham ($p=0.0073$), considering all timepoints. At 1wk post-injury, iron load in LFPI+DEF was significantly less than LFPI ($p=0.007$) and no significantly different than control or sham rats. A week after DEF discontinuation, LFPI+DEF had more total iron pixels than LFPI, control or sham rats ($p<0.01$). MRI revealed hypointensities on T2* consistent with hemorrhages at CC/EC in all LFPI rats at 9d and 5mo, and less frequently, at the left lateral cortex (9d) and left thalamus at 5mo post-LFPI. No hemorrhages were observed in sham rats in MRI data. All rats develop hemorrhages/iron deposits at the CC/EC fibers ipsilaterally to the injury side after TBI, which may be detectable up to 5mo. Continuous 1wk treatment partially reduced the iron load during the first week post-LFPI, but this was not sustained after treatment discontinuation, suggesting that longer DEF treatment would be needed to reduce iron load in the brain of LFPI rats.

Nacional de Neurologia y Neurocirugia, Ciudad de México, Mexico; [4]Natl. Inst. Neurol Neurosurg., Mexico City, Mexico

Abstract: Epilepsy is a neurological disorder that affects about one percent of the world's population and is characterized by an alteration in electrical activity that manifests itself in recurrent and spontaneous epileptic seizures (ES) within the central nervous system. One of the main cellular mechanisms of this neurological disorder is the oxidative stress (OS) which can be emulated in animal models through the use of chemical agents such as pethylenetetrazole (PTZ) and kainic acid (KA). A defense mechanism against OS cellular include the nuclear factor erythroid 2 related factor 2 (Nrf2), which is related to the regulation in the transcription of antioxidant enzymes such as superoxide dismutase, catalase and glutathione peroxidase. We studied the role of the transcription factor Nrf2 in experimental models of epilepsy, as well as its regulatory participation in the antioxidant system. Male Wistar rats were used, were divided into three experimental groups, a control group (Saline solution), KA group (10 mg/kg ip) and another administered with 3 doses of PTZ (25 mg/kg ip) in 15-minute intervals. Cresyl Violet stain and immunohistochemistry antibody for Nrf2 and Nitrotirosine (NNT), were applied. We have found that in rats treated with KA, there is a loss of pyramidal neurons of CA1 and CA3 6 h after the induction of ES and the presence of karyolysis and pyknotic cells becomes evident in a period of 6 at 48 h. Similar results were observed in rats treated whit PTZ at 12 h after the induction of ES and the presence of karyolysis and pyknotic cells but other times period of 12 at 72 h. The immunohistochemistry expression of Nrf2 starting at 12 h and reaching a maximum point at 24 h after the induction of ES and then gradually diminishing in the PTZ model; while that the immunohistochemistry expression of Nrf2 increases slightly 1 h reaching the maximum expression at 24 h after the induction of ES in the group treated with KA. NNT as a marker of OS, showed an increase in the immunoreactivity 1 h after the ES are induced, reaching their maximum point 24 h after the administration of PTZ, while that the reactivity to NNT was increased at the 12 and 24 h in group treated whit KA. The present results corroborate the OS as the main mechanism of seizures in animal models.

Title: Temporal characterization of the immune response following repeat mild traumatic brain injury

Authors: *O. IFEJEOKWU, C. HENNINGFIELD, T. LEANING, E. REINHARDT, R. NISHI, Q. TUFONO, B. CUMMINGS;
Univ. of California Irvine, Irvine, CA

Abstract: America is facing an epidemic with over 1.5 million individuals suffering from a traumatic brain injury (TBI) annually. While our understanding of TBI and its devastating effects is growing, less is known about a serious subtype of TBI called repeated mild TBI (rmTBI). Previous neurotrauma research suggests that immune cell activation is altered following injury. However, a comprehensive picture of immune cell infiltration and activation following rmTBI remains to be established. Therefore, this study will characterize the immune response at multiple timepoints following rmTBI using flow cytometry (FCM), immunohistochemistry, and stereological cell counting to establish a clear timeline for treatments to mitigate some of the damage seen in neurotrauma related conditions like chronic traumatic encephalopathy. Eight week old C57Bl6 male mice received five mild closed-skull hits once every other day for 10 days using a controlled cortical injury device. The mice were sacrificed 1, 3, 7, 14, 28, or 60 days post injury (dpi) with an average of 6 mice per time point. Fresh brains were dissected and a two millimeter thick coronal section from -1 to -3 bregma was cut. Bilateral 4mm diameter biopsy punches were made at the midline at the dorsal-most region to isolate the injury epicenter, which were then stained and processed by FCM. Macrophages/microglia, neutrophils, and T-cells were fluorescently labeled and counted via FCM. A subsequent study was performed and quantification of the immune cell populations within the tissue using immunohistochemistry and sterology are ongoing. An ANOVA and Tukey's post-hoc multiple comparisons tests showed significance between several timepoints in the FCM data. Macrophages/microglia were significantly different between 3 dpi and 28 dpi ($p=0.0235$), with an increase until 3 dpi, followed by a decrease until 28 dpi. A second significant time point occurred between 28 dpi and 60 dpi ($p=0.0008$), with a second peak at 60 dpi. Together, these findings suggest that the immune response after rmTBI is multiphasic, similar to that observed after spinal cord injuries. By establishing a profile of how the immune cells respond following injury, this may allow one to target specific cells within optimal time windows to ameliorate rmTBI.

Title: Aberrant fear extinction learning after mild traumatic brain injury in mice is associated with alterations in neural plasticity in the basolateral nucleus of the amygdala and medial prefrontal cortex

Authors: *G. B. KAPLAN[1], J. A. BABB[2], A. ZUBERER[3], S. HEINRICHS[3], K. RUMBIKA[3], L. ALFILER[3], G. LAKIS[4], K. A. LEITE-MORRIS[1];

Abstract: Mild traumatic brain injury (mTBI) and post-traumatic stress disorder (PTSD) have emerged as the signature injuries of the U.S. military who served in Iraq and Afghanistan, and frequently co-occur in both military and civilian populations. To better understand this co-occurrence, we utilized a mouse model of mTBI followed by auditory cued fear conditioning and fear extinction training (5 trials/day for 6 days). In addition to fear acquisition and extinction, we examined dendritic plasticity and neuronal count in the medial prefrontal cortex (mPFC) and basolateral nucleus of the amygdala (BLA), two regions critical for fear learning. Behavioral and brain endpoints in adult male C57BL/6J mice subjected to a lateral fluid percussion injury of 1.7 atmospheres of force (LFP mice) were compared to mice from two separate control groups: craniotomy controls (Sham mice) and unoperated controls (Unoperated mice). After surgery, no gross motor abnormalities or anxiety-like behavior were observed in Sham or LFP mice compared to Unoperated mice. Fear behavior was then compared between groups using linear mixed effects analysis. Acquisition of auditory cued conditioned fear (i.e. freezing to tone) was similar in all groups. Conditioned fear behavior decreased for all groups over the course of 6 days of extinction training, and the decrease across days was not impacted by experimental group. However, a significant interaction between within-session freezing behavior (i.e. across trials, collapsed across extinction test day) and experimental group was observed. Specifically, whereas freezing behavior in both Sham and Unoperated control mice did not change across trials, freezing behavior significantly increased across trials in LFP mice. These results suggest that brain injury produces an aberrant form of fear extinction learning with greater reactivity to the fear cue. Additionally, LFP mice demonstrated bilateral increased dendritic spine density in the BLA and decreased dendritic complexity in the mPFC, which could underlie the observed behavioral effects. These results have implications for patients with co-morbid mTBI and PTSD undergoing extinction therapy and suggest that aberrant learning and neuronal plasticity could be targeted for more effective treatment interventions.

Title: Swimming reduces changes in cerebral anatomy and motor behavior caused by NMDA lesions in corpus callosum of the neonatal rat

Authors: *A. R. ARRAZOLA[1], A. ESPINOSA-JEFFREY[2], C. GOMEZ-ACEVEDO[3], T. HARMONY[1], G. L. QUIRARTE[1];
[1]Dept. de Neurobiología Conductual y Cognitiva, Inst. de Neurobiología, UNAM, Querétaro, Mexico; [2]Res. on Intellectual and Developmental Disabilities, Semel Central Institute, UCLA, Los Angeles, CA; [3]Dept. de Farmacología, Facultad de Medicina, UNAM, Ciudad de México, Mexico

Abstract: The encephalopathy of prematurity is a pathology that can develop in premature babies due to several risk factors. These risk factors can cause cell death by excitotoxicity in the gray and white matter of the brain. Katona's neuro-habilitation procedures have been implemented in premature babies to reduce cerebral injuries and motor impairments, but we do not understand the mechanisms of recovery in the premature brain. We developed a rat model to study this problem. On the 5th postnatal day (PD) the corpus callosum of male rats was unilaterally lesioned with NMDA (5 µg in 2 µL), and a swim protocol from the 7th to 30th PD was followed. On PD 7 the rats were divided into six groups: Intact-sedentary (ISe), Intact-swim (ISw), Vehicle-sedentary (VSe), Vehicle-swim (VSw), Lesion-sedentary (LSe), and Lesion-swim (LSw). We evaluated the volume of the cortex (motor, cingulate and sensory), corpus callosum, and lateral ventricles on PD 20 and PD 30 of independent groups and, also, we counted the number of NeuN positive cells and the positive labeling of Myelin Basic Protein (MBP). We also evaluated the motor activity and learning in a water maze task from PD26 to PD30. On the 20th PD, the LSe group showed a decrease of cortical and callosal volume and an increase in the volume of the ipsilateral ventricle. We also found a reduced number of NeuN positive cells in the ipsilateral motor cortex. The MBP positive label was reduced in the ipsilateral cortex and corpus callosum. Importantly, in the LSw group, the number of positive NeuN cells in the contralateral cortex was not different from the Intact and Vehicle groups, and the labeling of MBP was not reduced in the contralateral cortex and corpus callosum. On the 30th PD the LSe group did not show the motor ability to stay on a rotarod and had high

latencies in a modified water maze task; by contrast, the LSw group had the motor ability to stay on the rotor and learned the water maze task similar to the control groups. In conclusion, swimming from the 7th PD to the 30th PD reduces the structural, motor behavior, and cognitive alterations produced by an excitotoxic perinatal injury in rats. We thank, Roberto A. Title: Impaired neurogenic response to a repeated head injury

Authors: A. WEINGARTEN[1], T. M. BAH[2], S. RAPHAEL[2], S. L. FELLER[2], ***L. E. VILLASANA**[1,2]; [1]Legacy Res. Inst., Portland, OR; [2]Apom, Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: In response to traumatic brain injury (TBI) neural stem cells undergo robust proliferation, increasing neurogenesis within the hippocampus, a brain region critical for learning and memory. Because new neurons develop properties similar to mature neurons and integrate into existing circuits, post-TBI neurogenesis is thought to contribute to hippocampal recovery. However, levels of neurogenesis eventually become depleted after TBI. Deficits in neurogenesis impair several processes of memory and mood regulation. Additionally, these deficits could significantly impact how the brain recovers from repeated TBI. Hence, in this study we addressed whether the hippocampus remains capable of eliciting increases in neurogenesis after a second TBI. We used a mild closed head injury that is similar to a concussive injury in two-month-old male and female POMC-GFP mice which transiently express GFP in immature hippocampal neurons. Mice were subjected to either a sham, single or a subsequent TBI (3wk treatment interval) and euthanized 18 days later to assess hippocampal neurogenesis. In comparison to mice with a single TBI, mice with a second TBI had significantly fewer GFP^+ cells which was further confirmed with a second marker of immature neurons, doublecortin. To determine whether proliferation is also impaired, we conducted a similar experiment but injected mice with the mitotic marker EdU 3 days after the second TBI and euthanized them the following day. The density of Edu^+cells and cells positive for Ki67, another proliferative marker, were lower in mice with a subsequent TBI compared to mice with a single TBI. Increasing the injury interval to 2 months did not restore the proliferative response. Using GFAP, SOX2, and Edu as well as Ki67 to label proliferating radial glia-like neural stem cells we observed that their proliferative response to the subsequent injury was also impaired. Importantly, there

were no differences in their overall density, suggesting these impairments are not merely due to reduced populations. Interestingly, we also observed attenuated increases in GFAP expression (intensity) within the hippocampus of mice with a second TBI, suggesting an adaptive process may be associated with these response deficits. Our results demonstrate that a history of concussion alters the proliferative behavior of neural stem cells and subsequently, the neurogenic response to a subsequent head injury which could in part explain why repeated TBIs have worse cognitive outcomes. These results point to a novel mechanism underlying vulnerability to repeated TBI.

Title: Tbi leads to persistent structural and functional deficits in the cerebellum of a gyrencephalic animal model

Authors: *K. MANETZ, A. OBASA, S. C. SCHWERIN, S. L. JULIANO;
Uniformed Services Univ., Bethesda, MD

Abstract: Traumatic brain injury (TBI) occurs frequently and leads to persistent problems. The cerebellum is critical to normal function, but understudied in response TBI. To create a more realistic TBI model in a gyrencephalic animal (the ferret), we used a combination of injuries consisting of multiple explosive blasts, interspersed with rotational head injuries (CHIMERA) over a period of 2 weeks, with or without stress. After survival of 4 weeks or 6 months and behavioral testing, we evaluated the cerebelli of animals receiving the combination injury. To assess cerebellar architecture, Purkinje cells, Bergmann glia, and astrocytes we used antibodies directed against GFAP and Calbindin. The animals surviving for 6 months showed substantial pathology including severe reduction of calbindin expression and limited ability to visualize Purkinje cells and their dendrites. In the injury plus stress condition, pathology occurred in the posterior lobe including strong reduction of calbindin expression in entire folia, including Purkinje cells and their dendrites. In other regions, visibility of Purkinje cells was intermittent and occurred in a striped pattern suggesting that zebrin-related units were reduced in function. The Bergmann glia appeared relatively normal and well oriented, and in most (but not all) instances maintained protective nests surrounding presumptive Purkinje cells. The animals surviving for 4 weeks post injury also showed pathology, but limited to restricted to spotty regions throughout the posterior lobe. Several folia exhibited a striped pattern of calbindin immunoreactivity from the Purkinje cell dendrites, again suggesting that functional cerebellar units were impacted. The deep cerebellar nuclei (DCN) showed

reduced calbindin immunoreactivity surrounding nuclei, especially in the animals surviving for 6 months post injury, indicating the influence of the Purkinje cell axons on the DCN was reduced. GFAP+ reactive astrocytes were observed in the granular layer and also surrounding Purkinje cells. Surprisingly, behavioral deficits for the injured animals were relatively minor and they did not display obvious motor deficits associated with cerebellar problems. Collectively, compared with Sham animals, the injured ferrets showed reductions in Open Field activities, decreased movements in the Light-Dark Box, and decreased ability to maintain Eye Contact. The injured animals also showed impaired Novel Object Recognition and Socialization tests. These findings reveal chronic neuropathology in the cerebellum after a combination TBI accompanied by behavioral deficits associated more with cognition and memory than motor activity.

Title: Differential effects of injury on multiple markers in a gyrencephalic animal.

Authors: *A. A. OBASA[1], **S. C. SCHWERIN**[1], S. L. JULIANO[2];
[1]Anatomy, Physiol. and Genet., [2]Anatomy, Physiol. and Genetics., Uniformed Services Univ., Bethesda, MD

Abstract: Traumatic Brian Injury (TBI) affects numerous individuals and leads to multiple persistent problems. We designed a model of TBI that included injuries incorporating repeated explosive blast and strong head rotation (CHIMERA), with or without stress. These types of combination injuries often leave functional issues that persist for years after the initial event, similar to those experienced by people. We wanted to compare the effects of this type of injury with animals receiving blast injury only. In order to effectively investigate this problem, we conducted a set of experiments using a gyrencephalic animal (the ferret), whose brain possesses many features similar to humans and are more likely to demonstrate responses that reflect those experienced by people. The injuries (and/or stress) took place over a period of two weeks; at the end of this time, the animals survived for either 4 weeks or 6 months. We evaluated several parameters including inflammatory markers (GFAP for astrocytic reactivity and aquaporin 4-AQ4), expression of tau-related markers including phosphorylated tau (pTau) and the isoforms of tau, 3R and 4R as well as prion protein (another marker often expressed in neurons of those with degenerative diseases). GFAP and AQ4 showed dramatic and significant increases at 4 weeks post injury, which persisted until 6 months post injury. Both GFAP and AQ4 showed especially strong reactivity surrounding blood vessels, for GFAP alone strong reactivity was seen in the subpial region, and at grey-white matter interfaces. Using western blot, pTau showed increases in the prefrontal and anterior

cingulate cortex at 4 weeks post injury, which persisted until 6 months post injury. Differences in the strength of the increase emerged between the animals with and without stress. Both the 3R isoform of tau and pTau showed stronger increases in the prefrontal cortex for the animals receiving stress compared with animals receiving the injury alone. The prion protein, however, showed stronger increases in the prefrontal cortex, the anterior cingulate cortex, and the hippocampus in animals that received the injury only. Overall, the ferrets receiving this combination injury showed astrocytic reactivity and increased expression of tau related proteins more quickly than the animals receiving blast alone. The pathology persisted for at least 6 months.

Title: Modifications of NeuN-RbFox3 expression pattern by monosodium glutamate in neonate rats

Authors: *A. M. GARCÍA-JUÁREZ[1], N. J. CARRILLO-GONZÁLEZ[1], Y. GASCA-MARTÍNEZ[1], M. UREÑA-GUERRERO[2], M. C. RIVERA-CERVANTES[3], C. BEAS-ZÁRATE[1], G. GUDIÑO-CABRERA[1];

Abstract: Anti-NeuN was generated using neuronal nuclei extracts to identify transcriptional regulation factors and cellular processes associated with development, differentiation and function of neurons. Now NeuN/RbFox3 is known as a splicing factor, which participates in mRNA maturation processes in neurons. Then, anti-NeuN may label neurons and their transcriptional state by showing nuclear DNA and RNA distribution and arrangement. On the other hand, glutamate-induced excitotoxicity is associated with neurodegenerative diseases and acute injuries of the central nervous system which results in neuronal death and modified NeuN immunoreactivity patterns. Monosodium glutamate (MSG) applied to newborn rats is an *in vivo* model that allows evaluating the consequences of excitotoxic neuronal damage throughout development. Then, to identify the changes in the expression pattern of NeuN/RbFox3 related to the rearrangements of nucleic acids produced by excitotoxicity, the anti-NeuN, DAPI and propidium iodide (PI) labeling were performed in brain slices on the postnatal day (PND) 14 after neonatal MSG treatment. MSG (4 mg/kg) was subcutaneously administered on PND 1, 3, 5, and 7 to male Wistar rats. At PND 14, treated and non-treated animals (n=4 for each group) were anesthetized and perfused with fixing solution, the brain was removed and coronal slices at level of the dorsal hippocampus (from 2.30 to 4.30 mm posterior to Bregma) were processed to immunohistochemistry and histological evaluation. The neurons of the cortex and hippocampus from MSG treated rats showed cellular damage (by IP labeling), dense chromatin bodies and a diffuse immunodetection pattern for NeuN/RbFox3 in the nucleus (DAPI) and cytoplasm. Whereas in non-treated group, NeuN/RbFox3 immunodetection pattern was intense in the

cytoplasm and showed typical speckles into the nucleus. Because NeuN/RbFox3 immunodetection pattern is modifying in response to excitotoxicity, its characterization offers a new perspective to study the neuronal damage. MSG-induced excitotoxicity modified the NeuN/RbFox3 expression pattern and chromatin rearrangements, which must be characterized as part of the early mechanisms involved in neuronal death.

Title: Early detrusor application of botulinum toxin A reduces fibrotic bladder development and improves bladder compliance after severe thoracic spinal cord injury in rodents

Authors: *J. M. Y. BUSHNELL[1], J. R. BERGQUIST[1], L. N. CATES[1], T. PRASSE[1], J. E. HYDE[1], C. P. HOFSTETTER[1], C. C. YANG[2], Z. Z. KHAING[1];

Abstract: After spinal cord injury (SCI), 80% of patients develop neurogenic bladders, which affects their quality of life significantly. Neurogenic bladders are associated with increased bladder infection, autonomic dysreflexia, and kidney damage. Altered spinal cord connectivity drastically impact activities of the bladder, which in turn can alter central nervous system plasticity in chronic SCI - for example, afferent C-fibers do not respond in intact animals to bladder distension, but are triggered by distension in chronic SCI animals. Currently, patients with neurogenic bladders are treated with oral anticholinergic medications once they begin to develop symptoms. However, there are significant negative side effects associated with peripheral and central anticholinergic drugs, which have also been associated with both physical and mental impairment. Furthermore, anticholinergic medications do not prevent the development of detrusor muscle hypertrophy which contributes to a non-compliant storage organ, high bladder pressure, and triggers autonomic dysreflexia. Onabotulinum toxin-A (BoNT-A) is currently approved for clinical use as a denervation agent after other treatment options fail. By that time, tissue hypertrophy has typically already caused permanent damage. We hypothesize that acute bladder chemodenervation with BoNT-A application into the detrusor muscle can prevent the onset of bladder wall hypertrophy after SCI, thereby improving bladder compliance and function post-SCI in a rat model.

Preliminary data shows that early (<1 hour post SCI) BoNT-A injections result in thinner bladder walls compared to early saline injected bladders (575.8 ± 40.4 μm vs. 1,094 ± 83.1 μm respectively; $p<0.0001$). BoNT-A injected bladders of SCI rats (SCI-BoNT-A) were significantly lighter compared to saline injected bladders of SCI rats (SCI-saline) (183 ± 42 mg vs 241 ± 25 mg respectively; $p<0.05$) as well. Bladder volume measurements post-injury also showed that SCI-BoNT-A group had their bladder reflexes return earlier than SCI-Saline. Initial cystometry data showed that patterns of detrusor activity during micturition functions in SCI-BoNT-A animals were similar to that of uninjured control animals. A current study is underway to compare early BoNT-A injections with late (defined as three weeks post injury) injections to confirm the benefits of novel acute BoNT-A injection.

Title: Sensory cortical-locomotor pathway stimulation restores walking after spinal cord injury

Authors: *C. DOLICK[1], D. GRAHAM[1], D. REINHARDT[1], N. POPP[1], A. KRONER-MILSCH[2], C. M. OLSEN[3], S. K. KARADIMAS[4], K. SATKUNENDRARAJAH[2];
[2]Neurosurg., [3]Neurosci. Res. Ctr., [1]Med. Col. of Wisconsin, Milwaukee, WI; [4]Neurosurg., Univ. of Toronto, Toronto, ON, Canada

Abstract: Spinal cord injury (SCI) often results in significant impairment in patients' locomotor abilities. Though there exists an increasing need for new ways of restoring function below the level of injury, treatment options remain limited. To date, motor cortex stimulation has only produced minimal improvements in functional recovery after SCI. A plausible explanation is that, in most cases, contusion injuries entirely disrupt the main corticospinal pathways originating from the motor cortex. The primary somatosensory cortex (SI) has direct neural control over the lumbar locomotor central pattern generator through cervical excitatory interneurons (SI locomotor pathway) independent of the motor cortex. We demonstrate the input-output architecture of the cervical projecting SI pyramidal neurons, and that part of this SI-locomotor circuitry is preserved after thoracic SCI. Furthermore, we used an intersectional viral approach to selectively stimulate the SI pyramidal neurons, that project to the cervical spinal cord (SI-cervical pyramidal neurons) after SCI. Chemogenetic activation of the SI-cervical pyramidal neurons after SCI restored a robust locomotor function without any adverse effects on movement, such as loss of balance or pain. Importantly, we demonstrate that the recovered locomotor function after SCI is attributed to the neuromodulation of this pathway. The modulation of the novel SI locomotor pathway not only enhances movement in health but emerges as a promising therapeutic approach for promoting locomotor recovery after SCI.

Title: Promoting respiratory recovery in the chronic phase via cervical excitatory interneurons

Authors: *N. POPP[1], D. GRAHAM[1], D. REINHARDT[1], C. DOLICK[1], S. K. KARADIMAS[2], K. SATKUNENDRARAJAH[1];
[1]Neurosurg., Med. Col. of Wisconsin, Milwaukee, WI; [2]Neurosurg., Univ. of Toronto, Toronto, ON, Canada

Abstract: Cervical spinal cord injury (cSCI) disrupts descending drive to the spinal respiratory circuitry resulting in significant respiratory compromise. Dysfunctional breathing is a significant cause of morbidity and mortality after cSCI, and although mechanical ventilation can support life, that can lead to further respiratory complications. The ability to restore breathing in the chronic phase after cSCI is an overwhelming yet essential goal. The diaphragm, the major inspiratory muscle, is innervated by phrenic motoneurons (PMNs) located in the cervical spinal cord (C3-C5). Cervical excitatory interneurons (eINs) synapse onto PMNs and discharge in synchrony with phrenic inspiratory motor output and modulate breathing. At the chronic stage, the respiratory network undergoes substantial modifications. This proposal builds upon our finding that chemogenetic stimulation of cervical eINs, while not necessary for normal breathing, plays an integral role in promoting plasticity and respiratory recovery immediately after cSCI despite a significant loss of PMNs. While there is tremendous evidence for a critical role for these neurons in modulating breathing in health and after pathological conditions, there are still critical gaps in our knowledge about the potential of these neurons to mediate plasticity and promote recovery of breathing after chronic spinal cord injury (SCI). Here, we demonstrate using art neuroanatomical techniques to detail the temporal changes in the connectivity of the respiratory neural circuitry following traumatic SCI, specifically looking at the plasticity of descending projections from premotor neurons in the brainstem to PMNs via eINs. Additionally, chemogenetic stimulation of cervical eINs, eight weeks after cSCI lead to significant enhancement of ventilation. Together, our findings demonstrate the capacity of cervical eINs in promoting respiratory plasticity and recovery after cSCI in the chronic state when promoting recovery is a daunting task.

Title: Effect of DREADDs activation of large diameter sensory afferents on recovery from contusion spinal cord injury in rats

Authors: *G. MOUKARZEL[1], K. M. KEEFE[2], G. T. KOMA[1], T. J. CAMPION, III[2], R. D. SMIT[2], S. OLDFIELD[1], B. RAUSCHER[1], G. M. SMITH[2], M. A. LEMAY[1], A. SPENCE[1];
[1]Col. of Engineering, Dept of Bioengineering, [2]Lewis Katz Sch. of Med., Temple Univ., Philadelphia, PA

Abstract: Spinal cord injury (SCI) causes life-long neurological impairment with loss of sensory and motor function distal to the point of injury. There are approximately 300,000 patients living with SCI in the United States and currently no effective treatment, reducing quality of life. Epidural Electric Stimulation (EES), that is thought to excite large diameter sensory afferents (LDSA), has been found to improve recovery from spinal cord injury in conjunction with movement rehabilitation in rats and humans. We sought to develop an alternative approach for excitation of LDSA using the chemogenetic modulator of neuronal activity Designer Receptors Exclusively Activated by Designer Drugs (DREADDs). DREADDs are activated by a putatively inert drug, clozapine-N-oxide (CNO), that crosses the blood brain barrier.
Long Evans rats were used in this study. Experimental animals had bilateral AAV2-DIO-hSyn-hm3dq-mCherry/Cre recombinase cocktail injections in L3-L5 dorsal root ganglia (DRG). Controls were injected with AAV2-mCherry into the same DRGs. 3 weeks post injection, all animals underwent a 200kDyn contusion on T10 spinal level. To assess recovery, The Basso Beattie and Bresnahan BBB locomotor rating scale, asymmetrical horizontal ladder and kinematics were scored before injury and at 3, 4, 6, 7 and 8 weeks after injury. Animals were exercised 3 times a week for 4 minutes with a 4mg/Kg intraperitoneal injection of CNO 30 minutes prior to exercise except for week 7. Week 7 was a CNO withdrawal week, seeking to determine if CNO is necessary for any observed changes in function at that time point. Horizontal ladder assays were scored on a hit/miss percentage system. Kinematics were extracted from video using DeepLabCut, and custom software written to derive parameters for each stride.
Preliminary results for 7 animals given excitatory DREADDs show a change in kinematics in week 7 with CNO withdrawal. Without DREADDs activation, these animals showed reduced minimum ankle height during the swing phase (1-way ANOVA across weeks 6, 7, 8; n=7 rats; p=0.025) and reduced anterior superior iliac spine (ASIS) height (test as above; p=0.016). CNO withdrawal on week 7 was associated with a trend towards worse ladder performance than the previous and following weeks. These results suggest that DREADDs activation may be necessary for changes in movement at longer times post injury. It does not rule out that plasticity in neural circuitry has occurred: plasticity may rely on afferent activation. As only 1 control animal completed the first study, statistical comparison of experimental animals to controls is not yet sufficiently powered; data collection is ongoing and will be added.

Title: Cervical spinal cord injury induces distinct changes in gut microbiome composition over time in rats

Authors: *J. S. NEWTON, C. E. TAYLOR, L. E. MENDENHALL, S. L. SPEED, C. M. CALULOT, W. J. ALILAIN;
SCoBIRC, Univ. of Kentucky, Lexington, KY

Abstract: Nearly 60% of all spinal cord injuries (SCI) occur at the cervical level. These high-level injuries can lead to quadriplegia, autonomic dysregulation, and interruption of the descending respiratory pathways required for breathing. As respiratory motor function is required for life, it is critical to restore breathing as soon as possible after cervical SCI. Indeed, therapeutic techniques in animal studies have been successful at restoring breathing function after SCI; however, these interventions appear to be more effective at chronic than acute timepoints post-injury. One potential cause for this observation is the impact the injury has on the gastrointestinal (GI) tract and gut microbiome, which have previously been shown to have detrimental effects on recovery outcomes, including lower limb motor function and emotional affect as indicated by increased anxiety-like behavior. However, the impact the gut microbiome has on the recovering spinal cord at different timepoints, levels, and injury severities still needs to be fully realized. We aimed to build upon these previous findings and investigate the impact of cervical SCI on the gut microbiome over time and up to chronic timepoints. We hypothesized that cervical SCI leads to transient changes in the gut microbiome, which are most severe acutely after injury impeding functional recovery of breathing, but resolve over time and thus eventually allow for more profound recovery. To test our hypotheses, we performed left C2 hemisections on adult female rats, collected fecal samples from injured, sham, and naïve animals, and assessed microbiome composition at various timepoints pre- and post-injury. Preliminary results suggest that following cervical SCI (up to 12 weeks post injury), robust differences in gut microbiome are apparent compared to non-injured animals. Future studies will classify bacterial identities and assess the impact of the post-injury gut microbiome on respiratory motor function and plasticity, as well as inter-institutional differences.

Abstract: Acute episodes of low oxygen breathing (i.e., acute intermittent hypoxia; AIH) improve breathing ability and overground walking in persons with chronic incomplete spinal cord injury (iSCI). Based on studies in rodents, repetitive AIH elicits plasticity of spared axonal projections bypassing the injury site, thereby increasing respiratory and non-respiratory motor outputs in rats with hemisected, cervical iSCI. However, hypoxia also causes spinal extracellular adenosine accumulation, initiating a distinct mechanism that undermines AIH-induced motor facilitation. Studies in rats with iSCI found that adenosine A_{2A} receptor inhibition increases AIH-induced motor facilitation more than twofold. Thus, drugs removing the adenosine constraint to AIH-induced plasticity may improve motor function (e.g., walking) in persons with iSCI. The purpose of this study is to identify the extent to which caffeine, an adenosine A_{2A} receptor antagonist, may augment AIH-induced motor recovery in persons with iSCI. We conducted a cross-over, randomized clinical trial in a cohort of adults with chronic iSCI (injury onset 8±3.5 years, ±1.S.E). Participants received daily (5 days) treatments of caffeine (6mg/kg) 30-min prior to AIH (C+AIH) or room air (C+SHAM) and placebo prior to AIH (P+AIH) in a randomized order. A minimum of two weeks was allowed between AIH treatments (15, 1.5 min episodes; FIO2=0.10±0.02) or SHAM (15, 1.5 min episodes; FIO2=0.21±0.02). Participant vital signs were monitored throughout AIH and SHAM sessions to ensure safety. To evaluate motor recovery, overground walking speed (10-meter walk test, 10MWT) was assessed at baseline and day 5, as well as one week and two weeks post-treatment. Consistent with our hypothesis, caffeine augmented AIH-induced gains in walking performance in persons with iSCI. Participants' 10MWT time decreased following AIH alone (P+AIH: -1.9±2.0s) and C+AIH (-4.9±1.8s). The greatest reduction in walking time occurred with C+AIH, an effect that persisted for 2 weeks post-treatment (-6.3±1.8s, $p<0.01$) versus baseline. This enduring effect did not occur following C+SHAM (1.2±2.1s) or P+AIH (0.2±2.0s). We also found that the CYP1A2 genotype influences the potency of C+AIH. Persons who demonstrated the greatest gains in C+AIH walking speed possessed the homozygous (A/A) CYP1A2 genotype (fast caffeine metabolizers). These results are in part consistent with pre-clinical studies demonstrating that a selective adenosine A_{2A} receptor antagonist reduces crosstalk inhibition and enhances AIH-induced functional recovery of walking speed in persons with iSCI.

Title: Sacral-coccygeal transcutaneous electrical stimulation for modulation of locomotion after spinal cord injury in humans

Authors: *R. SIU[1], E. H. BROWN, Jr.[1], S. MESBAH[1], F. GONNELLI[2], T. PISOLKAR[1], A. V. OVECHKIN[1], Y. P. GERASIMENKO[1,3];

Abstract: Following a spinal cord injury (SCI), the locomotor central pattern generator (CPG) loses supraspinal and propriospinal inputs leading to a loss of locomotor function. Our previous studies have shown improved locomotion after SCI using spinal cord transcutaneous stimulation (scTS) at the lumbar region (T11/T12 and L1/L2 vertebral levels). Yet, the effectiveness of scTS can be enhanced when paired locomotor training and/or pharmacological agents. In animals, the tail plays an integral role in locomotion, serving as an additional input to the locomotor CPG. While the tail is an atavism in human, the inherent anatomical connections between this area and locomotor-related neuronal network may still be present. Thus, it is possible that by stimulating the sacral-coccygeal region, we may influence the locomotor CPG. Here, we investigated the effect of stimulation over the Co1 vertebra on locomotor activity after spinal cord injury. Under approval of the University of Louisville Institutional Review Board, we conducted acute studies on non-disabled (ND) volunteers (n = 3) and a SCI volunteer with motor complete paraplegia. Continuous Co1 scTS was delivered by a constant current stimulator (BioStim5; Cosyma, Moscow) via transcutaneous electrodes using a cathode placed over the Co1 region and two bilateral anodes over the abdomen. Monophasic pulses were delivered at 30 Hz with a carrier frequency of 5 kHz, and a pulse width of 1 msec. Current amplitude was dictated by observed locomotor behavior and the absence of discomfort of the participant. Behavioral assessments in a gravity neutral setting showed that multiple muscles became active after Co1 scTS in the SCI group, increasing electromyography (EMG) power significantly ($p<0.001$). No change was observed in the ND group. Meanwhile, coefficient of variation of the EMG was lower in the SCI group ($p<0.005$) during Co1 scTS. Neurophysiological assessments using spinally evoked motor potentials (SEMPs) at the L1/L2 vertebral level during voluntary tasks with Co1 scTS showed no difference in the ND group, but showed inhibition in the SCI group when compared to control SEMPs ($p<0.005$). Furthermore, SEMPs evoked at Co1 showed an additional late response in the extensor muscles when compared against SEMPs at L1/L2. These results suggest that Co1 scTS targets the locomotor CPG through indirect pathways and this input can be considered as a modulator of locomotor function. These results establish a novel approach to scTS that may lead to increased rehabilitative effectiveness in improving locomotor recovery after SCI.

Title: Rapid Differentiation of iPSC Derived Dorsal Spinal Cord Progenitors for Use in Spinal Cord Injury

Authors: *A. HUNTEMER-SILVEIRA[1], D. MALONE[2], P. WALSH[2], A. PARR[3];
[1]Univ. of Minnesota Grad. Program In Neurosci., Minneapolis, MN; [3]Neurosurg., [2]Univ. of Minnesota, Minneapolis, MN

Abstract: In the United States, there are approximately 18,000 new cases of spinal cord injury (SCI) each year, and more than half of these cases result in paralysis of two or more limbs, with individual economic costs in the millions. SCI can diminish or abrogate both motor and sensory systems. With the advent of human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSCs), the future of regeneration of neurons in SCI is promising. In the past decade, deriving motor neurons (MNs) from both iPSCs and hESCs has increased our understanding of degenerative spinal motor diseases, as well as shown successful transplantation in rat models. However, comparatively little has been published to date applying the same strategies to the dorsal spinal cord and promotion of sensory recovery. This is critical, as the majority of SCI patients report both impaired sensory perception as well as debilitating chronic pain. Therefore, an imperative next step is to develop protocols to successfully differentiate stem cells into sensory neuron and interneuron populations. Unfortunately, this has been far less studied; a protocol to differentiate stem cells into these cell types in a short amount of time remains to be seen. We report here the preliminary results of our work generating a rapid differentiation protocol of region specific dorsal spinal cord progenitor cells in approximately 5-7 days from human iPSCs. Our ultimate goal is to combine these cells with our ventral MNs in a transplantation model in order to attain correct repair and reconnection at the site of injury, restoring both motor and sensory systems. These discoveries will push the field of spinal regeneration forward and offer hope to those affected by SCI.

Title: Rebuilding serotonergic regulation for cardiovascular functional recovery after spinal cord injury

Authors: *C. TRUEBLOOD, E. OATMAN, S. FERNANDES, J. DEFINIS, S. HOU;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Cardiovascular dysfunction is one of the leading causes of mortality and morbidity among the population with spinal cord injury (SCI). Recently, transplanting embryonic raphe nuclei derived neuronal progenitors (RN-NPCs) into the rat injured spinal cord has been shown to mitigate disordered cardiovascular function. To determine if both host and graft-derived serotonergic ($5HT^+$) transmission mediate this functional restoration, we grafted embryonic day 14 (E14) RN-NPCs into the lesion of crushed spinal cord, which allows for better graft-host integration, at the 4th thoracic level. Rats receiving transplantation of E14 spinal cord-derived neural progenitor cells (SC-NPCs), or injury alone served as controls. Using radio-telemetric recordings, we analyzed resting hemodynamics, daily occurring spontaneous autonomic dysreflexia (AD) events, and the severity of colorectal distension (CRD)-induced AD. Subsequently, pharmacological and chemogenetic interventions were employed to elucidate reestablished supraspinal or intraspinal serotonergic machinery of cardiovascular function. The results demonstrated that RN-NPC grafts decreased tachycardia at rest, mitigated AD severity, and decreased the number of daily spontaneous AD events. Intrathecal (*i.t.*) administration of the $5HT_{2A}$ antagonist, Ketanserin, increased the resting heart rate in RN-NPC grafted rats, suggesting that the reduction in tachycardia is mediated in part through graft-derived serotonergic mechanisms. Unexpectedly, injections of Lenti-TPH-hM4Di-mCherry into the host raphe magnus to silence serotonergic neurons reduced the heart rate in RN-NPC but not SC-NPC grafted or injury only rats. This might be due to the interaction between host $5HT^+$ cells and grafted neurons. In addition, administration of the α-1 adrenoreceptor, Prazosin, significantly decreased AD severity, indicating the involvement of catecholamines in the reflexic response. Overall, it illustrates that grafted RN-NPCs-induced cardiovascular recovery is partially mediated through reconstituted supraspinal and graft-derived intraspinal serotonergic mechanisms. The results provide vital guidance to develop cell-based therapeutic approaches for cardiovascular recovery in SCI patients.

Abstract: Traumatic spinal cord injury (SCI) affects millions of people of all ages around the world and can potentially lead to irreversible cognitive and motor damage without any immediate therapeutics available. There is a significant demand for physiologically relevant models of SCI. The rise of Organ-on-Chip technologies combined with human cells opens new route to limit the number of animal experiments. The major modeling challenge is to accurately perform the injury only on the neurites without affecting cell viability and to apply the pre-clinical stage compounds on cell soma only. Microfluidic chip designs applied to neuroscience research are based on connection between compartmentalized neuronal populations through guiding neurite outgrowth by using microchannels. The longitude of microchannels acts as a selective barrier for the exclusive passage of axons over dendrites and it promotes the unidirectional growth of the neurites from one compartment to the other.We will present the design and fabrication of a compartmentalized microfluidic device with three compartments capable of both inducing a localized axotomy and a fluidly isolated cell chamber. The device allows quantification of axonal regeneration post-injury using an innovant and unique triangular design. Human-induced pluripotent stem cell-derived motor neurons are seeded and maintained up to 3 weeks in vitro. We performed a chemically-induced axonal injury on isolated axons in the middle compartment only. We then follow the dynamics of the axonal regeneration using the triangular methodology with and without tested neuropharmacological compounds in soma chamber. We show that this model can be sucessfully used for quantitative analysis of neurite outgrowth dynamics. We will finally present how this model can be used to record the functional activity using multielectrode arrays (MEA) coupled to the microfluidic device. The access to functional data during the injury and the recovery process provides relevant insight on the mode of action of pharmacological compounds. Our data suggest that this model can be used for high-throughput drug-induced axonal regeneration screening for preclinical stages pharmaceutical compounds. In conclusion, this study shows the added value of neurofluidic design strategies for the investigation of neurite length dynamics. To further strengthen the efficacy of those strategies, future work should focus using such methodology to evaluate the effect of pharmacological compounds on neurite elongation and orientation on maturing and mature human culture as well as proving the impact of hydrostatic pressure on neural architecture manipulation.

Title: Bone loss following spinal cord injury: effects of age and time post injury

Authors: *J. RAU[1], C. METZGER[2], H. ALLAWAY[3], A. V. STEFANOV[1], M. ALLEN[2], M. HOOK[4]; [1]Texas A&M Inst. for Neurosci., College Station, TX; [2]Anat. and Cell Biol., Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Hlth. and Kinesiology, Texas A&M Univ., College Staion, TX; [4]Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Following spinal cord injury (SCI), more than 80% of individuals develop osteopenia or osteoporosis. This unseen consequence of SCI renders these people 104 times more likely to have a bone fracture before the age of 50. Post-fracture complications then occur in 50% of cases, including venous thromboembolism, respiratory and urinary tract infections, and fracture nonunion, further increasing healthcare costs, morbidity and mortality. Despite the high prevalence of osteoporosis after SCI, and the overwhelming effects on quality of life, very few studies have focused on bone loss. It is critical that we understand how SCI affects bone. Further underscoring this pressing need, the SCI population is aging, and the age at which trauma occurs is increasing. Surprisingly, however, there have been no studies on the effects of age on bone loss after SCI. This study aims to address this gap in knowledge. We hypothesized that bone loss after SCI would increase with age and would be exacerbated with increased time post injury. To test this, we assessed bone loss in young (2-3 months) and old (9-10 months) male rats given a moderate spinal contusion injury. We collected the proximal tibia of the rats 1 and 6 months after SCI and assessed changes in the cancellous and cortical bone. Despite recovery of plantar weight-supported stepping, SCI rats had significantly less trabecular bone volume at both 1 and 6 months post injury when compared to age-matched shams. Both young and old rats also had higher osteoclast surfaces at one month post SCI. This increased osteoclast activity persisted until 6 months in the young rats, but was not present in older rats. Alarmingly, decreased bone formation also persisted even 6 months post SCI in both young and old rats. This means that in addition to the dramatic bone loss seen in acute SCI, osteogenic potential remains insufficient in the chronic stage. Together these results suggest that following SCI, regardless of weight-bearing, male rats exhibit decreased osteoblast and increased osteoclastic activity, leading to sustained bone loss even six months after injury. These data suggest that as the SCI population continues to age, the effects of bone loss on health and quality of life will also increase exponentially. It is critical that we identify the mechanisms mediating bone loss in this model, and begin testing novel interventions that improve bone integrity in people with SCI.

Sci., Undergraduate School, Korea Univ., Seoul, Korea, Republic of

Abstract: Subsequent spinal vascular disruption following spinal cord injury (SCI) leads to breakdown of blood-spinal cord barrier (BSCB) which results in uncontrollable neuronal cell and glia necrosis and apoptosis. It is hard to prevent BSCB destruction because it occurs immediately after trauma and rapidly spread to rostral and caudal sites. Polyethylene glycol (PEG) is a hydrophilic polymer regarded to have fusogenic property which can seal the ruptured cell membrane and has been tried to use as a therapeutic substance for cell protection after SCI. In the present study, we investigated the effect of PEG on the vascular system after SCI, especially on the BSCB integrity. Spinal contusion was made at T11 segment in adult male SD-rats. Immediately after SCI, PEG was injected under the dura mater and 0.9% saline was injected for sham controls. Effect of PEG on BSCB integrity was proved with examining a leakage of molecules and number of blood vessel in lesion site by using Evans blue dye (EBD) and laminin staining in rats with contusive SCI. The damage of BSCB and blood vessels were assessed over time after spinal contusion (0, 3, 6, 12 and 24 hours after SCI). To confirm the actual function of blood vessels after SCI, we used 2,3,5-Triphenyltetrazolium chloride staining (0, 6 and 24 hours). Motor function was evaluated by using the Basso, Beattie, and Bresnahan (BBB) locomotor rating scale and combined behavioral score (CBS) (before and 1, 3, 5, 7, 10, 14, 21, 28, 35 and 42 days after SCI). Sparing tissues were analyzed with Luxol fast blue and cresyl violet staining after behavioral assessments. Leaked EBD from microvasculature started immediately after SCI and continued for 24 hours after SCI. In PEG group, Overall leakage of EBD was significantly decreased compared to sham control 0, 6, 12 and 24 hours after SCI. Blood vessels replaced more rapidly the lesion site at 6 and 24 hours after SCI in the PEG group compared to sham control and infarction sizes also were less in PEG group at 0, 6, 24 hours after SCI. In behavioral assessments, PEG group also showed earlier improvement of neurological locomotor function and prolonged recovery for 42 days post-SCI. The cavitation and shrinkage of spinal tissues in epicenter were also significantly less after PEG application. The present results demonstrated that PEG application in acute phase can attenuate ischemic injury in gray matter and improve earlier recovery of neurological functions through rapidly preventing the disruption of vascular system and preserving BSCB after SCI.

Title: Modulation of astroglia-neuron trophic coupling and functional recovery after spinal cord injury by targeting the thrombin receptor

Authors: *H. N. KIM[1,2], E. M. TRIPLET[1,2], M. RADULOVIC[2], S. BOUCHAL[1], L. S. KLEPPE[1], W. L. SIMON[1], H. YOON[1,2], I. A. SCARISBRICK[1,2,3];

Abstract: Excessive activation of the thrombin receptor, protease activated receptor 1 (PAR1) is implicated in diverse neuropathologies from neurodegenerative conditions to neurotrauma. PAR1 knockout mice show improved outcomes after experimental spinal cord injury (SCI), however information regarding the underpinning cellular and molecular mechanisms is lacking. Here we demonstrate that genetic blockade of PAR1 in female mice results in improvements in sensorimotor coordination after thoracic spinal cord lateral compression injury. We document improved neuron preservation with increases in Synapsin-1 presynaptic proteins and GAP43, a growth cone marker, after a 30 days recovery period. These improvements were coupled to signs of enhanced myelin resiliency and repair, including increases in the number of mature oligodendrocytes, their progenitors and the abundance of myelin basic protein. These significant increases in substrates for neural recovery were accompanied by reduced astrocyte (Serp1) and microglial/monocyte (CD68 and iNOS) proinflammatory markers, with coordinate increases in astrocyte (S100A10 and Emp1) and microglial (Arg1) markers reflective of pro-repair activities. Complementary astrocyte-neuron co-culture bioassays suggest astrocytes with PAR1 loss-of-function promote both neuron survival and neurite outgrowth. Additionally, the pro-neurite outgrowth effects of switching off astrocyte PAR1 were blocked by inhibiting TrkB, the high affinity receptor for brain derived neurotrophic factor. Altogether, these studies demonstrate unique modulatory roles for PAR1 in regulating glial-neuron interactions, including the capacity for neurotrophic factor signaling, and underscore its position at neurobiological intersections critical for the response of the CNS to injury and the capacity for regenerative repair and restoration of function.

Title: Transplanting embryonic raphe nuclei-derived neural progenitor cells into the injured spinal cord improves cardio-electric disorders

Authors: *S. FERNANDES, E. OATMAN, C. TRUEBLOOD, S. HOU;
Marion Murray Spinal Cord Res. Center, Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: High-level spinal cord injury (SCI) often interrupts supraspinal regulation of sympathetic activity to the heart. The loss of balance between autonomic components renders the occurrence of cardio-electric disorders such as arrhythmias. To reestablish serotonergic regulation of cardiac sympathetic activity, we transplanted embryonic day 14 (E14) raphe nuclei-derived neural progenitor cells (RN-NPCs) into the lesion of a crushed rat spinal cord at the 2nd thoracic (T2) level. Animals receiving E14 spinal cord-derived neural progenitor cells (SC-NPCs), injury alone or naïve served as controls. After 10-12 weeks, a radio-telemetric system was used to record electrocardiogram (ECG) and blood pressure (BP) for parameter analyses, including 24-h recording for heart rate variability (HRV), cardiac arrhythmias during colorectal distention (CRD) induced autonomic dysreflexia (AD) or dobutamine stress tests to mimic exercise. As a result, transplanting RN-NPCs significantly increased HRV which were characterized by increased values of root-mean-square of successive differences (RMSSD) in time domains and of low frequency (LF) in frequency domains, indicating enhanced sympathetic activity. The grafts decreased the occurrences of various arrhythmias during CRD-induced AD. When different doses of dobutamine were administered, the number of arrhythmias was significantly increased in rats grafted with SC-PNCs or injury alone but not those with RN-NPCs. Subsequently, pharmacological interventions showed that grafted RN-NPCs reconstituted sympathetic tone to the heart. Histological analysis revealed grafted serotonergic cell survival and well-integration with the host tissue. Numerous graft-derived serotonergic axons projected to the caudal autonomic regions innervating sympathetic neurons. The results indicated that RN-NPC transplants improve cardiac performance by possibly reestablishing serotonergic regulation for the recovery of sympathetic activity following SCI. Ultimately, this finding helps understand cardio-electric disorders in SCI subjects and provides insight on potential therapeutic strategies.

Title: Mapping the connections between motor cortex and pain circuits

Authors: *N. MERCER LINDSAY[1], P. YUAN[1], M. J. SCHNITZER[2], G. SCHERRER[3];
[1]Biol., Stanford Univ., Palo Alto, CA; [2]Depts. Biol. & Applied Physics, Stanford Univ. Dept. of Biol., Stanford, CA; [3]Cell Biol. and Physiol., Univ. of North Carolina Chapel Hill, Chapel Hill, NC

Abstract: The dual chronic pain and opioid epidemics have prompted an urgent search for alternative, non-addictive methods of analgesia. One promising alternative is non-invasive electrical or magnetic stimulation of the motor cortex (MC). While MC stimulation (MCS) has repeatedly been found to reduce chronic pain in human subjects and to decrease nocifensive behaviors in rodent models, how MC is connected with, and influences activity in, pain circuits remains unclear. To fill this gap in knowledge, we identified MC neurons active during pain and traced their connectivity by combining calcium imaging of thousands of cortical neurons in mice exposed to noxious stimuli with viral tracing from activity-determined MC nociceptive neurons. We identified a population of MC neurons that is distinctly more active during the application of a noxious stimulus than an innocuous stimulus. In particular, our calcium imaging studies revealed that the majority of MC nociceptive neurons activated following orofacial application of capsaicin are in the M2 subregion. Consistently, in TRAP2/Ai14 mice, in which neurons activated following capsaicin application express the fluorescent reporter tdTomato, we observed a population of tdTomato+ neurons in M2. The density of tdTomato+ neurons in M2 is comparable to that found in the primary somatosensory and anterior cingulate cortices (S1 and ACC, respectively), two cortical regions known to be important for pain perception. Finally, using viral tracing in TRAP2 mice, we labelled the outputs of M2 nociceptive neurons. Notably, we identify outputs to regions mediating the affective-motivational and cognitive-evaluative dimensions of pain experience, like the amygdala and medial thalamus, and regions involved in descending pain control such as the periaqueductal gray, through which motor cortex could influence nociceptive processing and pain perception. Altogether, our data suggests that motor cortex activity increases during pain and that this activity could influence downstream regions during pain perception. Determining how motor cortex influences pain experience could lead to improved stimulation protocols to relieve pain suffering in chronic pain patients.

Abstract: Based from our previous works on the P2X7 and central post-stroke pain(CPSP), we have known that the P2X7 gets raised under CPSP condition and targeting P2X7 could vary the CPSP. Published reports that utilized mice with genetic deletion of P2X7 have shown reduced pain sensation. Although adenosine 5′-triphosphate (ATP) has been reported as a transmitter in the peripheral nervous system, and, a recording of evoked and miniature synaptic currents in the rat medial habenula have supported such a role in the central nervous system(CNS), whether ATP and its receptor directly involved in nociceptive transmission as well as its presence along the pain path in the CNS remain unclarified. In views of the mentioned significance of P2X7 involved in chronic/neuropathic pain and views of its role as a receptor for a known neurotransmitter ATP, we set to study the functional role of this receptor particularly during pain signaling in the thalamocingulate path with established pain models. We 1st utilized major *in vivo* and *ex vivo* neuropharmacological methods to record the effects of manipulating P2X7 receptors during neuron transmission with electrical stimulations(sciatic nerve stimulation, SNS) to mimic nociceptive inputs along the thalamocingulate path and synergistically analyzed the changes of downstream neurotransmitters or molecules following the SNS and P2X7 activation in wild type and P2X7 knockout mice(P2X7 KO) with combined microdialysis and high performance liquid chromatography (HPLC) methods. Secondly, we utilized live-Ca2+ imaging to verify the functional presence of P2X7 in the medical thalamus (MT) and anterior cingulate cortex(ACC). Our result revealed that upper MD application of P2X7 agonist or antagonists promoted or inhibited of both MT and ACC neuron activities. Under SNS, an elevated amount of Glu and ATP, ADP was detected in dialysate collected from the MT, whereas accompanied P2X7 antagonist application could reduce such an elevation in the combined microdialysis and HPLC assay. Brain slice Ca2+ imaging at MT and ACC Cg2 region reveals responsive calcium influx post P2X7 agonist BzATP application. In brief, the information provide in this study may help to address the role of P2X7 playing in the pain transmission along the major ascending pain path, thalamocingulate circuit. Furthermore, resolve the controversial unclearness of the presence of P2X7 alone the ascending pain transmission path in the central nerve system (CNS). These results may contribute knowledge for the pathophysiology to the onset of abnormal painful sensation and hence could contribute therapeutic potentials.

Title: Higher brain entropy predicts mindfulness meditation-based pain relief

Authors: *A. JINICH-DIAMANT[1], G. POSEY[3], J. BAUMGARTNER[2], G. RIEGNER[2], N. GONZALEZ[2], J. BIRENBAUM[2], J. W. VAUGHAN[3], Y. JUNG[4], R. KRAFT[3], F. ZEIDAN[2]; [1]Anesthesiology; Cognitive Sci., [2]Anesthesiol., Univ. of California San Diego, La Jolla, CA; [3]Wake Forest Sch. of Med., Winston-Salem, NC; [4]Radiology, Univ. of California Davis, Sacramento, CA

Abstract: Mindfulness meditation (MM) significantly relieves pain after minimal training through multiple neural mechanisms that are yet to be fully understood. Shannon brain entropy is a quantifiable measurement of uncertainty in the probability distribution of spontaneous neural dynamics. Within a hierarchical Bayesian inference cortical framework that matches ascending sensory signals with higher-order predictions, higher entropy reflects a dynamic neural state in which expectations are weakened to facilitate new predictions. Thus, brain entropy is a novel mechanistic target for self-regulatory mind-body approaches. Although recent work has shown that long-term MM practice increases electrophysiological markers of entropy, no known studies have examined if MM-induced pain relief is associated with entropy modulation. The proposed exploratory fMRI and psychophysical pain study investigated if mindfulness-based pain relief is associated with higher cortical Shannon brain entropy. After a baseline pain testing session, 40 pain-free participants (mean age = 30 years, 20 females) were randomized to four, 20-minute sessions of mindfulness meditation training or book listening. After successful completion of the regimens, fMRI scans were acquired during noxious heat (ten trials of alternating 12 seconds of 49°C) stimulation of the right calf during rest (all subjects) as compared to meditation (MM group) and rest (controls). After each scan, visual analog scale ratings of pain intensity (0 = no pain, 10 = worst pain imaginable) were collected. A 2 (rest vs. manipulation) X 2 (group) repeated measures ANOVA tested for group X manipulation differences on pain. Time series correlations between 48 distinct cortical regions were used to build functional connectivity matrices and thresholded (r = 0.40) to build networks during noxious heat scans. The Shannon entropy of networks' nodal degree distributions was compared across groups and conditions. To test the study hypothesis, MM-driven entropic changes were regressed onto residualized pain ratings. The significant interaction, $F(1,38) = 26.31$, $p < .001$, $\eta_p^2 = .41$) was driven by the reduction in pain intensity (-32%) by MM when compared to controls (+20%). Preliminary results show that MM significantly increased cortical entropy as compared to controls ($F(1,38) = 5.097$, $p = .030$, $\eta_p^2 = .12$). Further, higher MM-driven entropy predicted lower pain. We postulate that MM induces a high entropic state that lowers the influence of pain predictions to downregulate the experience of pain.

Surgery, San Francisco, CA

Abstract: Chronic, neuropathic pain syndromes are often refractory to treatment and impose significant suffering and disability. Chronic pain severity is often measured through subjective report, while objective biomarkers that may guide diagnosis, monitoring, and treatment are lacking. It is further unknown what brain activity underlies clinical chronic pain experiences on clinically relevant timescales or how this relates to experimentally evoked, acute pain. To identify neural substrates of chronic pain, four subjects with refractory, chronic neuropathic pain were implanted with intracranial electrodes and underwent long-term ambulatory recording of neural activity from the anterior cingulate (ACC) and orbitofrontal (OFC) cortex over months. Subjects longitudinally reported chronic pain metrics coincident with neural recordings obtained multiple times daily over months. We successfully predicted intraindividual chronic pain severity scores from direct neural activity with high sensitivity using machine learning methods. Chronic pain decoding relied on signals from a novel brain region, OFC, which tended to differ from patterns of neural activity associated with acute, evoked pain states during a task. Intracranial signals from OFC can successfully be used to predict spontaneous, chronic pain state over ecological timescales in patients.

Title: Tiam1-mediated synaptic plasticity drives comorbid depressive symptoms in chronic pain

Authors: Q. RU[1,2], Y. LU[1], A. SAIFULLAH[1], F. BLANCO[1], C. YAO[1], J. CATA[3], D.-P. LI[4], K. TOLIAS[1], ***L. LI**[1];

Abstract: Chronic pain and depression are frequently comorbid, and their coexistence tends to worsen the severity of both disorders. Currently, the molecular mechanism underlying comorbid depressive symptoms in chronic pain is unclear. Ketamine, an *N*-methyl-D-aspartate receptor (NMDAR) antagonist, induces rapid and sustained antidepressant-like effects in chronic pain-induced depression in both patients and animal models. However, the mechanisms underlying ketamine's sustained antidepressant effects remain elusive. Here, we show that Tiam1, a Rac1-specific guanine nucleotide exchange factor (GEF) that was previously identified as a critical mediator of NMDAR-dependent dendritic spine development, is activated in the ACC in chronic pain mice displaying depressive-like behaviors. Conditional deletion of Tiam1 from postnatal forebrain excitatory neurons, specific deletion of Tiam1 from ACC neurons, or pharmacological inhibition of the Tiam1-Rac1 signaling pathway prevents chronic pain-induced depressive-like behaviors in mice. Biochemical, morphological, and electrophysiological assays reveal that Tiam1 orchestrates synaptic structural and functional remodeling in ACC neurons via actin cytoskeleton reorganization and synaptic NMDAR stabilization. This Tiam1-coordinated synaptic plasticity underpins ACC hyperactivity and drives chronic pain-induced depressive-like behaviors. Ketamine induces sustained antidepressant effects in chronic pain by blocking Tiam1-mediated synaptic structural and functional plasticity in ACC neurons. Our results reveal Tiam1 as a key factor in the pathophysiology of chronic pain-induced depression and in the sustained antidepressant effects of ketamine in ACC neurons. These findings highlight Tiam1 as a potential therapeutic target for the treatment of comorbid depressive symptoms in chronic pain.

Title: Neuronal Dynamics of the Sensory-Discriminative and Affective-Motivational Components of Pain during Sleep

Authors: *R. SANDOVAL ORTEGA, M. RENARD, P. DE LUNA, T. NEVIAN;
Dept. of Physiol., Univ. of Bern, Bern, Switzerland

Abstract: Painful somatosensation undergoes parallel processing. Thus, the pain response can be divided into a sensory-discriminative and an affective-motivational component, mediated by the lateral and the medial pain pathway, respectively. Yet, processing of these two pain components during sleep remains unknown. We performed multisite recordings in the ventroposterior nuclei of the thalamus (VPx) and the primary somatosensory cortex of the hindlimb (S1HL) to study the processing of the sensory component, and in the mediodorsal nucleus of the thalamus (MD) and the anterior cingulate cortex (ACC) to record the processing of the affective component. Freely moving implanted mice received either non-painful touch or painful pinprick stimuli to the hind-paws to identify differences between touch and pain processing in sleep and wake. We find the stimuli-evoked-dynamics of the sensory pathway to be different from the affective one. This is especially true in wake, where we have observed that top-down expectations activate the S1HL but not the ACC. However, Evoked Response Potentials (ERPs) in NREM sleep show that processing of pain is faster than touch and, contrary to touch, engages the sensory and the emotional component almost simultaneously. We further divided the data into the different behavioral responses evoked by the stimuli: presence or absence of paw withdrawal and awakening or maintained sleep. Non-painful responses activated both pain pathways in a similar fashion independently of the behavioral response or arousal state. On the contrary, pain-evoked neural dynamics were behavior-specific, waking up from sleep being the strongest response observed both in the S1HL and ACC, but not in thalamic areas. Finally, we assess how pre-stimulus neural activity affects the behavioral responses. In NREM sleep, high delta (1 - 4 Hz) power in the ACC had a protective effect on sleep, reducing the probability of waking up from painful stimuli, but not from non-painful ones. Unexpectedly, heightened ACC gamma (30 - 100 Hz) power was observed in maintained sleep trials in both stimulation types. S1HL neural activity did not influence the behavioral outcome in NREM trials but high gamma power in wake prior to the stimulation predicted paw withdrawal. These findings highlight for the first time the differences between the processing of the sensory and affective components of noxious and non-noxious somatosensory stimuli during sleep. Therefore, they open a door to understand how the processing of somatosensation during sleep may lead to the development and establishment of chronic pain, a disease which is still not fully understood and lacks standardized treatments.

Title: Painful laser-evoked potential reflects pain catastrophizing

Authors: D. WANG[1], X. ZHANG[1], P. GROTZ[1], P. FINAN[3], M. QUIGG[2], W. J. ELIAS[1], *C.-C. LIU[1]; [1]Neurosurg., [2]Neurol., Univ. of Virginia Sch. of Med., Charlottesville, VA; [3]Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Numerous studies show pain catastrophizing — a cognitive process characterized by ruminating, magnifying, and/or experiencing helplessness about pain — is a powerful predictor for adaptation and response to treatment for chronic pain. In this study, we aim to determine pain-related electroencephalography (EEG) characteristics associated with pain catastrophizing. Ten healthy individuals (21.8±1.9 yrs, 5 female) were recruited to the study. The 13-item Pain Catastrophizing Scale (PCS) was administered. A Nd:YAP laser stimulator was used for pain induction such that each laser stimulation induced a pin-prick acute pain challenge (about 40 to 50 pain on a scale of 0 to 100, where 0 indicates “no pain at all” and 100 indicates “maximum pain possible”). Thirty triplet (inter-stimulus interval 1 second, inter-triplet intervals 7-9 seconds) stimulations were delivered to the dorsum of the left hand. During the study, subjects wore protective goggles, rested comfortably on a couch, and kept their eyes open. To maintain stable attention, subjects were asked to actively appraise pain levels during each stimulus, and report them after each triplet stimulation trial. Evoked potentials were recorded by placing disc electrodes over the Fz, C3, C4, Cz, Pz, T7, and T8 locations (10-20 electrode placement referenced to linked earlobes). Analogous to the laser stimulation, non-painful electric shock stimulation (40-50 stimulus intensity) was also used in a separate session for pain versus non-painful comparisons. We measured the mean amplitude of the evoked potential after manual removal of artifacts. Overall, the amplitude of painful laser and non-painful electric shock evoked potentials attenuated significantly within each triplet stimulation where the first stimulation within the triplet evoked the largest potentials, then the second and followed by the third ($p < 0.01$). Furthermore, greater amplitude attenuations between the first and the second laser stimulation on the midline frontal Fz, as well as bilateral sensorimotor C3 and C4 correlated with higher pain catastrophizing scale (Spearman's rho > 0.73, $p < 0.05$). No significant correlation was found between PCS and non-painful electric shock. These results may help to better understand brain mechanisms of pain catastrophizing in relation to acute painful stimuli. Accordingly, we propose that if these EEG characteristics are modifiable and could be extended to chronic pain models, this knowledge could also inform the development of new neuromodulatory interventions for preventing and managing chronic pain.

Title: The influence of participant posture on laser evoked potentials

Authors: *L. D. LINDE, O. ORTIZ, J. L. K. KRAMER;
ICORD, Univ. of British Colombia, Vancouver, BC, Canada

Abstract: *Introduction:* Laser evoked potentials (LEP) are commonly employed to assess spinothalamic tract function within the human somatosensory system. Painful laser stimuli are typically delivered in the periphery, with responses recorded from multiple brain regions via electroencephalography (EEG).

Interestingly, there are discrepancies among research groups in the posture/positioning of participants during LEP assessments, be that either seated or lying. Our primary aim was to investigate the influence of altering participant posture (lying, sitting, standing) on LEP outcomes.
Methods: Twenty (20) healthy participants (Age 24.3±4.6) received noxious laser (Nd:YAP) stimuli on the left forearm and the left thigh, at participants' pain threshold (range 2.25-3.5 J), in three postural conditions (lying, sitting, standing). Participants received 20 stimuli at each location and in all three postures, in a randomized order. Participants reported their perceived pain following each laser stimuli, via a 0-10 numerical rating scale (NRS). Brain activity was recorded using 32 EEG electrodes, according to 10-20 international positioning. EEG data was band-pass filtered 0.5-30Hz, with baseline corrected EEG epochs (100ms pre-laser to +1000ms post-laser) averaged to produce N2P2 waveforms. We used linear mixed models to assess differences between postural conditions for N2P2 waveform amplitudes and latencies as well as NRS responses to laser stimuli.
Results: For leg stimulations, a main effect of postural condition was observed for N2 latency ($F_{(2,33.1)}$=5.28, p=0.01). We observed significantly shorter N2 latencies in sitting compared to standing (t=3.19, p=0.009), with similarly shorter N2 latencies in sitting compared to lying, albeit not significant (t=2.19, p=0.10). There were no significant differences for N2 latencies between lying and standing (t=1.1, p=0.95), nor were there any significant differences in any other LEP outcomes or NRS responses. There were no significant effects of postural condition for arm stimulations.
Conclusions: Previous studies have observed reducing N2 latencies following experimental pain induction, suggesting our reduced N2 latencies during sitting may be indicative of a heighted nociceptive response. For those employing LEPs, our findings suggest the choice of participant posture does indeed influence LEP outcomes, with the greatest influence on N2 latencies derived from the lower limb.

Title: Presurgery limbic brain structural properties predict pain persistence after joint replacement surgery for osteoarthritis

Authors: *J. BARROSO[1], P. BRANCO[2], J. PINTO-RAMOS[3], A. VIGOTSKY[2], T. J. SCHNITZER[2], V. M. GALHARDO[4], A. V. APKARIAN[5];

Abstract: Osteoarthritis (OA) is one of the most prevalent musculoskeletal diseases, affecting an estimated 10 percent of the world's population over the age of 60 and its prevalence is projected to increase - with an estimated 130 billion people affected by the year of 2050. Joint replacement surgery is a successful intervention, treating pain and OA-related disability, however a substantial proportion of patients (10-37%) still report moderate to severe pain after surgery. Mechanisms of persistent pain after surgery remain unclear. In this prospective longitudinal study, we studied structural properties of the subcortical brain, together with clinical and demographic indices, as possible predictors of pain persistence 6 months after surgery.We followed a population of 81 knee OA (kOA) patients from before total knee replacement surgery (TKR) until 6 months after the intervention. Longer pain duration, higher levels of pre-surgical anxiety and a neuropathic pain profile were predictive of pain persistence after surgery. Subcortical volumes were also predictive of the outcome: larger volumes of the bilateral thalamus, amygdala and left hippocampus were associated with pain persistence. Next, by studying shape properties, a more granular measure, we uncovered that an outward displacement of the right amygdala and right anterior hippocampus were also associated with pain persistence. Finally, we queried if the clinical/psychological predictors and subcortical properties had unique value to explaining the outcome. To do so, we built sequential regression models to explain the magnitude of post-surgical pain. We uncovered that adding brain parameters to clinical predictors led to a significant increase in the predictive value of the model (final model, R^2 0.44, $p<0.001$).Our results demonstrate that the predictive value of subcortical anatomic indices on post-surgical pain is additive to the clinical predictors and revealed a final model able to explain 44% of the variance of post-surgery pain intensity. Current notions of persistent pain after a technically successful TKR surgery have focused on clinical/psychological dimensions, without a clear mechanistic link to pain physiology. We show that structural properties of the brain's limbic circuitry are predictors of pain maintenance after TKR surgery. These results support the importance of limbic neuroanatomical factors in the persistence of chronic pain and open a new avenue not only for studying post-surgery pain mechanisms but also regarding clinical care of OA pain patients.

Title: Ultrastructure of the chemosensory rhinophore ganglion and its connective in the nudibranch mollusc Berghia stephanieae reveals an unexpectedly complex anatomical organization

Authors: B. D. DRESCHER[1], Y. MEIROVITCH[2], C. TAIT[3], ***H. H. SANT**[3], E. PAVARINO[2], R. SCHALEK[2], S. WANG[2], Y. WU[2], J. W. LICHTMAN[2], P. S. KATZ[3];
[1]Brown, Providence, RI; [2]Harvard Univ., Cambridge, MA; [3]Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Nudibranch molluscs use their rhinophores, a pair of dorsally positioned cephalic sensory appendages, to detect chemical cues in their environment. Little is known about the structure and function of the rhinophore ganglion itself, which is positioned at the base of each rhinophore. We used a volume electron microscopy approach to elucidate organization of the rhinophore ganglion and the connective to the cerebral ganglion, in the nudibranch *Berghia stephanieae*. The rhinophore connective carries the axons of primary sensory neurons and interneurons from the rhinophore and the rhinophore ganglion into the brain. Efferent neurons from elsewhere in the brain also project axons through the rhinophore connective into the rhinophore ganglion and further into the rhinophore. A single rhinophore ganglion and connective were serially sectioned at 33 nm and imaged at 4 nm resolution. Stitched and aligned sections from the connective were segmented using machine learning and proofread manually. The rhinophore ganglion neuropil contained a high density of vesicle-filled varicosities, which may be multi-neuronal complex synapses, as well as numerous vesicle-free neurite tracts. The ganglion contained almost 9000 neuronal nuclei, which were mostly clustered along the periphery. Thus, each rhinophore ganglion had nearly twice as many neurons as the rest of the brain (cerebropleural and pedal ganglia). The connective contained approximately 30,000 axon profiles with varied staining densities, clustered into distinct fascicles, which were surrounded by fewer than 50 large glial cells. While the range of axon cross sections was 90 nm to 500 nm, most of them were about 200nm. Two axon fascicles had distinct ultrastructure and extremely thin processes (~100nm); we determined that these were a set of primary sensory afferent axons from the rhinophore that bypass the rhinophore ganglion and project directly into the brain. These findings highlight the complexity of the rhinophore ganglion and connective. This is a first step in documenting the structural organization underlying chemosensory processing in *Berghia*. Completion of a full rhinophore ganglion connectome will greatly enhance our understanding of chemosensation in nudibranchs.

Title: Physiology of a specific local interneuron population in the Drosophila antennal lobe reveals non-spiking characteristic due to lack of voltage gated sodium current

Authors: *J. E. SCHENK, Q. GAUDRY;
Biol., Univ. of Maryland, College Park, MD

Abstract: Local interneurons (LNs) within the *Drosophila melanogaster* antennal lobe (AL) generally serve inhibitory functions, accomplished by spiking-mediated release of GABA at the first synapse of the olfactory relay. Here, we have identified a population of non-spiking LNs (nsLNs) within the *Drosophila* AL. While common in other insect species, nsLNs are a novel observation in this *Drosophila* brain region. To characterize these cells, we performed *in vivo* whole cell patch clamp electrophysiology and wide field calcium imaging with exposure to odor panels consisting of private and public odors. While nsLNs are still responsive to odor stimulation, we did not detect sodium current in this population of neurons. Additionally, we utilized fluorescent *in situ* hybridization and cell-specific protein tagging in the nsLNs to assess the expression of the insect voltage gated sodium channel, Para. The unique nature of these cells could lend itself to understanding functions not well characterized in *Drosophila* olfaction and odor coding. Moreover, the confirmation of nsLNs in the *Drosophila* AL suggests a commonality across many insect species, warranting further investigation.

Title: Understanding olfactory processing in the antennal lobe in aedes aegypti

Authors: *P. SINGH, S. GOYAL, S. GUPTA, S. GARG, V. RAJPUT, A. TIWARI, A. K. GUPTA, N. GUPTA;
Indian Inst. of Technol., Kanpur, India

Abstract: Antennal lobe, the primary olfactory processing center in the insect brain, receives odor information from the olfactory receptor neurons present in the sensory layer. Projection neurons (PNs) and local neurons (LNs) are the two major classes of neurons in the insect antennal lobe (AL). We used whole-cell patch-clamp recordings and post-hoc dye filling to study the physiology and morphology of antennal lobe neurons in the yellow fever mosquito, Aedes aegypti. A panel of odors were presented to the olfactory organs of immobilized insects and responses were recorded from the cell body of AL neurons. We obtained ~1200 PN-odor response pairs and ~250 LN odor response pairs. Additionally, we were able to observe the morphology of ~200 projection neurons and ~50 local neurons and classify them further into morphological sub-classes. Based on glomerular innervation, we found that projection neurons are majorly uni-glomerular but could also be bi- or multi-glomerular. On the other hand, the innervation patterns of LNs could be categorized as pan-glomerular, all-but-few, patchy, or continuous. We also extracted different electrophysiological features such as spike amplitude, spike half-width, spike adaptation, spike amplitude accommodation, and the size of after-hyperpolarization from the recordings. Pairwise distance matrix revealed that PN and LN clusters are well separated. Based on these parameters,

we were able to classify a cell as a projection or a local neuron with about 90% accuracy. Further, we analyzed the obtained odor-responses of uni-glomerular PNs. We compared the change in firing rate of sister PNs in response to the panel of odors. The odor-generated activity patterns of sister PNs were only weakly correlated, indicating functional diversity among sister PNs in mosquitoes. We also performed behavioral experiments using a custom-built set-up to quantify the preference of mosquitoes for each odor in the panel. The behavioral valence was then correlated with the PN-response trajectory of the odor. Next, we analyzed the role of local neurons in olfactory processing. Local neurons have been found to be neuromodulatory in other insect species. We performed immuno-histology against GABA and found some of the local neurons to be GABAergic. Additionally, we observed that in some cases, the inhibitory responses were abolished or small excitatory responses were revealed in the presence of GABA antagonists. Altogether, our study provides a comprehensive characterization of the mosquito antennal lobe neurons and will serve as a foundation for understanding the olfactory processing in the mosquito brain.

Title: Ultrastructural distribution of dense-core vesicles from electron microscopy images in Drosophila olfactory projection neurons

Authors: *M. KIM[1], S. GERHARD[2], H. E. SOMHEGYI[1], A. S. BATES[1], T. M. NGUYEN[1], G. S. X. E. JEFFERIS[3], W.-C. A. LEE[1];

Abstract: Internal physiological states and sensory processing are thought to be modulated by neuropeptides. Neuropeptides are a class of signaling molecules that are released from dense-core vesicles (DCVs) and mediate slow-onset, long-lasting modulation of synaptic transmission. In *Drosophila*, olfactory processing begins with olfactory sensory neurons (OSNs) which converge onto projection neurons (PNs) that innervate the central brain. However, the organizational principles of how neuropeptides modulate early olfactory circuits remain unclear. To investigate the localization pattern of neuropeptide-containing DCVs, we utilized machine learning to automatically identify DCVs in large-scale electron microscopy datasets and map their locations across the antennal lobe. This approach enabled us to investigate aspects of circuit modulation and flexibility from static wiring diagrams. We found that DCVs are preferentially localized in the presynaptic sites of feedback synapses from PNs back onto OSNs, suggesting that this peptidergic feedback modulation may modulate sensitivity within specific glomerular channels. Our work suggests that co-transmission of neuropeptides and small-molecule

transmitters provides additional modulatory mechanisms that increase the flexibility of neural circuit function.

Title: Responses of the antennal lobe neurons to carbon dioxide in mosquitoes

Authors: *S. GOYAL, P. SINGH, S. GUPTA, S. S. SINGH, M. GUPTA, A. K. GUPTA, N. GUPTA; Biol. sciences and bioengineering, Indian Inst. of Technol., Kanpur, India

Abstract: Mosquitoes are vectors of some of the deadliest human diseases across the world. Female mosquitoes need a mammalian blood meal for oviposition. They rely on various olfactory cues to locate suitable hosts. Carbon dioxide (CO_2), exhaled in human breath, is crucial for host seeking. Disrupting their CO_2-based host-seeking behavior may help in combating the growing threat of mosquito-borne diseases. Previous studies, using single sensillum recording, showed that CO_2 is detected by sensory neurons present in the capitate peg sensilla housed in the maxillary palps of the dengue mosquito, *Aedes aegypti*. We wanted to study how CO_2 is processed downstream of the sensory neurons. We measured the response of antennal lobe neurons (~200 projection neurons and ~40 local neurons) to CO_2 using *in vivo* whole-cell patch recordings. We found that ~25% of the projection neurons and ~42% of the local neurons responded to CO_2 in varying patterns. The responses ranged from purely excitatory or purely inhibitory patterns to combinations of both. Flying mosquitoes encounter fluctuating plumes of CO_2 in the environment, possibly affecting how the mosquito brain processes CO_2. We measured the responses of the antennal lobe neurons to CO_2 delivered in different temporal patterns: homogeneous versus non-homogeneous, single pulse versus multiple pulses. We found no significant difference in projection neuron responses to CO_2 when delivered as a homogeneous or a non-homogeneous plume. In contrast, local neurons showed slightly elevated responses to multi-pulse stimuli compared with a single pulse. Apart from CO_2, mosquitoes encounter different human skin volatiles and use them to orient towards the host in the natural environment. We measured the response of antennal lobe neurons to a skin volatile, lactic acid, and its binary mixture with CO_2. Analysis of single odor and mixture responses revealed that some mixture processing occurs in the projection neurons for the binary blend of lactic acid and CO_2, possibly mediated by lateral interactions. Overall, our study provides a better understanding of mosquito-host interaction by looking at the antennal lobe responses to an important olfactory cue, CO_2, and its synergy with other host volatiles.

Title: Multimodal, distributed connectivity of the chemosensory appendage the nudibranch mollusc, Berghia stephanieae suggests non-canonical olfactory processing

Authors: *C. C. TAIT, D. RAMIREZ, P. S. KATZ;
Biol., Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: The neuroanatomy of olfactory systems shares structural aspects across standard model organisms; specialized brain regions receive information from sensory neurons, with multimodal integration occurring in upstream processing centers. We explored the neuroanatomy of the distance-chemosensory appendage, the rhinophore, of the nudibranch mollusc *Berghia stephanieae*. The rhinophores emerge from the dorsal surface of the animal's head, each with a dedicated ganglion at its base. Extending into each rhinophore from the rhinophore ganglia are two thick nerves that branch extensively and contain thousands of fibers, as seen with tubulin immunohistochemistry. We identified populations of putative sensory neurons expressing histamine and APGWamide that project axons to the brain via these nerves. Neurobiotin fills of the cut rhinophore nerves revealed tracts terminating in the brain both ipsilaterally and contralaterally, indicating communication between opposite sides of the brain. One rhinophoral fiber tract ended in a neuropil region in the cerebral ganglion implicated in multimodal integration, where histaminergic mechanoreceptor hair cells also terminate. Thus, axons projected from the rhinophores directly to diverse brain areas. We also identified efferent neurons in the brain that project axons into the rhinophore. Among these were: 1) a single ipsilateral photoreceptor from each eye, suggesting interactions between chemosensation and vision occur in the periphery; 2) five neurons in each buccal ganglion, which plays a role in feeding behavior; 3) a single pair of cerebral serotonergic neurons, which projected bilaterally to the rhinophore tips; and 4) a single pair of cerebral neurons immunoreactive to Small Cardioactive Peptide, which projected to a specific region of the rhinophore ganglion. This region also had terminals immunoreactive to Neuropeptide Y, which seemed to emerge from cells intrinsic to the rhinophore ganglion itself. Thus, overall, *Berghia* neuroanatomy differs from canonical olfactory systems in that there is less convergence of input to central regions, more input from diverse central neurons into the chemosensory appendage itself, potentially more multimodal integration in the periphery, and distinct neuromodulatory innervation to specific areas. Although we do not yet know how stimuli are processed, these neuroanatomical details indicate that molluscan chemosensation may be fundamentally different from what is known in other taxa.

Title: Intermittent inputs reveal invariant odor representations

Authors: R. MOHANTA, ***C. ASSISI**;
Biol., Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: Olfaction, like other sensory systems, uses the timing of spikes to encode incoming sensory input. The identity of an odorant that arrives in a steady stream can be reliably ascertained by examining the spatiotemporal sequence of spikes that are generated by brain networks involved in olfaction. However, odor inputs come, not as a steady stream, but riding upon chaotically pulsed plumes of air. Each time an input arrives, it follows a unique temporal pattern. As a consequence, the spatiotemporal spike sequences that encode the odor must also be different every time an animal encounters temporally varying odor input. It really is a wonder then that animals are capable of decoding sensory cues and navigating highly complex and turbulent 'odorscapes'. Why, despite varying inputs, are odor percepts invariant (alternatively, why does a rose always smell like a rose)? What are the neural invariants of stable olfactory percepts? We address these questions in a computational model of the locust olfactory system. We show that when time-varying odor inputs intermittently perturb subsets of neurons in the antennal lobe network, the activity of the network reverberates in a manner that depends on both the nature of the inputs it receives and the structure of the neuronal sub-network that these inputs stimulate. We demonstrate that it is possible to decipher the structure of the perturbed sub-network by examining transient synchrony in the activity of the neurons. Follower neurons in the mushroom body are sensitive to coincident input and thus uniquely placed to pick out episodes of transient synchrony in antennal lobe projection neurons. We find that the ability to reconstruct the sub-network structure is vastly improved when odor inputs arrive or are sampled in an intermittent manner. Our model suggests, antennal flicking, a strategy employed by locusts when sampling a steady stream of air, injects intermittency in the input and might hasten the formation of an invariant odor representation. The exact temporal pattern in which intermittent perturbations arrive does not affect our reconstruction. Thus, the structure of the stimulated sub-network itself serves as a unique invariant code that represents the odor.

Title: Requirement for Lhx3 in the differentiation of bipolar cells and the inner retinal circuitry

Authors: *L. HUANG[1], L. GUO[2], X. XIE[1], X. DONG[1], L. GAN[1];
[1]Dept. of Neurosci. and Regenerative Med., Med. Col. of Georgia at Augusta Univ., Augusta, GA; [2]Col. of Life Sci., Zhejiang Univ., Hangzhou, China

Abstract: Retinal bipolar cells (BCs), the late-born interneurons in the retina, are located in the inner nuclear layer (INL) and act, directly or indirectly, to transmit visual information from photoreceptors to ganglion cells. The two major BC subclasses, ON-bipolar cells and OFF-bipolar cells based on their opposite responses to glutamate release, are classified into more than ten subtypes. How these subtypes are specified during retinogenesis is poorly understood. Previously, we have shown that the expression of LHX3, a LIM-homeodomain (LIM-HD) transcription factor, starts from postnatal day 4 (P4), peaked at P8 and maintained through adulthood. Its expression overlaps that of ISL1 and LHX4, two key LIM-HD factors for the differentiation of BC subtypes, in the developing retina. In this study, we further showed that LHX3 is selectively expressed in type 3a OFF-cone bipolar cells, type 5 ON-cone bipolar cells, and a subgroup of type 2 OFF-cone bipolar cells. To investigate the role of *Lhx3* in the specification of BCs, we conditionally deleted *Lhx3* in the developing mouse retina using *Six3-Cre* mice that express Cre recombinase in the developing retina and forebrain. In the absence of *Lhx3*, the b-wave and oscillation potential amplitudes of light-adapted electroretinogram (ERG) were significantly attenuated, suggesting a disruption in the cone-driven pathway. In *Lhx3*-null retinas, the number of rod bipolar cells and type 2 OFF-cone bipolar cells was reduced significantly while type 3a OFF-cone bipolar cells increased. Conversely, *Lhx3* over-expression in retinal progenitors during retinogenesis significantly promotes the generation of BCs. In addition, loss of *Lhx3* resulted in an increase in the number of Müller cells and a reduction in AII amacrine cells. Together, *Lhx3* plays an important role in regulating the differentiation and function of BCs, especially the cone-driven retinal circuitry.

Title: Trans-synaptic mechanism of cone photoreceptor wiring

Authors: *Y. WANG[1], Y. CAO[1], H. DUNN[1], K. MARTEMYANOV[1], N. KAMASAWA[2], D. FITZPATRICK[2], W. LI[3], W. HAUSWIRTH[4], C. ZEITZ[5];

Abstract: Our vision depends on two types of photoreceptors in the retina, rods and cones. Rods are superb at detecting extremely low level of light and essential for vision under dim conditions. In contrast, cones operate within an incredible broad range of light intensity and are responsible for most aspects of our daytime visions including color detection, visual acuity and contrast. To form vision, the information encoded in photoreceptors must been accurately transmitted to the correct downstream bipolar neurons. The faithful relay of information between photoreceptors and their corresponding ON-bipolar cells (ON-BCs) hinges upon the synaptic connection established between the two parties, a process known as the synaptic wiring. Increasing studies have shown that synaptic wiring of neurons is controlled by various families of trans-synaptic cell adhesion molecules (CAMs), which are cell-surface molecules critical for establishing cell-cell contacts and mediating subsequent intracellular signaling.Using an unbiased proteomics strategy, we identified a CAM, ELFN2, which is selectively expressed by cone photoreceptors and targeted at cone synapses. We found that elimination of ELFN2 did not lead to observable structural and functional change at cone synapse, probably due to the upregulation of ELFN1 in the cones. We next eliminated both ELFN1 and ELFN2 using several different conditional KO mouse models and demonstrated that the synaptic transmission between cones and ON-CBCs is completely abolished while the synaptic architecture remains normal in conditional double KO retinas.Mechanistically, we found that both ELFN1 and ELFN2 bind to the postsynaptic glutamate receptor, mGluR6, via an *in trans* fashion. Using cell-based assay, we showed that this trans-cellular interaction between ELFNs and mGluR6 decreased the potency and efficacy of glutamate induced signaling of mGluR6. Moreover, by using several mouse models where different levels of ELFN proteins are expressed at cone synapses, we discovered that the synaptic content of post-synaptic mGluR6 is tightly correlated with the synaptic content of pre-synaptic ELFN proteins, and more importantly, with the amplitude of cone synaptic transmission. Together, we have uncovered the molecular mechanism underlying the functional wiring of cone photoreceptors by showing that a pair of CAMs, ELFN1 and ELFN2, work collectively at cone synapses to trans-synaptically modulate the surface content and pharmacological property of post-synaptic mGluR6 and that the synaptic content of this trans-synaptic ELFN/mGluR6 complex is one critical factor determining the synaptic strength of cone photoreceptors.

Title: Loss of Trpm1, the gene for the On bipolar cell transduction channel, in 15q13.3 microdeletion syndrome contributes to central behavioral deficits

Authors: *C. KOIKE[1], T. HORI[2], S. IKUTA[3], S. HATTORI[4], K. TAKAO[5], T. MIYAKAWA[4]; [1]Ctr. for systems vision science, Ritsumeikan Univ., Kusatsu,Shiga, Japan; [2]Grad. Sch. of Pharmaceut. Sci., Ritsumeikan Univ., Kusatsu, Shiga, Japan; [3]Grad. Sch. of Life Sci., Ritsumeikan Univ., Kusatsu,Shiga, Japan; [4]Fujita Hlth. Univ., Toyoake, Japan; [5]Life Sci. Res. Ctr., Univ. of Toyama, Toyama-Shi, Japan

Abstract: 15q13.3 microdeletion syndrome is characterized by a broad spectrum of psychiatric disorders. Seven genes are located in the target region of chromosome 15 (MTMR10, FAN1, TRPM1, MIR211, KLF13, OTUD7A, and CHRNA7). While the contributions of several of the genes to the disorder have studied using mutant mouse models, no single mouse model has been able to recapitulate the whole behavioral spectrum of human 15q13.3 microdeletion syndrome.Trpm1, one of the genes located in the target region of 15q13.3 microdeletion syndrome, has been implicated as a retinal ON bipolar cell visual signal transduction channel. Trpm1 has not been investigated concerning this syndrome because the visual impairment in Trpm1$^{-/-}$ mice may confound the results of behavioral tests involving vision. Also, Trmp1 is reported to be exclusively expressed in the retina in the central nervous systems. We performed a comprehensive behavioral test battery using Trpm1 null mutant mice to investigate the role of Trpm1 in the central nervous system, and to examine the relationship between TRPM1 and 15q13.3 microdeletion syndrome. Our data demonstrate that Trpm1$^{-/-}$ mice exhibit abnormal behaviors that may explain some phenotypes of 15q13.3 microdeletion syndrome: including reduced anxiety-like behavior, abnormal social interaction, attenuated fear memory, and, most prominently, hyper locomotor activity. While the ON visual transduction pathway is impaired in Trpm1$^{-/-}$ mice, we did not detect compensatory higher sensitivities for other sensory modalities. The pathway for visual impairment is the same between Trpm1$^{-/-}$ mice and mGluR6$^{-/-}$ mice, but hyper locomotor activity has not been reported in mGluR6$^{-/-}$ mice. Unexpectedly, the data suggest that the phenotype of Trpm1$^{-/-}$ mice extend beyond that predicted from visual impairment alone. Here, we present the first evidence associating TRPM1 with impairment of cognitive function similar to that observed in phenotypes of 15q13.3 microdeletion syndrome.

Title: Pathways for processing local and global motion in primate retina

Authors: *T. APPLEBY[1], F. M. RIEKE[2], M. B. MANOOKIN[3];
[1]Univ. of Washington Grad. Program In Neurosci., Seattle, WA; [3]Ophthalmology, [2]Univ. of Washington, Seattle, WA

Abstract: When observing a visual scene, the image perceived by the eye is rarely static. Movement by the observer causes the visual world to pan across the eye, creating global motion on the retina. Global motion creates a two-part encoding problem for visual perception. First, form and position of objects must stay constant during global motion. Second, local motion of objects must be distinguished from globally moving counterparts. The neural pathways that mediate visual perception during global motion are not well understood. In many vertebrates, retinal ganglion cells separate object motion from global motion through interactions between their receptive field center and surround. In primates, however, many pathways of the retina have been insofar difficult to study, and it is unknown whether such specialized motion processing occurs in the primate retina. Here, we probe receptive fields of many lesser-studied ganglion cell types in the primate retina to understand how global motion affects visual encoding. Specifically, we first assess how global motion affects signal integration, and then measure each cell type's selectivity for local motion relative to global motion.Spike responses or whole-cell synaptic currents were recorded from several types of primate retinal ganglion cell in an intact, in vitro preparation of the macaque monkey retina. Custom light stimuli were used to probe sensitivity to global motion. Global motion activates the receptive field surround of many primate retinal ganglion cell types. However, the effects of global motion processing in the surround differs across cell types, ranging from facilitation of cellular responses to suppression of responses. We also report that at least three primate retinal ganglion cell types show selectivity for local motion.Our results indicate that selective processing of local and global motion in the primate visual system begins in the retina. The receptive field surround parsed global motion inputs in several ganglion cell types, resulting in increased or decreased cellular sensitivity based on cell type. Moreover, three ganglion cell types were selective for local motion. Prior to our study, the primate visual system was thought to reserve complex motion computations for the cortex. We show here that the primate retina is more computationally powerful than previously thought.

Title: Surround stimulation in the scotopic light regimen produces non-classical center-surround antagonism in the primate retina

Authors: *N. INGRAM, F. RIEKE;
Univ. of Washington, Seattle, WA

Abstract: Center-surround antagonism in the mammalian retina has long been appreciated to alter how retinal ganglion cells (RGCs) sample spatial inputs in bright light conditions but has appeared to be absent in dimmer environments. Consistent with this, we find that classical center-surround antagonism is present in primate RGC spatial receptive fields during mesopic and photopic conditions but is absent in scotopic light conditions. Despite the apparent absence of surround inhibition, the receptive field center of ON parasol RGCs still narrowed at scotopic light levels as background intensities increased. We confirmed pharmacologically that the changes in receptive field size persist without horizontal cell feedback. To explore possible mechanisms mediating this unexpected change in receptive field size, we measured the size of receptive field subunits. Subunits were 3-4-fold larger at dim vs bright light levels. We used modeling to explore how subunits combine to produce the classical difference of gaussians receptive field profile. This will allow us to determine whether overall changes in receptive field dimensions can be explained by changes in subunit size. Ongoing experiments are exploring the origin of larger subunit sizes measured in scotopic conditions. In addition to effects on spatial receptive fields, we also found that surround stimulation in scotopic backgrounds leads to surround-dependent temporal filtering. Both the time to peaks of the response generated by short steps and the linear filters extracted from noise sequences are speeded in scotopic backgrounds when the surround is driven with same polarity contrasts as the center. These results are particularly interesting since they occur in the absence of classical surround inhibition and because rod photoreceptors have relatively slow kinetics. Together these changes in receptive field features are likely to have important effects on an organism’s ability to perform complex visual tasks in scotopic environments especially those which depend on correlations between space and time (e.g. motion detection).

Title: A perturbative approach uncovers context-dependent processing of natural scenes in the retina

Authors: *M. A. GOLDIN[1], S. VIRGILI[1], B. LEFEBVRE[2], A. S. ECKER[3], T. MORA[4], U. FERRARI[2], O. MARRE[5];
[1]Inst. de la Vision - Sorbonne Univ., PARIS CEDEX 05, France; [2]Inst. de la Vision, Paris, France; [3]Ctr. For Integrative Neurosci., Tuebingen, Germany; [4]Lab. de physique statistique, Ecole Normale Supérieure, Paris, France; [5]Inst. de la Vision - UPMC, Paris, France

Abstract: Neurons in the early visual system are supposed to extract specific features from natural scenes. However, many works have shown that this processing depends on the visual context. It is thus not clear if the neurons extract always the same feature, and therefore a stable representation of the visual world, across different contexts. In the retinal output, some types of ganglion cells respond selectively to light increase (On cells), while others respond to light decrease (Off cells). However, it is unclear if this selectivity, characterized with synthetic stimuli, is maintained when they are stimulated with natural scenes. Here we address this issue by recording the responses of ganglion cells in salamander and mice to stimuli composed of natural images slightly perturbed by patterns of random noise. We measured a receptive field from the responses to many checkerboard patterns superimposed on the same natural image, i.e. an image-dependent receptive field. For the same cell, these receptive fields strongly depended on the natural image. When changing the image, the receptive field could switch its polarity from On to Off. Standard, linear models could not reproduce this result. However, a convolutional network model learned on the responses to many natural images could predict these context dependent receptive fields, and suggest that it is the result of the convergence of several circuits onto the same ganglion cell. This strong dependence of the On-Off polarity on the context makes it challenging to decode luminance from these ganglion cells. However, more abstract features could be reliably decoded. Our perturbative approach thus uncovered the selectivity of retinal ganglion cells to more abstract features, and could be used in other sensory areas to characterize the selectivity of neurons during natural scene processing.

Title: Contributions of retinal direction-selectivity to predation in mice

Authors: *J. M. KRIZAN, B. WANG, D. KERSCHENSTEINER;
Dept of Ophthalmology and Visual Sci., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Mice engage in complex, visually guided hunting behaviors. Circuits in superficial superior colliculus (sSC) link visual inputs from the retina to predation (Hoy et al., 2019). Yet, the contributions of specific visual circuits in the retina to predation remain unclear. Mice keep insect prey in their binocular visual fields during pursuit and capture (Johnson et al., 2021). Direction-selective narrow-field (NF) cells in sSC are necessary for efficient predation, suggesting a role for direction-selectivity (DS) in the behavior. Here, we test the hypothesis that retinal DS signals orient mice toward their target and maintain moving prey within their binocular visual fields.
Retinal DS originates in starburst amacrine cells (SACs) and is encoded in the spikes of direction-selective ganglion cells (DSGCs). We selectively ablated SACs by performing intraocular injections of diphtheria toxin (DT) into mouse eyes expressing the DT receptor only in SACs; we controlled for injection artifact by injecting saline in a subset of mice. We used immunohistochemistry to confirm SAC ablation and rule out off-target effects following DT injections. Patch-clamp experiments show that DSGCs in SAC-ablated retinas do not encode motion direction; similarly, the gaze-stabilizing optokinetic reflex generated downstream of DSGCs is absent in these mice. We trained these mice to hunt crickets in an arena and quantified various aspects of the behavior, as previously described (Johnson et al., 2021). DS in sSC is derived from the retinal DS circuitry (Shi et al., 2017). We show that DSGCs innervate NF cells in sSC; thus, we hypothesize that the NF cells in sSC of SAC-ablated mice will no longer be DS. If the DS feature of NF cells in sSC is necessary for orienting toward and keeping prey within the binocular field, we expect the distribution of the crickets in the head-centric visual field to broaden and capture times to increase. We are currently evaluating these parameters and comparing effects of chronic and acute suppression of retinal DS.

Title: Physiological function of Alzheimer's-linked Aβ oligomers in the developing CNS

Authors: *S. BARTLEY[1], H. XIA[2], J. ZHU[2], E. HO[2], M. A. BICCA[2], H. D. SECKLER[3], K. L. VIOLA[2], W. L. KLEIN[2];

Abstract: Amyloid beta oligomers (AβOs) are known to be toxic peptides that instigate multiple types of brain damage, *e.g.*, synapse loss, selective nerve cell death, and inflammatory gliosis. AβO buildup in adult brain is regarded a central toxic event in Alzheimer's disease. Results described here, however,

show that AβOs are not just pathogenic agents of brain damage. It has been found that AβOs are expressed physiologically for a brief period during CNS neural development and are essential for proper placement of neurons. Physiological expression of AβOs was discovered in retina of the embryonic chick, which forms an Aβ peptide identical to that of humans. Retina AβOs first appear in the optic nerve layer and then spread outward into specific cell bodies and synaptic layers. They subsequently down-regulate as the retina matures, becoming restricted to the outer retina. AβO expression is thus like a molecular wave progressing from inner to outer retina, virtually disappearing when formation of neural circuitry is completed. Identification of AβOs has been confirmed by Western blots and mass spectrometry. Intriguingly, use of different AβO selective antibodies indicates the presence of several proteoforms with different patterns of localization and developmental control. These differences appear to be linked to correspondingly different patterns of AD-type pTau expression, detected by AT8 and PHF1. If AβOs are lowered prematurely in embryos cultured *ex ovo*, the retina shows gross disruption of nerve cell placement. The distortions of retina laminar structure caused by intravitreal injection of a BACE-1 inhibitor or an AβO-selective antibody resemble the retina dysplasia previously described for various pathological conditions. Results suggest the hypothesis that embryonic AβOs constitute a new type of peptidergic hormone with a short-lived developmental role, perhaps triggering the same types of changes caused by their re-expression at the onset of Alzheimer's. A transient role for AβOs in CNS development of species with human sequence Aβ42 may be one reason evolution has conserved a peptide that manifests deleterious gain-of-function properties in the aging brain.

Title: Reading decreases foveal stimulation of ON visual pathways

Authors: *S. POUDEL, H. RAHIMI-NASRABADI, J. JIN, S. NAJAFIAN, J. M. ALONSO;
Dept. of Biol. Sci., State Univ. of New York, Col. of Optometry, New York, NY

Abstract: Visual experience plays a major role in the development of visual diseases associated with refractive error such as myopia and amblyopia. It is well known that the risk of developing myopia increases with the time spent reading and decreases with outdoor activity, however, the stimulus

parameters driving the disease remain unclear. To address this gap in knowledge, we compared the visual stimuli feeding the retina of humans that performed two tasks associated with different risks of myopia progression, reading and walking indoors. Human subjects (2 females, 6 males, 29.6 ± 6.1 years old) performed the two tasks while wearing glasses with cameras and sensors that recorded visual images and visuomotor activity (Tobii Pro Glasses 2). When compared with walking, reading reduced temporal contrast in central vision (5 degrees from fixation) and increased it in peripheral vision (8-60 degrees from fixation), leading to a pronounced reduction in the ratio of central/peripheral strength of visual stimulation (fovea/periphery temporal contrast: 24 ± 11 / 60 ± 19 when reading, 47 ± 4 / 39 ± 4 when walking, n = 2000 image pixel samples per subject and task, $p < 0.0001$, Wilcoxon test). Reading also made the luminance distribution heavily skewed towards negative dark contrast in central vision and positive light contrast in peripheral vision, leading to a pronounced reduction in the ratio of the central/peripheral stimulation of ON visual pathways (fovea/periphery luminance skewness: -2.8 ± 1.2 / 0.9 ± 1.5 when reading, 0.5 ± 0.2 / 0.5 ± 0.4 when walking, n = 2000 image pixel samples per subject and task, $p < 0.0001$, Wilcoxon test). Reading also reduced the average fixation distance (reading/walking 0.5 ± 0.3 / 1.1 ± 2 meters, $p < 0.0001$, Wilcoxon test), pupil size (reading/walking: 3.2 ± 0.5 / 4.3 ± 0.7 millimeters, $p < 0.0001$, Wilcoxon test), blink rate (reading/walking: 10.2 ± 7 / 31.6 ± 11.2 blinks/minute, $p < 0.0001$, Wilcoxon test), head velocity (reading/walking: 1.7 ± 0.7 / 14.4 ± 2.6 degrees/second, $p = 0.0002$, Wilcoxon test), and amplitude of the vestibulo-ocular reflex (reading/walking variation in eye position: 0.6 ± 0.3 / 1.2 ± 0.4 degrees, $p = 0.038$, triggered by variation in head velocity: 2.2 ± 0.8 / 13.3 ± 5.6 degrees/second, $p = 0.0002$, Wilcoxon tests). However, the reduction in fixation distance, pupil size, blink rate, and eye movements should be associated with relatively modest changes in the strength of visual responses. Therefore, we conclude that reading causes a pronounced reduction of the foveal/periphery ratio of visual stimulation driving ON visual pathways. These results are consistent with the hypothesis that ON visual pathways play an important role in myopia progression.

Title: A bi-monocular cortical theory for color (including brightness) sensations in human vision

Authors: *C. Q. WU;
Perception and Cognition Res., San Francisco, CA

Abstract: Color is the carrier of visual consciousness (VC). James Clark Maxwell expresses this idea succinctly: “all vision is color vision”. Thus, color sensation is an essential part of VC. Color sensation is primarily monocular. Hermann von Helmholtz claims this point as follows: “the content of each separate [monocular] field comes to consciousness without being fused with that of the other field by means of organic mechanisms; and that, therefore, the fusion of the two fields in one common image, when it does

occur, is a psychic act." Mapping the above point onto the neuroanatomical organization of the primate visual system, I assert that the thalamic recipient layer of the primary visual cortex (V1-L4) is the neural substrate for color sensation. Specifically, I propose the following six-pack model for this layer: Tangentially, it consists of different ocular dominance columns (ODCs) receiving thalamic inputs from the two eyes respectively; Vertically, it consists of three sublayers corresponding to the three primary color sensations: blue, red, and green. As to Helmholtz's notion of psychic fusion of the three primary color sensations for creating a whole gamut of perceivable colors, I map its physiological mechanism to single-moment synchronized firings of spiny stellate neurons within V1-L4. In this view, the magnitude of a sensation directly correlates with the number of cells within the sync-firing cell assembly; and monocular and binocular fusions are of the same type. Furthermore, I suggest that color complementarity (the Helson-Judd effect) is also created in this layer: Within each local area corresponding to one LE's ODC and its RE's counterpart, when the neural activity level of an eye's image is below the binocular adaptation-level within the locality, color complementarity will occur. Afterimage (AI) has traditionally been treated as retinal, but I claim that it is cortical. Also, +AI and -AI have usually been taken as due to different causes. William McDougall posits that both +AI and -AI are due to the same cause; here I further develop this concept: They are both due to the persistence of some neural activity (or potential) in V1-L4; an AI is positive if its activity level is over its adaptation level and is negative otherwise; an AI is of the same hue if the polarity between its activity-level and adaptation-level remains the same as in the primary stimulation and is complementary otherwise. Finally, I propose that AI is not only cortical but also a part of visual short-term memory (STM): Theoretically, it is possible to prolong an AI as long as one wishes. In this regard, visual STM is on a par with verbal STM where an acoustic item can be rehearsed as long as one wishes.

Title: Daily oscillation of the excitation/inhibition ratio is disrupted in two mouse models of autism

Authors: *M. BRIDI[1], N. LUO[1], G. KIM[1], C. O'FERRALL[2], R. PATEL[2], S. J. BERTRAND[2], S. KANNAN[2], A. KIRKWOOD[1];
[1]Zanvyl Krieger Mind/Brain Inst., [2]Anesthesiol. and Critical Care Med., Johns Hopkins Univ., Baltimore, MD

Abstract: Autism spectrum disorder (ASD) is an increasingly prevalent neurodevelopmental disorder involving sensory processing abnormalities. Alterations to the balance between excitation and inhibition (E/I ratio) are postulated to underlie behavioral phenotypes in ASD patients and mouse models. However, in primary visual cortex (V1) of wild type mice, the E/I ratio is not a fixed value. Rather, it oscillates

across the 24h day. Therefore, we hypothesized that the E/I oscillation, instead of the overall E/I ratio, may be disrupted in ASD mouse models. We tested this hypothesis in fragile X mental retardation protein knockout (*fmr1* KO) and BTBR *T+ Itpr3^{tf}/J* (BTBR) mice, models of syndromic and idiopathic ASD, respectively. We measured the E/I ratio at multiple times of day using whole-cell patch clamp recordings. We found that the E/I ratio in the V1 layer 2/3-2/3 pathway is dysregulated in both models, but in different ways: the oscillation is flattened in *fmr1* KO and phase-shifted in BTBR mice. These phenotypes cannot be explained by altered sleep timing, which was largely normal in both lines. Furthermore, we recorded miniature excitatory and inhibitory postsynaptic currents (mE/IPSCs) in V1 at multiple times of day and found that E/I dysregulation occurs due to alterations in both excitatory and inhibitory synaptic transmission: mE/IPSC frequency matched the dysregulated E/I pattern observed in each line. These findings provide a crucial perspective on the E/I ratio in ASD, suggesting that ASD phenotypes may be produced by a mismatch of E/I to the appropriate behavioral state, rather than altered overall E/I ratio *per se*.

Title: The endocannabinoid system in the primary visual cortex of the vervet monkey

Authors: *C. MICAELO-FERNANDES[1], S. MORYOUSSEF[1], H. HAÏMEUR[1], J. BOUSKILA[1], J.-F. BOUCHARD[1], M. PTITO[1,2];

Abstract: Cumulating evidence highlights the contribution of the endocannabinoid (eCB) system to visual perception. The primary visual cortex/V1 represents the first cortical stage of visual information processing and the presence of the cannabinoid receptor type 1 (CB1R) at this level has been previously reported for mice, macaque monkeys and humans. In this work, we aimed at reproducing and extending these findings, by performing a more comprehensive neuroanatomical and neurochemical characterization of the eCB system in V1 of the vervet monkey. Five young male vervet monkeys *(Chlorocebus sabeus)* were used in this study. The combined immunohistochemical labelling patterns of the neuronal nuclear antigen (NeuN), the neurofilament H non-phosphorylated (SMI-32), parvalbumin (PV), and the vesicular

glutamate transporter 2 (VGLUT2) were used to define the lamination of V1. The same markers were also applied in double immunofluorescence to study the distribution of CB1R and the eCB-synthesizing and degrading enzymes N-acyl phosphatidylethanolamine phospholipase D (NAPE-PLD) and Fatty Acid Amide Hydrolase (FAAH) respectively. The six-layered organization of V1 was clearly identified. Similarly to previous findings, CB1R-immunoreactivity was the greatest in the most superficial (L2-3) and the deepest (L5-6) layers of V1, with low labelling of L4. CB1R was present in axonal fibers rich in varicosities, surrounding (but not colocalizing with) NeuN-, SMI-32- and PV-positive cell bodies. CB1R-positive axons had very limited overlap with VGLUT2-positive axons. In contrast, NAPE-PLD and FAAH were expressed along the cortical depth of V1, in the somatodendritic compartment of diverse neurons, including SMI-32-positive pyramidal cells and PV-positive interneurons. Our results suggest a presynaptic localization of CB1R, in axons terminating in the superficial and deep layers of V1. L2-3 and L5-6 constitute precisely the main output layers of V1, whereby CB1R-positive fibers found on these layers might correspond to feedback projections originating from their cortical and subcortical targets, respectively. Since the degree CB1R/VGLUT2 colocalization appears to be minimal, the likely inhibitory, i.e., GABAergic nature of these projections is currently being investigated.

Title: A whole-brain monosynaptic input connectome to neuron classes in mouse visual cortex

Authors: *S. YAO, Q. WANG, K. E. HIROKAWA, B. OUELLETTE, P. BOHN, T. L. DAIGLE, T. ZHOU, M. MORTRUD, A. WILLIFORD, P. A. GROBLEWSKI, M. D. NAEEMI, M. MCGRAW, L. POTEKHINA, P. R. NICOVICH, W. WAKEMAN, S. MIHALAS, B. TASIC, A. H. CETIN, J. A. HARRIS, H. ZENG;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Identification of the structural connections between neurons is a prerequisite to understanding brain function. We have developed a pipeline to systematically map brain-wide monosynaptic inputs to specific neuronal populations using Cre-driver mouse lines and the recombinant rabies tracing system. We first improved the rabies virus tracing strategy to accurately identify starter cells and to efficiently quantify presynaptic inputs. We then mapped the presynaptic inputs to different excitatory and inhibitory neurons in the primary visual cortex and five higher visual areas. Our results reveal quantitative target-, layer- and cell-class-specific differences in the retrograde connectomes, despite similar global input patterns to different neuronal populations in the same anatomical area. The retrograde connectivity we define is consistent with the presence of the ventral and dorsal visual information processing streams, and supports a hierarchical, modular organization of the mouse visual circuit. This study expands our knowledge of the brain-wide inputs regulating visual areas and demonstrates that our improved rabies

virus tracing strategy can be used to scale up the effort in dissecting brain-wide connectivity of genetically defined cell populations in the whole mouse brain.

Title: Laminar functional connectivity in primary visual cortex

Authors: *J. NING[1], C. L. BAKER[2];
[1]Physiol., McGill Univ., Montreal, QC, Canada; [2]Ophthalmology, McGill Vision Res. Unit, Montreal, QC, Canada

Abstract: Laminar structure is a distinctive feature of cerebral cortex, which is broadly conserved not only across cortical areas but also across species. It comprises 6 layers characterized by cellular organization, specific inputs and projection targets. Previous studies have shown anatomical connectivity across laminae (Harris and Shepherd, 2015), but how different laminae are connected physiologically is still unclear. Here, by using a series of functional connectivity methods, we investigate association and causal relationship across laminae in primary visual cortex. While responding to visual stimuli, neurons across cortical depth in A17/18 of the anesthetized and paralyzed cat were recorded with a 32-channel linear array probe (NeuroNexus). Multiunit activity (MUA) was extracted from recorded neuronal responses for each channel, as times of level-crossings at 3 standard deviations of the bandpass digitally filtered (300 Hz - 3.0 kHz) signal. Current source density (CSD) analysis was applied to approximately locate recording sites into 3 layers (supra-granular layer, granular layer and infra-granular layer) (Mitzdorf and Singer, 1978). We implemented a series of functional connectivity methods in Matlab, including mutual information, Pearson correlation, and Granger causality, to measure statistical dependence of MUA across recoding sites. Since common input and indirect influence could introduce spurious connectivity, we applied conditional Granger causality, which could remove variance explained by other variables when estimating pairwise functional connectivity, using a version of the method designed to analyze spiking responses (Chen et al., 2006; Dhamala et al., 2008). For validation, we tested these methods on simulated spiking data from a small network of leaky integrate-and-fire models. These methods showed patterns of functional connectivity across laminae, suggesting association and causal relationships between neuronal layers of cortex. The results from mutual information and Pearson correlation exhibited a similar relation to the laminar structure measured by CSD, and Granger causality

provided indications of directionality. In simulated data, conditional Granger causality outperforms Granger causality in minimizing the effect of spurious correlations such as confounders and indirect influence, and therefore better reveals potential underlying mechanisms. In conclusion, these three functional connectivity measures, including mutual information, Pearson correlation and Granger causality, suggest how neurons in the primary visual cortex process sensory inputs in a laminar-dependent manner.

Title: Developmental changes in the temporal and laminar structure of responses to oriented gratings in primary visual cortex following eye opening

Authors: *A. A. LEMPEL, D. FITZPATRICK;
Max Planck Florida Inst., Jupiter, FL

Abstract: Cortical circuits develop in two main stages: an early stage driven by endogenous mechanisms that precedes sensory experience, and a later stage where maturation is driven by sensory input. Orientation maps in ferret primary visual cortex (V1) have served as a powerful model for studying these different phases of cortical maturation. The development of orientation maps begins before eye opening, where neuronal responses to oriented gratings are poorly selective yet organized in spatial patterns. Visual experience transforms these immature response patterns into a reliable representation of orientation. Response patterns elicited by gratings have so far been studied with calcium imaging techniques that provide low temporal resolution and are limited to superficial layers. Therefore, whether the temporal and laminar structure of these response patterns changes across development remains unknown. By combining imaging techniques with electrophysiology, we revealed that the poorly selective patterns of responses to gratings seen before eye opening emerge in superficial layers with long latency and do not extend to deeper layers. In particular, neuronal responses recorded in layer 4, the main target of thalamo-cortical input, showed poor correlation with and lower orientation selectivity than response patterns seen in layer 2/3. These results strongly suggest that, before eye opening, responses to gratings are shaped by recurrent mechanisms within layer 2/3 that generate spatial patterns and increased selectivity. After eye opening, responses became strongly selective with short latency across all cortical layers, consistent with the established view that mature orientation selectivity in V1 of carnivores is computed through feed-forward mechanisms in layer 4. This developmental difference in the laminar and temporal structure of responses to gratings could be due to the lack of experience with stimuli that include sharp edges before eye opening. If so, responses to stimuli that can be perceived through closed eyes should present a mature temporal and laminar structure before eye opening. To test this, we analyzed responses to homogeneous

changes in luminance across development. Indeed, responses to these stimuli showed high selectivity with short latency across all layers both before and after eye opening. Taken together, our results suggest that early in development neuronal responses to novel stimuli are structured across the cortical network by recurrent mechanisms that provide some degree of selectivity. Further experience with the stimuli would re-shape feed-forward connectivity leading to mature cortical representations.

Title: Layer-dependent modulation of gamma-band oscillations by stimulus size in primate visual cortex

Authors: *A. M. CLARK[1], M. BIJANZADEH[2], *A. ANGELUCCI[1];
[1]Ophthalmology and Visual Sci., Univ. of Utah, Salt Lake City, UT; [2]Dept. of Neurolog. surgery, Univ. of California San Francisco, San Francisco, CA

Abstract: Sensory processing is affected by context. In primary visual cortex (V1), a commonly studied form of this contextual modulation is surround suppression (SS), in which responses to stimuli inside a cell's receptive field (RF) are suppressed by nearby stimuli (Angelucci et al 2017). Previous studies have shown that in primate V1 stimuli that activate both the RF and surround increase the power of local field potential (LFP) gamma-band oscillations (Gieselmann, et al, 2008; Jia, et al, 2011). There is evidence that inter-areal feedback (FB) connections contribute to SS and modulate gamma oscillations. Specifically, surround stimulation in monkey V1 evokes the earliest LFP signals in FB-recipient V1 layers (Bijanzadeh et al, 2018), and inactivation of V2-V1 FB reduces SS (Nassi et al. 2013; Nurminen et al. 2018). Inactivation of V2/V3 FB also reduces the power of gamma oscillations in V1 (Hartmann et al, 2019). Because the strength and tuning of SS, as well as the pattern of FB connections, varies across V1 layers, we wondered whether V1 layers exhibit differences in SS-modulated gamma. To study laminar differences in stimulus-evoked LFP gamma power, we recorded across all V1 layers within a cortical column in macaque monkeys using linear electrode arrays oriented normal to the cortical surface. Stimuli were gratings of optimal position, orientation and spatiotemporal frequency that varied in diameter. Consistent with prior work, across all layers, V1 gamma power was size tuned and the peak frequency of the gamma oscillation decreased with increasing diameter. However, unlike in prior accounts, size tuning curves were suppressed for the largest stimuli. Furthermore, the effect of stimulus size on gamma power

varied across layers. In supragranular layers, gamma power peaked for stimuli about the size of the recorded multi-unit (MU) RFs; much larger stimuli suppressed both MU activity (MUA) and gamma power. Conversely, in granular and infragranular layers, gamma power peaked for diameters that far exceeded those eliciting the greatest MUA; thus stimulation of the surround suppressed MUA but increased gamma power. Across all layers, gamma size tuning peaked for smaller stimuli in the later portion of the response, further suggesting FB modulation of the gamma oscillation. In accordance with these findings, we did not observe a difference across layers in the orientation tuning of gamma power for stimuli that did not activate the RF surround. The above suggests models of cortical gamma in which excitatory-inhibitory interactions are modulated by a global feedback signal must be refined to take into account laminar differences in lateral, interlaminar and FB connectivity.

Title: A modular organization of looped interareal and thalamocortical pathways in mouse visual cortex

Authors: *R. D'SOUZA, W. JI, A. BURKHALTER;
Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: The dorsal lateral geniculate nucleus (dLGN) and pulvinar, the two main thalamic nuclei that innervate visual cortex, send strong axonal projections to layer 1 (L1) of mouse primary visual cortex (V1) in addition to their respective dense innervation of L4 and L5 of V1. L1 of mouse V1 is characterized by a modular organization wherein the afferents from dLGN and pulvinar terminate respectively in two spatially segregated, interdigitating zones termed ‘patches’ and ‘interpatches’ (D’Souza et al., 2019). Because dLGN and pulvinar inputs to L1 play diverse roles in the computation of predicted and unpredicted changes in the visual scene during locomotion (Roth et al., 2016), we hypothesized that patches and interpatches demarcate two distinct, specialized networks, each comprising preferential interareal and thalamocortical connections. Using a combination of anterograde and retrograde viral tracing of projection neurons in dLGN, pulvinar, V1, and several higher-order areas in wild type and Ai9-Cre mice of both sexes, we find that interareal and thalamocortical connectivity is governed by a ‘like-to-like’ rule: the postsynaptic targets of projection neurons residing in patch and interpatch zones preferentially send projections back to patches and interpatches, respectively. Patches and interpatches were identified by immunostaining tangential cortical sections for the M2 acetylcholine receptor. ‘Patch circuits’ included V1 neurons that projected to laterally located, higher visual areas LM (lateromedial), RL (rostrolateral), and AL (anterolateral), all of which, in turn, preferentially innervated

V1 patches. RL was recently shown to be specialized for processing posterior motion inherited from the retina (Rasmussen et al., 2020). Moreover, the apical dendrites of L5 and L6 cells that sent descending projections to dLGN were also preferentially located in patches, the preferred target of axons emanating from the dLGN shell. 'Interpatch circuits' included V1 neurons projecting to PM (posteromedial), whose direction selectivity likely depends on non-retinal mechanisms (Lien and Scanziani, 2018), the pulvinar, and the respective, reciprocal inputs back to L1 of V1. Furthermore, the axons of local V1 pyramidal cells and somatostatin-expressing interneurons were significantly denser in interpatches. Together, these connection motifs suggest the existence of two distinct brain-wide circuits: a patch network containing areas of the ventral stream (LM) including the posterior parietal branch of the dorsal stream (AL, RL), and an interpatch network containing the medial branch of the dorsal stream (PM).

Title: Vision is required for cell type specification in the visual cortex

Authors: *S. BUTRUS[1], S. CHENG[2], V. XU[2], S. SAGIREDDY[1], K. SHEKHAR[1], S. ZIPURSKY[2]; [1]UC Berkeley, Berkeley, CA; [2]UCLA, Los Angeles, CA

Abstract: Postnatal development of the visual cortex requires vision. However, how vision regulates gene expression in individual cortical cell types during this period is poorly understood. To this end, we assembled a postnatal developmental atlas of the mouse primary visual cortex (V1) using single nucleus RNA-sequencing of 225,000 neurons across six developmental stages between P8 and P38 and four light rearing conditions: normal rearing, dark rearing between P21-28 and P21-38, and dark-rearing between P21-28 followed by brief ambient light exposure. We used unsupervised machine learning approaches to identify molecularly distinct cell types at each age and developed a supervised learning framework to assess their postnatal maturation. We discovered that, under normal rearing conditions, the glutamatergic cell types in upper cortical layers (L2/3/4) were only specified following eye opening. By contrast, lower-layer glutamatergic (L5/6), GABAergic, and non-neuronal types were specified before this period. Using fluorescent in situ hybridization for L2/3 type markers identified in the atlas, we found that L2/3 glutamatergic types were organized in a sublaminar fashion that was established following eye opening, Furthermore, most genes that distinguished L2/3 types were expressed in a graded fashion across the three types, including markers that regulate axon projection specificity and inhibitory synapses. Finally, our dark rearing experiments revealed that early postnatal visual experience is required for both the establishment and maintenance of this continuous variation in L2/3 cell type identity. Visual deprivation disrupted both the transcriptional profiles of L2/3 neuronal types and their in situ organization, both of

which were partially recovered when visual stimulation was restored during the critical period. However, the maturation of L5/6 glutamatergic, GABAergic, and non-neuronal types was independent of vision. This selective influence of vision on cellular organization within L2/3 aligns with recent functional studies showing that only L2/3 neurons require vision to shape their tuning properties (Tan et. al., Neuron, 2020). In summary, our study provides an experimental and computational framework for investigating the role of experience in shaping the molecular, structural, and functional organization of the vertebrate brain.

Title: Cone-specific orientation sensitivity in macaque primary visual cortex

Authors: *M. A. SAVAGE, C. V. DIENI, P. D. GAMLIN, L. C. SINCICH;
Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Color and orientation sensitivity are two fundamental aspects of vision encoded in primary visual cortex (V1). Early work suggested that these features are specific to anatomically segregated regions of primate V1, with color sensitive neurons residing in cytochrome oxidase (CO) patches and orientation sensitive neurons in CO interpatch regions, but recent research has shown that such a functional segregation is not so strict. We investigated the interaction of cone-specific signals and orientation tuning in macaque V1 with 2-photon calcium imaging and classified the recorded neurons by CO compartment. One animal was injected with a fluorescent calcium reporter (AAV1-syn-gCamp7s). After 3 months transfection time, we imaged through a cranial window while the animal was anesthetized and under neuromuscular blockade. Visual stimuli consisted of drifting cone-isolating gratings (L, M or S) of 6 different orientations. Postmortem CO histology was aligned with the imaged field using vascular landmarks. We imaged 252 transfected neurons within a 460 μm diameter field at 200 μm depth and found that 62% were in a CO interpatch area and 33% were in CO patches. Half of the labeled neurons were visually responsive (Z score > 2.5), with a median orientation tuning width of 26°; of these cells 58% were highly orientation selective (1-circular variance > 0.5). The CO patch and interpatch neurons displayed similar median orientation tuning widths, 28° and 24° respectively, consistent with recent reports. The cohort of 125 responsive neurons exhibited either L cone dominant weighting (60% L/M ratio > 1) or M cone dominance (40% L/M ratio < 1). When comparing S cone vs LM cone inputs, the

responses were more skewed, with 32% S cone dominant (S/LM ratio > 1) and 68% LM cone dominant (S/LM ratio < 1). Orientation tuning width was similar for each group of cone dominant neurons. Cone weighting ratios were compared in relation to CO patch or interpatch regions, and the same prevalence of L vs M cone dominance was found in each region as in the overall population. The S vs LM cone inputs differed slightly, with the CO patches having 41% S cone dominance and 59% LM cone dominance while the CO interpatch neurons were less S cone dominant (27%) than LM cone dominant (73%). Notably, in a subset of neurons, orientation tuning changed by >30° depending on the cone-isolating stimulus. We found 18% of CO patch and 20% of CO interpatch neurons displayed shifts in orientation tuning based on which cone class was being modulated. Our results show that cone-isolating stimuli drive well-oriented responses in CO patch and interpatch areas of V1, with some neurons apparently displaying cone-specific orientation tuning.

Title: Holographic activation of neural ensembles reveals both space and feature based cortical microcircuitry

Authors: *I. A. OLDENBURG, W. D. HENDRICKS, H. ADESNIK;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Visual perception involves the coordinated effort of thousands of interrelated and often genetically similar neurons. Privileged interconnectivity between excitatory cells in co-active ensembles can amplify sensory input and facilitate perception. However, as these ensembles are physically intermingled, understanding the causal influence that ensembles of cells exert on other neurons requires new advanced technologies. We use multiphoton holographic optogenetics (3D-SHOT) to gain temporally precise, individual cell resolution control of groups of neurons in vivo. We drive specific ensembles of excitatory neurons in L2/3 of mouse primary visual cortex to determine their influence independent of sensory stimulation. We find, across hundreds of different stimulated ensembles, that most groups reliably recruit recurrent inhibitory circuits, but that individual responding neurons may be excited or inhibited depending on both their physical proximity and feature preference similarity to the stimulated ensemble. Furthermore, the selection of which cells make up a stimulated ensemble impacts the inhibition

observed. Together, these space- and feature-dependent rules refine our understanding of the cortical microcircuit, reconciling the Hebbian ‘like to like’ connectivity, with smooth spatial rules, and a balanced role of inhibition.

Title: High-density recordings with flexible electrodes in macaque primary visual cortex

Authors: *L. MERKEN, M. SCHELLES, F. CEYSSENS, P. JANSSEN;
KU Leuven, Leuven, Belgium

Abstract: Chronically implanted multi-electrode arrays are capable of recording multiple neurons for several months. However, in most applications, rigid electrodes are used which cause scar tissue formation over time. In order to upscale to a large number of electrodes, scar tissue formation should remain minimal. Another limitation of some multielectrode arrays is the limited length of the electrodes, which precludes investigating cortical areas that are buried in sulci. We developed ultra-thin flexible electrode arrays for long-term single- and multi-unit recordings that can also reach deeper cortical areas.The multi-electrode arrays were designed in a comb-like shape, with one to three electrodes on each needle, and a needle spacing of 700 µm. This allows insertion of multiple electrodes at the same time, while also spanning a large area of cortex. The electrode arrays consisted of a 10-20 µm thin flexible, biocompatible polymer (polyimide) with metal traces and iridium oxide as electrode material. Ongoing in vitro accelerated lifetime experiments have already demonstrated a lifetime of over 1.5 years. To allow the array to pierce the pia mater, it was temporarily reinforced with resorbable PLGA. A coating technique combined with a dedicated electrode array design was developed to create a sharp tip (< 10 µm²) needed for insertion. In a first in vivo test we implanted one macaque monkey with 92 electrodes in the primary visual cortex. Preliminary electrophysiological measurements were performed and histological analysis (NeuN, GFAP, CD 68, H&E stainings) was completed 3 months after implantation. We observed minimal scar tissue formation and viable neurons up to 10 microns from the site of implantation. In another macaque monkey, we implanted 139 electrodes and performed awake recordings while the monkey fixated during presentation of flickering checkerboards of 1 to 4 degrees. Over a time period of 2 months (10 sessions), we recorded multi- and single-unit activity from up to 68% of the active electrodes. In total, we observed 66 to 92 channels with a significant visual MUA response (Wilcoxon rank sum test comparing pre- and post-stimulus; $p<0.05$). The receptive fields were located in the lower contralateral visual field at eccentricities of 1 to 4 degrees, and measured between 1 and 3 degrees in diameter. In conclusion, we achieved long-term recordings of neural activity with highly flexible arrays in

primary visual cortex, which induced minimal scar tissue formation. These electrodes can be upscaled to 1000 electrodes to cover a large volume of cortex, including cortex in sulci, which is crucial for developing a high-resolution cortical visual prosthesis.

Title: Mapping activity in macaque primary visual cortex using simultaneous micro-ECoG and depth arrays

Authors: *R. T. RAGHAVAN[1], K. A. KATLOWITZ[2], M. A. LONG[3], J. A. MOVSHON[1];
[1]Ctr. for Neural Sci., [2]Neurosci., New York Univ., New York, NY; [3]Neurosci. institute, NYU Sch. of Med., New York, NY

Abstract: Understanding the spatial precision of ECoG signals and the fidelity with which they reflect neuronal activity is critical to evaluating their utility as a recording method in both basic and clinical settings. This has grown more relevant with the development of high resolution ECoG arrays (micro ECoG) which have electrode spacing similar to intracranial silicon probes. We used micro-ECoG arrays to measure evoked activity in the visual cortex of anesthetized macaques, a circuit in which the content and spatial scale of sensory responses is well understood. We used sinusoidal grating stimuli to measure spatial frequency and orientation selectivity, and the spatial extent of visual activation that could be resolved on individual micro-ECoG array contacts. Stimulus-evoked responses had maximal SNR in the gamma band (40-300 Hz). Variations in the spatial frequency selectivity of gamma band signals agreed with the scale of spatial frequency maps in visual cortex as measured with calcium imaging (Nauhaus et al. 2012). Receptive field sizes from individual contacts were similar to intracranial spiking activity that we recorded simultaneously using laminar silicon arrays, and were roughly 3x smaller than reported for macro-ECoG recordings over primate cortex (Dubey and Ray 2019). These signals also exhibited strong surround suppression, a characteristic of superficial layer cortical activity. 48 hr post-implantation, sites continued to show tuning for both orientation and spatial frequency, as did intracranial spiking activity from these regions of surface visual cortex. We determined the stability of these measurements in one animal by recording over 6 days. Receptive field size remained stable over this time, while spatial frequency and orientation selectivity broadened, suggesting increasing pooling of underlying cortical

signals. Together, these results reveal conditions under which micro-ECoG arrays provide an excellent readout of cortical population activity. Moreover, they suggest micro-ECoG arrays can approximate the spatial resolution afforded by intracranial recording electrodes, but with a significantly less invasive footprint.

Title: Validating White Matter Tractography using Topographic Mapping

Authors: *C. PEDERSINI[1], N. MILLER[2], K. DESIMONE[1,3], A. TEMUDO[1], K. K. SREENIVASAN[1], O. ABDULLAH[1], B. ROKERS[1];

Abstract: Methods for identifying and assessing the structure of white matter pathways in the brain have advanced significantly in recent years. However, it is still difficult to determine if a method captures a tract in its entirety. Here, we present a pipeline to assess tractography methods by leveraging population receptive field (pRF) mapping data, which estimates topographic organization in gray matter.
We collected neuroimaging data of 7 healthy participants in a 3T MRI scanner. We extracted an estimate of the optic radiation (OR) white matter tract based on either probabilistic (Constrained spherical deconvolution) or deterministic (Generalized q-space imaging) methods. We extracted LGN, pulvinar and V1 ROIs based on anatomical templates (Freesurfer, Neuropythy), identified connecting streamlines, and cleaned the results when necessary. For each streamline we assigned a preferred polar angle and eccentricity based on the median value of the pRF estimates of V1 voxels it innervated. To validate this procedure, we checked the extent to which the estimates assigned to each streamline reproduced a relatively uniform spatial representation. Finally, we propagated tract-based estimates to LGN and pulvinar and visualized the resulting spatial representation. Thus we assessed the ability of the pipeline to recover the retinotopic organization of thalamus based on the combination of V1 retinotopy and white matter tractography.
Overall we observed a uniform representation of the contralateral visual field and fewer streamlines represented locations in the periphery rather than the central visual field, mirroring the pRF mapping results in gray matter, although this pattern was better preserved when using the probabilistic rather than the deterministic method.In thalamus we observed that the tract-based estimates provided a greater representation of the angular locations around the horizontal midline, consistent with previous studies. Both methods were slightly biased towards locations in the upper visual field and showed a greater representation of spatial locations around 2-5 degrees of eccentricity. These results highlight the potential and limitations of methods that estimate the retinotopic organization of the thalamus based on retinotopic organization in V1.

In conclusion, these results provide a means for leveraging functional data to identify and validate white matter pathways in topographically organized brain areas, and provide a means to compare tractography methods based on functional imaging data.

Title: Causal testing of a topographic code in macaque V1 using a model-assisted all-optical read/write experimental platform

Authors: *S. KOBAYASHI, Y. Y. CHEN, X. X. WEI, E. SEIDEMANN;
Univ. of Texas At Austin, Austin, TX

Abstract: The encoding of coarse-scale visual features such as shape must involve pooling of information across populations of neurons with small receptive fields (RFs). Previous studies suggest that under some circumstances this may be done by exploiting topography in primary visual cortex (V1)—namely retinotopy, where neurons are organized by their RFs in visual field. We hypothesize the existence of a topographic decoder that can parse shape via the spatial structure of mean evoked V1 activity. To test this hypothesis, we trained macaque monkeys to discriminate aspect ratio (AR)—an important determinant of shape—by reporting the AR of bright 2-D Gaussians on a gray background. We used an encoding/decoding model of V1 with realistic noise, retinotopy, and tuning diversity to see how V1 may process information relevant to this task. We created decoders accessing different scales of encoded information—a purely retinotopic decoder only accesses the shape of mean activity across cortex, while a "labelled line" decoder accesses all information, including individual unit tunings. We find retinotopic decoders perform the AR task well, despite discarding substantial task-relevant information that is otherwise retained by a labelled line decoder. Macaques are sensitive to minute differences in AR, being able to correctly report AR of stimuli only slightly elongated from circular. Analysis of physiology of macaque V1 population activity via widefield voltage-sensitive dye and calcium imaging show that stimulus AR can indeed be decoded from the retinotopic shape of V1 activity, with sensitivity comparable to that of the animals. The ability to decode AR from retinotopic information is not sufficient to prove it is actively used by the visual system. We wish to test our hypothesis more directly using an all-optical platform to simultaneously record and manipulate population activity in primate V1 via co-expression of genetically encoded green calcium indicators and red-shifted opsins. By adding a projector to spatially pattern the evoked activity, we can inject retinotopic-only information into V1—activity indiscriminate to

individual tunings, only holding information in the shape of activity across cortex—while animals perform the AR task. We plan to run an experiment where we seek to bias perception using the above platform—if a purely retinotopic decoder truly exists, the injection of retinotopic-only information would bias perception. The results will be interpreted together with the models described above. Our model-assisted read/write methods in awake behaving macaque will allow for a causal approach in understanding visual processing.

Title: A fast and robust retinotopic-scale representation of occluding edges in macaque V1 suggests an active role for V1 in scene segmentation

Authors: *S. KUMAR, Y. Y. CHEN, E. SEIDEMANN;
Univ. of Texas at Austin, Austin, TX

Abstract: Despite the complex and cluttered environment that often surrounds us, our visual system rapidly and accurately interprets natural scenes and supports visually-guided behaviors. There are two competing hypotheses regarding the role of primate V1 in scene segmentation, a key component of scene interpretation. The segmentation computation may be partially implemented in V1, leading to a fast V1 representation of occluding edges that is invariant to the local features in the figure and background. Alternatively, V1 represents only the local features, the segmentation takes place downstream from V1, and delayed segmentation V1 signals reflect post-segmentation top-down modulations. To distinguish between these possibilities, we are studying V1's representation of camouflaged targets, where a figure obscures a background of identical texture. We trained two macaque monkeys to detect a small 2°x2° rectangular figure that occludes a large background. The target and figure contain identical sine-wave gratings that differ only in their phase. The target appears on half of the trials at a known location at an eccentricity of 2°, and the monkey reports target presence by making a saccade to the target location and target absence by maintaining fixation. As expected, the monkeys' performance improves with increasing target-background phase difference. Detection phase-difference thresholds are ~60° at 6 or 8 c/°. Behavioral masking experiments reveal that segmentation can be completed based on 80 ms of pre-mask edge stimuli, suggesting a rapid segmentation computation. To measure V1 population responses to occluding edges, we chronically expressed GCaMP6f in excitatory V1 neurons and recorded neural responses during passive fixation and behavioral detection tasks using widefield imaging. We find fast and robust elevated V1 population response along the retinotopic representation of the occluding edge that monotonically increases with phase difference and is largely insensitive to the local target and background features and to the behavioral task (passive vs. active). Decoding analysis reveals that these

responses can support fast and accurate camouflaged target detection and that V1 activity is elevated at the expected edge location on false-alarm trials relative to correct rejections. In summary, our results reveal a fast mechanism that represents occluding edges at the retinotopic scale in V1, supporting the hypothesis that V1 plays an active role in the segmentation computation. This conclusion is further supported by the finding that the edge-related V1 representation is correlated with variability in perceptual decisions.

Title: A comparison of top-down and bottom-up representations of visual objects in the human brain

Authors: *V. WADIA[1], A. MAMELAK[2], U. RUTISHAUSER[2], D. Y. TSAO[1,3];
[1]Caltech, Pasadena, CA; [2]Dept. of Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]Howard Hughes Med. Inst., Ashburn, VA

Abstract: A comparison of top-down and bottom-up representations of visual objects in the human brain. Mammalian visual processing has long been thought of as a combination of top down and bottom up processing. An extreme instance of top-down processing occurs in imagination, when a subject can be directed by verbal cues to perceive a stimulus in the absence of any bottom-up input. Animal studies have yielded rich insight into neural mechanisms for bottom-up processing. However, the neural mechanisms for top-down processing have been more elusive, in part due to the impossibility of verbal instruction in animals. Here, we performed single-neuron recordings in epilepsy patients implanted with modified depth electrodes that contain embedded microwires. These patients are implanted for the purpose of localizing the source of their focal epilepsy. We use this rare opportunity to examine the neural mechanisms underlying visual imagination in humans by directly comparing top down and bottom up representations of visual objects at a single neuron and population level across two different recall tasks (cued and free). Subjects were required to view images and, after a visual search distraction period, recall the images in either a cued (alternating tones specifying which two images to cyclically visualize) or a free (verbal description) manner. We find cells that were selective during encoding and maintained that selectivity during recall, corroborating previous findings (Kreiman et al, 2000; Gelbard-Sagiv et al, 2008; Khuvis et al, 2021). However, we report the existence of two additional cell populations distributed across multiple brain regions: cells that were exclusively active during viewing, and surprisingly, cells that were exclusively active and selective during recall periods either cued or free. These three functional groups perform complementary functions to give rise to perception and memory as we experience it.

Title: Chronic recordings reveal the face cell's cross-category encoding model

Authors: *Y. SHI[1], P. BAO[2], D. Y. TSAO[1];
[1]Caltech, Pasadena, CA; [2]Peking Univ., Beijing, China

Abstract: Inferior temporal (IT) cortex is considered the final stage for object recognition in the ventral visual stream. Macaque IT cortex contains 6 face-selective patches where most cells respond much stronger to faces than to other objects. Interestingly, these face cells also respond differently to different non-face objects, thus raising the question: What is a face cell's full encoding model to all object categories? It has long been thought that face cells use a specialized coding mechanism dedicated to faces, but with the advent of deep neural networks, a general-purpose coding mechanism becomes plausible. Specifically, can we predict the responses of face cells to faces using their weak responses to other objects? Previously our lab found that face cells encode faces by projecting each face stimulus onto a preferred axis in the face space (Chang & Tsao, Cell 2017). To address the question raised above, we mapped the preferred axes of cells for both faces and non-face objects in order to perform a further comparison. Traditional acute recording only allows a few thousand stimuli to be shown to the monkey within a recording session, which is not enough to build an accurate cross-category model. We thus used chronic brush arrays (McMahon & Leopold, J Neurophys 2014) to record from the same cells for days and even months, allowing us to show an order of magnitude larger number of stimuli to the monkey. Preliminary results suggest that face cells use different models for faces and non-face objects. We hypothesize that the chimeric encoding behavior may arise from local circuit plasticity shaped by early developmental experience.

Title: Neural representation of continuous, visual experience in the primate hippocampus

Authors: *K. MOHAN, J. LU, D. Y. TSAO;
Caltech, Pasadena, CA

Abstract: The mammalian brain is remarkably efficient at building memories of our conscious experience. We effortlessly reconstruct experienced events, and we are able to establish and maintain detailed episodic memories even after single, one-shot episodes. This ability to rapidly create a coherent internal model of the world is thought to rely on the hippocampus and its interactions with the cortex. Decades of experimental work have emphasized the role of the rodent hippocampus in constructing a spatial map of the environment but the underlying hippocampal code for representing visual experience, beyond simple awareness of egocentric spatial location, remains unknown. To tackle the question of how the primate hippocampus represents rich, naturalistic visual experience, we recorded neural population activity in the hippocampus (N=247) with 24-channel V Probes. During recordings, animals navigated a 3D immersive virtual reality (VR) environment tiled with visual objects at distinct spatial locations. Using VR headsets customized for macaques, animals actively explored the environment using a two-axis joystick to receive juice rewards. In addition to active experience during exploration, the same visual objects were presented passively to explore how predictable, spatially organized experience is learned. We also compare neural responses of the same cells to the same visual objects during active versus passive experience. We characterized the selectivity of individual hippocampal neurons to environmental variables (such as object identity, spatial location of animal, spatial location of currently viewed object, etc.), behavioral variables (such as joystick position, eye position, reward, etc.), as well as interactions between these variables. Single neurons showed spatially selective activity around salient events in virtual space, such as arena start, arena end, and approach towards objects in the arena, suggesting that hippocampal cells encode key events in continuous experience. We test the hypothesis that the hippocampus represents the ingredients of a visual scene - multiple objects and their locations - through an abstract, compositional representation. Overall, our results provide an understanding of visual representations in the hippocampus during exploration of object-rich environments.

Title: Reversible silencing of primary visual cortex with a chemogenetic system in rhesus monkey

Authors: *M. SMITH, M. ELDRIDGE, W. LERCHNER, M. MCDOUGALL, J. SHIM, B. RICHMOND;
Section on Neural Coding and Computation, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Chemogenetic silencing is a powerful tool in systems neuroscience research because it allows for selective and reversible silencing of neuronal activity. Ivermectin-gated chloride channels (GlyCl)

have been used to silence neurons and modify behavior of freely-moving mice. The goal of this study is to test whether the GlyCl-ivermectin system can be used to reduce neuronal activity in non-human primates (NHPs), using a behavioral task sensitive to inhibition of primary visual cortex (V1). A modified ivermectin-gated chloride channel was expressed unilaterally in V1 of a single monkey, using a mixture of two viruses, AAV2-syn::GluCl2a-YFP and AAV2-syn::GluCl2b-YFP, which respectively expressed the α and β units of a glutamate-gated chloride channel (GluCl). The virus was injected at 0.5μL per second in a 3x3 grid. In the contralateral hemisphere, an aspiration lesion was performed as a positive control. A saccade-based visual detection task was used to determine the locations in the visual field that corresponded to the placement of the virus and lesion-induced scotoma. Gabor patches of varying frequency and contrast were then presented at four sites in the visual field: two control locations, the location corresponding to viral expression and that corresponding to the permanent scotoma. Contrast sensitivity curves were derived from the results obtained following ivermectin injection vs. vehicle injections. After vehicle injections, contrast sensitivity at the two control sites and the viral site were indistinguishable, whereas sensitivity was significantly lower at the scotoma site. Ivermectin injections significantly reduced sensitivity at the viral expression site without affecting the other three sites. Thus, the GlyCl-ivermectin inhibition in V1 caused an observable behavioral impact, suggesting that this chemogenetic tool may be suitable for reversible silencing of neuronal activity in NHP cortex (pending replication in a second subject).

Title: Dissociation of function of visual areas TEO and TE in tests of visual recognition memory and perceptual categorization

Authors: *M. A. G. ELDRIDGE[1], T. SETOGAWA[2], J. E. PEARL[3], B. J. RICHMOND[1];
[1]NIMH, Bethesda, MD; [2]Univ. of Toyama, Tsukuba, Japan; [3]Harvard Univ., Cambridge, MA

Abstract: It is widely accepted that a set of interconnected cortical brain regions running from the occipital pole to the ventral temporal lobe underlie the ability to perceive and recall visual stimuli.This pathway, labeled the ‘ventral visual stream’, consists of architectonic areas starting with primary visual cortex (V1) in the occipital lobe through V2, to V4, to the inferior temporal cortex areas TEO and TE. Although it has been established that there are reciprocal anatomical connections between areas, this system is often modeled as a multi-layer, feed-forward network (a deep network).
We performed two experiments to study the contributions of two areas thought to be at the final stages of complex image processing, areas TEO and TE. In a visual perceptual categorization task (the monkeys

had to judge whether a morphed image was more dog-like or cat-like) bilateral removals of either area TEO or area TE led to a modest impairment in performance, and when both TEO and TE were removed, the deficit was severe. Thus, the two regions seemed to contribute to the ability to categorize stimuli accurately, and each could at least partially compensate for the loss of the other. Conversley, in a visual recognition task (the monkeys had to indicate whether a series of novel images were being presented for the first or second time within a session), TEO removal had no effect on performance, whereas TE removal caused a severe impairment. The combined TE + TEO removal produced no additional deficit to that observed in the group with TE removals.
Both of these results demonstrate that TE receives high resolution visual information even when TEO has been removed. Further, the dissociation in the pattern of effects observed in these two studies demonstrates specialization of function in areas TE and TEO.

Title: Retrograde viral tracing demonstrates bifurcating V4 projections to areas TEO and TE in the rhesus monkey

Authors: *B. RICHMOND, **N. MIYAZAKI**, B. LI, M. A. ELDRIDGE, W. LERCHNER;
Lab. of Neuropsychology, NIMH, Bethesda, MD

Abstract: The classic hierarchical structure of visual processing (V1 -> V2 -> V4 -> TEO -> TE) posits that visual information reaches TE via TEO. A previous behavioral study from our lab suggests that visual categorization can be performed in areas TEO and TE in parallel. These findings challenge the classic hierarchical structure of the ventral visual stream. Previous anatomical studies show that a direct projection from V4 to TE exists, independent of the V4-TEO-TE pathway. But it is unknown whether V4 neurons provide bifurcating afferent projections terminating in TEO and TE. In the present study, we injected nonreplicating viruses that are transported retrogradely from axon terminals throughout the neuron. We injected viruses expressing a colored fluorescent reporter into area TEO and a reporter with another color into TE. From these viral injections we can judge 1) the relative strengths of V4 projections to TEO and TE, 2) the general distribution of TEO-projecting and TE-projecting neurons in V4, and 3) the presence or absence of V4 neurons with bifurcated projections to both TEO and TE. To cover V4 axon terminals across large areas of TEO and TE, we used custom multichannel microinjector arrays. The high density of fluorescently labeled neurons in the targeted areas TEO and TE show that the viral delivery method worked well. We found populations of TEO-projecting neurons and TE-projecting neurons in V4, V4t and V4v, with intermixing of colored neurons in V4, and separation of colored neurons in V4v. In V4v, TEO-projecting neurons are in the more medial aspect, and TE-projecting

neurons are in the more lateral aspect. In addition, there was sparse population of neurons projecting to both TEO and TE in V4, V4t and V4v (shown by co-localization of two colors).

Title: Different roles for area TE and rhinal cortex in visual categorization in rhesus monkeys

Authors: *B. LI, M. A. ELDRIDGE, K. A. LOWE, S. CHANDRA, B. J. RICHMOND;
Lab. of Neuropsychology, NIMH, Bethesda, MD

Abstract: Visual perceptual categorization groups objects based on shared features, hence this process requires both visual perception and visual memory. Area TE and rhinal cortex are two candidate regions for the neural substrates serving visual categorization processing. Area TE is considered to be involved in the late stages of visual perception and object recognition. Rhinal cortex is an important node of visual memory, and its role in visual perception is heavily debated. A previous selective lesion study from our lab showed that bilateral rhinal cortex lesions did not impair visual categorization, and that bilateral TE lesions mildly impaired visual categorization. Here we investigated the role of TE and rhinal cortex in visual categorization further by making selective lesions of each area and then testing the monkeys under conditions of increased task difficulty. We presume the monkeys need to accumulate perceptual evidence to respond correctly. To vary task difficulty, we manipulated the presentation duration of visual stimuli. Monkeys were trained to perform a two-interval-forced-choice (2-IFC) task, i.e., release the bar in one of two different intervals based on the identity of a cue image (morphed between dogs and cats at in at one of 11 levels). The set of possible cue image durations was 25, 50, 100, 250 or 500ms, selected randomly trial-by-trial. Compared to unoperated controls, monkeys with bilateral TE lesions showed impaired categorization performance at all stimulus durations, but information processing time was not significantly different between these groups. Bilateral rhinal cortex lesions did not impair monkeys' categorization performance but was followed by longer information processing time. For all groups, processing time increased with longer cue image durations and with increasing ambiguity of morph level. We also adopted a failure rate analysis to study the decision-making process. The results suggest that it takes more time for monkeys to make decisions after rhinal cortex lesions but not after TE lesions. On the other hand, results from simulations with a wide range of decision-making models suggest that there is no consistent difference in decision-making strategy between TE lesion, rhinal cortex lesion and unoperated control groups. Overall, our results support the idea that TE might play a more perceptual role and rhinal cortex might play a more cognitive role in categorization-based decision making. One possibility is that rhinal cortex facilitates perceptual evidence accumulation via memory-guided attention.

Title: Art expertise and aesthetic preference for visual properties

Authors: *J. SONG, C.-Y. KIM;
Sch. of Psychology, Korea Univ., Seoul, Korea, Republic of

Abstract: Accumulating evidence suggests that aesthetic appreciation for visual properties is influenced by art expertise. However, the scattered evidence has not been integrated into a coherent explanation. The recent psychological models of aesthetic appreciation also did not point to the interaction between expertise and aesthetic preference for visual properties at the perceptual processing stage. The present study aimed to examine the interaction between expertise and aesthetic judgment for visual properties including curvature, complexity and symmetry. By analyzing published research findings, we specifically examined which side experts prefer among two competing dimensions of the properties (i.e. curvature-angularity, complexity-simplicity, symmetry-asymmetry) and how aesthetically sensitive they are to the dimension of the properties compared to non-experts. This study also aimed at investigating whether the interaction varies according to the processing level of visual properties. More information and later processes are expected to be involved in appreciation as you move from curvature, complexity, to symmetry. It was found that aesthetic preference for visual properties differs depending on the extent of expertise, and both preference and aesthetic sensitivity of experts are more influenced by higher level properties. We proposed that the results of experts' preference are mainly derived from their enhanced perceptual fluency and cognitive pursuit of atypicality. The study suggests that art expertise affects aesthetic appreciation from the perceptual processing stage, the first stage of the aesthetic appreciation process.

Title: Similarities and differences between the outcomes of a neural network model of contrast discrimination and human visual perceptual learning

Authors: *T. BARNES-DIANA, Y. SASAKI, T. WATANABE;
Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: Neural Networks have been used to replicate a variety of phenomena in Visual Perceptual Learning, or VPL. These replicated phenomena include learning in orientation discrimination, task difficulty effects, and location specificity (Cohen & Weinshal 2017). Neural network models have been adapted, with a twin network modification, to perform 2-AFC (alternating force choice) tasks (Wenliang & Seitz 2018). This twin network methodology uses two parallel networks whose outputs are compared. Here, to examine similar and different aspects of a twin network model from human VPL, we use a twin network instantiation of a deep neural network (5 convolutional layers, 3 pooling layers, and one fully connected layer) to model VPL of contrast discrimination. This model provides each trail an estimate of which of two images has higher contrast. In the present study, we tested this model in a classic behavioral contrast discrimination protocol inspired by Yu et al 2004. Specifically, we examined whether the model can replicate important characteristics of human VPL such as 1) location specificity, 2) feature specificity (i.e., reference contrast), and 3) roving, whereby random interleaving of different reference contrasts annihilates the learning that would happen in the same amount of training in a blocked design. Similarly to human VPL, partial location specificity was observed. However, in contrast to human learning, no specificity to the reference contrast was obtained. In addition, learning did occur in the roving condition, though the amount of VPL was smaller than in the blocked condition. The failure of the feedforward network model to replicate the feature specificity and roving effect observed in human VPL could be because the model does not have a temporal chunking system, whereby temporarily adjacent similar trials are grouped together into meaningful categories.

Title: Learning orthogonalizes visual cortical population codes

Authors: *S. W. FAILOR, M. CARANDINI, K. D. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: When an animal sees a stimulus, this triggers a pattern of activity across a multitude of neurons in its visual cortex. These neurons' firing rates together define a representation of the stimulus in a high-dimensional space, similar to the representations constructed by machine learning algorithms. The similarity of the representations of two stimuli can be quantified by the angle or dot product between the corresponding vectors. In machine learning this similarity measure, known as the "kernel function", determines the generalizability of stimuli: stimuli evoking identical representations will generalize perfectly, while stimuli evoking orthogonal representations will not generalize at all. Allowing the representations to themselves change with learning is the heart of flexible learning algorithms such as neural networks.

In the brain, stimuli that evoke similar neural representations are likely to evoke similar behavioral responses. Furthermore, stimulus representations evolve as animals learn, even in primary sensory cortices. One might expect that after learning, the number of neurons selective for behaviorally-important stimuli increases, as has been observed in auditory, somatosensory, and visual cortex. Other studies, however, have found a paradoxical decrease in the number of cortical neurons responding optimally to learned stimuli, and in primary visual cortex (V1), neurons increase their slope at the task stimulus in a manner dependent on orientation preference. It is not yet clear whether these complex and apparently contradictory findings result from a single principle governing plasticity of cortical representations at a population level.

Here, we use two-photon calcium imaging to show how the tuning of 4,000-neuron populations in V1 change after mice learn an orientation discrimination task. At a single-cell level, the results appear complex: neuronal tuning curves evolve according to a lawful but complicated dependence on their prior orientation preference and tuning strength. At the population level, a simple principle emerges: learning transforms response vectors by a nonlinear function, whose convexity is largest for task-informative stimuli and small for the task-distractive stimulus. This transformation sparsens the population representations of the task-informative stimuli and orthogonalizes them from each other. A model of F-I curve modulation, requiring no synaptic plasticity, quantitatively predicted the learning effect. Lastly, the degree of sparsening varied across the population on a trial-by-trial basis, suggesting it emerges from rapid circuit dynamics, rather than slower plasticity mechanisms.

Title: Reward-associated images elicit enhanced responses and resist surround suppression in macaque area V2

Authors: *M. M. CARR[1], N. P. WILLIAMS[2], C. R. OLSON[3];
[1]Ctr. for Neurosci. at the Univ. of Pittsburgh, Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Biol. Sci. Dept., [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Previous studies exploring if reward associated images elicit enhanced visual responses in early primate visual cortex are inconclusive. We set out to resolve this issue by monitoring the activity of neurons in V2 of a rhesus macaque trained to associate some natural images with large rewards and others with small rewards. Each image subtended 3° visual angle and was positioned in the lower visual quadrant contralateral to the hemisphere destined for recording. On each training trial, while the monkey maintained central fixation, a single image was presented for 320 ms and, following a 320 ms delay, the associated reward was delivered. “High value” images received three times the volume of liquid reward as “low value” images. Training involved over 600 exposures to each image-reward pair over 18 weeks. After training, we measured the visual responses of V2 neurons to high and low value images presented within the classical receptive field (RF). The timing of each trial was the same as in training, except that stimulus duration was 620 ms. On average, high value images elicited stronger visual responses than low value images. This effect was of moderate strength (20% increase in response) and significant ($p < 0.01$; $n = 80$; sign test). Under natural viewing conditions, images are invariably embedded in clutter. It is conceivable that association with large reward would benefit the image representation in V2 by also conferring enhanced resistance to interference from clutter. To explore this possibility, we presented high and low value images in the RF along with a high contrast, reward-neutral display in the surround. The surround stimulus was an annulus centered on the RF with an inner diameter of 4° and outer diameter of 8°. Surround suppression, measured as a reduction in response strength when the annulus was present compared to when it was absent, was robust for low value images (9% reduction in response; $p <0.01$; $n = 80$; sign test) but was minimal for high value images (2% increase in response; $p = 0.43$ $n = 80$; sign test). This effect emerged 17 ms following visual response onset, a latency shorter than that commonly associated with top-down effects. It was not simply a secondary consequence of the difference in response strength, as surround suppression scaled with response strength over a wide range of firing rates for low value images but not for high value images. It persisted during sessions in which the reward was fixed and thus did not predict the size of the impending reward. We conclude that repeated pairing of an image with large reward produces a long-term effect whereby the image elicits stronger responses in V2 and independently exhibits immunity to surround suppression.

Title: Transfer of high-level learning rules in visual perceptual learning

Authors: *A. MARZOLL, T. WATANABE;
Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: Visual perceptual learning (VPL) refers to long-term performance enhancement as a result of visual experience (Watanabe & Sasaki, 2015). Under classical VPL training conditions, improvement has been found to be highly specific to stimulus features such as retinal location and orientation (e.g., Karni & Sagi, 1992; Schoups, Vogels & Orban, 1995). However, recent research has revealed that transfer can take place under some circumstances (e.g., Harris, Gliksberg & Sagi, 2012; Tan et al., 2019). Additionally, some studies have emphasized the role of higher-level decision areas in VPL (Kahnt et al., 2011; Dosher et al., 2013). In the current study, we investigated if transfer of VPL to new stimulus features can be aided by previously established, complex decision rules. Human subjects (n=12 in total) first learned a category boundary in a categorization task with four relevant stimulus feature dimensions, with the boundary being diagonal to all axes of the stimulus parameter space. This arrangement forces subjects to integrate all stimulus features at once to improve their performance, preventing simple decision strategies. Difficulty in terms of boundary distance was adapted by a staircase procedure with feedback. After subjects learned this first categorization task for 7 sessions, they learned a second task with a set of new stimulus parameters (7 sessions). One group of subjects (n=5) categorized the stimuli across a boundary parallel to that of the first task, while the other group categorized across an orthogonal boundary (n=7). We hypothesized that the brain may be able to repurpose the previously learned decision boundary in the parallel condition—leading to transfer—while no such transfer should occur in the orthogonal condition. Preliminary results, however, paint a different picture: The difference between final performance in the first task and initial performance thresholds in the second task was +12.1% in the parallel condition and +4.8% in the orthogonal condition. Final performance in the second task was similar in both conditions (.158±.006 vs .159±.006 [a.u.]). Pending further investigation, this suggests that contrary to our prediction, established complex decision rules may be a hindrance to transfer if too similar. Alternatively, sufficiently dissimilar decision rules may enhance such transfer.

Title: The remarkable visual specificity of visual recognition memory behavior is shaped by representational sharpening, reflected in inferotemporal cortex

Authors: *B. G. L. JANNUZI, T. MEYER, M. HAY, C. M. HACKER, N. C. RUST;
Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: We can remember the images that we have seen, even after seeing thousands, and we remember those images with considerable visual detail. How our brains manage to store visually detailed image memories at vast capacity is not well understood. 'Representational sharpening' proposals suggest that the visual representations of images that are reflected in high-level visual cortex are too overlapping to support the visual specificity of visual memory, and that downstream computations in the medial temporal lobe (including hippocampal pattern separation) act to sharpen them before visual memory storage. To investigate the assumptions and predictions of these proposals, we focused on the degree to which visual and visual memory representations in inferotemoporal cortex (IT) are more broadly tuned than visual memory behavior. To quantify behavior, subjects performed a Mnemonic Similarity task in which they were asked to judge whether images were novel or repeated in the presence of visually similar lure images. We found behavioral evidence for representational sharpening in humans as well as one rhesus monkey, reflected as sharpening relative to the benchmark of visual representations in the IT-analogous layer of a deep artificial neural network. To investigate the neural correlates of these behavioral effects, we recorded IT neural data as the monkey performed the task. We quantified the specificity of IT visual representations as the representational similarity of novel images and their lures, and we quantified the specificity of IT visual memory representations using a linear decoder optimized to extract IT visual memory information. Consistent with predictions of representational sharpening proposals, IT visual representations were more broadly tuned than visual memory behavior. However, at odds with predictions that representational sharpening is only reflected downstream of IT, we found that the visual specificity of IT visual memory behavior was well-aligned with IT visual memory representations. These results suggest that that the visual specificity of visual recognition memory behavior is shaped by representational sharpening, and that both the inputs to this process (visual representations) as well as the outputs (visual memory representations) are reflected in IT.

Title: Increased pupil dilations are associated with unexpected false familiarity for faces

Authors: *K. ZIMAN, J. R. MANNING;
Dartmouth Col., Hanover, NH

Abstract: Our subjective sense that something we encounter is familiar to us is reflected by changes in pupil size. Although pupil dilation effects of familiarity have been well documented, familiarity is not the

only, or even the strongest, contributing factor to pupil dilation. Changes in pupil dilation also reflect changes in brightness, affective or emotional responses, hormonal release, expected value or utility, and surprise, among others. Because many factors can affect pupil dilation, important questions remain about how pupil dilation changes reflect high-order cognitive processes, like attention and memory. For example, because surprise and familiarity are often difficult to fully distinguish (since new experiences can be surprising or unexpected), it can be difficult to tease apart pupil dilation effects of surprise versus familiarity. To better understand the effects of surprise and familiarity on pupil dilation, we examined pupil responses during a recognition memory task involving photographs of faces and scenes. When participants rated novel face images as "familiar," we observed a robust pupil dilation response.

Title: A comparison of abstract categorical encoding in the primate superior colliculus and lateral intraparietal area

Authors: *B. PEYSAKHOVICH[1], S. TETRICK[1], O. ZHU[1], G. IBOS[2], W. J. JOHNSTON[1], D. J. FREEDMAN[1];
[1]Univ. of Chicago, Chicago, IL; [2]CNRS, Marseille, France

Abstract: Primates have a remarkable ability to recognize the abstract categorical significance of sensory stimuli to guide decisions. Investigations of visual categorization in primates have focused on a hierarchy of neocortical areas for transforming sensory encoding in early visual cortex into abstract categorical encoding in higher-order areas. However, flexible categorical behaviors are evident throughout the animal kingdom, including in species with very different brain architectures and even those lacking a neocortex, such as birds and reptiles. Furthermore, recent work from multiple groups has shown that the primate superior colliculus (SC), a midbrain sensory-motor region that is evolutionarily conserved across all vertebrates, is engaged in complex behavioral functions such as decision-making and attention, going beyond its widely studied role in reflexive orienting movements. However, those studies of SC either used tasks in which the animals reported their choice with a saccadic eye movement, or tasks that involved modulation of spatial attention by directing animals to covertly orient to stimuli at particular locations. This raises a question about whether the cognitive or behavioral roles of primate SC are restricted to contexts involving orienting, whether overt (through saccadic eye movements) or covert (through modulation of spatial attention).
To determine whether SC is more generally involved in abstract cognition, we trained two monkeys to perform a novel abstract visual categorization task and compared activity in SC and the lateral intraparietal area (LIP), a cortical region shown to be causally involved in categorical decisions. In the task, monkeys grouped motion stimuli into two categories based on two orthogonal boundaries, such that directions that are 180° apart belong to the same category. Monkeys compared the category membership

of two stimuli (presented peripherally and separated by a 1200-ms delay) and indicated their choice by releasing a manual touch-bar while maintaining gaze fixation throughout the trial. We analyzed neuronal spiking activity in LIP (n = 189 neurons) and SC (n = 121 neurons) from one monkey during performance of the categorization task. SC exhibits robust abstract categorical encoding that is stronger and arises with a shorter latency than LIP, is evident during both stimulus viewing and short-term memory, and is independent of the actions subjects used to report their decisions. This suggests that primate SC is engaged in abstract cognition, even in tasks involving neither saccadic eye movements nor explicit manipulation of spatial attention, thus extending the role of SC beyond orienting behaviors.

Title: Disentangling neural signatures of sensory and decisional biases in visual working memory

Authors: *H. GU, S. KIM, D.-G. YOO, J. LEE, H.-J. LEE, H. LEE, J. LIM, M. CHOE, S.-H. LEE; Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: We guide our behavior based on visual working memory (VWM), a workspace that holds visual information when it is no longer present. The recall of such information is known to be biased by both external and internal drives: it can be attracted to intervening visual input (‘sensory bias’) or shifted in the direction consistent with our own decision (‘decisional bias’). Recently, a computational-level account has been provided for these biases. However, it remains unknown at which time points over the time course of VWM the biases occur; specification of their dynamics will provide clues about how VWM is maintained amidst the confluence of feedforward and feedback neural information flows. To this end, we tracked the neural signatures of sensory and decisional biases of VWM in the human visual cortex. Inside an fMRI scanner (Siemens 3T Tim Trio), human subjects (n=48) viewed an oriented grating (‘target’) and estimated its orientation following a substantive (16.5s) delay. To elicit sensory and decisional drives, we presented an oriented bar (‘reference’) during the delay (4.5s or 10.5s after the stimulus offset) and asked subjects to decide whether the target was tilted clockwise or counter-clockwise against the reference. We found that subjects’ recall of target orientation was attracted toward the reference and shifted in the decision-consistent direction as predicted by the previously proposed computational account. On top of that, we reconstructed the target orientations from the multivariate blood-oxygenation-level-dependent signals localized in the visual cortex using the inverted encoding model and inspected how the reconstructed orientation drifted over the course of the trial. We found that the reconstructed orientations drifted in a way consistent with the behavioral biases. Importantly, however, the neural signatures of the sensory and decisional biases markedly differed in temporal

dynamics: the drifts toward the sensory drive were short-lived, appearing abruptly at reference onset and dying quickly thereafter, whereas the decision-consistent drifts persisted throughout the post-decisional epoch, peaking at the moment of target recall. Our findings suggest that the cortical system of VWM disentangles the influences from the external and internal drives by incorporating them into neural memoranda in the visual cortex over different time windows.

Title: Amygdala contributions to motivational biases in perceptual decision-making

Authors: *Y. LEONG, R. PATERSON, Y. LYU;
Dept. of Psychology, Univ. of Chicago, Chicago, IL

Abstract: People are biased towards seeing outcomes that they are motivated to see. For example, sports fans of opposing teams often perceive the same ambiguous foul in favor of the team they support. Why are people more likely to see what they are motivated to see? Here, we test the hypothesis that amygdala-dependent allocation of visual attention mediates motivational biases in perceptual decision-making by enhancing sensory evidence accumulation in favor of desirable perceptual outcomes. We had human participants (N=30) perform a visual categorization task for reward while undergoing functional magnetic resonance imaging. On each trial, we used financial incentives to motivate participants to see one category over another. Even though the reward maximizing strategy was to perform the categorization task accurately, participants were biased towards categorizing the images as the category we motivated them to see. Participants with higher amygdala activation exhibited stronger motivational biases in their perceptual decisions, and performed worse on the task. Trial-by-trial amygdala activation was also associated with participants categorizing an image as the desirable category. Amygdala activation preceded image onset, suggesting that it was not in response to having seen the desirable category. Instead, the results suggest that heightened amygdala activity predisposed participants towards motivationally biased categorizations. To examine how amygdala activity was associated with biased sensory processing, we used a multivariate classifier to decode the neural representation of the presented image in the visual cortex. Trial-by-trial fluctuations in pre-stimulus amygdala activity tracked increased neural activity encoding desirable percepts, suggesting that amygdala activity biased attention towards perceptual features associated with desirable outcomes. Analyses using drift diffusion models indicated that amygdala activity was specifically associated with biases in evidence accumulation - on trials with higher pre-stimulus amygdala activity, sensory evidence accumulates more quickly in favor of desirable percepts. Prior work examining biases in perceptual decision-making have focused on the role of frontoparietal regions. Our work highlights an important contribution of the amygdala to perceptual

decision-making. When people are motivated to see one outcome over another, the amygdala biases perceptual decisions towards those outcomes.

Title: A common mechanism for choice, reaction time, and confidence in a multisensory heading discrimination task

Authors: D. HARSCH, *S. J. JERJIAN, C. R. FETSCH;
Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Successful decision-making requires accurate inference of the state of the world from available sensory information. This information is often noisy or ambiguous and arises from multiple sources. For perception of self-motion, previous studies have suggested that optic flow and inertial motion cues are optimally weighted on a trial-to-trial basis according to their reliability. However, conventional cue-combination models do not explain the speed of multisensory decisions (i.e., response time, RT), and it is unclear whether and how decision confidence emerges from the same decision process that accounts for cue weighting. We adapted a psychophysical task where subjects report their perceived heading direction (left or right of straight ahead) based on inertial motion, optic flow, or a combination of both. Cue weighting was assessed by varying the coherence of optic flow and spatial congruency of the two cues. Human subjects reported choice and continuous confidence ratings simultaneously via a saccade to one of two graded color bars. One male macaque monkey performed the same task but reported choice via saccades to a left or right target, followed by a second saccade to indicate high or low confidence (post-decision wager). In most sessions, subjects made their decision as soon as they were ready, allowing for the measurement of choice, confidence, and RT on the same trials. Choice behavior revealed trial-by-trial reweighting of the cues based on relative reliability, as shown previously. We found that, conditioned on a particular stimulus, confidence was inversely related to RT and predictive of choice accuracy. Importantly, the trial-by-trial reweighting process was also evident in subjects' RT and confidence judgements, quantitatively matching the effect of reliability on choices for a given cue-conflict condition. To account for these observations, we built a race model comprising two anti-correlated accumulators, which combined momentary evidence in a weighted fashion, with parameters determining stimulus sensitivity, diffusion noise, decision bounds, and sensorimotor delays. Confidence depended on the value of the losing accumulator and elapsed decision time. Model fits to empirical data suggest that choice and confidence in multisensory environments arise from a common mechanism of bounded accumulation of

reliability-weighted evidence, furnishing a quantitative framework for linking belief states to perceptual inference.

Title: Locus coeruleus neurons track variability in neural and behavioral signatures of perceptual decision making

Authors: *K. ACAR[1], M. A. SMITH[2];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: In a complex and dynamic environment, our brains repeatedly make decisions about sensory inputs (perceptual decision making), wherein the available sensory information is evaluated and used to form an appropriate behavioral response. The accuracy of perceptual decisions fluctuates, in part because the brain drifts between higher and lower levels of arousal, attention and motivation throughout the day. Previous work indicates that changes in activity of locus coeruleus (LC) neurons, along with corresponding changes in brain-wide norepinephrine (NE) release, contribute to transitions in arousal state. These shifts in arousal in turn correlate with changes in performance of simple decision tasks. However, it is still unknown what aspects of the decision process LC may influence, and how its influence manifests in the population activity of cortical neurons.
We examined the role of LC in perceptual decision making by testing the hypothesis that changes in LC activity influence a specific component of the perceptual decision process, namely the animal's criterion as defined by signal detection theory. We simultaneously recorded from single LC units and a population of prefrontal cortex (PFC) neurons in area 8Ar, using a 100-electrode "Utah" array. These recordings were performed in rhesus macaques performing a visual 2-AFC change detection task with sinusoidal gratings. The trials were structured such that the stimuli containing the sensory evidence for a decision were temporally distinct from the saccade target stimuli for reporting choices. We found that on a trial-to-trial time scale, LC responses were not modulated during sensory evidence presentation, but rather increased substantially when aligned to choice period onset, peaking at ~100ms before a saccade. This suggests that LC phasic responses may be closely linked to the transformation of perceived sensory information into a behavioral response. We also found that slow (tens of minutes) fluctuations in LC activity were related to slow changes in pupil diameter, criterion, and a slow-varying, arousal-related signal in the population of neurons in PFC, a brain region previously linked to criterion changes during

decision making. Together these results provide novel insights into the role of the Locus Coeruleus-Norepinephrine system in decision making.

Title: Isolating metacognitive sensitivity with a process model for confidence

Authors: *C. M. ZIEMBA, Z. M. BOUNDY-SINGER, R. L. T. GORIS;
Ctr. for Perceptual Systems, Univ. of Texas at Austin, Austin, TX

Abstract: Perceptual systems interpret the environment on the basis of sensory information that is often impoverished and noisy, making perceptual errors inevitable. Observers are aware of the fallibility of perception and can introspect about the correctness of a perceptual decision. Which computations underlie this metacognitive ability? One prominent proposal is that confidence judgments reflect the observer's estimated probability that a decision is correct. While this hypothesis identifies a theoretical objective, by itself, it does not specify the operations that underlie confidence, nor does it clarify the factors that determine the quality of the confidence computation. Here, we develop a doubly stochastic process model that offers exactly such insight. In our model, confidence reflects the magnitude of a normalized perceptual distance estimate. The perceptual distance estimate is subject to noise, and so is the normalization term, which is an imperfect estimate of the magnitude of the perceptual noise. Our model naturally separates bias and sensitivity for confidence reports, just as signal detection theory does for perceptual decisions. We fit the model to a large set of previously published perceptual confidence judgments, and found that it captures a variety of confidence phenomena exceptionally well. In doing so, our analysis provides a new perspective on metacognitive ability — how good observers are at evaluating perceptual decisions. We show that the model parameter expressing precision of the perceptual uncertainty estimate, or "metanoise", provides a better metric for metacognitive ability than the non-process-model based alternatives that currently prevail in the literature. Specifically, metanoise has higher test-retest reliability, is less affected by task difficulty and confidence reporting strategy (i.e., the tendency to declare "high confidence" in one's judgments), and has higher cross-domain stability. These findings illuminate the computations that give rise to our sense of confidence, and they suggest that the quality of perceptual introspection is fundamentally limited by observers' imperfect knowledge of their perceptual uncertainty.

Title: Neural correlates of static and dynamic decision-criterion adjustments based on expected evidence strength and advance warning cues in continuous sensory detection.

Authors: *A. GEUZEBROEK, L. PIRET, H. CRADDOCK, S. KELLY;
Sch. of Electrical and Electronic Engin., Univ. Col. Dublin, Dublin, Ireland

Abstract: To accurately detect unpredictable targets within a noisy environment, a beneficial mechanism is to accumulate perceptual evidence over time until it reaches a decision bound - a criterion amount of evidence. Such decisions are highly dependent on top-down processes to adapt this bound to suit environmental conditions. Bound adaptations made to regulate the speed-accuracy tradeoff are much investigated, but there are other factors arising in continuous monitoring contexts that call for strategic bound adjustments. Here, we examine the neural processes underlying static and dynamic bound adjustments based on knowledge of prevailing evidence strength and on external warning cues. In Experiment 1, participants detected intermittent 1-second periods of coherent upward motion within an otherwise incoherent, continuously playing motion stimulus, in blocks with all weak (25% coherence), all strong (70% coherence) or randomly mixed targets. Participants made far more false alarms in the Weak than Strong context, and exhibited a baseline motor preparation (beta-band EEG amplitude) closer to the response "threshold" level, together indicating a static bound lowering to facilitate weak target detection. In line, a motor-independent signature of evidence accumulation, centro-parietal positivity (CPP), reached lower amplitudes for Weak targets. However, the mixed context further revealed that a portion of this effect arose from random fluctuations in motor preparation associating the successful detection of weak targets with a pre-target preparation level that happened to be high. These fluctuations also resulted in increasing CPP amplitude as a function of RT.In experiment 2, participants indicated the direction (left/right) of intermittent coherent motion targets of two interleaved coherences, this time with a warning beep sound played 1-second before half of the target. Not surprisingly, participants missed fewer targets and were faster when given a warning signal. They were however less accurate, consistent with a lowered decision bound. Participants' motor preparation signals dynamically shifted closer to the pre-response threshold level after warning signals. This indicates that the bound dynamically lowers to facilitate detection and faster responses. In line, the CPP reached lower amplitudes for the targets that were introduced by a warning signal. Thus, behavioral data and neural dynamics of both accumulation and motor preparation converge to indicate that bounds are statically lowered in contexts with weak target strength, and dynamically lowered on shorter timescales when an auditory warning signal heralds an upcoming target.

Title: Autocorrelation of errors in visual estimation tasks

Authors: *J. LIM, H. GU, S.-H. LEE;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: A primary goal of vision is to estimate the visual feature of a target object in an unbiased and stable manner. However, a mounting volume of evidence indicates that our visual estimates are systematically biased by the stimuli encountered in previous estimation episodes, dubbed 'serial bias in estimation (SB)'. Here, we report another important kind of serial dependence: estimation errors are correlated between adjacent trials. Compared to SB, this phenomenon is not well studied but substantially contributes to the variance of visual estimation errors. We will refer to this intriguing phenomenon as 'autocorrelation of errors in estimation (AE)', to distinguish it from SB. To examine how AE differs from SB in basic properties, we collected two data sets from human subjects (n=28 and 33, respectively), who viewed oriented gratings and estimated their orientation after a short (1 s) delay by reproducing it with nonius dots. On each trial, a single grating was shown in the first set whereas two gratings were shown in different hemifields, only one of which was post-cued for estimation, in the second set. AE was consistently observed in both data sets: orientation estimation errors were significantly correlated between neighboring trials, especially between those in which the target orientations were similar to one another. We also found that, compared to SB, AE was spatially narrow-tuned, but temporally broad-tuned. We further validated the presence of AE and its tuning properties in other publicly available data sets in which different visual features (e.g., color) were estimated with different parameters. In principle, current estimation errors can be attributed to previous stimuli or previous estimation errors. In this regard, the previous work on SB showed that the previous-stimulus-conditioned expectation of current estimation errors is biased. By contrast, AE indicates that a considerable portion of the remaining estimation errors is related to previous errors, not stimulus. Further, the sharp contrast between SB and AE in spatial and temporal tuning properties suggests that the two phenomena, although both fall under the umbrella concept of 'serial dependence', are likely to be mediated by different cognitive and neural mechanisms.

Title: Effects of dorsal pulvinar perturbations during perceptual decision-making

Authors: *K. KADUK[1,2], L. GIBSON[1], M. WILKE[2,1], I. KAGAN[1];
[1]Decision and Awareness Group, Cognitive Neurosci. Lab., German Primate Ctr., Goettingen, Germany;
[2]Univ. Med. Goettingen, Goettingen, Germany

Abstract: Studies of visuospatial decision-making emphasize the interactions in the frontoparietal networks. These direct cortical connections are paralleled by indirect routes through the higher-order thalamic nuclei such as the pulvinar, raising the question how does pulvinar contribute to the selection of behaviorally relevant stimuli. Perturbations of the dorsal pulvinar (dPul) induce an overt spatial selection bias during free choices (Wilke et al., 2010, 2013; Dominguez-Vargas et al., 2017). Pulvinar has also been implicated in attentional and confidence processing (Petersen et al., 1987; Desimone et al., 1990; Komura et al., 2013; Fiebelkorn et al., 2019), suggesting a role in perceptual discrimination. It remains unclear whether the spatial selection bias is caused by contralateral perceptual deficit or a more general motor / orienting deficit. To address this question, we assessed changes in perceptual sensitivity (dprime) and response criterion after unilateral pharmacological inactivation and time-resolved electrical microstimulation of dPul. Two macaques performed a color discrimination task where the perceptual difficulty was determined by the color similarity of target vs. easy or difficult distractor. Target or distractor was either presented alone or with a second stimulus (either distractor or target) in the opposite hemifield. Monkeys had to saccade to the target or to continue fixating when only distractor(s) were presented. The dPul was either reversibly inactivated by the GABA-A agonist THIP or stimulated before or after stimuli onset in multiple sessions. After inactivation, we observed criterion shifts away from contralateral selection, especially when two competing peripheral stimuli were present. Criterion shifts manifested as reluctance to select stimuli in the contralateral hemifield for both difficulty levels. The reaction times for the contralateral selection increased for all conditions. Importantly, the dprime and the overall accuracy remained largely unaffected. The accuracy decreased substantially only in the target-difficult distractor condition in which one animal avoided contralateral hemifield and did not utilize the information from this hemifield for target selection. Early microstimulation matched the inactivation results showing an ipsilateral choice bias. Late microstimulation induced an opposite, contralateral choice bias for the double stimuli. Together, our results emphasize the role of dorsal pulvinar in facilitation of contralateral orienting and motor decision signals during spatial competition, rather than the specific role in perceptual discrimination.

Title: Dynamics of momentary decision evidence and its leverage on choice and confidence in a peri-decision wagering task

Authors: M. VIVAR-LAZO, *C. R. FETSCH;
Neurosci. & Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Previous work has shown that a common process of bounded evidence accumulation can jointly explain decision speed, accuracy, and confidence. However, standard models of this process assume a simple and static pooling mechanism for converting sensory cortical activity into momentary evidence for the decision. In contrast, recent studies have emphasized the complexity of sensory representations, exemplified by the dizzying interplay between correlated variability, choice-related signals, and readout weights. This work motivates a more nuanced investigation into the nature of sensory evidence, including whether and how these population-level descriptions change during decision formation, and how they shape response time (RT) and confidence.
To address these questions, we devised a 'peri-decision wagering' task which isolates the temporal window in which momentary evidence could be constructed to support choice and confidence. Monkeys discriminated the direction of motion in a random-dot display, and whenever they were ready, indicated their choice (left or right) and confidence (high or low bet) with a single saccade to one of four targets: left-high, right-high, left-low, right-low. Relative to low-bet trials, a high bet yielded a larger juice reward if the direction choice was correct, but a longer penalty timeout if the choice was incorrect. Behavioral results validated the peri-decision wager as a measure of confidence: accuracy for a given stimulus strength was greater for high versus low bets. RTs were inversely related to confidence, conditioned on the stimulus, as shown previously in humans.
Using linear arrays and 128-ch high-density probes, we recorded population spiking activity in visual area MT during the task. We quantified the relationship between spike rates and behavior using conventional choice probability (CP) and an analogous metric for confidence (ConfP), computed in sliding windows aligned to the motion onset and to the saccade. We then used these metrics to compute the spatiotemporal weighting profile, separately for choice and confidence, guided by a dynamic estimate of the correlation structure. Preliminary results suggest that, compared to choice, confidence is more heavily influenced by MT activity later in the decision epoch, and shows a broader spatial weighting profile across preferred directions. This may indicate distinct readout mechanisms for choice and confidence, contrary to earlier conclusions, at least when both are reported simultaneously. Our approach furnishes new constraints on the construction of momentary decision evidence, and poses challenges for how the readout is implemented downstream.

Title: Blind source separation using ICA reveals event-specific components of primate motor cortex LFPs

Authors: *D. ORELLANA[1], J. B. HYNES[2], J. DONOGHUE[2,3], C. VARGAS-IRWIN[2,3,4];
[1]Pontificia Univ. Javeriana (Pontifical Xavierian Univ), Bogota, Colombia; [2]Neurosci., Brown, Providence, RI; [3]Robert J. and Nancy D. Carney Inst. for Brain Sci., Providence, RI; [4]Ctr. for Neurorestoration and Neurotechnology, Rehabil. Res. and Develop. Service, Dept. of Veterans Affairs Med. Ctr., Providence, RI

Abstract: The cortical local field potential (LFP) is a composite signal derived from multiple, complex neural sources. What are the individual neural sources that make up the LFP, how are these sources distributed throughout the cerebral cortex? Here, we used a blind source separation approach to isolate the statistically independent signals that contribute to the LFP recorded from neural ensembles in primary motor (MI) and two premotor (PMv, PMd) regions in two nonhuman primates (NHP) during an object grasping task where the object, grasp type, and go cues were presented independently across separate task stages. We analyzed 5 recording sessions for each monkey, each containing approximately 80 correctly performed trials. We used Independent Component Analysis (ICA) in the 0.1-4Hz band to separate the LFP components. To explore the relationship of the extracted components to the seven stages of the movement task, we performed an analysis of the shape and latency of the independent components (IC). To estimate the contribution of the cortical areas studied in the context of the extracted ICs, we performed a statistical analysis of the spatial distribution of the unmixing matrix. We found that the independent components of the low-frequency(lf) LFP are strongly linked to task stages. We were able to isolate seven independent components, where each task stage was associated with a distinct and reliable component and characteristic latency distribution. We observed that the LFP ICs typically arise from electrodes distributed across multiple cortical areas - rather than originating from adjacent electrodes confined to a specific cortical area. Furthermore, the spatial distribution of the components is consistent across the five sessions studied, with higher correlations observed between sessions recorded on consecutive days. Altogether our results show that it is possible to isolate lf-LFP ICs associated with specific behaviorally relevant events. These signals potentially represent internal markers of changes in the network's computational state. Additionally, the distributed nature of the components suggests that specific computations engage sub-networks distributed across multiple cortical areas, instead of being localized to anatomically defined subregions of the motor cortex. The temporal consistency observed in the components suggests their potential utility for the development of BCI systems to align and scale computational epochs.

Title: Cortical dynamics underlying vocal production in freely moving minipigs

Authors: *M. LION[1], M. PALMA[1], M. KHOSH-NEVIS[1], C. ZENGA[1], F. BOCQUELET[1], M. AUBERT[1], S. KEFS[2], F. FALLEGGER[3], G. SCHIAVONE[3], I. GABELLE-FLANDIN[2], S. P. LACOUR[3], B. YVERT[1];
[1]Grenoble Inst. of Neurosciences, Saint Martin d'Hères, France; [2]CHU, Clinique universitaire de Cancérologie-Radiothérapie, Grenoble Alpe, France; [3]EPFL, Geneva, Switzerland

Abstract: Vocal production pathways of non-human primates show strong similarities with those of speech in humans (Hage & Nieder, 2016; Loh et al.,2017). However, the extent to which they can generalize to non-primate mammals still remains an open question. We developed a paradigm to investigate this question in miniature pigs, which are social and domestic animals easy to handle and producing spontaneously different vocalizations (Garcia et al., 2016; Kiley, 1972; Marino & Colvin, 2015). One Yucatan and two Aachner minipigs were chronically implanted with surface ECoG grids over their left hemisphere, one using a soft implant over the motor and premotor region, and two with a larger grid covering more extensively their left hemisphere including part of the inferior frontal area. The two Aachner minipigs were implanted between 3 and 5 months of age, a period when their frontal sinuses were not yet developed thus allowing to proceed with conventional craniotomy to access motor and frontal brain areas without further risks of infection. Cortical activity and vocalizations of these animals were recorded synchronously in a freely moving environment with a wireless system. We observed vocal-evoked cortical potentials over the motor and premotor regions initiating 45 ms before vocal onset and lasting beyond vocal offset. Moreover, in the two animals implanted with larger grids, we observed activity in the inferior frontal cortex starting about 400 ms before vocal onset and ending more than 1 second after the start of the vocalization. These preliminary results suggest that a complex cortical dynamics underly vocal production in minipigs, making this animal an interesting model to study vocal production networks in non-primate mammals.

Title: Subtle contact events guide ongoing movements during licking

Authors: *B. S. ITO[1], J. H. GOLDBERG[2];
[2]Dept. of Neurobio. and Behavior, [1]Cornell Univ., Ithaca, NY

Abstract: During non-visually guided grasping, subtle contact events guide ongoing movements. For example, when holding a cup of coffee, we readjust our grip in response to fine details of a slip - an upward slip on the index finger may recruit a different response than a downward one on the pinky. To study how fine tactile information is used to guide ongoing movements, we created a novel lick paradigm in head-fixed mice. First, we use kilohertz frame-rate imaging and a deep neural network to track tongue kinematics in 3D as mice retrieve water from a spout. Next, we detected the offset of tongue-spout contact on the first lick (L1) within a lick bout and randomly displaced the spout left or the right before the onset of the second lick (L2). Spout displacement magnitude was calibrated so that mice would nick the displaced spout with either the left or right side of the tongue during L2. We find that mice use this nick event to guide the immediately ensuing lick to the new target: left nicks guided the third lick (L3) left, and right nicks guided L3 right. Across-lick adjustments were not only aimed in the correct direction, but the magnitudes of these corrective responses were scaled appropriately depending on the tongue tip position at L2 contact: mice made larger corrections to the left or right on L3 if the tongue tip was farther away from the spout at L2 contact, and smaller corrections on L3 if the tongue tip was closer to the spout. Populations of neurons in anterolateral motor cortex (ALM) encoded nick position and lick direction fast enough to implement tactile feedback-guided corrections but, surprisingly, bilateral photoinhibition of ALM or tongue-jaw primary somatosensory cortex (TJS1) did not impair nick-guided corrections. Together, these data implicate yet-to-be identified subcortical circuits in implementing directionally specific contact-driven corrections.

Title: Dynamics and directionality in the motor cortex during reaching

Authors: *H. MAO[1], A. B. SCHWARTZ[2];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Dept Neurobiol, Univ. of Pittsburgh Dept. of Neurobio., Pittsburgh, PA

Abstract: As neural recording technology advances, scientists are recording activity of ever larger populations of neurons. Many computational tools have been employed to model neural population activity. Among them, the dynamical systems approach has gained interest in recent years. This approach treats firing rates of all simultaneously recorded neurons as the state of a dynamical system. With this perspective, the time-varying state of neural population activity is determined by the initial condition, internal dynamics (interaction between neurons), and external inputs to the recorded neurons. The dynamical systems approach has been used to model motor cortical neural activity during a delayed reaching task. In that experiment, the animal held its hand at a starting position during a delay period after a reach target was presented and waited for a go signal to start the reach. Neural activity during the delay period was assumed to set the initial condition. The neural population response during reaching was

modeled to be governed by internal dynamics alone, as no external input was explicitly included after movement onset. Further analysis revealed rotational patterns in neural trajectories, which have been used to support the hypothesis of an oscillatory pattern generator in the motor cortex for creating muscle activity during movement. However, these findings can be reconsidered to include external input to the neural population. Here, using simulation and empirical data, we studied the relation between movement direction and the dynamics of neural population activity. Two rhesus monkeys were trained to perform a standard center-out reaching task. We found that individual motor cortical neurons changed firing rate patterns during single reaches and the correlational structure between these patterns went through several robust phases. We then performed simulation to produce multiphasic activity patterns induced by directional input. In simulated data, neural activity in an earlier phase was well predicted by population activity in later phases, although there was no deterministic mechanism between them. Rotational neural trajectories were observed in neural subspaces defined by dimensions from two temporally overlapping phases. Results found in neural recordings from behaving monkeys matched these findings from simulation data. Our results suggest that instead of modeling neural population activity during movement as generated merely from interaction of recorded neurons, it is also subject to influence of external input carrying movement-related information.

Abstract: Multiple sclerosis (MS) is an inflammatory, demyelinating disease of the central nervous system (CNS) and patients with MS display impaired motor function. Previous work shows that demyelination slows action potential propagation and drives hyperexcitability in cortical neurons. Recently, we showed that demyelination leads to increased primary motor cortex (M1) neuronal hyperexcitability *in vivo,* which recovers concurrently with oligodendrogenesis and remyelination. This aberrant neuronal activity was associated with deficits in dextrous reaching, a skilled motor behavior. However, how demyelination-induced M1 hyperexcitability leads to impairments in motor performance remains unclear. This work aims to understand the cell-type specific consequences of myelin loss on M1

circuit function and resulting motor deficits.To explore the effects of myelin loss and repair on changes in motor circuit activity during skilled motor performance, we chronically implanted NeuroNexus arrays in M1 of mice to track longitudinal dynamics of motor representation. Demyelination was induced through dietary administration of 0.2% cuprizone for three weeks. Recordings were performed at multiple timepoints before, during and following cuprizone administration. Single units were clustered from extracellular activity and classified based on putative cell type (fast vs regular spiking), cortical depth, and movement-related activity. In demyelinated mice, we found increased neuronal hyperexcitability in both excitatory and inhibitory populations, but hyperexcitable excitatory neurons were specific to cortical layers 5 and 6, while inhibitory neurons were excitable throughout the cortex. During the reach, movement-related neurons had a decreased signal to noise ratio during reach representation and increased latency of peak firing with respect to the reach movement. To explore the neural population dynamics in greater detail, we performed acute recordings with Neuropixels arrays at three key timepoints (one week before, 0, and 3 weeks following cuprizone treatment). Acute Neuropixels experiments confirmed findings from chronically implanted NeuroNexus arrays and will allow for analysis of latent factors in the neural population. Together, these findings demonstrate that demyelination alters neural representation of dexterous reaching in M1 resulting in motor deficits characteristic of movement impairments of MS patients.

Title: Neural responses in ventral premotor cortex during action execution and action observation

Authors: *S. DE SCHRIJVER, T. DECRAMER, P. JANSSEN;
KU Leuven, Leuven, Belgium

Abstract: Mirror neurons that respond both to action execution and action observation were discovered in area F5c of the ventral premotor cortex. Recent studies have shown that these neurons also respond to videos of actions, and even, to videos of abstract shapes that causally interact with other shapes. To investigate the visual selectivity and motor properties of mirror neurons in F5c, we implanted 96-channel Utah arrays in area F5c in two macaque monkeys that were trained to grasp objects and to fixate videos of actions. We tested mirror activity during passive fixation of videos of a human or a monkey hand grasping the same object, together with control videos in which an ellipse either moved towards the object or moved on a scrambled background in the absence of the object. In 9 sessions, we recorded the activity of 96 mirror neurons and 198 MUA sites with mirror activity. The majority of the cells did not respond

during the entire video, but rather during a specific epoch of the action video, with a peak in the activity that occurred when the hand made contact with the object in 70% of the neurons. Furthermore, the large majority of mirror neurons (71%) also responded to the ellipse moving towards the object, indicating that meaningful actions are not required for mirror activity. Moreover, we measured very high correlations between the responses to the ellipse videos on a normal background and on a scrambled background (0.74 for SUA and 0.82 for MUA), indicating that the presence of the object was not necessary for the large majority of the mirror neurons. To test the motor properties of F5c neurons, we microstimulated F5c sites for 1s at 100Hz. We could evoke simple and complex movements with currents ranging from 60 to 130µA. Furthermore, subthreshold microstimulation of F5c sites while the monkey performed a visually guided delayed grasping task significantly increased the grasping time (i.e. the time necessary to reach towards, grasp and pull an object). This effect was observed both when stimulating mirror (65%) and non-mirror (33%) sites. Finally, we stimulated mirror sites in F5c during the delay period of the grasping task (for 700ms at 16Hz) while recording activity in primary motor cortex (M1) with another Utah array. Subthreshold stimulation of F5c mirror sites evoked extensive activations in M1. Thus, mirror neurons in F5c respond to surprisingly simple visual stimuli without any interaction with the object, and their output is highly directed towards the motor system. Together, these results have important implications for the interpretation of mirror neuron activity in the ventral premotor cortex.

Title: Wavelimit: a spike-sorting algorithm that includes interspike interval information to improve performance

Authors: *X. SCHERSCHLIGT, A. ROUSE;
Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Spike sorting algorithms have continued to improve, especially for large channel count, high-density recordings. However, these improvements are largely based on models with arrays that experience substantial crosstalk, such as dense silicon CMOS probes; which depend on evaluating cross correlograms that are less informative in larger microwire multielectrode arrays. Here, we propose a novel spike sorting algorithm, WaveLimit (WL), which incorporates information about interspike interval violations to improve performance, especially for channels with less crosstalk, and rivals other state-of-the-art sorters.
WL, like most sorting algorithms, first performs principal component analysis on all the waveshapes of spike events for every channel in a recording individually and putative units are subsequently assigned by cluster centers. The ideal threshold for assigning individual waveshapes (or spikes) to those putative units

is then made using the optimal trade-off between the estimated fraction of included true spikes and fraction of false spikes, which is derived from the identifying interspike time interval violations using idealized Poisson process statistics.
WL, along with three other state-of-the-art sorting algorithms, SpykingCircus (SC), IronClust (IC), and Tridesclous (TC), was used to sort three recording sessions from two different monkeys. The performance of each algorithm was further evaluated by comparing the number of units found as well as the number of spikes, ISI violations, and Signal-to-Noise ratio (SNR). Additionally, since the recordings were gathered while the monkeys performed a center-out-task, we compared the linear regression R2 of the rate of firing for each putative unit.
Our algorithm, on average, found more behaviorally tuned units per recording than the other algorithms. Our algorithm also found more spikes per unit for each unit found than both IC and TC and found a comparable number of spikes to that of SC. WL found not only more units per recording and more spikes per unit, the units had fewer ISI violations and better SNRs per unit. Interestingly, we found that the regression R2 mostly improved with the number of spikes included in the unit even as SNR worsened, suggesting R2 may be a poor measure of sorting quality.
Using ISI violation information, our WL sorting algorithm significantly improves the number of well isolated, single units from chronic multielectrode arrays in non-human primates.

Title: Motor cortex activity across movement speeds is predicted by network-level strategies for generating muscle activity

Authors: *S. SAXENA[1], A. A. RUSSO[2], J. CUNNINGHAM[2], M. M. CHURCHLAND[3];
[1]Univ. of Florida, Gainesville, FL; [3]Neurosci., [2]Columbia Univ., New York, NY

Abstract: Learned movements can be skillfully performed at different paces. What neural strategies produce this flexibility? Can they be predicted and understood by network modeling? We trained monkeys to perform a cycling task at different speeds, and trained artificial recurrent networks to generate the empirical muscle-activity patterns. Network solutions reflected the principle that smooth well-behaved dynamics require low trajectory tangling, and yielded quantitative and qualitative predictions. For a rhythmic trajectory, the lowest-tangled geometry is a circle. This yields the first prediction: regardless of the trajectory of muscle activity, the neural trajectory should - across all speeds - be dominated by two-dimensional circular structure. A second prediction arises from the observation that traversing a trajectory at different speeds would increase tangling. Thus, the near-circular trajectories (one per speed) should be separated by a translation and/or tilt into new dimensions. To evaluate predictions, we recorded motor cortex population activity during the same task. Responses supported the hypothesis that the dominant neural signals reflect not muscle activity, but network-level strategies for generating muscle activity.

Single-neuron responses were better accounted for by network activity than by muscle activity. Similarly, neural population trajectories shared their organization not with muscle trajectories, but with network solutions. We first analyzed the data for each speed separately. In the top two principal components, muscle trajectories varied greatly across speeds. Neural trajectories did not, but instead remained consistently circular. Analyzing all speeds together revealed that these circular trajectories were separated by a translation and tilted modestly into new dimensions. As a result, neural trajectory tangling remained low despite high muscle trajectory tangling. Thus, cortical activity could be understood based on the need to generate muscle activity via dynamics that allow smooth, robust control over movement speed.

Title: Preparatory neural states in monkey premotor cortex differ for reaches to visual and predicted targets

Authors: T. J. ARAKERI, C. E. LARKIN, K. M. GOTHARD, *A. J. FUGLEVAND;
Physiol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: To reach to an object, motor areas of the brain need to efficiently plan the path of the hand to the object (based on information about object location and limb configuration) and then execute the command. The neural basis of such fundamental processes as planning and execution of voluntary commands remains relatively obscure. Recent findings, however, based on neural recordings in non-human primates, suggest that population activity in motor and premotor cortices exists in two orthogonal neural subspaces during movement preparation and movement execution. Furthermore, studies have also shown that population activity must reach a unique preparatory state, regardless of context, to subsequently generate appropriate population dynamics during movement execution (e.g., Lara et al. *eLife* 2018). Yet most of that work involved reaching toward overt visual targets. In many circumstances (e.g., hitting a baseball), however, visual input by itself is too slow to appropriately plan for such movements. Instead, there is increasing reliance on predictions based on internal models of the situation. Therefore, we asked whether motor-cortical population dynamics representing preparatory states were the same for reaches to visual targets versus those whose locations were predicted. In visually guided condition, a monkey was trained to make center out reaches to targets displayed on a computer screen. In the predicted condition (recorded in the same sessions), the monkey had to reach to the predicted location of a target using a "pre-target" visual cue that flashed momentarily. The actual target location was offset by a fixed angle from the pre-target. Our preliminary data recorded from dorsal pre-motor cortex indicates that there is a significant reduction in preparatory subspace occupancy when preparation was driven by a predicted target compared to a visual target. Subsequent neural dynamics in the movement subspace, however, were essentially the same. These results suggest that the sources of planning information (i.e., visual or internally generated) conveyed to the premotor cortex can differentially shape preparatory dynamics, and that different preparatory states can give rise to the same movement.

Title: Vagus nerve stimulation modifies the neural representation of a skilled reach in motor cortex

Authors: *X. PENG, R. HUANG, K. GAGNON, S. BOWLES, J. HICKMAN, C. WELLE;
Dept. of Neurosurgery, Dept. of Physiol. & Biophysics, Univ. of Colorado, Anschutz Med. Campus, AURORA, CO

Abstract: Vagus nerve stimulation (VNS) technology has broad therapeutic applications for a range of neurologic conditions including epilepsy, depression and stroke. However, the mechanism of action underlying VNS is unclear, hindering optimization of this therapeutic tool. Preclinical work suggests that while VNS drives cortical map plasticity in injured and healthy animals, cortical plasticity does not necessarily correlate with behavioral improvements. Thus, questions remain regarding if VNS can be

used to drive behavioral improvement in healthy nervous system, and if so, by what mechanism. Recently, we have shown that in a skilled reach-to-grasp task, VNS paired with a successful reach (Success VNS) can enhance motor learning in healthy mice. To understand how paired VNS can influence motor outcomes, we examined the effects of VNS on neurons in primary motor cortex (M1), which is required for learning and performance of the skilled reach task. We monitored neural activity in freely-moving mice expressing a calcium indicator (GCaMP6m) in L2/3 of M1 using a head-mounted miniature microscope. To measure VNS-driven neural modulation, animals were implanted with a cuff electrode on the left cervical vagus (Microleads), and neural activity was monitored during VNS delivery (30 Hz, 15 pulses, 0.1 ms pulse width). Approximately 10 ~ 30% of L2/3 neurons are modulated by VNS, with neurons showing either firing suppression or activation, but not both. Interestingly, the average peak timing of the suppression precedes the peak timing of activation by ~ 1.2 seconds, and both responses depend on acetylcholine receptor (AChR) mediated signaling. To measure VNS-driven modulation in skilled reach learning, neural activity during successful reaches was measured in two training sessions; one with and one without VNS. When applied following a successful reach, Success VNS modulates 80% of neurons that are activated by a successful reach, but does not influence the activity of neurons that are suppressed or non-modulated by reach success. Moreover, the effects of Success VNS on this population are not temporally limited to the acute window following VNS application. Instead, these neurons also show differential activity in the reach phase that precedes VNS during the VNS session. Together, these data suggest that Success VNS not only modulates success outcome representation in M1, but also modifies the neural representation of movement throughout the reach duration.

Center, Tsukuba Advanced Res. Alliance, Univ. of Tsukuba, Ibaraki, Japan

Abstract: The salt-inducible kinase (SIK) is a family of the AMP-activated protein kinase (AMPK) related kinases. SIK3 is expressed in various tissues and required for the proper development of the skeletal system, adipose tissues, and glucose/lipid metabolism, macrophage differentiation, and interleukin production. Recently, we found a gain-of-function *Sleepy* (*Slp*) mutation in the *Sik3* gene, which produces the mutant SIK3(SLP) protein, increases sleep amount and non-REM sleep (NREMS) EEG delta density, an index of sleep need. Since sleep is affected by peripheral organs and tissues, it remains to be elucidated whether neurons or other types of cells are responsible for the increased NREMS in *Sleepy* mutant mice.Here, we investigated whether SIK3(SLP) in mature neurons is sufficient for increasing sleep amounts and NREMS EEG delta density. Newly developed *Synapsin1*^{CreERT2}*;Sik3*$^{Sleepy\text{-}flox}$ mice enabled us to induce *Sik3(Slp)* in mature neurons upon tamoxifen injections. *Synapsin1*^{CreERT2}*;Sik3*$^{Sleepy\text{-}flox}$ mice administrated tamoxifen at late infancy exhibited increased NREMS time and NREMS EEG delta density. In addition, simulated sleep-homeostatic Process S of *Sik3*^{Slp} and *Synapsin1*^{CreERT2}*;Sik3*$^{Sleepy\text{-}flox}$ mice showed that increased ratio between the rates of sleep-need accumulation and dissipation. These results suggested that SIK3 plays important role regulating sleep amounts and sleep need in mature neurons.Furthermore, we explored neural populations which are responsible for the sleep phenotype of *Sleepy* mutant mice with SIK3(SLP) expressing AAV vectors. We found that mid-anterior medial parts of hypothalamus increased NREMS amounts upon SIK3(SLP) expression. However, no increase in NREMS EEG delta density was observed. These results imply that neural populations that increase NREMS and NREMS EEG delta power in *Sleepy* mutant mice are not identical. Now, we try to narrow down and characterize these NREMS-promoting neurons in *Sleepy* mutant mice.

Title: Beneficial Effects of a Plasma Fraction on Normalizing Sleep Disturbances Associated with Aging

Authors: I. GALLAGER, E. PICKUP, S. LEE, V. KHEIFETS, *E. CZIRR;
Alkahest Inc., a subsidiary of Grifols, San Carlos, CA

Abstract: RBD (REM sleep behavioral disorder) occurs 6-15 years prior to the onset of neurodegenerative disorders and is present in 90% of patients with Parkinson's disease, dementia or Lewy Body disease and MCI (mild cognitive impairment) commonly resulting in accelerated institutionalization. The process of aging is multifactorial, therefore single agent interventions would be unlikely to attenuate the myriad pathologies associated with advancing age including sleep disruptions. Plasma contains many beneficial factors which have been shown in animal models to ameliorate multiple age-related deficits across varied organ systems, including the brain. We focused on age-related hippocampus-dependent cognitive deficits, as the hippocampus is well accessed by the vascular system, especially within the subgranular zone. This makes it an attractive target for evaluation of plasma and plasma-derived factors. We confirmed that human plasma from young (18-22-year-old) donors reverses age-related cognitive decline and enhances hippocampal neurogenesis and cell survival in aged immunocompromised mice, while plasma from aged individuals (62-68 years old) has detrimental effects in young mice. We have extended these findings to show the benefits of a fractionated plasma product (PF) with enhanced properties. In addition, we examined PF in an α-synuclein mouse model of Parkinson's disease, where treatment significantly reversed functional, inflammatory, and neuronal deficits. Here we demonstrate in 22mo old C57BL/6J mice that additional to modifying CNS histological endpoints, PF normalizes sleep disruptions: Increasing REM sleep time, nREM time and length and decrease waking bouts and time. These results suggest direct physiological impact from plasma fraction treatment and provide a direct translatable endpoint for monitoring within future PF neurodegenerative clinical trials.

Title: The impact of acute sleep deprivation on the synaptic proteme is distinctly different between juvenile and adolescent mice

Authors: *S. GAY[1], N. K. BARKER[2], A. PREVATTE[2], J. M. SIMON[2], L. E. HERRING[2], G. H. DIERING[3];
[1]Neurosci., [2]Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [3]Cell Biol. and Physiol., Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Sleep is essential for proper cognitive function and brain maturation. Even a single night of disrupted sleep can have immediate measurable deficits on cognitive functions. The importance of sleep during development is suggested by the comorbidity of sleep disruptions and numerous neurodevelopmental disorders. We hypothesize that sleep loss is not just a symptom of these disorders but also contributes to the cognitive and social deficits observed. Thus, making sleep a promising therapeutic target. There is little understanding of the restorative mechanisms of sleep and how sleep loss impacts the developing brain, leading to a lack of sleep therapies for children. Recent studies have shown that the synapse is remodeled during sleep and greatly impacted by sleep deprivation. As such, the synapse has emerged as a primary benefactor of the restorative functions of sleep, making it a locality of interest. Our present study aimed to understand how sleep deprivation impacts juvenile (postnatal, p21) and adolescent (p42-45) synapse biochemistry in mice. To analyze synapse biochemistry, we used mass spectrometry proteomics. We observed that acute gentle handling sleep deprivation significantly changed the expression of hundreds of proteins in both the juvenile and adolescent cortex and hippocampal synaptic proteome. Few proteins were similarly changed, due to sleep deprivation, at the juvenile and adolescent synapse. Interestingly, many proteins that increased in the juvenile synapse during sleep deprivation were found to decrease in the adolescent synapse during sleep deprivation. This data suggests that sleep, and consequentially loss of sleep, has a unique impact on synapse biochemistry in juvenile and adolescent mice. It further suggests that the impact of sleep loss is distinct at different developmental time periods, supporting a role of sleep loss in neurodevelopmental disorders.

Title: Characterization of Basal Forebrain Npas1+ Neurons In The Mouse

Authors: *R. E. BROWN[1], C. YANG[1], F. KATSUKI[1], D. D. AGUILAR[1], I. E. LIN[2], L. K. RADZIK[1], J. M. MCNALLY[1], C. S. CHAN[3], J. T. MCKENNA[1];
[1]Psychiatry, VA BHS/Harvard Med. Sch., West Roxbury, MA; [2]Wheaton Col., Norton, MA; [3]Dept. of Physiol., Northwestern University, Feinberg Sch. of Med., Chicago, IL

Abstract: The basal forebrain (BF) is an important brain region for regulating sleep-wake behavior, cortical electrical activity, attention and reward processing. Furthermore, degeneration or dysfunction of BF neurons is implicated in cognitive deficits in neurodevelopmental disorders and in dementia.

Therefore, it is important to decipher the composition, connections and functional role of BF neurons. Here we report preliminary findings concerning a novel population of BF neurons which express the transcription factor neuronal PAS domain 1 (Npas1), a master regulator of neuropsychiatric risk genes. Npas1-cre-TdTomato mice were used for experiments. Immunohistochemical staining showed that BF Npas1+ neurons were distinct from parvalbumin (PV) or cholinergic projection neurons. Crossing Npas1-cre-tdTomato mice with GAD67-GFP knock-in mice revealed that the vast majority of Npas1+ neurons expressed GFP, suggesting they are a novel GABAergic population. Transduction of BF NPAS1 neurons with channelrhodopsin2-enhanced yellow fluorescent fusion proteins was used to identify projections. Initial examination suggested prominent projections of BF Npas1+ neurons to frontal association cortices, perifornical hypothalamus, amygdala, ventral tegmental area (VTA), supramammillary nucleus (SuM) and ventrolateral periaqueductal gray (vlPAG). Fibers were sparse or absent in the lateral habenula, a prominent target of BF vesicular glutamate transporter 2 (vGluT2) neurons and in the thalamic reticular nucleus, a notable target of BF PV and cholinergic neurons. Chemogenetic activation of BF Npas1+ neurons strongly increased wakefulness in three mice. However, there was no change in gamma band power during wakefulness, locomotor activity or sleep spindle density. Clozapine-N-oxide (0.3 mg/kg) alone had no significant effect on sleep-wake behavior or cortical EEG in mice without transduction of BF neurons, when compared to vehicle (saline) injections (N=4) Our experiments suggest that BF Npas1+ neurons represent a novel subtype of BF wakefulness-promoting neurons, distinct from previously characterized PV, cholinergic and vGluT2 neurons. Wake-promoting actions of Npas1+ neurons may be mediated by projections to perifornical hypothalamus, VTA and SuM.

Title: Testing the role of alpha-1 and alpha-3 containing GABAARs in thalamic neurons in sleep delta wave activity using CRISPR-Cas9 gene editing

Authors: *D. S. UYGUN, R. E. BROWN, R. BASHEER;
VA Boston Healthcare Syst. & Harvard Med. Sch., West Roxbury, MA

Abstract: High power of electroencephalographic (EEG) delta (0.5-4 Hz) waves is associated with restful non-rapid-eye-movement sleep (NREM) and is linked to longevity and good overall health, including psychiatric health. Problematically, sleep medicines which potentiate the activity of synaptic GABA-A receptors containing alpha1 and alpha3 subunits suppress these healthy delta waves, but it is unknown how. Though delta waves are recorded cortically, they are generated in large part by the thalamus, by self-oscillating "pacemaker" cells called thalamocortical (TC) relay neurons. TC neurons generate delta waves when they are in "burst firing" mode, which occurs when they are hyperpolarized. TC relay neurons receive their main source of inhibition from the neighboring GABAergic thalamic reticular nucleus (TRN) neurons. TRN neurons express synaptic receptors containing the alpha3 subunit whereas TC neurons express the α1 subunit. Here we use innovative *in vivo* CRISPR-Cas9 technology to dissect the role of α1 and α3 containing $GABA_A$ receptors in the thalamus. For experiments targeting TC neurons, we crossed lox-stop-lox-Cas9 mice with VGlut2-cre mice to generate VGlut2-Cas9 mice, introducing Cas9 in glutamatergic cells such as TC neurons, whereas for experiments targeting TRN neurons we used PV-Cas9 mice, targeting the large majority of TRN neurons which contain parvalbumin (PV). KD of α3 subunits in TRN increased the power of NREM delta waves (n=6). More fine-grained analysis revealed that there was no effect on the slower component (0.5-1.5 Hz) but a strong effect on a faster delta-band (2-4.5 Hz) which was recently shown to be homeostatically regulated (Hubbard et al., 2020). Effects were pronounced at NREM-REM transitions. In contrast, α1KD in the TRN caused no effect on delta waves [Mean (SEM): BL 50±2.5 vs KD 52.83±3.8; two-tailed paired t-test: $t(6) = -0.86$, $p = 0.4209$]. In ongoing analyses (N=3), we predict α1KD in TC neurons will reduce hyperpolarization in TC neurons and thereby attenuate NREM delta power, i.e. the opposite effect observed with α3KD in TRN. Our work suggests differential actions of α3 and α1 subunits in regulating NREM delta activity. This work could improve our understanding of the mechanisms of widely used sleep medicines.

Title: Sleepless in C. elegans: Sleep duration affects the formation and clearance of stress granules

Authors: *L. CARMAN, M. DOUGHERTY, C. SAUL, J. C. TUDOR, M. NELSON;
St. Joseph's Univ., Philadelphia, PA

Abstract: Sleepless in *C. elegans*: Sleep duration affects the formation and clearance of stress granulesLynly Carman, Mary K. Dougherty, Christopher Saul, Matthew Nelson, Jennifer C. TudorSleep is conserved across the animal kingdom, and lack of sleep results in numerous detriments to an organism's health and wellbeing, including memory impairment. Memory formation requires protein synthesis, which is attenuated after sleep deprivation. We have previously shown that sleep deprivation impairs protein synthesis through suppression of the mammalian target of rapamycin (mTOR) pathway. Downregulation of the mTOR pathway has separately been linked to the formation of RNA aggregates called stress granules. Taken together, these observations suggest a possible relationship between sleep and stress granule production. This study uses the nematode *Caenorhabditis elegans* to observe how stress granule formation and clearance are modified by sleep duration. *C. elegans* exhibit two major forms of sleep: developmentally-timed sleep (DTS), which occurs during the lethargus phase of its lifecycle, and stress-induced sleep (SIS), occurring after exposure to noxious stimuli. By performing genetic crosses, we developed novel strains of *C. elegans* to model deprivation and enhancement of DTS and SIS. Stress granules were visualized in each strain through RFP-labeling of the poly-A binding protein (PAB-1) protein. We found that lack of SIS causes physiological changes within cells resulting in increased stress granule formation, and these changes are reversible concomitant with enhanced SIS. Manual deprivation of DTS increased stress granule count during sleep. Interestingly, stress granule count was reduced during DTS regardless of genotype or condition. These data suggest that sleep duration has an active role in altering stress granule dynamics. This has implications concerning how gene regulation is affected by sleep, providing a key contribution in the ongoing effort to understand the functions of sleep.

Abstract: Hypertension related illnesses are a leading cause of disability and death in the United States. Due to the high prevalence of adverse effects of pharmacological interventions for hypertension, there is increased interest in the development of nonpharmacological interventions. A Mindfulness-based blood

pressure reduction program (MB-BP) is effective in attenuating hypertension, but the neural correlates of this intervention are unknown. The objectives of the present study were to identify structural neural correlates of MB-BP using diffusion tensor magnetic resonance imaging (DTI) and assess potential correlations with key clinical outcomes. In subset of participants from a larger randomized controlled trial, MB-BP participants exhibited increased mindfulness and decreased depression compared to controls. Analyses of DTI data revealed significant group differences in several white matter neural tracts in the limbic system and/or associated with hypertension. Specific changes in neural structural connectivity were significantly associated with clinical measures of blood pressure, depression, anxiety, mindfulness, and emotional regulation. It is concluded that MB-BP has extensive and substantial effects on brain structural connectivity which could mediate beneficial changes in mindfulness, depression and related clinical measures in individuals with hypertension.

Title: Running on fumes: Glycogenolysis transforms a circuit to operate without oxygen and glucose delivery

Authors: *N. BUESCHKE[1], J. M. SANTIN[2];
[1]Univ. of North Carolina at Greensboro, Greensboro, NC; [2]Univ. of North Carolina At Greensboro, Greensboro, NC

Abstract: The central nervous system has a high energy demand for proper function which will result in permanent neuronal damage when not adequately fueled. We describe a series of experiments that show a 20-30 fold increase in time until metabolic failure during anoxic and ischemic conditions in the American bullfrog, the largest documented in a vertebrate species. Although several hypoxia-tolerant species exist, American bullfrogs are not considered highly resistant to energetic stress, and the brainstem network that produces breathing provides an example of this “lack” of hypoxia tolerance. Brainstems from control bullfrogs (n=6) produce rhythmic output for 11±5 minutes in hypoxia (0% O_2) and 4±0.5 minutes during simulated ischemia (O_2 and glucose deprivation; OGD; n=8). In contrast, hibernation (i.e., 1 month of cold-acclimation to simulate the overwintering environment) resulted in transformation that allowed for activity to persist for 230±13 minutes in hypoxia (n=8) and >120 minutes in OGD (n=6). Despite bubbling with 0% O_2, we controlled for the possibility that O_2 might not be 0% within the tissue and that aerobic metabolism may still operate at low levels in hibernation preparations. To do this, we applied OGD+ 1 mM sodium cyanine for 1 hour. All preparations (n=5) produced rhythmic activity at 1 hr. We

then applied 1 mM iodoacetate in the presence of OGD+ 1 mM cyanine to confirm that glycolysis fuels the network after hibernation. All 5 preparations stopped within 5±1 minutes following exposure to iodoacetate. Finally, to understand which energy substrate fuels glycolysis in the absence of oxygen and glucose delivery, we tested the hypothesis that brain glycogen breakdown can support network activity after hibernation. To test this, we applied OGD in the presence of an inhibitor of glycogen phosphorylase (250 µM DAB) in hibernation preparations. In the presence of DAB, hibernation preparations produced rhythmic output for 25±1 min, significantly less 120 minutes typical of hibernation preparations ($p<0.0001$), but still significantly greater than the ~4 minutes observed in controls ($p<0.0001$). Thus, a large fraction of hibernation-induced OGD tolerance stems from a shift to glycolysis supported by glycogen breakdown; however, additional physiological or biochemical mechanisms likely play a role. Future work will address additional possibilities, as well as the source of brain glycogen that maintains activity. Given the unprecedented shift to function during energetic stress, understanding the underlying mechanisms will provide insight to neuronal energetics and novel strategies for neuroprotection.

Title: Maternal hyperglycemia and snack intake effects on offspring behavior and metabolism in adulthood and senescence

Authors: *M. G. MARTINS[1,2], B. WOODSIDE[3], A. C. I. KISS[1,2];
[1]Physiol. Dept., Inst. of Biosciences, Univ. of São Paulo, São Paulo, Brazil; [2]Dept. of Structural and Functional Biol., Inst. of Biosciences, São Paulo State Univ., Botucatu, Brazil; [3]Psychology Dept., Ctr. for Studies in Behavioral Neurobiology, Concordia Univ., Montréal, QC, Canada

Abstract: Maternal metabolism and nutritional status are key to a healthy offspring's intrauterine and postnatal development, with previous studies showing that snack intake during pregnancy and lactation further impairs glucose tolerance in hyperglycemic female rats. However, their long-term consequences to offspring behavior and metabolism are unknown. To investigate those effects, newborn female Wistar rats were divided into Control (citrate buffer, s.c.) or STZ (streptozotocin, 100 mg/kg, s.c.) groups. On postnatal (PND) 90, rats from both groups were mated and subdivided into four groups: females fed with standard chow (Control, n = 22; STZ, n = 23); and females fed with standard chow plus potato chips and 1.5% sucrose solution from pregnancy day 0 to lactation day 14 (Control-snack, n = 23; STZ-snack, n = 23). Dams gave birth naturally and, on PND 1, litters were culled to 6 pups (3 males, 3 females). On PND 90 and 360, male and female offspring behavior was evaluated in the marble-burying test, the open field arena, and the elevated plus-maze, followed by a glucose tolerance test and a sucrose preference test. All

experimental procedures were approved by the local ethics committee (Protocol number 919). Maternal hyperglycemia and snack intake association did not affect burying and exploratory in adulthood and senescence. Although there were no changes in anxiety-like behavior in adult offspring, maternal hyperglycemia and snack intake association led to an increase in anxiety in 360-days-old offspring. Sucrose preference in adulthood was reduced due to maternal snack intake. Offspring glucose tolerance was not affected by either maternal manipulation, still, offspring from hyperglycemic dams showed an impaired return to glucose baseline levels in adulthood. In sum, while no differences related to maternal metabolism and diet were observed in adulthood, senescent offspring had increased anxiety-like behavior, showing that the effects of a disrupted maternal metabolism may manifest only in the long term. Since both maternal diabetes and inappropriate nutrition have been linked to offspring cognitive impairments, future studies should evaluate deficits in learning and memory. Despite aggravating maternal hyperglycemia, snack intake leads to glucose levels within the mild hyperglycemic range in pregnant females, which may explain why there were no major behavioral impairments in the offspring. Nonetheless, changes in offspring behavior reinforce the importance of women sustaining target glucose levels and a healthy diet during pregnancy and lactation.

Title: Action potential firing ability is preserved in motoneurons during network collapse due to anoxia

Authors: *L. DO AMARAL-SILVA[1], J. M. SANTIN[2];
[1]Biol., Univ. of North Carolina, Greensboro, NC; [2]Biol., Univ. of North Carolina at Greensboro, Greensboro, NC

Abstract: Neural circuits activity is costly for vertebrates requiring ongoing ATP production through aerobic metabolism. Work in our lab shows that rhythmic network activity in the AmericanBullfrogs brainstem (*Lithobates catesbeianus*) stops within few minutes of anoxia. However, after hibernation, this network transforms to maintain activity up to 4h in anoxia and more than 2h in oxygen and glucose deprivation (OGD), the largest improvement among vertebrates. We aim to understand the mechanisms that underlie this remarkable response. As the first step, we characterized network components and cellular processes responsible for failure during energy deprivation in control frogs. We used whole-cell patch-clamp electrophysiology to assess function of labeled motoneurons isolated from the network (transverse slices) or within the intact rhythmic network by using a novel preparation. This preparation allowed us to monitor the firing of single motor neurons and whole network output simultaneously. Neural function was recorded under baseline conditions (1.5%, CO2 and 98.5% O2) followed by anoxia

exposure (1.5% CO2 and 98.5%N2) or OGD (sucrose substituted glucose in the aCSF bubbled with 1.5%, CO2 and 98.5%N2). When the rhythmic preparation was exposed to anoxia, activity stopped in 14±3 min(n=3). Motoneurons fired in phase with the network 100% of the time and fired spontaneously for 5±1 min after coordinated network activity stopped because anoxia, which shows they can generate action potentials despite loss of phasic synaptic input. Indeed, motoneurons isolated from the network could fire undisturbedly in anoxia for up to one hour under a rhythmic current injection protocol that mimics physiological synaptic inputs (19±4 Hz before / 20±3 Hz after 1h, n=3). Surprisingly, firing rate also did not change during OGD exposure for up to 1h (31±5 Hz before / 34±5 Hz after 1h, n=8). Glycolysis was inhibited by iodoacetic acid in 3 slices under OGD, and firing stopped in 8±2 min, indicating that action potential generation can be supported exclusively by local fuel sources for glycolysis. Given that control cells had the striking capacity to fire without oxygen and glucose, our data suggest that network collapse in anoxia derives from the loss of synaptic input to motoneurons. Thus, network failure seems to be caused by greater energetic demands of either action potential firing of upstream rhythm generating neurons or synaptic communication between the rhythm generator and motor pools. Subsequent work will address these possibilities and seek to understand how these large physiological costs are overcome to function for hours without energy delivery following hibernation.

Title: Sexually dimorphic effects of Western Diet on brain mitochondrial bioenergetics and neurocognitive function

Authors: *M. LORD, J. HOFFMAN, K. DONOHUE, M. SPAULDING, A. SCHIFINO, J.-W. HEO, J. CALL, E. NOBLE;
Univ. of Georgia, Athens, GA

Abstract: Western Diets (WD), high in added sugars and saturated fats, have been shown to impair learning and memory function and contribute to weight gain in both human and animal models, however, neural mechanisms mediating these effects are not completely understood. Mitochondria in the brain provide essential energy for neural plasticity and have been suggested to play a role in whole body energy metabolism. Our objective was to determine whether a WD consisting of sugar-sweetened beverages and high-fat food impacts brain mitochondrial bioenergetics, behavior, and metabolic outcomes. Male and female Sprague Dawley rats were singly housed and randomized to receive a WD consisting of high-fat pellets (60% kcal from fat), an 11% high fructose corn syrup beverage, and water (WD; n=10 males, n=12 females) or standard laboratory chow with access to two bottles of water as the control diet (CTL; n=10 males, n=12 females). Behavioral outcomes tested were anxiety-like behavior (Elevated Plus Maze)

and hippocampal-dependent learning and memory (Novel Location Recognition). Food intake and body weight were monitored daily, and glucose metabolism, body fat, and liver fat were measured. Whole hypothalamus (HYP) and hippocampi (HPC) were collected for analyses of mitochondrial oxygen consumption, membrane potential, and redox status of NAD(P)H. Results revealed a sexually dimorphic macronutrient preference between male and female rats, where females on the WD consumed a greater percentage of calories from sugar compared to males, who consumed a greater percentage of calories from fat. Both males and females on WD gained significantly more fat and showed impaired glucose tolerance when compared to same-sex CTLs. Males on WD demonstrated impaired HPC-dependent learning and memory functioning, whereas females did not. Comprehensive bioenergetics analysis of WD effects on HPC and HYP brain revealed a tissue-specific adaption to WD in the HYP, where males on the WD oxidized more fat, and females oxidized more fat and sugar at peak energy demand compared to same sex CTLs. In the HPC of males, analyses showed an elevated tendency toward a high membrane potential, which has been linked with oxidative stress. Taken together, these results suggest that adult male rats show a susceptibility toward HPC dysfunction on a WD, and that HYP mitochondrial bioenergetics are altered by WD in a sex-specific manner.

Abstract: The cerebral cortex is organized in cortical layers that differ in their cellular density, composition, and wiring. Cortical laminar architecture is also readily revealed by staining for cytochrome

oxidase - the last enzyme in the respiratory electron transport chain located in the inner mitochondrial membrane. It has been hypothesized that a high-density band of cytochrome oxidase in cortical layer IV reflects higher oxygen consumption under baseline (unstimulated) conditions. Here, we test the hypothesis using direct measurements of the partial pressure of O_2 (pO_2) around diving arterioles in cortical tissue obtained with 2-photon phosphorescence lifetime microscopy (2PLM) in awake mice. For that, we injected the new red-shifted oxygen sensing probe Oxyphor-2P through a port in the window into the brain. From 6 arteriole of 4 subjects more than 20 planes were analyzed. Previously, we introduced a method for extraction of $CMRO_2$ based on 2PLM that relies on the Krogh-Erlang model of O_2 diffusion from a cylinder and applied this method to estimate $CMRO_2$ in the rat cerebral cortex. However, periarteriolar spaces void of capillaries in the mouse cortex are narrower than those in the rat. Therefore, the basic Krogh-Erlang assumption of the center arteriole serving as the sole O_2 source is challenged. We revisited the model to account for contribution of the capillary bed and then applied the revised model to estimate baseline $CMRO_2$ in awake mice across cortical layers. Our results show that, in contrary to the common notion, baseline $CMRO_2$ in layer IV is lower than that in upper layers. In agreement, there was a significant increase in the low tail (the lower 35%) of the pO_2 distribution with depth indicating an increase in oxygenation of tissue in between capillaries in layer IV compared to layer I. Our results imply that capillary, cytochrome oxidase, and mitochondrial densities cannot serve as a proxy for oxidative energy metabolism under baseline conditions. We speculate that the cytochrome oxidase band in layer IV may fulfill higher metabolic demands during transient surges in neuronal activity. These findings are important for interpretation of cortical-layer-resolved Blood Oxygen Level Dependent (BOLD) functional Magnetic Resonance Imaging (fMRI) studies.

Title: Calorie-restricted mice display activation of the reward-related brain centers and saccharine overconsumption, in a growth hormone secretagogue receptor-dependent manner

Authors: *D. CASSANO, C. SAENZ, N. DE FRANSCESCO, G. FERNÁNDEZ, M. CORNEJO, G. GARCÍA ROMERO, M. PERELLÓ;
IMBICE, La Plata, Argentina

Abstract: Several evidences indicate that calorie restricted (CR) animals display short and long-term changes in their reward-related behaviors towards palatable stimuli, but the molecular basis underlying

such adaptations remain uncertain. Ghrelin is a stomach-derived hormone that acts via growth hormone secretagogue receptor (GHSR) and enhances reward-related behaviors. GHSR is expressed in the ventral tegmental area (VTA), which is a hub of the so-called mesolimbic pathway that innervates the ventral striatum (i.g, the nucleus accumbens (Acb)) in order to control reward-related behaviors. Since plasma ghrelin levels increase under calorie restriction, GHSR signaling could act in the mesolimbic pathway and affect the short- and long-term behavioral adaptations toward rewarding stimuli observed in CR animals. Here, we investigated the induction of the marker of neuronal activation cFos in the mesolimbic pathway as well as the saccharine consumption in wild-type (WT) mice and GHSR-deficient mice during a 5-day 60% calorie restriction protocol. We observed that GHSR-deficient mice showed: 1) a more severe weight loss and hypoglycemia, 2) a similar increase of cFos in the VTA but a smaller increase of cFos in the Acb, and 3) a reduced overconsumption of saccharin, than WT mice during the calorie restriction protocol. When CR mice where refed, we found that GHSR-deficient and WT mice did not show different hyperphagia, glycaemia or saccharine consumption, in a similar fashion as seen before the calorie restriction. Thus, we conclude that GHSR plays a main role during, but not after, a calorie restriction condition. In particular, we found GHSR seems to be required for the maintenance of energy balance and glucose homeostasis during calorie restriction as well as for the full calorie restriction-induced activation of the reward-related brain centers and saccharine overconsumption.

Title: Brain mechanisms in cancer associated cachexia

Authors: *D. KALTENECKER[1,2,3], M. TODOROV[2,3], S. ZHAO[4], P. MORIGNY[1], J. ZUBER[1], S. HERZIG[1], M. BERRIEL DIAZ[1], A. ERTURK[2,3];

Abstract: Cancer alters diverse metabolic activities in the body. Cancer-associated cachexia (CAC) is a prominent one characterized by loss of body weight via muscle and adipose tissue wasting. It negatively affects cancer treatments and is responsible for up to 40% of cancer deaths, highlighting the urgent need for novel treatment options. While the brain contributes to cachexia development by promoting anorexia, the neuronal circuits that govern CAC establishment and progression remain poorly understood. Here, we studied changes in neuronal activity in brains of tumor-bearing mice (weight-stable vs. CAC). To this end, we performed whole-brain cFos labeling using a modified SHANEL protocol (Zhao⋯Ertürk, Cell, 2020). After light-sheet imaging of whole mouse brains, we used ClearMAP (Renier et al., Cell, 2016) to identify cFos+ cells automatically. Subsequent registration to the Allen brain atlas yielded in the

identification of brain regions with significant alterations. We observed increased neuronal activity in multiple brain areas in mice transplanted with a cancer cell line that does not induce weight loss (weight-stable mice). These include the lateral hypothalamic nucleus involved in regulating feeding behavior and cortical regions, which were not implicated in metabolic activities before. Interestingly, increased cFos expression in these brain regions disappeared in cachectic animals, suggesting that their over-activation is involved in blocking CAC in weight-stale mice. Thus, our findings highlight novel brain regions that can be targeted to ameliorate weight loss in cancer as novel CAC treatment options.

Title: Neural ensemble encoding context-dependent food consumption

Authors: *H. MOHAMMAD[1], E. SENOL[1], M. GRAF[2], C.-Y. LEE[3], G. AUGUSTINE[2], Y. FU[1]; [1]Inst. of Mol. and Cell Biol. , Agency for Science, Technol. and Res., Singapore, Singapore; [2]Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore; [3]Singapore bioimaging consortium, Singapore, Singapore

Abstract: Feeding is not only controlled by metabolic needs, however there are number of external cues associated with food that can elicit excessive consumption in sated animals. The availability of palatable food along with environmental context promotes excessive food intake which is one of the major contributor to obesity. However the neural mechanisms that drive contextual feeding are not well understood. Here, we designed a novel paradigm for studying contextual feeding using chemogenetic approach, and identified a novel subset of neurons in the hypothalamus of the brain that are capable of driving robust contextual feeding in mice. Using modern tracing tools available, we show here that these neurons are connected to hippocampus, and, this hippocampus to hypothalamus connection is critical for the establishment of context dependent food intake. Altogether our data reveal a novel circuit that enables an environmental context to promote excessive food intake.

Title: Brain glycogen serves as a critical sugar cache required for protein glycosylation

Authors: *M. GENTRY[1], R. C. SUN[2];
[2]Neurosci., [1]Univ. of Kentucky, Lexington, KY

Abstract: Glycosylation defects are a hallmark of many nervous system diseases. However, the molecular and metabolic basis for this pathology is not fully understood. In this study, we demonstrate that N-linked protein glycosylation in the brain is critically and directly connected to glycogenolysis. The primary function of glycogenolysis is to liberate glucose-1-phosphate from glycogen. We demonstrate that in addition to glucose, glucosamine is an abundant covalent constituent of brain glycogen. We define the biosynthetic incorporation of glucosamine into glycogen by glycogen synthase and glucosamine release by glycogen phosphorylase *in vitro* by biochemical and structural methodologies, *in situ* in primary astrocytes, and *in vivo* by isotopic tracing and mass spectrometry imaging. We establish that glycogen-derived glucosamine is a significant source of amino sugars required for protein glycosylation in the brain. Further, we demonstrate that disruption of cerebral glycogen metabolism causes global decreases in free UDP-N-acetyl-glucosamine and N-linked protein glycosylation using two glycogen storage disease models. These findings reveal a previously unknown yet key fundamental biological role for brain glycogen in protein glycosylation that has direct relevance to multiple human diseases of the central nervous system.

Abstract: <META NAME="author" CONTENT="하재선">Background: Despite feeding behavior assessment method using rodent model is long been used, no study reported the specific feeding behavior assessment method of Non-Human Primate(NHP). The aim of the present study is to provide feeding behavior assessment method of NHP, which could dissect multi-phase component of feeding behavior and quantify the effect of palatability and hunger.Methods: Three Rhesus macaques (Macaque mulatta) was used. To assess the approach and consumption phase of feeding behavior, specialized cage and tray were designed. Fourteen different behavioral indices (e.g. approach to the food, pushing the cheek, etc) were developed for approach and consumption phases. Additionally, two food test indices were developed to compare behaviors for two different food items. The feeding behavior of NHP is video recorded and is viewed in slow motion to identify the feeding behavior index of approach and consumption phase. Further, to reflect the temporal dynamics, every 5min bins during total 15-20mins were analyzed. To validate the application efficacy for palatability assessment, different level of palatability foods was used. And, for hunger effect assessment, both sated and fasted NHP were studied. Results: As designed, among fourteen behavior indices, most of the indices showed robust efficacy of quantifying palatability and hunger effect. For several indices, hungry NHP showed significantly higher index score compared with sated NPH. Two-dimensional analysis of two indices showed that the internal hunger state and calculated palatability value of NHP could be plotted in 2D plots. Conclusion: For the first time, multiple behavioral indices for feeding behavior assessment methods for NHP were developed. The validation results showed that these methods could be applied for hunger effect and palatability effect assessment. These novel feeding behavior assessment methods could open new research platform for multiple areas of NHP research.

Title: Social status regulates looking behavior indicative of theory of mind

Authors: *T. M. CHAMP[1], S. LEE[1,2], E. A. HILLIER[1], D. O'NEILL[1], T. GANAPATHY[3], N. R. LINGENFELTER[1], S. MARX[1], K. M. GOTHARD[1];

Abstract: Theory of mind is necessary for human and non-human primates to successfully function in a complex hierarchical society. An elemental manifestation of theory of mind is the production of gaze-following saccades. Shared attention is a version of gaze following that occurs when both partners fixate on the same target. The goal of the study was to determine whether gaze following and shared attention are influenced by social status. We generated artificial hierarchies by juxtaposing videos of threatening and appeasing behaviors to simulate that a subordinate monkey responds submissively to the threats of a dominant monkey. Each artificial hierarchy had four members of the same sex, which resulted in six pairwise hierarchical interactions. All individuals shown in the videos were unfamiliar to our male and female viewer monkeys. We recorded the scanpaths of the viewer monkeys as they watched these hierarchical interactions, and identified the saccades that met criteria for gaze following or shared attention: gaze following saccades that ended in a fixation on the social partner in the video were classified as shared attention saccades. We confirmed previous findings that higher ranking individuals command longer viewing times. Increased viewing time was expected to also increase the likelihood of following the gaze of the dominant animal. Our preliminary data from two viewer monkeys, however, show that subordinate monkeys elicited a higher frequency of both gaze following and shared attention saccades (ANOVA $p<0.001$, N = 3 hierarchies, 1500 saccades). This effect was more prominent for hierarchies of the same sex as the viewer. Furthermore, when viewing the subordinate monkey, the subjects generated a higher proportion of shared attention vs. gaze following saccades suggesting that they were more closely tracking the gaze interactions from the subordinate to the dominant. We then compared the temporal distribution of gaze following and shared attention saccades between viewer monkeys and found that videos that generated the highest correlation values depicted interactions of the lowest ranking animal in each hierarchy (Hierarchy 1, Pearson rho = 0.5596, $p<0.001$; Hierarchy 2, rho = 0.3823, $p<0.001$). Taken together, these findings suggest that although the dominant animals receive most of the viewer's attention, the subordinate triggers behaviors more suggestive of theory of mind.

Title: Quantitative assessment of information content and learning extracted from the scanpaths of macaques viewing videos of social interactions

Authors: *S. LEE[1,2], T. M. CHAMP[1], E. A. HILLIER[1], B. T. SEATON[3], D. O'NEILL[1], N. N. JACOBSON[4], B. R. DENNIS[1], J. W. ROZENBLIT[2], K. M. GOTHARD[1];

[1]Dept. of Physiol., [2]Dept. of Electrical & Computer Engin., [3]Dept. of Chem. & Biochem., [4]Dept. of Neurosci., The Univ. of Arizona, Tucson, AZ

Abstract: Videos of social interactions contain rich information about the protagonists including their social status. The content of the video often determines the scanpath of the viewer. The scanpath also contains information about the viewer, specifically the amount of information the viewer extracted and learned from the video. The goal of our study was to quantify the information in videos of macaque interactions and determine whether the social status of interacting macaques can be identified from the scanpaths of conspecific viewers. We generated multiple virtual social hierarchies, each consisting of four individuals of the same sex strictly organized by linear dominance. In these hierarchies, the highest and lowest ranking individuals show only threatening or appeasing expressions, but the mid-ranking individuals show both dominant and submissive expressions. By watching the pairwise interaction videos, the viewer learns about the hierarchical position of everyone. Each male and female macaque learned each two sets of male and female hierarchies. From their scanpaths we generated a map of fixation density in each region of interest. These became terms in an equation that generated descriptors for each video type. We also generated a ground truth model quantifying the ratio of the number of the pixels corresponding to the face, body, and background in videos. Then, we used the ground truth model to generate a second set of descriptors. A support vector machine (SVM) classified the descriptors for the ground truth model and the experimental data. The SVM performance was assessed by cross validation, and we used the generalized classification error (GCE) as a performance indicator. As previously shown, the viewing time of the subject was proportional with the rank of each individual, showing a rank-related staircase pattern of viewing time. We then explored whether there was a relationship between GCE and the emergence of the rank-related staircase viewing pattern. This pattern emerged when GCE was low (approx. 20%) and its cumulative trend followed the cumulative trend of GCE in the ground truth model. When we compared the classification performance across male and female hierarchies and male and female viewers, we found a learning advantage for hierarchies of the same sex as the viewer. Taken together these findings suggest that this approach is adequate to quantify the information relevant for social hierarchy in videos of interacting macaques. Moreover, this approach can also evaluate the viewer's knowledge about social hierarchy and highlights sex-related differences in social learning. Lastly, this approach can be generalized and applied to related studies.

Title: Does social rank subvert attention allocation to novelty?

Authors: *N. N. JACOBSON[1], S. LEE[2,3], B. R. DENNIS[2], C. M. BOLLES[1], S. KIM[2], B. T. SEATON[4,5], T. M. CHAMP[2], D. O'NEILL[2], K. M. GOTHARD[1,2];
[1]Neurosci., [2]Physiol., [3]Electrical and Computer Engin., [4]Chem., [5]Biochem., Univ. of Arizona, Tucson, AZ

Abstract: All human and non-human primates who live in hierarchical societies, use knowledge about the status of others for social decision making. Dominant individuals command visual attention. Novelty also captures visual attention. The goal of this study was to determine whether Rhesus macaques prioritize social rank over novelty when they perform a Visual Paired Comparison (VPC) task. We hypothesized a conflict between the natural inclination to look at novel faces and the drive to view dominant faces changes accuracy and reaction time in a VPC task. We generated artificial social hierarchies and independently assessed that the viewer monkeys learned the position of each individual in the hierarchy. During the VPC task, the viewer was first familiarized with a video of a conspecific selected from the learned hierarchy. This was followed the presentation of two images: a static frame from the prior familiarization video (familiar image) next to a static image of another monkey chosen from the rest of the same hierarchy set (novel image). Both the familiar and novel images contained only neutral facial expressions. To successfully complete a trial and receive a juice reward, the viewer monkey was required to fixate on the novel image. We measured the choice accuracy of one viewer monkey, and compared the proportion of errors when choosing a dominant familiar vs. a subordinate familiar monkey. We found a higher probability (ANOVA $p < 0.05$, $N = 34$ sessions) of errors when the familiar individual was dominant. The probability of incorrectly choosing the highest ranking animal when paired with the second highest was even higher ($p < 0.01$). Thus, we confirmed that preference for dominance can influence the preference for novelty in a VPC task. These errors in novelty selection may be related to the viewer's certainty of rank, because the effects were strongest for both the highest and lowest ranking individuals ($p < 0.01$). Furthermore, preliminary data indicate that this dominance effect is temporary and depends on social context, as the effect was not present when the stimulus monkeys were not engaged in hierarchical interactions ($p = 0.5$). The interference between preference for novelty and for high social status suggests that the VPC task can be used to probe the perception or knowledge of social status.

Title: Autonomic state predicts engagement of macaques with videos of conspecific social interactions.

Authors: *M. A. CARDENAS[1], S. LEE[2,3], T. M. CHAMP[3], N. N. JACOBSON[4], E. A. HILLIER[3], C. M. BOLLES[3], S. KIM[3], D. O'NEILL[3], A. B. MARTIN[3], K. M. GOTHARD[3];

Abstract: Video playback studies in both humans and non-human primates typically report the effect of video content on looking behavior and autonomic responses. The inverse causality, where the autonomic state of the viewer determines the looking behavior, has been rarely explored. The justification for this approach rests on the assumption that interoceptive states, signaled by autonomic afferents, influence the processing of external stimuli. We quantified the relationship between the moment-to-moment autonomic state of macaques (indexed by heart rate and heart rate variability) and their interactive looking pattern with unfamiliar conspecifics. Videos depicting conspecifics engaged in aggressive and appeasing displays were juxtaposed to simulate dominant-subordinate interactions. Previous studies have shown that such videos capture the attention of viewer monkeys and trigger gaze-following saccades, or saccades of shared attention. We found an inverse correlation (rho: -0.23) between heart rate and total looking time ($p<.001$). Related to looking time duration, the probability of a gaze following/shared attention saccade also increased during trials with lower heart rates ($p<.05$). No change in heart rate was found in response to events in the videos, suggesting these trends are not the result of a response to video content, but instead due to the state of the animal. This is reinforced by the observation of similar correlation power in the pre-stimulus period. To determine whether lower heart rate indicated a decrease in sympathetic arousal or an increase in parasympathetic drive (vagal tone), the high frequency band (~0.2-0.35 Hz) in the R-R interval power spectrum was used as an index of vagal tone. Periods of enhanced vagal tone were positively correlated ($p<.05$) with an increased number of shared attention saccades, but not with looking time. We then determined whether during periods of low and high vagal tone, gaze following/shared attention saccades originated mainly from the dominant or the subordinate monkey. Typically, these saccades started when the viewer's gaze was on the subordinate video monkey. However, with low heart rate and high vagal tone, the viewers were more likely to follow the gaze of the dominant monkey ($p<.001$). These results suggest the viewer monkey is more likely to engage in observing dominant-subordinate social interactions and more inclined to engage with the dominant monkey when the vagal tone is higher. These observations reinforce the viewpoint that vagal tone is correlated with increased social openness and suggest that interoceptive states influence the extraction of relevant information from socio-emotional stimuli.

Title: Neurons in the primate amygdala signal social context through sustained changes in baseline firing rates

Authors: *A. BOWMAN[1], K. R. ANDERSEN[2], M. A. CARDENAS[1], A. B. MARTIN[3], E. A. HILLIER[3], K. M. GOTHARD[1,2,3];
[1]Neurosci., [2]Col. of Med., [3]Physiol., Univ. of Arizona, Tucson, AZ

Abstract: Typical neurophysiological experiments used to explore the role of the amygdala in affective and social behavior involve rapid presentation of stimuli that induce an emotional reaction or require a behavioral response. These studies bring to light the cellular basis of immediate emotional reactivity and its impact on decision-making. However, this approach leaves the cellular underpinning of long-term changes in mood unexplored. Natural social behavior also unfolds on a larger time scale. To explore the representation of social context in the amygdala, we designed an experiment where the subjects experienced alternating blocks of non-social and social touch. During the delivery of non-social tactile stimuli (directed gentle airflow), the animal was alone in a closed booth. Social touch, akin to grooming, was delivered by a trusted social partner who sat in front of the animal. Both types of touch were delivered to the same area of the skin. Under these experimental conditions, a subset of neurons in the amygdala (98 neurons from 624 recorded from 2 monkeys) showed sustained elevations of baseline firing rate in either social or non-social touch blocks. To identify these neurons, baseline activity in each condition was concatenated and smoothed with a wide window (Gaussian $\sigma = 2$ minutes). To determine whether activity in one condition was sustained relative to the other condition, we measured a proportion value defined as the proportion of time that the baseline activity in one condition was greater than the mean baseline firing rate of the other condition. Neurons were classified as "context-responsive" if the proportion value of one condition was at least 1.5 times higher than the other condition. A fraction of these context-responsive neurons (62%) also responded to the instantaneous presentation of airflow, grooming, or both. These neurons were found throughout the amygdala, with 44% recorded in the basal nucleus. Their characteristics mirror previously reported neuronal properties seen in the primate amygdala - multidimensional responses, distribution across multiple nuclei, and encoding through temporal patterns of firing. In addition, each monkey's heart rate varied across sessions and conditions, and these cells indicated context regardless of changes in the heart rate. These results suggest that the amygdala is involved in orchestrating temporally protracted affective states which transcend moment-to-moment emotional reactions elicited by external stimuli. As such, changes in the baseline firing of neurons in the amygdala may represent the neural substrate for sustained affective states.

Title: Decoding of Expression and Identity from Neural Responses to Faces and Vocalizations in Primate Prefrontal Cortex

Authors: *K. K. SHARMA[1], M. DILTZ[2], L. M. ROMANSKI[3];
[1]Univ. of Rochester Sch. of Med. and Dent., Rochester, NY; [2]Univ. of Rochester Sch. of Med. and Dent., University of Rochester, NY; [3]Dept Neurosci., Univ. of Rochester Sch. of Med. and Dent., Rochester, NY

Abstract: The ventrolateral prefrontal cortex (VLPFC) is a multisensory integrator that is highly responsive to social stimuli. In both humans and macaques, areas within the VLPFC exhibit robust and specific responses to faces that are modulated by the emotional or expressive qualities of the face. In macaques, the VLPFC contains neurons with selective firing for species-specific vocalizations, head-orientations, and faces. Furthermore, macaque VLPFC neurons exhibit non-linear multisensory integration of visual and auditory information suggesting a rich and complex population response. In light of the VLPFC's established multisensory integration and putative social function, we sought to investigate the relationship between VLPFC neuronal activity and the perception of socioemotional expressions. In this study, we recorded single and multi-unit neurons in VLPFC using multi-electrode arrays, while non-human primate subjects (*Macaca mulatta*) viewed movies of macaques vocalizing with accompanying facial gestures. Stimuli consisted of 400-1000msec movies of 3 different audiovisual expressions from 3 different conspecifics. Linear Discriminant Analysis of neural firing rates revealed neurons with greater than chance decoding accuracy for expression and identity within the VLPFC. Combined as a pseudo-population, these cells exhibited increasing decoding accuracy for both variables as a function of population size, with decoding accuracy of identity increasing faster than expression. Principle component analysis of pseudo-population mean responses to each stimulus revealed that, along the first two principle components, responses to the same identity occupy separable regions of the response space. Additionally, a two-way ANOVA analysis of single neuron firing rates revealed that the majority of VLPFC neurons with a significant main effect of expression or identity also had a significant interaction effect. Our data show that sufficient information for the classification of different expressions and identities is present at the population level in the VLPFC, with identity as the primary driver of the population response. At the single cell level, responses to natural stimuli are highly complex, mirroring non-linearities seen in multisensory integration. Our results encourage further investigation into the role of the VLPFC in social communication as well as the perception and interpretation of emotional expressions.

Abstract: Social cognition is a dynamic process that requires the perception and integration of a complex set of idiosyncratic features between interacting conspecifics or during the observation of these interactions. A promising nonhuman primate model for investigating the neural basis of social cognition, and in particularly social interaction, is the common marmoset (*Callithrix jacchus*), a small New World primate that shares a rich social repertoire with humans. Here we used functional magnetic resonance imaging (fMRI) in awake marmosets to investigate the neural basis of primate social cognition. First, we acquired fMRI at 9.4 Tesla to map brain areas activated by social interaction observation, i.e., while a marmoset was viewing a video of two other marmosets interacting with each other (grooming, playing, fighting). In the second study we simultaneously measured whole-brain activations of two socially interacting marmoset monkeys at 3 Tesla. We discovered a network of subcortical and cortical areas, predominately in the anterior lateral frontal and medial frontal cortex, that was specifically activated by social interaction observation. Interestingly, while two marmosets where facing each other in-person, we observed increased activation in these regions, compared to when the marmoset viewed a video of the other marmoset. These findings show similarities with a recent social interaction networks identified in Old World macaque monkeys and suggest that this network is largely conserved between New and Old World primates. Our findings support the use of marmosets for studying the neural basis of primate social cognition.

Title: Representations of actual and counterfactual choice outcomes in the primate orbitofrontal cortex, ventral striatum, and midbrain dopamine neurons

Authors: *M. YUN, M. NEJIME, T. KAWAI, H. YAMADA, M. MATSUMOTO;
Univ. of Tsukuba, Tsukuba, Japan

Abstract: Individuals evaluate their past decisions by assessing what was gained (the actual outcome) as compared to what would have been gained by making a different choice (the counterfactual outcome). A large body of studies have shown that actual outcome value processing is distributed in many cortical and subcortical areas. On the other hand, although some studies reported that the orbitofrontal cortex (OFC) is involved in counterfactual outcome value processing, the entire picture of neural mechanisms underlying this process remains unknown. To address this issue, we focused on the OFC and two core regions of the subcortical system signaling actual values: the ventral striatum (VS) and midbrain dopamine (DA) neurons, and investigated how and whether they process counterfactual values in monkeys. We developed a value-based decision-making task in which two options were sequentially presented. When the first option was presented, the monkey needed to decide whether to choose it though the animal did not yet see the second option at that time. If deciding to choose the first option, the monkey was unable to choose the second option even if the value of the second option was better than that of the first option, and then obtained the reward associated with the first option. If deciding not to choose the first option, the monkey obtained the reward associated with the second option. Thus, the value of the second option became counterfactual or actual depending on whether the monkey chose the first option or not. We observed that a substantial number of OFC, VS and DA neurons represented the actual value of the second option. By contrast, we found that a larger proportion of OFC neurons represented the counterfactual value of the second option than VS neurons, and DA neurons did not represent this type of value. The latency of the counterfactual value signal was shorter for OFC neurons than VS neurons. Notably, during the presentation of the second option, the OFC population represented not only the counterfactual value of the second option but also the actual value of the first option but in an opposite direction, suggesting that the OFC population compares the actual and counterfactual values. This opposite value representation was not observed in the VS population. Previous studies have shown that the OFC is involved in subjective feelings of decision outcome evaluation such as relief and regret, which are generated by the comparison between actual and counterfactual values. Taken together, our findings reveal a gradient in the capability of processing counterfactual value from the cortical to subcortical reward systems, and suggest the key role of the OFC in decision outcome evaluation.

Title: Suboptimal inference inverts the bias-variance trade-off in decisions with asymmetric evidence

Authors: *T. EISSA[1], J. I. GOLD[3], K. JOSIC[4], Z. P. KILPATRICK[2];
[2]Dept. of Applied Mathematics, [1]Univ. of Colorado Boulder, Boulder, CO; [3]Dept Neurosci, Univ. Pennsylvania, Philadelphia, PA; [4]Mathematics, Univ. of Houston, Houston, TX

Abstract: Solutions to challenging inference problems are often subject to a trade-off between bias (being wrong) that is minimized with complex strategies and variance (being noisy) that is minimized with simple strategies. However, when strategies are suboptimal but complex, the implications of the bias-variance trade-off are unclear. To better understand sources of errors in human suboptimal inference, we examined people's responses in a two-alternative forced choice task for which each choice had asymmetrically available evidence. Unlike most decision tasks, asymmetric evidence direct impacts evidence weights of the ideal Bayesian observer, resulting in choice asymmetries (i.e., a tendency to chose one alternative over the other across all trials), even when the alternatives are equally likely. Human choice strategies were individually variable and reflected both Bayesian-like as well as heuristic decision strategies. These suboptimal strategies displayed an inversion of the classic bias-variance trade-off: subjects who used more complex, but imperfect, Bayesian-like strategies tended to have lower response variance but excessive biases because of incorrect tuning to latent task features, whereas subjects who used simpler heuristic strategies tended to have higher variance but minimal biases. This inverted form of bias-variance trade-off followed from the differences in the two strategies: suboptimalites in Bayesian-like strategies involved mistuned estimates of task-relevant latent variables, which led to excess choice biases without adding choice variability. Suboptimalities in simple heuristic strategies that did not infer latent variables tended to add variability that also smoothed out choice asymmetries. Our results highlight how breaking the symmetry of standard decision tasks and considering the diversity of strategies used in large subject cohorts can reveal novel and unexplored relationships between strategy complexity, bias-variance balance, and the sources of human errors.

Title: Rewards elicit choice reactivation for credit assignment

Authors: *C. D. CARRASCO, Y. ZHANG, S. LUCK, E. BOORMAN;
Univ. of California, Davis, Davis, CA

Abstract: The process of identifying what set of choices leads to an outcome, known as credit assignment, can be formalized as occurring in a model-free or a model-based manner. In the model-free case, reward is thought to be tied back to the most recent choices through eligibility traces that weigh these actions with an exponential decay over time. In the model-based case, when the choice and outcome are separated by a sufficient delay, it is theorized that a reactivation of a causal choice's representation triggered by an outcome is needed for a given choice-outcome association to form through Hebbian plasticity. However, if and when this reactivation occurs during learning is still unknown.
In order to test for reactivation of neural representations associating outcomes with choices separated in time, we had participants perform a decision-making task where they had to gamble between two stimulus options (faces and houses) which predicted rewards with slowly drifting and independent probabilities. For each of these stimuli participants received feedback as to whether their choice led to reward and if the unchosen stimulus would have led to reward. Using electroencephalography, we generated event related potentials (ERPs) while participants performed this task that were time locked onto stimulus presentation, choice, and feedback portions of the task. We then used these ERPs to train a series of support vector machines to test if we could identify a reactivation of neural representations tied back to a specific stimulus choice.
Preliminary behavioral results (N = 16) as predicted by reinforcement learning theory, showed that subjects learned from both the experienced and counterfactual outcomes, with effects decaying over time when performing logistic regression analyses ($p < .05$). Neural results suggest a neural reactivation of the choice identity, specifically at the time its feedback is delivered (200 - 400 ms), to form associations between favorable outcomes and chosen stimuli. However, we did not find evidence that these representations were the same as sensory representations measured at stimulus presentation. There was no significant reactivation triggered by counterfactual feedback. Our results suggest that model-based credit assignment indeed elicits a reactivation of neural representations in order to form associations between choices and delayed outcomes at times of feedback, but that these neural representations may be distinct from purely perceptual representations of a given stimulus.

Title: Speed-accuracy tradeoffs in a disinhibition-based neural circuit model of decision-making

Authors: *B. SHEN[1], K. LOUIE[2,1], P. GLIMCHER[1,2];
[1]Neurosci. Inst., NYU Grossman Sch. of Med., New York, NY; [2]Ctr. for Neurosci., New York Univ., New York, NY

Abstract: Objective: Speed-accuracy tradeoffs (SAT) in decision-making have long been a phenomenon of interest in psychology and neuroscience. As a signature of decision dynamics, the SAT has been considered a necessary benchmark for neural decision circuits but how such dynamics arise is unknown.

Sequential models of decision-making predict behavioral SAT on the assumption of the shifting of decision criteria. However, this assumption is contradicted by recent neurophysiological findings on neural decision thresholds and does not capture the empirical evidence for baseline elevation or gain tuning in neural dynamics. Here we examine how well a novel biologically-based circuit - the local disinhibition decision model (LDDM) - captures the behavioral and neural signatures of SAT across different datasets. Methods: The LDDM implements recurrent excitation and global gain-control inhibition drawn from existing models and incorporates a biologically plausible element of local disinhibition that governs "top-down" control of the network. The model was implemented as a dynamical system capturing firing rate responses. We tested this model in capturing the behavioral and neural dynamics in a range of empirical datasets: 1) behavior and neural dynamics of SAT in monkeys (Heitz and Schall, 2012; Hanks et al., 2014; Thura & Cisek, 2016, 2017), 2) SAT under individual differences in working memory (Heitz and Engle, 2007), and 3) causal manipulation of NMDA antagonism on the behavior of SAT (Shen et al., 2010). Results: We show that the LDDM captures the behavioral tradeoff between reaction time (RT) and choice accuracy by controlling the intensity of local disinhibition during the process of decision making. The best-fitting models to the behavior capture the neural dynamics of baseline elevation and increased gain across different datasets. Increasing the network recurrent excitation, a parameter related to working memory, steepens the slope of accuracy log-odds as a function of RT, consistent with the empirical findings on working memory. Reducing excitatory connectivity as an analog of NMDA antagonism predicts slower and more accurate performance, consistent with the empirical causal manipulation results. Conclusion: We find that local disinhibition in a biologically plausible decision circuit with recurrent excitation and global inhibition captures a broad range of behavioral and neural SAT dynamics. These findings show that different SAT characteristics such as baseline elevation and increased gain can arise from a single circuit mechanism, highlighting the critical role of disinhibition in biological decision-making.

Title: Monkeys appear to detect abstract order in randomness

Authors: *Y. JIN[1], G. G. JENSEN[2], J. P. GOTTLIEB[4], V. P. FERRERA[3];
[2]Psychology, [3]Neurosci., [1]Columbia Univ., New York, NY; [4]Neurosci., Columbia Univ. Med. Ctr., New York, NY

Abstract: An animal's survival often depends on learning features of the environment that predict reward, and distinguishing those learnable features from others that are not predictive. However, subjects often mistake accidental patterns for learnable ones and phenomena like auto-shaping and past-trial biases

suggest that animals impose spurious structures onto objectively random events. Those phenomena of spurious learning are examples of innate approach behaviors that can be explained by model-free reinforcement learning (RL). However, it is unknown to what extent animals also impose model-based representational structures onto unstructured feedback when presented with more abstract cognitive tasks. Therefore, we tasked monkeys (N=3) with discovering the implicit ordering of sets comprising 5 pictorial stimuli. In the case of "learnable" lists (indicated here by the letter "L"), the stimuli were implicitly ordered in a way that could be inferred by trial and error. When presented pairs from the L list, a reward was given only if the monkey chose the image with the higher rank. In the "unlearnable" case (indicated by the letter "U"), feedback was delivered at random regardless of which image the monkey chose. Both L and U lists comprised 5 images. Each day, 2 lists of novel images were presented with L and U trials randomly interleaved. We replicated prior results that monkeys reliably learned the implicit order of L lists. Surprisingly, we also found that monkeys behaved as though some ordering existed among items from U lists even though the reward scheme did not incentivize subjective ordering. They showed consistent preferences that were stable over the course of an entire behavioral session. In simulations, we found that a model-free RL algorithm (Q-learning) also displayed a degree of consistent subjective ordering among U list items. Under a follow-up task designed to break subjective preferences by giving rewards more frequently to whichever item was selected less often, Q-learning failed to show spurious learning, but monkeys still showed preferences indicative of a subjective ordering. Our results suggest that the spurious learning extends beyond reward-driven conditional learning, a result that is best understood in terms of more cognitive model-based learning mechanisms.

Title: Assessment of risk aversion in depression and anxiety by computational modeling based on the Cumulative Prospect Theory

Authors: *K. HAGIWARA, C. CHEN, H. LEI, M. HIROTSU, T. MATSUBARA, S. NAKAGAWA; Div. of Neuropsychiatry, Dept. of Neurosci., Yamaguchi Univ., Ube-shi, Japan

Abstract: Both depression and anxiety have been associated with risk aversion in decision-making, but the underlying cognitive computational mechanisms remain uninvestigated. Furthermore, given the high comorbidity between depression and anxiety, their independent association with risk aversion is unclear and no study has evaluated them simultaneously. In the present study, we set out to investigate the underlying cognitive computational mechanisms of risk aversion in depression and anxiety using a value-based decision-making task and computational modeling based on the Cumulative Prospect Theory. We also aimed to specify the unique versus common mechanisms of risk aversion in depression and anxiety.

This study was conducted with the approval of the Ethics Review Committee of the Yamaguchi University Hospital. 56 healthy subjects conducted a decision-making task to maximize the amount of reward, considering both the amount of money won and the probability of winning. In model-based analysis, we estimated risk aversion due to a concave utility function (λ, a power function) and risk aversion due to nonlinear probability weighting (γ, the one-parameter Prelec weighting function) for each subject, respectively. Depression and anxiety were measured by BDI-II and STAI state anxiety subscale. Correlation analysis showed a significant positive correlation between depression/depression-pure (BDI-II without anxiety-related items) and γ, and no correlation between depression/depression-pure and λ, and anxiety and γ/λ. Partial correlation analysis showed that the significant correlation between depression/depression-pure and γ remained after controlling anxiety, and a positive correlation trend was observed between anxiety and λ after controlling depression. To our best knowledge, this is the first study to assess risk aversion due to a concave utility function and nonlinear probability weighting separately for depression and anxiety using a computational modeling approach. Depression is independently associated with underweighting of small probabilities and overweighting of large probabilities. We are currently recruiting clinical patients to confirm the above findings. By using computational models based on decision-making theories, the current study may improve our understanding of decision-making deficits in depression and anxiety.

Title: Rats infer hidden-states in a temporal wagering task

Authors: *A. MAH[1], S. SCHIERECK[1], V. BOSSIO[2], C. M. CONSTANTINOPLE[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Columbia Univ., New York, NY

Abstract: A principle of modern decision theories is reference dependence, in which the subjective value of a reward is computed relative to an internal reference point that is thought to reflect outcome expectations. Previous work has often assumed that reference points are retrospective, deriving directly from past experiences. Here, we use behavioral modeling to show that rats use inference to compute and switch between multiple reference points. We have designed a behavioral paradigm with partially-

observable states - blocks of trials offering small (low blocks) or large rewards (high blocks). Rats must determine how long to wait for uncertain rewards, providing an explicit behavioral readout of a rat's subjective value of rewards. Rats' wait times are sensitive to the reward volumes and also the block structure: rats wait longer for the same volume of water reward in low blocks compared to high blocks. We developed computational models based on optimal foraging theory that instantiate retrospective or inferential strategies for computing the reference point. Our high-throughput, semi-automated training facility generates thousands of trials from dozens of rats per week, which allows for well-powered model fits across a large population of rats. Using model comparison, we found that inferential computational models better describe the rats' wait-time data (74 out of 74 rats). The inferential model outperforms the retrospective model most strongly at block transitions, consistent with a sudden change in the inferred block. We corroborated these results using complementary analyses of latency to start trials, which also covaries with blocks. Our models allow us to discriminate rats' behavioral strategies, and estimate latent cognitive variables underlying decision-making processes, such as an internal reference point that reflects the learned opportunity cost of time. We apply these models to a variety of problems in value-based decision making, including the role of lOFC in hidden-state inference and hormonal regulation of decision-making.

Title: Insight and compensation under distorted perception

Authors: *A. MIHALI[1], M. BROEKER[2], G. HORGA[3];
[2]Psychiatry, Teachers Col., [3]Psychiatry, [1]Columbia Univ., New York, NY

Abstract: Insight is a complex form of metacognition that denotes an agent's ability to recognize the extent to which their subjective internal perceptual experiences track with the actual states of the external world. Insight can help discern which conscious experiences will be used to alter our existent beliefs and which will be discounted as "not real", for instance dreams, illusions or hallucinations. To induce strong perceptual distortions, we created a task based on a variant of the motion after-effect (MAE) illusion. To measure insight in a quantitative manner, we quantified participants' ability to report beliefs in which they demonstrate compensation for their perceptual distortions. Healthy participants compensated for the MAE illusion in the condition in which they were asked to infer the actual direction of motion ('Believe' condition) as opposed to reporting perceived motion ('See ' condition). In a second experiment, a parametric choice of the test stimuli allowed us to apply an optimal-observer model to the participants' responses and confidence reports which provided a good fit to the data. This model revealed that a

possible mechanism for belief compensation is updating the category prior in the 'Believe' condition. Furthermore, confidence reports, reaction times and pupil dilation patterns shifted in tandem with the psychometric curves, suggesting changes in perceptual uncertainty during belief compensation and supporting an interpretation in terms of adjustments at an intermediate perceptual-decision stage, consistent with the model. In sum, we show that healthy individuals may plausibly achieve effective insight – and compensate for distorted perception – through adjustments in perceptual-decision variables such as prior beliefs.

Title: Monkeys learn to maximize the accumulation of tokens associated with the preferred outcome in a reinforcement learning task

Authors: *D. BURK, B. AVERBECK;
NIH, Bethesda, MD

Abstract: Reinforcement learning (RL) is a theoretical framework that describes how agents learn to select options that maximize rewards and minimize punishments over time. In many RL tasks, reward size and/or probability are varied, and animals learn to make choices to maximize the total reward received. We often make choices to obtain secondary reinforcers that can later be exchanged for primary reinforcers. In the present study we have examined how monkeys learn, through secondary reinforcers defined by tokens, to make choices that maximize either juice or water rewards. At the beginning of each task block we introduce unfamiliar visual images, each associated with a fluid type and quantity. In each trial, after a baseline fixation period, we present two of the images to the monkeys. They make a saccade to one of the images to indicate their choice. We associate four different outcomes with the images such that the monkeys receive either 3 juice tokens (orange), 1 juice token (orange), 3 water tokens (blue) or 1 water token (blue) after choosing the corresponding image. The monkeys learn from the outcomes of their choices, represented by a change in the number of tokens on the screen. Tokens are accumulated across trials and cashed out after a variable number of correct trials. Preliminary data show that the monkey learned to primarily select images that delivered juice tokens, even when the offer pair included an option with more water tokens than juice tokens. Thus, they had a strong preference for juice tokens, that were later traded for primary juice rewards. Furthermore, trial abort frequency was higher for trials in which only water tokens were available, which suggests that those choices were relatively aversive. Together, these results show that monkeys can learn to associate differently colored tokens with different liquid reward outcomes, and they can learn to choose images that maximize accumulation of tokens for the preferred outcome. This task allows us to explore how traditional RL models do and do not capture

learning from secondary reinforcers when there is more than one, as is typical in a real-world environment.

Title: Inferring cross-region differences in mammalian interneuron physiology using single-cell transcriptomics

Authors: A. HOGGARTH[1], A. NIGAM[2], F. M. KRIENEN[5], Y. CHEN[3], S. MCCARROLL[6], S. I. HILL[4], ***S. TRIPATHY**[4];

Abstract: Single-cell transcriptomics offers a potentially powerful way to bridge single cell gene expression with cellular phenotypes such as in vitro electrophysiology and morphology.
Here, we used data from the emerging Patch-seq method to infer electrophysiological features from single-cell transcriptomes using multi-modal datasets collected from publicly-available data from 3486 interneurons collected from the mouse visual cortex. Specifically, we identified over 500 genes strongly correlated with within-cell type heterogeneity in electrophysiological features such as action potential width, rheobase, and input resistance.
We applied these methods to infer cross-region gradients in cellular phenotypes using unimodal single-nucleus transcriptomics data collected from different cortical regions from mice, non-human primates, and humans. Based on region-specific patterns in gene expression, we inferred that interneurons in primary sensory areas are likely to be more electrically excitable, with greater maximum firing rates and more narrow action potential widths, relative to orthologous interneuronal cells types present in association cortices. These cross-region differences are inferred to arise based on the expression of key ion channel genes, such as KCNC1 and KCNC2 (Kv3.1 and Kv3.2), and calcium binding proteins, such as parvalbumin. In vitro experiments to confirm these cross-regional gradients in cellular physiology are ongoing.
In summary, this work suggests novel patterns of interneuron functional specialization in different areas of the neocortex.

Title: Characterizing neuronal diversity in intrinsic properties across non-human primate species and cortical areas

Authors: *M. FEYERABEND[1], E. S. KUEBLER[1], M. S. JIMENEZ-SOSA[1], J. K. SUNSTRUM[1], S. MESTERN[1], S. MATOVIC[1], M. WIEDERMAN[1], K. PRADEEPAN[1], S. EVERLING[1], A. NEEF[2], J. F. STAIGER[3], D. A. LEWIS[4], G. GONZALEZ-BURGOS[4], W. INOUE[1], J. C. MARTINEZ-TRUJILLO[1]; [1]Univ. of Western Ontario, London, ON, Canada; [2]MPI For Dynamics and Self-Organization, Göttingen, Germany; [3]Inst. für Neuroanatomie, Georg-August-Universität, Göttingen, Germany; [4]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Higher order mental representations underlying working memory function, are believed to arise in primates, with the development and expansion of the granular prefrontal cortex (PFC). For example, in vivo extracellular recordings from behaving non-human primates (NHPs) have shown that persistent firing representing the contents of working memory can be found in lateral PFC, but is absent in early sensory areas such as primary visual (V1) cortex. However, the mechanistic basis of potentially unique primate PFC circuitry remains speculative partly due to the lack of data on the biophysical and morphological features of diverse cell-types directly obtained from different brain areas of NHPs. Furthermore, potential differences in PFC single-neuron properties among different NHP species (e.g. New-world monkey Marmoset and old-world monkey Macaque) remain unknown. The latter is an important question, as marmosets are increasingly being used as models for human cognition, yet their neural correlates remain poorly documented. In the international consortium funded by NeuroNex, we aim to characterize the biophysical and microanatomical properties of cortical neurons from the dorsolateral (DL)PFC and V1 of multiple NHP species (*Macaca mulatta, Macaca fascicularis, Callithrix jacchus*) using patch clamp electrophysiology in acute brain slices. We systematically collect membrane voltage responses to different characterization protocols and analyzed intrinsic neural properties, similar to the Allen Institute Cell Type Database. To date, we accumulated about 300 electrophysiological recording. In addition, we examine morphological features including dendritic type and laminar location of reconstructed neurons. Some of these data can be browsed on the website 'PrimateDatabase.com', a collection of publicly available NHP intracellular recordings. In addition, the neuronal morphology of a proportion of recorded cells have been digitally reconstructed. The goal of our project is to provide data that will allow the search for differences in intrinsic properties across cortical areas and across NHP species and enable modelling studies of working memory using realistic single neurons simulations.

Title: Trial-to-trial variability of spiking delay activity in prefrontal cortex constrains burst-coding models of working memory

Authors: *D. LI[1], C. CONSTANTINIDIS[3], J. D. MURRAY[2];
[1]Yale Univ., NEW HAVEN, CT; [2]Dept. of Psychiatry, Yale Univ., New Haven, CT; [3]Biomed. Engineering,, Vanderbilt Univ., Nashville, TN

Abstract: A hallmark neuronal correlate of working memory (WM) is stimulus-selective spiking activity of neurons in prefrontal cortex (PFC) during mnemonic delays. These observations have motivated an influential computational modeling framework in which WM is supported by persistent activity in stable attractor networks. Recently this framework has been challenged by arguments that observed persistent activity may be an artifact of trial-averaging, which potentially masks high variability of delay activity at the single-trial level. In an alternative scenario, WM delay activity could be encoded in bursts of selective neuronal firing which occur intermittently across trials. However, this alternative proposal has not been tested on single-neuron spike-train data. Here, we developed a framework for addressing this issue by characterizing the trial-to-trial variability of neuronal spiking quantified by Fano factor (FF). By building a doubly stochastic Poisson spiking model with biophysically constrained parameters, we first demonstrated that the burst-coding proposal implies a significant increase in FF positively correlated with firing rate, and thus loss of stability across trials during the delay. Simulation of the corresponding spiking cortical circuit WM models further confirmed that FF is a sensitive measure that can well dissociate distinct WM mechanisms. We then tested these predictions on datasets of single-neuron recordings from macaque prefrontal cortex during three WM tasks of different modalities. In sharp contrast to the burst-coding model predictions, in each one of these tasks, we only found a small fraction of neurons showing increased WM-dependent burstiness, and stability across trials during delay was actually strengthened in empirical data. Therefore, reduced trial-to-trial variability during delay provides strong constraints on the contribution of single-neuron intermittent bursting to WM maintenance. Our study provides a benchmark in terms of across-trial stability for future computational modeling studies of WM.

Title: Temporal structure of persistent activity in macaque lateral prefrontal cortex during a naturalistic working memory task

Authors: *M. ROUSSY[1], A. N. BUSCH[1], M. KHAKI[1], R. LUNA[1], A. J. SACHS[2], L. PALANIYAPPAN[1], L. E. MULLER[1], J. C. MARTINEZ-TRUJILLO[3];

Abstract: Neural activity in the primate lateral prefrontal cortex (LPFC) has been causally linked to working memory (WM)—the maintenance and manipulation of task relevant information for short periods of time. Some researchers have described this pattern of activity as persistent firing. One issue that remains unclear, due to traditionally limited numbers of simultaneously recorded neurons, is whether persistent firing has a spatiotemporal structure within populations of LPFC neurons. Here, we hypothesize that precise temporal sequences of individually active neurons enable persistent firing and thus coding of WM in LPFC. We report precisely structured and behaviorally relevant temporal sequences of spiking activity in the LPFC of two macaque monkeys performing a naturalistic WM task in a virtual environment. We implanted two 96-channel Utah microelectrode arrays in each animal (areas 9/46 dorsal and ventral to the principal sulcus). During the task, a target was presented in 1 of 9 locations in a virtual circular arena. The target then disappeared and following a 2 second delay period, subjects navigated to the cued target location using a joystick.
We analyzed responses of 7116 isolated units (median 201 per session). Spiking activity showed clear temporal structure, with short bursts of action potentials occurring in individual units. When ordered by peak firing time, these short bursts formed clear “bands” spanning the duration of the trial. We next sought to understand whether these temporal sequences of bursts were related to memory content, so we developed a novel computational method to analyze spike sequences across trials. This method, which works by representing individual sequences as a complex-valued vector and performing dimensionality reduction on the resulting covariance matrix, allows efficient unsupervised discovery of consistent spike patterns across trials. With this new method, we find that sequence structure, independent from firing rate information, is related to target location in the WM task. Consistent with this, many individual neurons also fired at consistent times during the WM trial. The relation between temporal structure and WM content was less consistent on incorrect trials and following injections of ketamine at subanesthetic doses (0.25-0.8 mg/kg), which disrupts task performance. Taken together, these results reveal a striking spatiotemporal organization of spiking activity during WM in LPFC neuronal ensembles. They also suggest that persistent firing in LPFC has a precise temporal structure that allows neuronal ensembles to robustly maintain and manipulate task relevant information in the absence of sensory inputs.

Title: Role of calcium-related schizophrenia risk gene CACNA1C in primate dorsolateral prefrontal cortex layer III microcircuits

Authors: *D. DATTA[1], S. YANG[1], F. M. KRIENEN[2], S. MENTONE[1], Y. M. MOROZOV[4], S. MCCARROLL[3], M. WANG[6], A. F. ARNSTEN[5];

Abstract: Calcium dysregulation is increasingly linked to cognitive disorders, e.g. calbindin-containing pyramidal cells are most vulnerable to Alzheimer's degeneration, and calcium channels are a focus of genetic insults. Gain of function mutations in the *CACNA1C* gene encoding the l-type calcium channel, Cav1.2, are a risk factor for schizophrenia, and are associated with impaired working memory and reduced connectivity of the dorsolateral prefrontal cortex (dlPFC). However, it is not known why a gain of function mutation in Cav1.2 would impair dlPFC function. The current study examined the localization and function of Cav1.2 in the rhesus monkey dlPFC, and related findings to transcriptome signatures in human dlPFC neurons. Previous studies in monkeys showed that layer III dendritic spines contain the molecular machinery for cAMP to magnify internal calcium release near NMDAR-GluN2B synapses, where moderate levels sustain neuronal firing, but high levels weaken connectivity via opening of nearby K^+ channels. These pyramidal cells also express calbindin when young, but lose it with age. The current study used immunoEM and found extensive labeling of Cav1.2 on dlPFC layer III dendritic spines and shafts. Cav1.2 in spines were predominantly localized on the plasma membrane near glutamatergic synapses, often in association with the smooth endoplasmic reticulum spine apparatus where they may contribute to the magnification of calcium release. These findings were consistent with transcriptomic expression patterns in human dlPFC, where CACNA1C (Cav1.2) expression was highest in the subset of layer II/III pyramidal cells that also express very high levels of GRIN2B (NMDAR-GluN2B) and CALB1 (calbindin), likely needed to regulate high levels of cytosolic calcium. We also examined the physiological effects of Cav1.2 manipulation on dlPFC "Delay cells" in rhesus monkeys performing a working memory task. We found an inverted U dose-response, where either too little or too much Cav1.2 signaling reduced Delay cell firing, and a low dose of the Cav1.2 blocker, diltiazem, enhanced persistent firing, likely by reducing calcium-cAMP-K^+ channel signaling to strengthen connectivity. In sum, these data reveal a population of dlPFC pyramidal cells with extensive calcium signaling essential to persistent

neuronal firing during working memory, but where excessive signaling actually reduces firing. These data help to explain why gain-of-function mutations in *CACNA1C* would be linked to dlPFC cognitive deficits and increased risk of schizophrenia, and why loss of calbindin with age may be especially damaging to this subset of pyramidal cells with high levels of Cav1.2 signaling.

Title: A dopamine gradient controls access to distributed working memory in large-scale monkey cortex

Authors: *S. FROUDIST-WALSH[1], D. P. BLISS[1], X. DING[1], L. RAPAN[2], M. NIU[2], K. KNOBLAUCH[3], H. KENNEDY[3], N. PALOMERO-GALLAGHER[2], X.-J. WANG[1];

Abstract: Dopamine is required for working memory, but how it modulates large-scale cortical networks is less known. Here we report that dopamine D1 receptor density per neuron, measured by in-vitro receptor autoradiography, displays a macroscopic gradient that increases along the macaque monkey's cortical hierarchy. This gradient is incorporated in a connectome-based large-scale cortex model endowed with multiple neuron types. The model captures an inverted U-shaped dependence of working memory on cortical D1-receptor stimulation, and spatial patterns of persistent activity observed over 90 experimental studies. Moreover, we show that dopamine is crucial for filtering out irrelevant stimuli by enhancing inhibition from dendrite-targeting calbindin/somatostatin interneurons. Our model revealed that an activity-silent memory trace can be realized by short-term synaptic facilitation of long-range connections, and adjusting dopamine levels in the cortex could induce a switch from the activity-silent state to active persistent activity. Taken together, our work represents a cross-level understanding from molecules and cell types to recurrent circuit dynamics underlying a core cognitive function distributed across the primate cortex.

Title: Interactions between synaptic inhibition and excitatory synaptic drive modulate gamma oscillation frequency in prefrontal and parietal cortex networks

Authors: *G. GONZALEZ-BURGOS[1], T. MIYAMAE[1], N. REDDY[1], S. DAWKINS[1], J. ENWRIGHT[1], C. CHEN[2], A. HILL[3], B. ERMENTROUT[1], D. LEWIS[1];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Carnegie Mellon Univ., Pittsburgh, PA; [3]Wheaton Col., Wheaton, IL

Abstract: The primate dorsolateral prefrontal (DLPFC) and posterior parietal (PPC) cortices are high-order nodes in the network of cortical areas mediating working memory (WM). These regions interact functionally during WM tasks and are reciprocally connected by projections from layer 3 pyramidal cells (L3PCs). Functional interactions across the primate cortex depend on superficial layer gamma oscillations (γOs). Hence, L3PC properties that may contribute to γO production are crucial for DLPFC-PPC interactions during WM.
The peak frequency of γOs observed during WM tasks is higher in monkey DLPFC relative to PPC (J Cogn Neurosci 32:2024). Since γOs seem associated with information maintained in WM, and are correlated with spiking activity during various phases of WM tasks, the regional differences in γO frequency and the mechanisms generating these differences may be critical for information processing in WM.
γOs are thought to be generated via rhythmic $GABA_AR$-mediated synaptic inhibition, and γO frequency depends strongly on the properties of inhibitory post-synaptic currents ($GABA_AR$-IPSCs) on L3PCs (Cereb Cortex 25:4076). Moreover, L3PCs show ~2 times greater number of dendritic spines in monkey DLPFC than PPC (J Neurosci 39:7277), suggesting that stronger excitatory drive from local recurrent excitation may provide a substrate for higher γO frequency in DLPFC.
Here, we studied $GABA_AR$-IPSCs using patch clamp recordings from L3PCs in acute slices from macaque monkey DLPFC and PPC. No $GABA_AR$-IPSC properties differed between DLPFC and PPC L3PCs. Moreover, gene expression for $GABA_AR$ subunits known to be localized synaptically did not differ between DLPFC and PPC L3PCs, consistent with the lack of differences in synaptic physiology.
In a subset of the L3PCs in which $GABA_AR$-IPSCs were studied, we quantified dendritic spines in basal dendrites. DLPFC L3PCs exhibited higher dendritic spine numbers, suggesting that while $GABA_AR$-IPSC features are similar, excitatory synaptic drive is stronger in DLPFC.
Finally, using computational simulations, we assessed γO properties in a recurrent network of excitatory (E) and inhibitory neurons in which the strength of excitatory synaptic coupling between E cells was manipulated. Preliminary results suggest that increases in E-E synaptic coupling (primarily the NMDAR-mediated component) promote an increase in γO frequency as the $GABA_AR$-IPSC properties were kept

constant.
Our data suggest that whereas the mechanisms of $GABA_AR$-mediated inhibition are highly conserved between DLPFC and PPC, stronger drive from local recurrent excitation may produce inhibition-based rhythms with higher frequency in the DLPFC network.

Title: Chemogenetic manipulation of astrocytes in prelimbic cortex during spatial working memory.

Authors: *L. A. NEWMAN[1], J. BONANNO[3], **J. L. LIN**[2], J. A. D'ORAZIO[2], K. U. TANG[2], H. TANAKA[2], T. ZIMMER[2], S. KUKRETI[4];
[1]Psychological Sci., [2]Vassar Col., Poughkeepsie, NY; [3]Yale Univ., New Haven, CT; [4]Spackenkill High Sch., Poughkeepsie, NY

Abstract: Astrocytes are glial cells within the brain that modify blood flow, energy production, neurotransmitter levels and ionic balance. All of these functions influence synaptic plasticity, a critical component of memory. However the specific role of astrocytes in memory is still being characterized. Our study focuses on the relationship between astrocyte activity and spatial working memory. We employed a chemogenetic technique (Designer Receptors Exclusively Activated by Designer Drugs, or DREADDs) to activate astrocytes in the prelimbic cortex of rats during a delayed spontaneous alternation task. Bilateral injections of either hM3D(Gq)-mCherry with a GFAP promoter or an GFAP-eGFP control virus (AAV, serotype 5) were given into the prelimbic cortex of Long Evans male and female rats. After 2 weeks to allow for viral expression, rats underwent delayed spontaneous alternation testing in which they received intraperitoneal injections of either the corresponding hM3D(Gq) receptor agonist, Compound 21 (C21), or the vehicle 30 minutes before delayed spontaneous alternation testing in a counterbalanced order. Extra-maze cues were changed to provide novel stimuli for each testing session. Preliminary results unexpectedly showed 3 mg/kg of C21 significantly inhibited the number of arm entries made as compared to 1 mg/kg of C21. With the 1 mg/kg dose of C21 there is an interaction of sex and DREADDs activation on spatial working memory such that males showed improvements and females showed impairments when astrocytes are activated. Morphological characterization of the astrocytes and GFAP staining suggest possible astrocytic sex differences in this study. Our research indicates astrocytes play an integral role in memory processes in the prefrontal cortex and are a novel target for treatment in neurodegenerative diseases.

Title: Synaptic correlates of working memory: spectral DCM study with MEG data

Authors: *A. SANTO-ANGLES, K. K. SREENIVASAN;
Div. of Sci., New York Univ., Abu Dhabi, United Arab Emirates

Abstract: Working memory (WM) has been largely associated with persistent neural activity in prefrontal circuits. A key question is how different neural populations within these circuits contribute to meso- and macro-level WM activity and how changes in these populations drive behavior. Biophysical models and monkey single-unit studies continue to shed light on these questions, but it is unclear the degree to which these findings translate to humans. Here, we used dynamic causal modelling (DCM) of MEG data to infer prefrontal synaptic changes supporting WM in humans. Subjects (n = 26) performed a delayed continuous report task. Behavioral responses were fitted with a 3-component mixture model to classify individual responses into one of three trial types: accurate, inaccurate, and swap (i.e., transposition) error. We observed greater synchronization in theta and low alpha in accurate compared to inaccurate and swap trials. Source reconstruction of the MEG signal identified a prefrontal source in superior frontal gyrus whose 12-Hz activity significantly varied as a function of trial type; this source was subsequently used to fit a spectral DCM with a canonical microcircuit model. Subject- and trial-specific DCMs were inverted using the grand-averaged DCM parameters as priors. Model estimates were evaluated using Parametric Empirical Bayes (PEB). In accord with biophysical circuit models of WM as well as recent investigations into layer-dependent activity in humans and monkeys, we found that activity during the WM delay for accurate trials was associated with (i) increased excitability of superficial pyramidal cells and (ii) decreased excitability of inhibitory interneurons. Additionally, these trials also exhibited (iii) reduced coupling strength from inhibitory interneurons to spiny stellate cells, and (iv) reduced coupling from superficial to deep pyramidal cells. Critically, the DCMs differed for inaccurate and swap error trials. Although both types of error trials displayed increased excitability of superficial pyramidal cells, as in accurate trials, the reduction of excitability in inhibitory interneurons was notably weaker in inaccurate trials, while swap error trials exhibited increased, rather than reduced, coupling from superficial to deep pyramidal cells. These results indicate that, despite similar oscillatory profiles, inaccurate responses and swap errors arise from distinct neurobiological substrates. Importantly, this work also demonstrates the feasibility of DCM approaches to measure synaptic-level modulations in humans.

Title: Complementary roles of AMPA and NMDA receptors in a connectome-based model of conscious access in monkey cortex

Authors: *U. KLATZMANN[1], S. FROUDIST-WALSH[2], D. BLISS[4], P. THEODONI[3], J. MEJIAS[5], M. NIU[6], L. RAPAN[6], N. PALOMERO-GALLAGHER[7], C. SERGENT[8], S. DEHAENE[9], X.-J. Abstract: When consciously perceived, a stimulus triggers a sudden non-linear bifurcation event across multiple cortex areas called 'ignition.' In contrast, the same stimulus might only drive transient linear activity largely restrained to sensory areas when not detected. Computational models of ignition have mainly focused on local cortical regions, neglecting the large-scale nature of the phenomenon. In contrast, large-scale models of the cortex have failed to produce critical aspects of ignition, such as its rapid non-linear increase in activity and strong, sustained stimulus-related activity throughout the cortex. Here, we develop a large-scale model of the macaque cortex and show how feedforward connections targeting excitatory populations with fast AMPA receptors and feedback connections targeting essentially inhibitory populations with slow NMDA receptors play an essential role in signal propagation from sensory to associative areas; while preventing sustained activity in sensory areas. Our model predicts, counterintuitively, that fast responding sensory areas contain a higher ratio of NMDA to AMPA receptors compared to higher cortical areas that show slow, sustained activity. We validate this prediction using in-vitro receptor autoradiography data. Finally, we show how this model can account for various behavioral and physiological effects linked to consciousness. Together, these findings help us understand how a large-scale network of the cortex can exhibit bifurcation ignition-like events and how gradients of receptor densities along the cortical hierarchy contribute to such higher cognitive functions.

Title: The effects of sex on working memory in Fischer F344 rats

Authors: *T. GOHAR[1], S. DUNN[2], E. A. WEST[3];
[1]Rowan Univ. Sch. of Osteo. Med., Stratford, NJ; [3]Cell Biol. and Neurosci., [2]Rowan Sch. of Osteo. Med., Stratford, NJ

Abstract: Working memory is the online retention of a small amount of information that helps to guide behavior during a cognitive task. Working memory depends on the hippocampus and its functional connection with the prefrontal cortex. Some studies have reported sex differences in working memory while others suggest no sex difference exists during working memory performance tasks. Patients with early-stage Alzheimer's disease (AD) show impaired working memory. Critically, sex differences have been observed in the prevalence of AD and the rate of cognitive decline. Specifically, women with AD experience a faster cognitive decline compared to men. Addressing underlying sex differences is therefore critical for the development of effective therapeutics. Here, we tested working memory in male (n=8) and female (n=8) Fischer F344 rats using a delayed nonmatch to position (DNMTP) task. The DNMTP task consisted of 3 phases; sample, delay, and choice phase. During the sample phase, the house light was illuminated and one of two levers (e.g. right) extended into the chamber. The rats were required to press the lever for a reward, which then initiated the delay phase. During the delay, all lights extinguished and the levers retracted. After the delay, the house light illuminated and the rats were required to nosepoke to initiate the choice phase. During the choice phase, both levers extended and the rats were required to press the opposite lever (i.e., nonmatch) from the sample phase (e.g., left) to obtain a reward. After training the rats, both the sexes were tested for 3 DNMTP sessions each employing 4 different delays (2-32 seconds) intermixed pseudorandomly with 15 trials/delay. Session 1 consisted of shorter delays, session 2 had relatively longer delays and session 3 had the longest delays. Any trial for which the rat did not press lever during the choice phase was recorded as an omission. The percent correct for each sex was calculated (i) for choice-only trials and (ii) for all trials including the omissions. A two-way repeated-measures ANOVA with sex and delay as factors showed no significant difference in percent correct between male and female rats during the choice-only trials for any of the three sessions. However, when percent correct was obtained from all the trials including the omissions, a significant difference was found during session 1 ($F(1, 14)=8.32$, $p=0.012$). Specifically, females performed better during session 1 but no sex difference was observed later during sessions 2 and 3. Our future aim is to investigate working memory impairments in transgenic rats (TgF344-AD) on this Fischer 344 background strain that is developed to recapitulate AD pathology in both sexes.

Title: Replay detection methods- How can we tell which one is best without a ground truth?

Authors: M. TAKIGAWA[1], M. HUELIN GORRIZ[2], M. TIROLE[3], Y. QIAN[1], ***D. BENDOR**[1]; [1]Univ. Col. London, London, United Kingdom; [2]Inst. of Behavioural Neurosci., Univ. Col. of London, London, United Kingdom; [3]UCL, London, United Kingdom

Abstract: Since the discovery of hippocampal replay almost 30 years ago, replay detection methods have gradually become more advanced and sophisticated. All of these approaches measure the statistical significance of the match between a behaviourally-related template and a replayed sequence, however one important caveat is that these methods operate without a ground truth. For this reason, it is challenging to compare replay detection methods, as while one method may detect more statistically significant events, we do not know if it is "better" as the proportion of false positives may have also increased. Here we present a new framework for addressing this problem, relying on hippocampal recordings from rats exploring two different novel linear tracks. We propose that "true events" should have a match between sequence-based and sequenceless decoding methods (i.e. the track with the significant trajectory is also the track with the larger proportion of posterior probability). Using this framework we can quantitatively compare the detection performance of different replay analysis methods and determine if one approach is indeed better than the rest.

Title: Experience-driven rate modulation is reinstated during hippocampal replay

Authors: *M. TIROLE[1], M. HUELIN GORRIZ[2], M. TAKIGAWA[3], L. S. KUKOVSKA[4], D. A. BENDOR[4];
[1]UCL, London, United Kingdom; [2]Inst. of Behavioural Neurosci., Univ. Col. of London, London, United Kingdom; [3]Inst. of Behavioural Neurosci., [4]Univ. Col. London, London, United Kingdom

Abstract: Replay, the sequential reactivation of a neuronal ensemble, is thought to play a central role in the hippocampus during the consolidation of a recent experience into a long-term memory. Following a contextual change (e.g. entering a novel environment), hippocampal place cells typically modulate their in-field firing rate and shift the position of their place field, providing a rate and place representation for the behavioral episode, respectively. However, replay has been largely defined by only the latter- based on the fidelity of sequential activity across neighboring place fields. Here we show that dorsal CA1 place cells in rats can modulate their firing rate between the replay of two different contexts, mirroring the same pattern of rate modulation observed during behavior. This context-driven rate modulation within replay events was experience-dependent, observable during both behavioral episodes and throughout the subsequent rest period, but not prior to experience. Furthermore, we demonstrate that both the temporal order and firing rate of place cells can independently be used to decode contextual information within a replay event, revealing the existence of two separable but complementary neural representations available for memory consolidation processes.

Title: Replay fields -- single cell measures of tuning to imagined position during replay.

Authors: *J. WIDLOSKI, M. R. KLEINMAN, D. J. FOSTER;
Helen Wills Neurosci. Inst. and Dept. of Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: Hippocampal cells show precise spatial tuning to the animal's position during behavior. During stopping periods, the hippocampus encodes spatially coherent trajectories through the environment called replays that resemble the animal's behavior. Replay has been proposed as a form of virtual experience that supplements real experience for the purposes of learning and planning. However, it is unknown whether the precise spatial tuning of place cells as a function of animal position is preserved as a function of encoded replay position, independent of the animal's location. This is far from obvious, given that replay unfolds at much higher speeds and is likely to involve different mechanisms and circuits. We show that in a 2D environment, spatial tuning is preserved as a function of the encoded position during replay (its

"replay field"), using a leave-one-out analysis that removes the cell's contribution to replay before evaluating its replay field. Replay fields are shown to match place fields on both coarse- and fine-grained measures, including spatial information, field shape and skewness, as well as in the relative positions and peak rates of the primary and secondary fields. Crucially, however, we show that replay fields do not exhibit the overdispersion or excess temporal variance of spiking that is characteristic of place fields, suggesting that firing patterns during replay are well predicted by a spatial, inhomogeneous Poisson process and therefore less subject to covert shifts in attention and context as during behavior. Lastly, we show that similarity between place fields and replay fields is increased if we relax the requirement that replays form smooth trajectories and instead include all spatially coherent activity during stopping periods (encompassing approximately half of all spikes emitted during such periods), demonstrating that tuning to encoded position is a persistent feature not just restricted to times during traditionally-defined replay.

Title: Offline Memory Reactivation Predicts the Consolidation Of Spatially Unbiased Long-Term Cognitive Maps

Authors: *A. GROSMARK[1], F. T. SPARKS[2], M. J. DAVIS[4], A. LOSONCZY[3];
[2]Dept. of Neurosci., [3]Neurosci., [1]Columbia Univ., New York, NY; [4]Inst. for Neurosci., The Univ. of Texas At Austin, Austin, TX

Abstract: Spatial memories which can last a lifetime are thought to be encoded during ‘online’ periods of exploration and subsequently consolidated into stable cognitive maps through their ‘offline’ reactivation. However, the mechanisms and computational principles by which offline reactivation stabilize long-lasting spatial representations remain poorly understood. Here we employed simultaneous fast calcium imaging and electrophysiology to track hippocampal place cells over two weeks of online spatial reward learning behavior and offline resting. Here, we describe that recruitment to persistent network-level offline reactivation of spatial experiences in mice predicts place cells’ future representational stability days in advance of their online reinstatement. Moreover, while representations of reward-adjacent locations are generally more stable across days, offline-reactivation related stability is, conversely, most prominent for reward-distal locations. Thus, while occurring on the tens-of-milliseconds time-scale, offline reactivation is uniquely associated with the stability of multi-day representations which counter-balance the overall reward-adjacency bias, thereby predicting the stabilization of cognitive maps which comprehensively reflect entire underlying spatial contexts. These findings suggest that post-learning

offline-related memory consolidation plays a complimentary and computationally distinct role in learning as compared to online encoding.

Title: A dynamic shift in hippocampal replay length and focus follows spatial reversal learning in rats

Authors: H. DEN BAKKER[1,2], *F. KLOOSTERMAN[1,2,3,4];
[1]Neuro-Electronics Res. Flanders, Leuven, Belgium; [2]Brain & Cognition, KU Leuven, Leuven, Belgium; [3]VIB, Leuven, Belgium; [4]imec, Leuven, Belgium

Abstract: Spatial reversal learning depends on the ability to select behavioral strategies, to learn which behavior is rewarding, and to flexibly change one's behavior as a response to changing reward contingencies. Both the hippocampal long-term memory system and the prefrontal executive system have been shown to contribute to spatial reversal learning.
Reactivation of task-specific neural activity patterns (replay) is thought to be an important neural mechanism to support such flexible behavior. In the hippocampus, reactivation of place cell sequences occurs predominantly during fast, transient "sharp-wave ripple" oscillations. Sharp-wave ripple associated replay is thought to be crucial for spatial navigation and planning when it occurs during awake exploration, and for memory consolidation when it occurs during sleep.
It is still unclear, however, in what way reactivation patterns during sharp-wave ripples differ between awake, rest and sleep periods; how replay properties change as a function of learning and how this affects the interaction between the hippocampus and the medial prefrontal cortex.
Adult Long Evans rats were trained on a plus-shaped maze to follow allocentric or cue-based rules to obtain food reward. An array of tetrodes was implanted in the hippocampus and medial prefrontal cortex to monitor cellular activity and field potentials while the rats were learning and executing the task, as well as during inter-trial intervals and post-task sleep.
Reactivation of spatial locations and trajectories was observed during sharp-wave ripple activity in the hippocampus. As the animals learned spatial rules on the maze, the replay trajectories in the hippocampus became shorter in length, and there was a stronger reactivation of the end platform where the animals found a reward. The medial prefrontal cortex field potential activity peaked following ripples that contain a strong reactivation of the end platform, especially when the rule had been learnt.
Together, these findings suggest that hippocampal activity and its interplay with the medial prefrontal cortex in spatial reversal learning depends strongly on behavioral performance and that memory consolidation may favor either the entire maze or rather focus on the reward sites, depending on the stage of learning.

Abstract: Mice and other animals learn about their environments by integrating information across many experiences. Although the hippocampus supports many forms of learning, its role in memory integration is less understood, including how it determines which experiences to integrate. We hypothesized that mice selectively retrieve memories that facilitate learning, thereby promoting the integration of new information into the retrieved memory trace. To test this, we trained mice on a series of tone discrimination problems whereby mice learn to wait longer in response to a rewarded tone than to an unrewarded tone. The problems were interleaved with probe tests to observe how mice responded to tones across their entire auditory range, and to see how their responses changed after each problem. Mice undergoing 'integration' training, where similar frequencies were used for the rewarded tones in every problem, showed improved discrimination performance and more rapid learning on later problems, while mice undergoing 'non-integration' training showed no improvement. The responses on the probe tests supported the idea that the integration group formed a single memory combining information from all problems, while the non-integration group formed distinct memories of each problem. Additionally, probe responses predicted future performance on novel problems: if mice already preferred the soon-to-be rewarded tone during the preceding probe test, then they learned the problem faster during subsequent training. Furthermore, mice updated their memory less (i.e. similar probe responses before and after learning) if they already preferred the soon-to-be rewarded tone. Calcium imaging of hippocampal CA1 neurons throughout training revealed that memory integration was accompanied by the reactivation of ensembles and activity patterns associated with prior problems. In the integration group, the roster of active neurons changed from session to session early in learning before stabilizing with the repeated reactivation of overlapping ensembles, while no such shift was observed in the non-integration group. Similarly, we saw that individual hippocampal neurons were active at reliable times during individual trials, and that the pattern of activity across all neurons was stable between later training sessions in the integration group but not in the non-integration group. Together, these results suggest that memory

retrieval and the associated reactivation of hippocampal activity states during learning supports the integration of new information into pre-existing memories.

Title: Hippocampal GABAergic cell type selectively controlling local and extra-hippocampal interneurons during sharp-wave ripples

Authors: *G. G. SZABO[1], B. DUDOK[1], W.-H. HOU[2], J. S. FARRELL[1], A. ORTIZ[1], C. VARGA[3], P. MOOLCHAND[1], C. I. GULSEVER[1], T. GSCHWIND[1], G. J. FISHELL[4], M. CAPOGNA[2], I. SOLTESZ[1]; [1]Dept. of Neurosurg., Stanford Univ., Stanford, CA; [2]Univ. of Aarhus, Aarhus, Denmark; [3]Univ. of Pecs, Pecs, Hungary; [4]Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Sharp wave-ripples (SPW-Rs) are short, synchronous population patterns critically involved in learning and memory. Distinct interneuron classes exhibit diverse behaviors during these events including interneurons becoming silent during SPW-Rs. Sources of inhibition silencing these neurons in a SPW-R-timed manner is unknown. Here we identify and characterize in behaving mice a GABAergic cell population that is dedicated to deliver inhibition shortly before and during SPW-Rs and provides selective control over certain hippocampal interneuron subtypes including parvalbumin- and cholecystokinin expressing cells. Unlike other GABAergic neurons, these cells reduce their firing frequency during running, likely due to a combination of septo-hippocampal GABAergic inputs and activation of inhibitory cholinergic receptors. The unique behavior of such cells (i.e. SPW-R entrainment and suppression during theta) remains unchanged across brain states. In addition, these cells broadcast inhibition beyond the hippocampus, forming a substantial fraction of long-range GABAergic projections originating from the CA1. Our findings suggest an important role of GABAergic disinhibition in shaping SPW-R related network functions. Title: Differential memory consolidation features of localized and global neocortical spindle oscillations in rats

Authors: *O. RAUHALA[1], ***O. RAUHALA**[1], P. DAHAL[1], J. GELINAS[3], D. KHODAGHOLY[2]; [2]Electrical Engin., [1]Columbia Univ., New York, NY; [3]Columbia Univ. Med. Ctr., New York, NY

Abstract: Memory consolidation depends on synaptic plasticity and changing strength between neuronal connections. Spatiotemporal memory encoding for example, is hippocampus-dependent. The mechanism involves local labile memory traces in the hippocampus being transferred to long-term neocortical storage in quiescence and non-REM sleep by hippocampal sharp-wave ripple (SWR) oscillations. However, many types of memories are also consolidated without the hippocampus playing a causal role such as object recognition and motor skills. The mechanisms for non-hippocampal memory encoding are more varied and less defined. However, sleep may play an important role in some aspects of non-hippocampal learning as well. In this work, we explore the neocortical activation patterns and SWR dynamics during non-REM sleep after spatial navigation, object recognition and spatially-cued object recognition in rats. We focus specifically on spindle oscillations, which have been implicated in memory processes and can occur both independently or exhibit strong coupling to SWRs. This feature makes the spindle a good target for investigating the dynamics in non-hippocampal and hippocampal-dependent memory. Each of our rats is trained on the three tasks in sequence to allow us intrasubject comparison between the modes of learning. We record from the whole dorsal surface of one cerebral hemisphere using a high-resolution multi-channel ECoG array (NeuroGrid), and from the medial prefrontal cortex and the hippocampus using silicon probes. We then detect spindles and SWRs from sleep recordings before and after learning and evaluate the spatial patterns of spindles, the dynamic coupling between SWRs and spindles and how these vary across our behavioral protocol. We find that a spindle event can occur simultaneously in all brain regions covered by our ECoG array (global spindle) or be restricted to a local region (local spindle) and that SWRs show stronger coupling to global spindles. Our investigation finally addresses how this phenomenon varies across behavioral tasks and how it is related to task performance.

mail: Yuri.A.Dabaghian@uth.tmc.edu
Extracellular Local Field Potentials (LFP) play a key role in organizing and synchronizing neuronal activity across the brain. However, a detailed understanding of the LFPs functions depends on our interpretation and explication of their structure: it matters, e.g., whether the basic constituents of the signal are mathematically formal, indirect or whether they reflect the actual organization of the underlying circuit dynamics. We study the LFP oscillations using a recently developed adaptive technique that may capture the physical architecture of synchronous oscillations in neuronal ensembles. This approach reveals new level of organization of the brain rhythms—a small number of discrete, phase-modulated waves processes—the *oscillons*—embedded in a weak noise background. In this study, we focus on the lowest-frequency oscillons that correspond to the traditional hippocampal and cortical θ-waves, and analyze their dynamics during active and quiescent behaviors of male rats. We find that the dynamics of the θ-oscillons is characterized not only by the changes of their amplitudes but also by overt frequency modulations. In particular, we find that both the mean frequency and the embedded frequencies are coupled to the animals' speed and acceleration. These results expand and refine a number of previously observed relationships between the traditionally defined θ-wave and the animal's physiological state and provide a number of qualitatively novel observations that pertain specifically to θ-oscillons. Importantly, our results dovetail with several theoretical models that explain the emergence of θ-rhythms from neuronal synchronization, thus providing a direct link between modeling and experiment.

Title: Rodent hippocampus encodes angle and distance of a simple visual cue.

Authors: *C. PURANDARE[1], S. DHINGRA[2], R. RIOS[3], C. VUONG[4], T. TO[2], A. HACHISUKA[3], K. CHOUDHARY[5], M. R. MEHTA[6];

Abstract: Rodent hippocampus is believed to be critically involved in generating a cognitive map of allocentric space, using neurons firing in localized regions of space, a.k.a. place cells. Such abstract responses are thought to require both distal visual cues and self-motion cues and are prospective in nature. In primates, however, hippocampal neurons encode object-place association without any locomotion requirement, and such visual sensory responses are typically retrospective in nature. Previous studies have suggested that spatial selectivity depends crucially on self-motion while change in the visual cues causes remapping. The precise contribution of vision and locomotion to these processes are unknown. Hence, we manipulated these variables independently. To dissect the contributions of these different variables on hippocampal spatial selectivity, we have recently developed a virtual reality apparatus. Here, the rat runs on a spherical treadmill that floated freely on an acoustically quiet air cushion, to receive liquid rewards through a tube in front of the rat. Our VR system employs a hinged harness that gently body-fixes the rats but allows for head movements around body. In prior work, we have shown that the distal visual cues in the VR causally control direction selectivity in hippocampal neurons from region CA1 (1). Here, we investigated the selectivity of hippocampal neurons with respect to a simple bar of light in the VR apparatus. We find that nearly 40% of CA1 pyramidal neurons showed significant angular tuning to the position of the bar of light. The angular position of the bar could be decoded from only a few hundred neurons' activity. This selectivity was further invariant with respect to the pattern and color of the bar. Similar to the angular representation, hippocampal neurons also encoded the distance from the bar of light. These experiments further allowed us to compute the differential contribution of visual cues, different types of behaviors and experience on neural selectivity and stability. We posit that these responses would influence the cortico-hippocampal circuit and form the basis for generating place cells.

Title: Disrupted phase coding, remapping, and sharp-wave ripple generation in a rat model of traumatic brain injury

Authors: *C. ADAM[1], C. COTTONE[1], K. GAGNON[1], V. JOHNSON[1], J. WOLF[1,2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]CJC VA Med. Ctr., Philadelphia, PA

Abstract: Cognitive deficits, including learning and memory impairments, are commonly reported following TBI, and hippocampal dysfunction is often linked with these deficiencies. TBI-associated cognitive deficits can be present even in the absence of overt cell loss in the hippocampus, suggesting functional impairments of hippocampal circuits following even mild TBI. In order to investigate the physiological mechanisms underlying these functional impairments, we subjected rats to a lateral fluid percussion injury of 1.8 atmospheres (resulting in a mild impairment in the Morris Water Maze without overt hippocampal cell loss) then implanted them with high-density, laminar probes in the dorsal CA1 region of the hippocampus. Electrophysiological recordings were obtained one-week post-injury while rats explored a familiar and novel environment. In injured rats, we found that a greater percentage of cells were active in both the familiar and novel environment compared to sham-injured animals, and that cells active in both environments had firing rates that were strongly correlated between environments in injured but not sham animals. This suggests that TBI rats have a deficit in remapping, an important mechanism for pattern separation processes that allow the hippocampus to create and store distinct representations of different contexts. In addition to these population and rate coding deficits, we found that TBI rats had a decrease in theta and gamma power along the apical dendritic arbor of CA1 and a large decrease in theta-gamma phase-amplitude-coupling where CA3 and entorhinal inputs synapse. Reduced gamma power and coupling to theta was localized in a frequency-band specific manner with low gamma power and coupling losses localized to stratum radiatum where CA3 inputs synapse, and mid gamma power and coupling losses localized to stratum lacunosum moleculare where entorhinal inputs synapse. Additionally, there was a substantial decrease in the strength of entrainment of CA1 interneurons to theta in injured rats, which provides a potential mechanism for the decrease in power and coupling. Lastly, TBI rats had fewer and shorter sharp-wave ripples (SWRs) compared to sham rats which suggests a deficit in memory consolidation mechanisms. Sharp-wave amplitudes increased when rats were in the novel environment, but this increase was less pronounced in injured rats suggesting a loss of CA3 input. Ripples in TBI rats had a larger fast ripple index and entropy which is indicative of potential epileptogenic activity. Overall, TBI rats showed deficits in remapping, phase-coding, and SWR generation all of which are capable of impairing cognition post-TBI.

Title: Attractor network theories of mammal spatially-responsive neurons in one, two, and three dimensions

Authors: K. J. JEFFERY[1], ***A. V. SAMSONOVICH**[2];
[1]Inst. of Behavioural Neurosci., Univ. Col. London, London, United Kingdom; [2]Cybernetics Dept., Natl. Res. Nuclear Univ. MEPhI, Moscow, Russian Federation

Abstract: Attractors, and their use as a theoretical model of neuronal spatial encoding, have been one of the most influential ideas in the field of spatial cognition. Attractor-based theoretical models of spatially responsive cells have allowed researchers to explain a number of mysterious phenomena and make sense of behavioral semantics of neuronal activity. Yet, the theory of attractor brain dynamics is not generally accepted today as the mechanism of place cell (PC), grid cell, and head direction (HD) cell phenomena. Spatially responsive cells are known to model the environment geometry, but the question is whether this property follows from attractor dynamics or from learning in deep networks driven by perceived or imagined sensory input, without attractors involved. Moreover, the concept of an attractor seems incompatible with realistic brain conditions and is understood differently by different scholars. Here we use the definition of an attractor given by Strogatz (1994, p.324) for describing continuous attractors, in which every element is an irrelevant equilibrium. This mathematical abstraction applied to the mammal brain translates to a quasi-continuous attractor (Samsonovich & McNaughton, 1997). Because brain networks cannot be considered isolated from external inputs and noise and in addition are plastic, attractor dynamics in them are hard to prove. Nevertheless, we argue that it is possible, after a refinement of the notion of an attractor. Here we present our analysis of previously documented experimental data that support continuous attractor hypotheses for a number of brain systems, including HD cells and PCs. We argue for the cases of 1D and 2D attractors in rodents and bats and then consider their possible extension to three dimensions. The HD system has a 1D attractor, and the PC attractor is 2D; support of the attractor hypothesis includes the persistence of the internal state of the system at a time when sensory input is absent, such as during sleep. Extending the topology of these attractors during 3D navigation is nontrivial. The grid cell pattern becomes irregular in 3D (Grieves et al., Nat. Neurosci., 2021 in press). This is reportedly true not only for rodents, but also for bats. Furthermore, observations of angular correlates and "forbidden" states in cell pairs at a millisecond time scale suggest that the mechanism is intrinsic to the network. Observed 3D properties of the 1D and 2D attractors further support this conclusion. While there is no evidence for 3D attractors, we investigate the properties and constraints of such systems too, evaluate the consequences for spatial encoding, and suggest experimental paradigms for validation of our findings.

Title: Hippocampal encoding of positions of static visual objects

Authors: *D. LEVCIK[1], T. DVORAKOVA[1], K. HRUZOVA[1], N. AHUJA[1], V. LOBELLOVA[1], S. DIEZ-HERMANO[2], A. SANCHEZ-JIMENEZ[2], J. A. VILLACORTA-ATIENZA[2], A. STUCHLIK[1]; [1]Inst. of Physiol. CAS, Prague, Czech Republic; [2]Complutense Univ. of Madrid, Madrid, Spain

Abstract: The hippocampus is a key structure for processing spatial information including the discrimination of the location of objects in space. We combined single-unit electrophysiological recordings in rats with an operant behavior task using visual stimuli presentation to decipher neural mechanisms involved in the encoding of positions of visual objects. Our unconventional experimental design provided us with the possibility to study the discrimination of positions of visual objects located in a part of an environment that is not accessible to the animal. This is a crucial advantage of the present behavioral task as it prevents the rats from associating their position with the object at that location. We trained rats to press a lever for food reward when an object displayed on a distant computer screen was at particular reward positions and not to press it when the object was at other positions. Once a rat reached asymptotic performance, we implanted an array of tetrodes and recorded the activity of dorsal hippocampal CA1 neurons during the task. For each individual principal cell, a general linear mixed model was calculated with the firing rate (spikes/100-ms bin) as the outcome variable. The fixed factors were behavioral and task-related variables (object's position, lever presses, time from the onset of the stimulus, etc.). Preliminary analysis showed that the firing rate of hippocampal neurons can be influenced by particular positions of a visual object in our discrimination task. These data suggest that hippocampal neurons encode the positions of visual objects.

Title: Novel application of nonlinear modeling algorithms on juvenile hippocampal local field potentials recorded during maze exploration

Authors: *D. A. GONZALEZ[1], J. H. PEEL[1], T. PAGADALA[3], J. LEVERET[1], J. R. CRESSMAN[1], T. C. DUMAS[2];
[2]Psychology, [1]George Mason Univ., Fairfax, VA; [3]Thomas Jefferson High Sch., Alexandria, VA

Abstract: Juvenile and mature animals encode spatial memories differently. Prior to maturation of learning systems in the brain, young animals form memories, but they become rapidly irretrievable). Work from our laboratory implicates alterations in AMPA receptors in the switch from juvenile to mature memory formation. A shift in the AMPA receptor composition at hippocampal synapses facilitates the induction of activity-dependent synaptic plasticity in the older animals permitting mature behavior in spatial mazes. The observation that a positive modulator of AMPA receptors (such as CX614), promotes more mature synaptic plasticity and spatial behavior in younger animals reinforces the causal nature of AMPA receptor composition on hippocampal integrity. Recently, we addressed network operations and showed that peak frequency of slow gamma oscillations remained constant throughout the age range of P18-P24 while peak frequency decreased with age. CX614 application impacted slow (25-55 Hz) and fast gamma (65-100 Hz) differently at different ages, decreasing slow gamma event rate in older animals and increasing fast gamma power in younger animals. Both slow and fast gamma have been implicated in spatial memory retrieval and performance on spatial navigation tasks in adult animals. Our work begins to shed light on the function of gamma oscillations on network activity and spatial cognition in juveniles. However, due to the nature of frequency analyses, the exact underlying temporal dynamics of these oscillations are not well understood. To account for this, we analyzed the previously recorded local field potentials (LFPs) with a novel method, Diffusion Mapped Delay Coordinates (DMDC). DMDC operates under the assumption that each temporal measurement is a sample of a dynamic manifold, and attempts to analyze the overall minimum dimensionality and volume. DMDC is being used to model nonlinear and dynamic physical systems, but has yet to be applied to neurological signals. We will compare our results in DMDC to previous data on gamma rhythms during Y-maze navigation, with the prediction that differences in the temporal dynamics of gamma rhythms will be detected in DMDC. We expect differences to increase as our filters approach gamma ranges. Current results comparing alternation trials in the Y-maze show significant differences in the dimensionality of the signal between P17-18 and P23-24 animals as well as between control and drug conditions. Thus, we have shown that DMDC may be a valuable tool in relating dynamics of brain oscillations to cognitive states.

Title: Anatomically plausible Hippocampome.org Hopfield spiking neural network

Authors: *D. J. HAMILTON, J. D. KOPSICK, D. W. WHEELER, G. A. ASCOLI;
George Mason Univ., Fairfax, VA

Abstract: The hippocampal CA3 subregion has been described as an autoassociative network [Marr, 1971], and computational models of CA3 have been constructed to demonstrate this property [Zhang et al., 2016; Zhao et al., 2009]. However, these models were only abstractions of the actual CA3 circuitry. In contrast, our research implements Hopfield Net [Hopfield, 1982] behavior in a neuroinformatic-sourced Spiking Neural Network (SNN), the circuitry of which is derived from Hippocampome.org [Wheeler et al., 2015]. The potential connectivity of the CA3 computational model, as defined by Hippocampome.org, is based on experimental evidence mined from peer-reviewed publications, making it anatomically plausible. The biological circuit is fundamentally distinct from classical Artificial Neural Networks (ANNs) by the facts that (i) its sparse connectivity depends on the axonal and dendritic patterns of the constituent neuron types (as opposed to feedforward or all-to-all), (ii) it communicates through spiking dynamics, and (iii) it contains a diversity of inhibitory and excitatory neurons. In particular, the inhibitory interneuron connections with principal excitatory neurons dampen oscillations and cancel noise. The excitatory/inhibitory circuitry may also form cell assemblies that can provide a latching mechanism for instant memory storage, without the need for Hebbian-style [Song et al., 2000] synaptic strengthening. The ability to substitute an ANN implementation of a Hopfield Net with an anatomically plausible Hippocampome.org Hopfield Spiking Neural Network (HHSNN) implementation, while still observing similar behavior, lends credence to the theory that the CA3 subregion of the hippocampal formation functions as an autoassociative network.

Title: Theory of interaction between networks: Persistent activity and inactivity in vivo

Authors: *K. CHOUDHARY[1], M. R. MEHTA[2], S. BERBERICH[3], T. T. HAHN[4], J. MCFARLAND[5]; [1]Univ. of California Los Angeles (UCLA), Los Angeles, CA; [2]Departments of: Physics & Astronomy, Neurology, Neurobio., Univ. of California at Los Angeles (UCLA), Los Angeles, CA; [3]Central Inst. of Mental Hlth., Mannheim, Germany; [4]Zentralinstitut Fuer Seelische Gesundheit, Mannheim, Germany; [5]Univ. of Maryland, College Park, MD

Abstract: Interactions between large brain networks govern all cognition. A mechanistic understanding of these interactions is a major challenge. Here, we present a simple, analytically tractable, mean field theory of cortico-entorhinal interactions *in vivo* during the 'Up-Down' state oscillation (UDS). The theory predicts new phenomena: spontaneous persistent activity (*SPA*) and inactivity (*SPI*). We confirm these using simultaneously recorded parietal cortical local field potential (LFP) and the membrane potential (V_m) of identified excitatory neurons from several brain areas *in vivo*, especially from layer 3 of the medial (MECIII) and lateral entorhinal cortex (LECIII), which show *SPA* and *SPI*; the latter has never been seen before in experiments or models. Further, the theory reproduces quantitatively, not just qualitatively, several *in vivo* features, on average and on a cell-by-cell basis. The theory predicts, and the

experiments confirm, that *SPA* and *SPI* are quantized by cortical UDS and result from a nonlinear amplification of small fluctuations in afferent cortical gamma power. These convergent, theory-experiment results provide a novel way to generate persistent activity, which has been implicated in a wide range of conditions, and persistent inactivity, and help to understand the rich dynamics of interactions between large networks of neurons *in vivo*.

Title: Theta and gamma band oscillatory decoupling in macaque hippocampus

Authors: S. ABBASPOOR[1], A. T. HUSSIN[2], A. P. MAURER[3], *K. L. HOFFMAN[1];
[1]Vanderbilt Univ., Nashville, TN; [2]York Univ., Toronto, ON, Canada; [3]Evelyn F. McKnight Brain Inst., Univ. of Florida, Gainesville, FL

Abstract: The rodent hippocampus supports a broad range of spectral frequencies including theta and gamma bands during exploration. The coordination of these rhythms is thought to reflect important canonical mechanisms of temporal coding; however, these rhythms are less apparent in primates, and their coordination during species-relevant exploration in primates is unclear. To investigate the relationship between different frequency bands during primate behavior, we measured local field potentials (LFPs) and single unit activity in the hippocampus of two adult female macaques during visual exploration and in quiescence. In contrast to the nested coupling described in rodents, we found that 3-14 Hz oscillations encompassing the theta band had greater power during quiescence than visual search, whereas 20-50 Hz beta/gamma oscillations had greater relative power during search than quiescence (both results: Wilcoxon rank sum test, $F < 0.05$). To address this more directly, we examined cross-frequency coupling between these oscillations. Consistent with the general behavioral-epoch results, delta/theta band amplitude (2-5 Hz) was negatively correlated with slow gamma band amplitude (25-35 Hz; $p < 0.05$). In contrast, delta/theta band amplitude was positively correlated with higher frequency oscillations (gamma and high-frequency oscillations, 50-150 Hz; $p < 0.05$). Single units were most frequently phase-locked to LFPs in the 3-12 Hz, 25-40 Hz, and >60 Hz bands ($n = 404$ isolated units, Rayleigh test $p < 0.05$). Isolating sharp-wave-ripples (SWRs), however, revealed that the low-frequency (3-12 Hz) and>100 Hz bands were dominated by spikes phase-locking to the slow and fast components of

the SWR. This may account in part for the low-frequency power during quiescent states, when SWRs are most prevalent. Furthermore, spike autocorrelograms (n = 184 cells), yielded no clear examples of intrinsic delta/theta oscillatory modulation resembling those seen in the rodent hippocampus. The present results support a role for ~20-40 Hz slow gamma oscillations during active exploration in the primate that is decoupled from - and therefore not simply a harmonic of - theta oscillations. In contrast, theta oscillations were not prevalent during search in primates, did not modulate single units, and may be susceptible to contamination by other LFP phenomena such as SWRs. These results will be discussed in the broader context of exploratory behaviors, encompassing walking and reaching movements in macaques, as well as active sensing strategies in other species.

Title: Hippocampal neurons code individual episodic memories in humans

Abstract: When you remember the last time you had a coffee with a loved one you rely on your hippocampus to reinstate that episode. This episode will contain a multitude of features (weather, smell of the coffee, music playing), but how the hippocampus binds all these elements into one episode remains unsolved. The indexing theory (Teyler and DiScenna, 1986) proposes that neurons in the hippocampus achieve this through a conjunctive code that binds all features within the episode. In contrast, others have suggested that hippocampal neurons code for specific categories (Quiroga, 2012). In search of an answer to this issue, we have recorded the activity of 625 single neurons in the hippocampus of human epileptic patients (N = 16). During a self-paced memory association task patients formed unique episodic memories comprising an animal cue and two associate images (places or faces). Each episode was learned and retrieved only once. We contrasted the empirical firing reinstatement (firing rate at encoding multiplied with retrieval) of every single unit during every episode with a shuffled distribution. Next, we excluded potential concept neurons that showed increased firing to the animal cue at encoding. In a second level

shuffling procedure we show that a significant number (N = 147/625; $p < 0.001$) of single units showed a memory specific reinstatement of neural firing during individual episodes. We termed these single units Episode Specific Neurons (ESNs). We still find a significant number of ESNs when limiting our analysis to single units that reinstate one episode with face associates and one with place associates ($p < 0.01$). Such neurons unlikely code for a specific concept because the stimulus material in these episodes does not overlap. To rule out that single units are firing in response to recurring time points we partitioned all encoding blocks into 40 equally sized bins and used a Kruskal-Wallis test to assess periodic firing. This approach did not reveal a significant number of time cells and there was no significant overlap with ESNs (p values > 0.5). In conclusion, we provide evidence that individual neurons code discrete episodes via an increased firing rate during encoding and retrieval. We demonstrate that these Episode Specific Neurons do not reflect the coding of a particular feature in the episode (i.e., concept or time). Instead, they code for the conjunction of the different elements that make up the episode.

Title: Simulating sleep spindles and slow oscillations EEG and MEG in a multiscale thalamocortical network model with hierarchical connectivity

Authors: *Y. SOKOLOV[1], B. Q. ROSEN[2], E. DELANOIS[2], O. C. GONZALEZ[3], G. P. KRISHNAN[5], E. HALGREN[4], M. V. BAZHENOV[6];

Abstract: Magneto- and electro-encephalography (M/EEG) are complementary, noninvasive imaging techniques, which are used to investigate macroscopic brain activity. However, how the microscopic activity of ion channels gives rise to these electromagnetic signals is yet to be fully understood. To

address this question, we developed a multi-scale thalamocortical network model that exhibits the essential activity states of NREM sleep: sleep spindles and slow oscillations. Using a recently developed computationally efficient neuronal model, we considered a network of about a hundred thousand of cells, which are embedded on a structural-MRI reconstructed cortex, with realistic laminar organization. The network model incorporates the fundamental principles of cortical connectivity. First, the connection probability between a pair of cortical cells decayed exponentially with respect to the diffusion-MRI derived white matter tract distance between the pair. Second, a hierarchical index was assigned to each functional region that is inversely proportional to region's average myelination. Third, inter-areal hierarchically feed-forward and feed-back connections were pruned into distinct laminarly-separated counter-streams, distinct from local connectivity. The synaptic delays and synaptic strengths of intra-cortical and thalamocortical connections were derived from dMRI distances and laminar patterns. We examined the role of synaptic delays on the propagation of spindles and slow oscillations, and found that a characteristic traveling wave structure is preserved even for relatively high delays consistent with human brain long-range connectivity delays. We analyzed the spatiotemporal patterns of microscopic activity and identified characteristic propagation of activity during the stage 2 and stage 3 of NREM sleep. We compared mesoscale cortical correlativity structure in simulated and empirical data. By embedding the simulated cortical currents in a volume conduction model of the head we produced simulated M/EEG, enabling investigations of how multi-scale dynamics and detailed connectivity give rise to these complex signals.

Title: Optimality of pulsed processing by recurrent neural networks

Authors: *T. MCPHERSON[1], A. KUCZALA[2], T. SHARPEE[2];
[1]UCSD Dept. of Neurosciences, La Jolla, CA; [2]Physics, UCSD, La Jolla, CA

Abstract: Neuronal processing in the brain occurs rhythmically across a set of discrete frequency bands, spanning almost two orders of magnitude. The function of these rhythms remains a matter of debate, as well as why activity seems to be organized in canonical bands. Here we show that the rhythmic structure seen in neuronal activity can be derived from the processing timescales of hierarchically organized recurrent networks operating in an optimal regime. Specifically, we find that to achieve optimal error correction, a recurrent network must receive inputs with noise comparable to what is observed in cortical networks, as well as operate in a pulsed manner where inputs are disconnected for the majority of computation. When input noise is above or below the optimal value, the ability of a network to converge on the correct solution is limited, resulting in reduced error correction. Pulsed inputs need to be brief enough to initially activate the network, but should not exceed the integration time of constituent neurons.

When input duration is too long, continuous drive distorts the endogenous dynamics of the network, disrupting good error correction. In this regime, optimal processing timescale and performance are predominantly independent of network size. The optimal timescale is dictated by the integration time constant of constituent network nodes. At the scale of local neuronal circuits, a typical neuronal time constant of 10 ms yields an optimal timescale of approximately 21 ms (48 Hz), corresponding to gamma oscillations—a fast rhythm observed in cortical networks that is putatively linked to local computation. When circuits exhibiting this timescale are connected to create a higher-order recurrent network, the resulting optimal timescale occurs at 46 ms (22 Hz), representative of canonical beta oscillations**.** In this framework, the timescale for a network at one scale becomes the time constant for a constituent node at a larger scale, affording the theoretical prediction of a hierarchy of discrete timescales. Extending our predictions to larger spatial scales produces a full sequence of frequencies observed in the brain covering gamma (48 Hz), beta (22 Hz), alpha (10 Hz), theta (4.8 Hz), delta (2.2 Hz), and slow wave sleep oscillations (1 Hz). We also find the optimal timescale can be modulated by adjusting the gain of neurons, providing an explanation for why the frequency of rhythmic activity can be variable within bands of finite width. Collectively, our results illustrate the optimality of rhythmic processing observed in the brain and how this property allows for the apparent hierarchical organization of oscillatory activity.

Title: Orchestrated Excitatory and Inhibitory Learning Rules that Lead to the Unsupervised Emergence of Self-sustained Inhibition-stabilized Dynamics

Authors: *S. SOLDADO MAGRANER[1], R. LAJE[2], D. BUONOMANO[1];
[1]UCLA, Los Angeles, CA; [2]Univ. Nacional de Quilmes, Buenos Aires, Argentina

Abstract: #2300 characters max (no spaces)
Orchestrated Excitatory and Inhibitory Learning Rules that Lead to the Unsupervised Emergence of Self-sustained Inhibition-stabilized Dynamics.
Self-sustaining dynamics maintained through recurrent connections are of fundamental importance to cortical function. Although a balance between excitatory and inhibitory activity is essential for the generation of self-sustained dynamics, it not known how these two populations coordinate their activity during development to lead to self-sustained inhibition-stabilized regimes. One of the best studied examples of self-sustained network dynamics are Up-states. Using two-photon calcium imaging in cortical organotypic cultures, we first show that Up-states emerge in parallel in excitatory and PV^+ inhibitory neurons across three weeks of *ex vivo* development, establishing the presence of unsupervised

synaptic learning rules that lead to globally stable emergent dynamics. Computational models of excitatory-inhibitory networks have established that four sets of weights (*WE←E, WE←I, WI←E, WI←I*) cooperate to generate stable self-sustained dynamics, but have not addressed how learning rules can operate in parallel at all four weight classes to generate self-sustained inhibition-stabilized regimes. Using a two-population firing rate model and numerical and analytical methods we show that standard homeostatic rules are not robust enough to account for the emergence of self-sustained dynamics due to a characteristic feature of inhibition-stabilized networks: the paradoxical effect. We demonstrate that homeostatic rules are only stable in a narrow parameter regime in which plasticity of synapses onto inhibitory neurons is sufficiently slow. We also show that these results hold for a second family of widely used homeostatic rules, synaptic scaling. We have, however, derived a novel family of rules with cross-homeostatic influences that robustly leads to self-sustained regimes and balanced excitation-inhibition, and additionally, reproduces the experimental developmental emergence of Up-states. Finally, we show that the cross-homeostatic rules are also successful in driving a multi-unit firing rate model to a stable Up regime. We conclude that unless plasticity of inhibitory neurons is negligible, rules other than standard forms of homeostatic plasticity must underlie the emergence of self-sustained inhibition-stabilized regimes.

Title: Optimal degree of recurrent and feedback connections for information storage

Authors: *C.-Y. LIN[1,3], A. KUCZALA[3], T. O. SHARPEE[1,3,2];
[1]Dept. of Neurosciences, [2]Dept. of Physics, UC San Diego, La Jolla, CA; [3]Computat. Neurobio. Lab., Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: As our personal experiences suggest, neural networks have a large capacity for retaining information about input signals. Previous studies have demonstrated that networks need to be primarily feedforward to maximize information recall. However, only small networks were considered. Here we use mean-field methods to characterize information storage in large networks composed of a small number of blocks, with the possibility of recurrent connections within and between blocks. We find that there is an optimal degree of recurrent interactions within each block corresponding to the transition to chaotic behavior within that block. Considering the relative distribution of neurons between blocks, we find that typically networks have larger storage capacity when the first block has fewer neurons than subsequent blocks. Small networks do not benefit from feedback connections between blocks. There is a critical network size beyond which feedback connections increase information storage capacity. These studies highlight previously under-appreciated functions of feedback and recurrent connections in neural circuits. We find the optimal network structures undergo sharp phase transitions as the connection strengths

increase, and these transitions involve redistributing synaptic budgets and reorganizing the population size of different cell types in the network.

Title: Circuits for mismatch: Dissecting the structure and dynamics of spiking neural microcircuit models trained to report temporal regularity violations

Authors: *F. B. KERN, Z. C. CHAO;
Intl. Res. Ctr. for Neurointelligence (IRCN), Univ. of Tokyo, Tokyo, Japan

Abstract: The predictive coding theory (PC) states that, rather than passively receiving information, the brain actively predicts its future input. According to PC, this is achieved through a cascade of computational modules that receive bottom-up inputs and top-down predictions, which they compare to yield a prediction error that is sent up, and an updated prediction that is sent down along the processing hierarchy. As a domain-general algorithm, PC is believed to be employed widely throughout the brain, supporting its computational goal of Bayesian inference.
PC has been intensely studied in primate and human EEG in auditory sequence learning paradigms, which involve presenting sequences of tones with certain regularities and observing the neural responses to regularity violations, i.e., the prediction error signals. While the dynamics and hierarchical organisation of sequence processing and its concomitant prediction and prediction error signals have been studied in great detail at the mesoscopic scale, there has been comparatively little progress in elucidating the mechanisms underlying these computations.
Since mismatch signals are so readily observed in EEG, we believe that error neurons, that is, neurons that fire specifically in response to unexpected or unpredicted events, must be common in cortex. However, we are not aware of any work identifying such neurons or analysing the circuit mechanisms supporting their function.
To approach this question, we build small, biologically plausible model circuits of leaky integrate-and-fire (LIF) neurons with firing threshold adaptation, a simple short-term plasticity mechanism, and we train these models to generate mismatch signals in response to input regularity violations. We use surrogate gradient backpropagation through time on the machine learning platform PyTorch to adjust the circuit structure, the synaptic weights, as well as the dynamics of threshold adaptation, in order to encourage a subset of neurons to increase their firing probability when a stimulus is turned off (violation of continuity), or when a periodic stimulus is suddenly changed or omitted (violation of regularity).
We analyse the structure of the resulting circuits as well as the activity dynamics leading to the error responses, elucidating in detail the mechanistic underpinnings of mismatch signal generation in the

model. We then draw parallels to known connectivity patterns in mammalian cortex and suggest circuit and activity motifs that may play a key role in signalling prediction errors in sensory processing pathways.

Title: Supercomputers, Neural Network Simulations and Reverse Engineering of Neuron Firing Patterns

Authors: *M. CHARDON[1], C. WANG[3], M. GARCIA[4], R. K. POWERS[5], C. HECKMAN[2]; [1]Physiol., [2]Dept. of Physiol., Northwestern Univ., Chicago, IL; [3]Electrical Engin., CalState LA, Los Angeles, CA; [4]Argonne Natl. Lab., Lemont, IL; [5]Dept Physiol & Biophysics, Univ. Washington, Seattle, WA

Abstract: High speed computation via supercomputers offers the possibility of remarkably extensive parameter searches, a capacity well matched to the multitude of possible inputs driving a particular set of neurons. Our recent studies combine 3 advances: 1) novel array electrodes to measure firing patterns of populations of motoneurons in humans, via motoneuron connections to muscle fibers, 2) highly realistic computer simulations of these motoneurons and 3) implementation of these models using the High Performance Computing facility at Argonne National Labs. The huge advantage of the supercomputer approach is that their massive parallelism allows thousands (soon millions) of simulations to be carried out simultaneously. In this particular application, we use this computational power as the basis of a brute force approach to reverse engineer motoneuron firing patterns to identify the organization of their synaptic inputs. More specifically our goal is to identify the patterns of excitatory, inhibitory and neuromodulatory inputs. Our initial simulations show that, although a given motor output pattern could potentially be generated by a huge number of combinations of these three types of input, neuromodulatory input makes motoneuron input-output properties so nonlinear that the effective “solution space” is restricted. These high levels of neuromodulatory inputs are coupled to strong inhibitory inputs, with interaction between these two input types providing the “amplifier” upon which excitation acts to execute the pattern of the movement. This is a novel insight into the synaptic organization of motor commands in humans. Overall our results show that this reverse engineering approach can achieve deep insights about the organization of synaptic inputs that drive a set of neuronal firing patterns. Identifying the separate patterns of excitatory and inhibitory inputs appears to require highly nonlinear processing within the neurons.

Title: Nonequilibrium response functions for functional connectivity in the brain

Authors: *F. RANDI[1], A. LEIFER[2];
[1]Dept. of Physics, [2]Princeton Neurosci. Institute, Dept. of Physics, Princeton Univ., Princeton, NJ

Abstract: Despite the power of the *C. elegans* connectome, the community currently lacks systematic direct measures of the strength, sign (excitatory vs. inhibitory), and temporal properties of the connections between neurons. We refer to these properties as functional connectivity, and they are crucial to understand circuit function. Functional connectivity can now be measured on larger scales thanks to the combination of optogenetics and neural activity imaging. These experiments, however, do not directly measure the direct (monosynaptic) connections between neurons, but only the effective connections, which are a combination of the direct and the indirect (polysynaptic) paths connecting neurons in the network. We sought a mathematical framework to describe the results of those experiments and obtain the direct contributions from the effective connections observed in experiments. Conventional models start from a description of the direct connections and then consider network effects through numerical simulations. Response functions, which give the activity of a neuron through convolutions with the inputs to that neuron, allow us instead to obtain explicit relations between the properties of the direct and effective connections between neurons. Traditionally, however, this is possible only for linear networks that do not have synaptic adaptation or neuromodulation. We will present a framework based on nonequilibrium response functions, that extends the application of response functions also to nonlinear and time-dependent networks and allows for the description of time-varying functional connectivity.

Title: Conserved canonical circuits & computations, continued

Authors: *D. GARDNER[1], E. P. GARDNER[2];
[1]Cornell University: Weill Cornell Med. Col., New York, NY; [2]Dept Neuroscience/Physiology, New York Univ. Sch. of Med., New York, NY

Abstract: Once you have a good thing, stick with it. Evolution leverages this principle in the design of nervous systems, which are gratifyingly similar across species, even phyla. Nervous systems use evolutionarily-conserved small molecules, neurotransmitters, proteins, synapses, and neurons specialized for excitation or inhibition. At higher levels, vertebrate and mammalian neuroanatomy conserves relative operation and connectivity of nuclei, layers, and regions. At still higher levels, the goals and functions of all nervous systems are similar. But at intermediate levels: are neural circuits and the computations they perform evolutionarily-conserved? At the last SfN, our nanosymposium examined this question, as well as potential candidates for canonical circuits and computations. We now continue the quest by suggesting roles for in-development connectomics and under-scrutiny astrocytology.
Connectomes:
The NINDS and DoE are exploring development of a mouse connectome, but a complete connectome may be less useful than one that confirms multiple canonical microcircuits—and variants—and places their function in context. The distinction between equipment schematic diagrams and wiring paths emphasizes that that the functional ground truth sought may be subtly different from complete images of somas and processes. Also, the behavior of a circuit or device is revealed by viewing it as a set of interconnected modular elements. Physiologically, identification of canonical functional microcircuits would reduce the computational burden of interpreting and analyzing data now routinely obtained from thousands of neurons. Complete connectomes may be less informative than more readily detected repeated, Identifying patterns revealing potentially canonical, functional, microcircuits performing specific computations would be feasible, perhaps in real time, given today's computing power.
Astrocytes:
Artificial neural networks routinely use global error data to adjust specific weights, suggesting that networks of neurons might use a similar mechanism. Recent work on astrocytes emphasizes that their often-multisynaptic spread could be a canonical, conserved way to mediate synapse-specific short- and long-term actions as well as *f-I* nonlinearities under global, modulatory control.
Plans:
Continuing onward, new collaborative approaches are needed to explore this broad question across regions, species and phyla, involving many techniques and analytic tools. Toward this goal, we advance an upcoming Neuromorphic Neural Networks (**N**^{3}, or Encubed) Next Cool Virtual Meeting.

Title: Plasticity of short-term synaptic dynamics enhances the computational power of neural networks

Authors: *S. ZHOU, D. V. BUONOMANO;
Neurobio., Univ. of California, Los Angeles, Los Angeles, CA

Abstract: The principle that changes in synaptic strength are the primary mechanism underlying learning and memory is among the most influential concepts in neuroscience and has contributed to the revolution in machine learning. Implicit in this principle is that in the absence of learning synapses have a fixed and constant weight. Biologically speaking however, there is no such thing as a fixed synaptic weight in the sense that even in the absence of learning synaptic efficacy is highly dynamic on the time scale of hundreds of milliseconds—i.e., the strength of synapses can facilitate or depress in a use-dependent fashion, a phenomenon referred to as short-term synaptic plasticity (STP). The computational function of STP remains poorly understood, but it has been proposed to contribute to temporal processing (Seay et al, 2018). The vast majority of neurocomputational and machine learning models do not incorporate STP and the few that do assume that STP itself is fixed. Here we propose that STP itself undergoes plasticity, and contributes to learning and memory—i.e., that plasticity of STP (PSTP) enhances the computational power of neural networks. To examine this hypothesis we implemented STP in a *synapse-specific* manner, i.e., each synapse has its own set of STP parameters. In these models the τ_D, τ_F, and U parameters of the Tsodyks STP model were tuned along with the weight through gradient descent. We first demonstrated that PSTP endows simple single-layer feedforward networks with the ability to solve three tasks that would not be solvable by a circuit without STP, or with fixed STP. These tasks included a single-layer feedforward network that can generate a neural sequence. To further test the computational contribution of PSTP in neural networks with more general architecture, we have trained large-scale firing rate recurrent neural networks (RNNs) with synapse-specific PSTP on an interval timing task. To date, we have found that compared to RNNs without STP, that RNNs with fixed STP dramatically faster learning, and more so with PSTP. In ongoing work we contrasting the ability of RNNs without STP, with fixed-STP, and PSTP on a series of standard cognitive tasks. Results to date demonstrate that STP significantly enhances the computational power of neural networks, and that PTSP further enhances performance on some tasks.

Title: Ca2+ activity-mediated gene expression drives aberrant neurogenesis in a mouse model of epilepsy

Authors: *G. CHANGARATHIL[1], P. VARMA[1], Z. LYBRAND[2], M. COPPIN[1], A. ADEYEYE[1], J. HSIEH[1];
[1]Dept. of Biology/Neurobiology, Univ. of Texas, San Antonio, TX; [2]Texas Woman's Univ., Denton, TX

Abstract: Studies show that seizure induced aberrant hippocampal neurogenesis aggravate the development of chronic seizures. We previously identified that 2 week old (2w) adult-born granule cells (abGCs) in mouse dentate gyrus show elevated Ca^{2+} activity after pilocarpine (pilo) induced seizures compared to sham. Moreover, this amplified Ca^{2+} activity is reduced by chemogenetic DREADDs/hM4Di silencing in pilo treated mice. Ca^{2+} transients have been shown to modulate neuronal Ras/Raf/MEK/ERK signalling, as well as govern the migration of mouse cerebellar granule cells – but less is known regarding how Ca^{2+} activity drives aberrant hippocampal neurogenesis and, in turn, epileptogenesis. Based on these studies, we hypothesize that early activity in abGCs alters Ca2+-mediated gene expression programs that promote aberrant maturation, including ectopic migration of abGCs associated with spontaneous recurrent seizures. Therefore, we performed RNA-sequencing analysis from FACS sorted 2w old abGCs after pilo treatment and hM4Di silencing. We identified 387 differentially expressed genes (DEGs) between pilo and sham groups. The gene ontology classification revealed that 149 upregulated genes with pilo treatment belonged to neuron differentiation/development and oxygen carrier activity pathways. However, lipid/small molecule metabolic process, mitochondrial membrane complex, NADH dehydrogenase activity genes were over-represented among 238 genes downregulated with pilo treatment. This could imply that impairments in cellular metabolism of immature neurons might play in role in epileptogenesis. Additionally, we found 33 DEGs between pilo and hM4Di silenced groups. Among these, 25 genes were downregulated and belonged to functional categories such as glutamatergic synapse, while 8 upregulated genes appeared to regulate niche remodeling and cellular migration. Taken together, these results suggest that alterations in Ca^{2+}activity within 2w old abGCs after pilo leads to changes in niche remodeling, migration and metabolism – controlling aberrant neurogenesis. Further experiments with select candidate genes are being performed to address specific pathways that regulate aberrant maturation of abGCs involved in epileptogenesis.

Title: Single-cell RNA-sequencing reveals discrete steps in the transformation of developmental precursors into adult neural stem cells

Authors: *A. BOND, D. JIMENEZ-CYRUS, G.-L. MING, H. SONG;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: The dentate gyrus region of the hippocampus is one of only two regions in the adult mammalian brain where substantial levels of neurogenesis occur throughout adulthood. Quiescent adult neural stem cells in the subgranular zone of the dentate gyrus occasionally become reactivated in adulthood to generate new neurons which integrate into the existing network and contribute an added layer of plasticity to the hippocampus. Previously, our lab showed that $Hopx^+$ embryonic neural stem cells which contribute to developmental cytogenesis in the mouse dentate gyrus transition into quiescent adult neural stem cells, suggesting that a common lineage of neural stem cells contributes to developmental and adult neurogenesis. However, the molecular mechanisms regulating this developmental transition remain completely unknown. Here we used single-cell RNA-sequencing of $Hopx^+$ dentate gyrus progenitors across multiple stages of early postnatal development in mice to identify the molecular cascade associated with the transformation of developmental precursors to quiescent adult neural stem cells. We discover that early postnatal dentate gyrus neural stem cells exist in multiple heterogeneous states, and we identify a trajectory of cycling neural stem cells as they transition into a quiescent state. We also discover that dentate gyrus precursors gradually acquire an adult-like state after they exit cell cycle. This suggests that the developmental transition consists of two sequential steps: first precursors exit cell cycle to enter a quiescent state and then precursors acquire an adult-like state throughout a quiescence maturation period. We further identify transcription factor networks associated with each stage of the transition and biological processes that change over the course of the transition. Collectively, our work identifies molecular and cellular mechanisms associated with the transformation of developmental precursors to quiescent adult neural stem cells, and serves as a foundation for future studies investigating mechanisms that regulate formation of the adult neural stem pool.

Title: Characterization of the cellular and molecular diversity in the postnatal piglet subventricular zone following chronic hypoxia

Authors: *C. T. SHEPARD[1], C. LEONETTI[3], Z. LI[1], C. S. FOSTER[1], E. MONAHAN[1], L. BLEICKEN[1], T. F. HAYDAR[2], N. ISHIBASHI[4];

Abstract: Congenital heart disease (CHD) is among the most common birth defects, affecting nearly 40,000 births each year in the United States. Children with CHD frequently exhibit a wide range of neurological deficits and cognitive impairments that alter brain function later in life. Thus, there is a crucial need to define the mechanisms underlying cortical disturbances to develop therapeutic interventions to lessen the impact of these impairments. Recently, migrating neuroblasts were discovered within the infant subventricular zone (SVZ). These cells migrate tangentially along the lateral ventricles and populate the frontal cortex, a region responsible for higher-order cognitive functions. However, the cellular identity and generation mechanisms of these immature neurons are not yet defined. Our previous work in the piglet has shown that chronic hypoxia induces a significant decrease in SVZ neurogenic activity associated with reduced populations in the frontal lobe. In this project, we first characterized the cellular and molecular heterogeneity of the postnatal normoxic 2-week-old piglet SVZ using single-nuclei RNA sequencing and state-of-of-the-art bioinformatics approaches. This study generated an extensive list of genes that are differentially expressed throughout various stages of neural stem cell differentiation and revealed the complex heterogeneity of neuroblast subpopulations in the postnatal piglet SVZ. From these studies, we identified a unique population of immature excitatory neurons and have verified their existence in normoxic piglet tissue using immunohistochemical quantification and RNAScope. We then sought to determine whether this population of cells was altered as a result of chronic hypoxia by using a piglet CHD model. Overall, our study provides new insights into the underlying molecular mechanisms of cortical dysmaturation and decreased postnatal SVZ neurogenesis after chronic hypoxic insult. Ultimately, these studies will help to identify therapeutic targets in improve long term neurological outcomes in pediatric CHD patients.

Title: Consumption of high-saturated fat diet during adolescence leads to hippocampal atrophy and impairment of cognitive functions potentially through involvement of TACE/ADAM17.

Authors: *F. SHARAFEDDIN[1], J. D. VEGA-TORRES[1], P. ONTIVEROS-ANGEL[1], E. TERRONES[1], E. STUFFLE[1], S. SOLAK[2], E. TYNER[2], M. OROPEZA[2], I. DELA PENA[2], A. OBENAUS[3], B. D. FORD[4], J. D. FIGUEROA[1];

Abstract: Background: Adolescent obesity is strongly associated with deviant hippocampal maturation. Molecular mechanisms involved in obesity-induced structural alterations of the hippocampus are yet unknown. Synaptogenesis and synaptic pruning in the hippocampus during brain development depend on balanced signaling between the growth factor neuregulin 1 (NRG1) and its tyrosine kinase receptor ErbB4. NRG1-ErbB4 signaling is tightly regulated by proteolysis, particularly by the metalloprotease TACE/ADAM17. In this study we investigate the potential involvement of TACE/ADAM17-NRG1-ErbB4 pathway in early obesity-induced neuropathological alterations in the adolescent rat hippocampus. **Methods:** Adolescent Lewis rats were fed from PND21 to PND49 with either a Western-like diet, which had a high-saturated fat content (WD, 41% kcal from fat) or an ingredient-matched control diet (CD, 13% kcal from fat). Behavioral assessments were performed between PND43 and PND49. Animals were euthanized at PND49. Ex-vivo magnetic resonance imaging was performed and hippocampal tissue collected to evaluate TACE/ADAM17-NRG1-ErbB4 activities and inflammatory biomarkers using qRT-PCR, Western blot, and flow cytometry. **Results:** We found that consumption of an obesogenic high-saturated fat diet during adolescence leads to anxiety-like behaviors and hippocampal atrophy, specifically in the CA1 region of the hippocampus. Alterations in WD-induced behaviors were concurrent with changes in hippocampal pro-inflammatory cytokine profiles and microglial morphology. WD consumption increased ErbB4 phosphorylation (pErbB4) and TACE/ADAM17 protein levels in the hippocampus.TACE/ADAM17 protein levels were positively associated with pErbB4 and interleukin-6 (IL-6) levels in the hippocampus. Interestingly, TACE/ADAM17 protein levels were associated with reduced ErbB4 and post-synaptic density 95 (PSD95) protein levels in the hippocampus. **Conclusions:** We demonstrate that brief exposure to an obesogenic diet during adolescence is sufficient to induce hippocampal dysfunction and structural impairments in rats. We identify TACE/ADAM17-NRG1-ErbB4 pathway as a potential signaling axis linking adolescent obesity with hippocampal structure abnormalities.

Title: Neurocircuit-modified hippocampal neurogenesis modulates memory and anxiety

Authors: *Y. LI[1], Y. LUO[1], L. QUINTANILLA[1], Y. CHERASSE[2], M. LAZARUS[2], J. SONG[1];

Abstract: Adult neurogenesis in the dentate gyrus (DG) plays a critical role in regulating memory and emotion, and this process is dynamically regulated by neural circuit activity. It remains unknown whether stimulating neural circuits achieves sufficient long-term neurogenic effects for behavioral modulation. Here we identify a long-range neural circuit projecting from the supramammillary nucleus (SuM) of the hypothalamus to the DG, which co-releases GABA and glutamate to positively regulate hippocampal neurogenesis by acting on multiple developmental stages. By combining circuit manipulation with lineage tracing of adult neural precursors, we demonstrate that chronic stimulation of SuM neurons leads to increased number of behaviorally relevant adult-born neurons with enhanced maturity and improved dendritic and spine features. Functionally, selective manipulation of the activity of these circuit-modified young adult-born neurons further modulates memory performance and anxiety-like behavior. Our study identifies a unique neural circuit that can be manipulated to increase the quantity and improve the quality of adult-born neurons, and importantly, the activity of these neurocircuit-modified young neurons causally modulates hippocampal dependent behavior.

Abstract: The presence of neurogenesis in the adult human dentate gyrus (DG) is a contentious issue. Previous studies based on detection of cell proliferation and doublecortin (DCX) protein expression to identify neuroblasts and immature granule cell neurons have reported controversial results (Eriksson et al., 1998; Spalding et al., 2013; Dennis et al., 2016; Cipriani et al., 2018; Sorrells et al., 2018; Moreno-Jimenez et al., 2019). To add insight to these controversial sets of observations, we performed high-coverage single-nucleus RNA sequencing (snRNA-seq) on the DG and four anatomically defined subregions of the adult human hippocampal-entorhinal system comprising ammonic fields CA4-2, CA1, subiculum and entorhinal cortex. Our results showed widespread expression of DCX in hippocampal cell populations, particularly in inhibitory neurons, but also in some pyramidal and mossy cells, and in glial cells. We did not identify discrete clusters of DCX-expressing cells in the hippocampus,but we found 125 cells within the cluster of 14,703 DG granule cells with at least one DCX mRNA molecule. Although some of these granule cells co-expressed migrating or immature neuron markers including NEUROD2 (61.6%) or FXYD7 (32.8%) (Hochgerner et al., 2018), we found no specific enrichment of these markers compared to DCX non-expressing DG granule cells (nominal p-value > 0.05). Furthermore, we found no evidence of neural stem cells, and for example all nestin-expressing cells in the astrocytic cluster co-expressed AQP4, a marker for cells committed to the astrocytic lineage. Similarly, putative neural progenitor cells expressing MKI67 did not constitute an independent cluster in DG. Additional immunohistochemistry to detect DCX showed numerous cells in the amygdala as previously shown (Sorrells et al., 2019) and occasional cells in the entorhinal cortex, but only rare cells with interneuron morphology in the DG, consistent with our snRNA-seq data. Our results indicate that DCX at the RNA level is not a specific marker of neuroblasts or immature neurons in the adult hippocampus, and overall, show that neurogenesis does not continue, or is extremely rare, in the adult human hippocampus.

Title: Caveolin-1 cell autonomously regulates neural stem cells in adult hippocampal neurogenesis

Authors: *T. K. L. STEPHEN[1], J. A. BONDS[2], A. SHETTI[1], E. QUIROZ[1], K. OWUSU-ANSAH[1], L. APONTE-COFRESI[1], R. D. MINSHALL[1], O. LAZAROV[1];

Abstract: Adult Hippocampal Neurogenesis (AHN) is the generation of new neurons from neural stem and progenitor cells (NSPCs) in the dentate gyrus of the hippocampus. AHN is highly dependent on the cerebrovascular and thought to play a critical role in memory and cognition. Several mouse models of cardiovascular disease risk factors and neurological disease including Type II diabetes (T2DM) and Alzheimer's disease (AD) have impairments in AHN. Caveolin-1 (Cav-1) is a scaffolding protein that is enriched the cerebrovascular. Reduced brain expression of Cav-1 is associated with the cognitive deficits seen in T2DM. We observed that Cav-1 is also expressed in NSPCs. We hypothesize that Cav-1 has a novel cell autonomous role in NSCs and is an endogenous regulator of NSC quiescence. To test this, we have developed a new mouse model harboring conditional deletion of Cav-1 in NSPCs (NestinCreER^{T2};Cav- 1$^{lox/lox}$). Isolation of NSPCs from the hippocampus of these mice at 4-6 weeks of age revealed that deletion of Cav-1 reduces NSPCs proliferation levels. Further, deletion of Cav-1 in NSPCs results in altered expression of key neurogenic pathways regulating quiescence and metabolism of AD link signals such has full length Amyloid Precursor Protein (APP-FL) and β-secretase 1 (BACE-1). These results suggest that Cav-1 regulates neurogenesis via signals implicated in AD, at least in part. Elucidating the role of Cav-1 in neurogenesis may provide novel insight into mechanisms of learning and memory dysfunction in AD.

Title: Proteomic analysis of maturing adult-born hippocampal mossy fiber boutons

Authors: *K. MURRAY[1], X.-B. LIU[2], H.-J. CHENG[3];
[1]Univ. California Davis, Davis, CA; [2]Univ. of California Davis, DAVIS, CA; [3]Ctr. for Neurosci., Univ. California, Davis, Davis, CA

Abstract: The birth of new neurons (called neurogenesis) in the adult hippocampus is critical for learning and memory and disruption of this process is associated with human neurological disorders such as Alzheimer's disease. Rates of adult hippocampal neurogenesis (AHN) are tightly linked with changes in physiological activity. Activities such as enhanced exercise or learning as well as pathophysiological changes such as epilepsy, profoundly alter AHN. Knowing how ANH neurogenesis regulates neuronal circuitry is therefore important for understanding its overall impact on brain physiology. Central to this issue is understanding how newborn neurons in adult brain achieve long-term integration. Understand the molecular and cellular mechanisms regulating synaptic integration in AHN could lead to selective pharmacological targets for functional improvement during pathological conditions or in aging where levels of adult neurogenesis are dramatically decreased. Neuronal progenitors in the adult hippocampal

dentate gyrus give rise to newborn granule (GCs) cells that, when fully differentiated, receive synaptic inputs from entorhinal cortex and send axons along the mossy fiber pathway to form synaptic outputs with CA3 pyramidal neurons. We and others have shown that it takes about eight weeks for the newborn GCs to fully differentiate and form mature synaptic inputs and outputs. Here we assessed molecular changes in the synaptic outputs when newborn mossy fiber boutons (MFB) from GC are forming synapses with mature CA3 pyramidal cells in mouse brain. We utilized superresolution immunofluorescent array tomography to profile the proteomic changes of the pre- and post-synaptic elements during the establishment of mature synapses. We present a timeline of proteomic development in the maturing MFB terminals in young adult brain and in aging brain. In addition, we describe a novel heterogeneity in molecular composition of synaptic contacts within single adult-born MFB terminals. These experiments are some of the first to address the intricate proteomic changes essential for establishing new synaptic outputs during adult neurogenesis in young and old mouse brain.

Title: Function of oncogene Mycn in adult neurogenesis and oligodendrogenesis

Authors: J. CHEN, *Z. GUAN;
UCSF, San Francisco, CA

Abstract: Human *MYCN* is an oncogene amplified in neuroblastoma and many other tumors. Both human *MYCN* and mouse *Mycn* genes are important in embryonic brain development, but their function in adult healthy nerve system is completely unknown. Here, with *Mycn*-eGFP mice and quantitative RT-PCR, we found that *Mycn* was expressed in specific brain regions of young adult mice, including subventricular zone (SVZ), subgranular zone (SGZ), olfactory bulb (OB), subcallosal zone (SCZ), and corpus callosum (CC). With immunohistochemistry (IHC) we found that many *Mycn*-expressing cells expressed neuroblast marker doublecortin (DCX) and proliferation marker Ki67. With *Dcx-creER* and *Mki67-creER* mouse lines, we fate mapped *Dcx*-expressing neuroblasts and *Mki67*-expressing proliferation cells, along with deleting *Mycn* from these cells in adult mice. We found that knocking out *Mycn* from adult neuroblasts or proliferating cells significantly reduced cells in proliferation in SVZ, SGZ, OB, SCZ, and CC. We also demonstrated that the *Mycn*-deficient neuroblasts in SGZ matured quicker than wild type neuroblasts, and that *Mycn*-deficient proliferating cells were more likely to survive in SVZ, SGZ, OB, SCZ, and CC compared to wild type. Thus, our results demonstrate that, in addition to causing tumors in nervous system, oncogene *Mycn* has crucial function in neurogenesis and oligodendrogenesis in adult healthy brain.

Title: Rgs6 mediates effects of voluntary running on adult hippocampal neurogenesis

Authors: Y. GAO[1], M. SHEN[2], J. GONZALEZ[3], Q. DONG[2], S. KANNAN[2], B. EISINGER[1], Q. CHANG[2], D. WANG[2], L. S. OVERSTREET-WADICHE[4], ***X. ZHAO**[2];

Abstract: Voluntary running enhances adult hippocampal neurogenesis, with consequences for hippocampal dependent learning ability and mood regulation. However, the underlying mechanism remains unclear. Here, we show that voluntary running induces unique and dynamic gene expression changes specifically within the adult-born hippocampal neurons, with significant impact on genes involved in neuronal maturation and human diseases. We identify the regulator of G protein signaling 6 (RGS6) as a key factor that mediates running impact on adult-born neurons. RGS6 overexpression mimics the positive effects of voluntary running on morphological and physiological maturation of adult new neurons and reduced sensitivity of adult-born neurons to inhibitory effect of $GABA_B$ receptor activation. Knocking down RGS6 abolishes running-enhanced neuronal maturation and hippocampal neurogenesis-dependent learning and anxiolytic effect. Our study provides the data resource unveiling the genome-wide intrinsic molecular changes in adult-born hippocampal neurons that contribute to voluntary running-induced neurogenesis.

Title: Early postnatal signatures of prenatal stress exposure in rats: corticogenesis and brain activity

Authors: *K. C. CREUTZBERG[1], V. BEGNI[1], F. MARCHISELLA[1], I. PISANO[1], F. DE ROSA[1], N. LOPIZZO[2], M. MAZZELLI[2], V. ZONCA[3], A. CATTANEO[1], M. A. RIVA[1];
[1]Univ. of Milan, Milan, Italy; [2]IRCCS Inst. Ctr. San Giovanni di Dio Fatebenefratelli, Brescia, Italy; [3]King's Col., London, United Kingdom

Abstract: The prenatal period is a sensitive life stage during development since the organism is rapidly evolving and can undergo the influence of positive and negative stimuli from the womb environment. Accordingly, it is known that exposure to prenatal stress (PNS) can lead to long-lasting neurobiological and behavior consequences in the offspring, which may enhance the susceptibility for mental disorders. Indeed, we found that adolescent rats that were exposed to PNS show a range of behavioral changes that may reflect emotional dysregulation. However, it is still unclear if and how such abnormalities may be driven by alterations during early development. On this basis, here we aimed to characterize early postnatal changes in neurogenesis and brain activity following PNS exposure. In this sense, pregnant Sprague Dawley rats were randomly assigned to the control (CT) or PNS group (n = 15, 6 CT and 9 PNS). Briefly, PNS females were restrained in cylinders under bright light for 45 minutes 3 times a day from gestational day 14 to delivery. Two days after birth a maximum of 4 animals per litter was sacrificed, half brain was post fixed for immunofluorescence analysis while the prefrontal cortex (PFC) and hippocampus from the other hemisphere were dissected for transcriptional analysis. Two-way ANOVA was used for all analysis with a sex factor (male x female) and a rearing condition factor (CT x PNS), when an interaction effect was detected Tukey's *post hoc*test was applied. Immunofluorescence analysis of the proliferating marker Ki67 in the PFC showed a PNS effect ($p = 0.0049$), with a significant decrease in the number of Ki67 positive cells in newborn PNS rats. Accordingly, real-time PCR analysis showed that PNS animals have decreased expression levels of *Tbr1* on the PFC, an important transcription factor for the differentiation of glutamatergic neurons ($p = 0.0064$). Next, we analyzed the expression of different activity-regulated genes (*Arc*, *Zif-268* and *Npas4*) and calculated a Z-activation score in order to establish changes in the functional activity of the PFC and hippocampus. PNS animals showed increased Z-activation score in both PFC ($p = 0.0036$) and hippocampus ($p = 0.0148$). The enhanced activity in newborn PNS rats may also lead to an unbalance in redox mechanisms, as measured by a significant decrease of the antioxidant factor *Nrf2*, although such effect was only found in female animals (-22%, $p = 0.0478$ for the PFC; -67%, $p = 0.0198$ for the hippocampus). Our data suggests that exposure to stress in utero produces early changes in the newborn, which may ultimately contribute to functional dysregulation becoming evident later during development.

Title: Cause-effect structures of cortical columnar activity

Authors: *A. MAIER[1], B. M. CARLSON[2], J. A. WESTERBERG[3], N. TSUCHIYA[4];
[2]Psychology, [3]Dept. of Psychology, [1]Vanderbilt Univ., Nashville, TN; [4]Monash Univ., Clayton, Australia

Abstract: Cortical columns have been hypothesized to act as elementary (canonical) units to carry out neuronal computations. However, few columnar computations have been described to date. Thanks to advances in linear microelectrode arrays (LMAs), in vivo measurements of up to several hundreds of neurons within isolated cortical columns are becoming increasingly commonplace. This wellspring of data promises to offer new breakthroughs in understanding the role of cortical columns for neuronal processing. Here we describe a novel technique to derive intra-columnar interactions (cause-effect structures) from LMA data. The specific analytical technique is derived from the mathematically formalized framework of integrated information theory (IIT). A major advance of this approach is that it quantifies neural interactions similar to a cross-correlation at lag+1, but between multiple measurement sites of brain activity rather than just two. Earlier work demonstrated viability of this approach in invertebrates (Leung et al., 2021). Here we extend this approach to sensory responses of primate visual cortex. Cortical responses are non-linear across time, rising steeply at stimulus onset and slowly decaying (adapting) thereafter. We aimed to eliminate these transients by subtracting the average evoked response for each LMA electrode contact (channel) from trial-by-trial individual responses. Next, we binarized the data into periods of activity exceeding or staying below the trial average (UP- vs. DOWN states). Then, we computed the relative frequency with which UP or DOWN states at one columnar location ("causes") preceded UP or DOWN states elsewhere ("effects"). This computation was iterated for sets of channels across the LMA to derive the probabilities with which any possible state at one part of the column transitions to any possible state at other parts of the cortical column (transition probability matrix, TPM). Using IIT, TPM can be further deconstructed into integrated information magnitudes (Phi) as well as information structures for different states or stimuli. Here we show that the onset of a visual stimulus increases both the number and frequency of state transitions of V1 columnar spiking responses. We will discuss these findings in context of other causal and informational structures derived from neural data.

Title: Stretching and squeezing of neuronal log firing rate distribution by psychedelic and intrinsic brain state transitions

Authors: *B. DEARNLEY, M. DERVINIS, M. SHAW, M. OKUN;
Neuroscience, Psychology and Behaviour, Univ. of Leicester, Leicester, United Kingdom

Abstract: How psychedelic drugs modulate the activity of cortical neuronal populations and whether transition into a psychedelic brain state has shared features with other brain state transitions is not well understood. Here, we used Neuropixels 1.0 probes to perform acute extracellular recordings from large populations of neurons in medial prefrontal cortex of awake, head-fixed adult mice given the potent synthetic 5-HT2a receptor agonist (4-Bromo-3,6-dimethoxybenzocyclobuten-1-yl)methylamine hydrobromide (TCB-2). Oral administration of the drug significantly stretched the distribution of log firing rates of the population of recorded neurons, compared to control recordings (N=14 animals, one control and one drug recording were performed in each mouse in a random order). Stretching of the log firing rate distribution was previously observed across transitions between sleep and wakefulness, which suggested that it is a more general phenomenon and prompted us to examine it in more detail. We found that modulation of the width of the distribution of log firing rates of a neuronal population also occurred in different parts of the cortex and the hippocampus during intrinsic increases in the arousal level of awake mice, and thus constitutes a ubiquitous rather than a solely sleep-related phenomenon. Arousal, however, did not explain the stretching of the log-rates by TCB-2. In both psychedelic and naturally occurring brain state transitions, the stretching or squeezing of the log-rate distribution of an entire neuronal population reflected the concomitant changes in the log firing rate distribution of two subpopulations, with one subpopulation undergoing a downregulation and often also stretching of its neurons' log firing rates, while the other subpopulation undergoes upregulation and potentially a squeeze of its log-rates. In both subpopulations, the stretching or squeezing were a signature of a larger relative impact of the brain state change on the rates of the slow-firing neurons. These findings reveal a generic pattern of reorganisation of neuronal firing rates by brain state transitions.

Title: Circuits of reciprocally inhibitory neurons with escape and release mechanisms are differentially robust to perturbations and modulation

Authors: *E. O. MOROZOVA, P. NEWSTEIN, E. MARDER;
Volen Ctr. and Biol. Dept., Brandeis Univ., Waltham, MA

Abstract: Identifying key cell-intrinsic and circuit-level properties that influence the output of neural circuits and their resilience to perturbations is key for the brain. Small reciprocally inhibitory circuits provide an excellent platform for studying these questions due to their abundance in the nervous system and well-defined output. We used the dynamic clamp to build reciprocally inhibitory circuits of two gastric mill (GM) neurons of the crab stomatogastric ganglion (STG) by connecting them via artificial inhibitory synapses and adding a hyperpolarization-activated inward (H) current. Depending on the position of the synaptic threshold within the envelope of membrane potential oscillations, the circuit operates in either an “escape”, “release” or “mixed” mode. The release mechanism is characterized by the presynaptic cell falling below its synaptic threshold, releasing the suppressed cell from inhibition. The escape mechanism is characterized by the inhibited cell depolarizing above its synaptic threshold, terminating the firing of the active cell. We characterized the behavior of the circuits with different mechanisms of oscillation to alterations in circuit parameters, such as synaptic threshold, conductances and activation rates of synaptic and H currents. We further explored how circuits with escape and release mechanisms respond to temperature perturbations and neuromodulation. We showed that reciprocally inhibitory circuits with different underlying mechanisms of oscillation are not equally robust to perturbations. Particularly, circuits with a release mechanism are robust to variations in synaptic and H conductances but are fragile in response to an increase in temperature, while circuits with an escape mechanism rely on the tight correlation between synaptic and H conductances to generate robust bursting but are resilient to an increase in temperature. Further, the circuits with a release mechanism are significantly more sensitive to neuromodulators, such as serotonin, proctolin, oxotremorine and artificially generated modulatory current (I_{MI}), than the circuits with an escape mechanism. The differences in the dynamical mechanisms of oscillation can potentially explain a significant variability in individual responses of reciprocally inhibitory circuits to neuromodulation. These data indicate that the same perturbation can have dramatically different effects depending on the circuit mechanisms that may not be observable from baseline circuit output. Thus, knowing the dynamical mechanisms underlying the generation of antiphase oscillations is crucial for predicting the effects of perturbations.

Title: A novel frontal cortical input to the thalamic reticular nucleus (TRN) mediates instantaneous correlation between cortical and TRN activity

Authors: *N. HADINGER, L. ACSADY;
Inst. of Exptl. Med., Budapest, Hungary

Abstract: Neocortex is known to be organized into areas with different cognitive functions. However, we are only beginning to understand how cortico-thalamic interactions are regionally specialized. Emerging data shows that thalamus is involved in basically all cortical functions, including higher order cognitive processes. Thus, understanding regions specific cortico-thalamic communication is necessary to disentangle the rules of these long range interactions. In the present study we revealed an instantaneous and graded correlation between the frontal cortical LFP activity and the spiking of the anterior TRN cells. This correlation was mediated by a newly described pathway, specific for the frontal cortex. Until know, layer 5 (L5) cortical output, which otherwise exerts profound control over thalamic activity, was thought to reach thalamus without innervating its GABAergic nucleus, the TRN. Conditional viral tracing from the frontal (but not from other) cortical areas in the L5-specific Rbp4-Cre mouse however revealed dense, topographically-organized L5 projection in the anterior TRN. Optogenetic activation of L5 cells in anesthetized mice elicited bursts in anterior TRN cells with short latency and high fidelity. Gradually increasing the number of optogenetically actived L5 cells converging on the TRN neurons resulted in gradual change of the TRN burst properties. It increased both the intraburst frequencies and the number of spikes per bursts. Spontaneous firing actvity of L5-recipient TRN neurons showed tight and graded correlation with the ongoing frontal cortical oscillations. While single spike events showed low correlation with the cortical LFP, burst firing was tightly coupled to the LFP activity. Higher frequency burst with more spikes were correlated with faster, high amplitude cortical events. This correlation disappeared upon optogenetic perturbation of L5 to TRN input via ArchT. The data suggests powerful and temporally precise cortical control in frontal cortico-thalamic circuits by the strong coupling of anterior TRN cells to the ongoing cortical oscillations. Since the L5-TRN connection is region specific and is restricted to frontal cortex and anterior TRN our data demonstrate a qualitative regional difference in the organization of thalamocortical circuits.

Title: Median raphe heterogeneous neuronal populations differentially regulate hippocampal theta oscillations

Authors: *W. HUANG[1], S. IKEMOTO[2], D. V. WANG[1];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Behav Neurosci Br, Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Theta oscillation during rapid eye movement (REM) sleep plays an important role in mnemonic processes by coordinating hippocampal and cortical activities. However, how the theta activity is regulated by subcortical regions including the median raphe nucleus (MnR) is not fully understood. It is thought that the MnR mainly suppresses hippocampal theta activity through its serotonergic outputs. Complementally, our study revealed a more complex framework indicating a role of non-serotonergic MnR outputs in regulating hippocampal theta oscillation. By using Optogenetics and dual-site electrophysiological recordings on wild-type and transgenic mice, we found that most Vglut3+, but not serotonergic or GABAergic MnR neurons exhibited decreased or silent activity during hippocampal theta activity. Additionally, most GABAergic and a small subset of Vglut3+, but not serotonergic MnR neurons exhibited hippocampal theta phase-locked activity, and that the GABAergic MnR neurons innervated nearby Vglut3+ and serotonergic MnR neurons. Lastly, optogenetic activation of the MnR induced robust hippocampal theta activity, and that Granger causality analysis confirmed a causal effect from MnR theta to hippocampal theta. These results suggest that MnR non-serotonergic neurons have a causal role in driving hippocampal theta activity during REM sleep associated memory processes.

Title: A single cell correlate of theta-gamma phase amplitude coupling during working memory in the human hippocampus

Authors: *J. DAUME[1], A. G. P. SCHJETNAN[3], T. A. VALIANTE[3], A. MAMELAK[1], U. RUTISHAUSER[1,2,4];
[1]Dept. of Neurosurg., [2]Dept. of Biomed. Sci., Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]Krembil Res. Inst. and Div. of Neurosurg., Univ. Hlth. Network (UHN), Univ. of Toronto, Toronto, ON, Canada; [4]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Theta-gamma phase amplitude coupling (PAC) reflects the coordination of neural activity across different frequency bands. Especially in working memory, where prolonged interactions between cognitive control and stimulus processing take place, theta-gamma PAC has been observed in various brain regions of the animal and the human brain. To date, however, there is no established single-cell correlate demonstrating the effect of local field potential (LFP)-level PAC on the activity of single cells. Here, we recorded single cell activity and population level LFPs from the human medial temporal lobe

and medial frontal cortex while patients performed a Sternberg working memory task with pictures (36 sessions in 29 patients, 1444 neurons). We observed local theta-gamma PAC in the amygdala and hippocampus during the working memory delay period. Only in the hippocampus, however, PAC differed as a function of working memory load with stronger PAC observed in load 1 as compared to load 3, reflected by longer bouts of gamma activity coupled to the underlying theta rhythm with higher memory load. Weak to no PAC coupling was observed in the frontal lobe. We identified neurons in the hippocampus that followed the phase of theta oscillations and the power of gamma oscillations. These "PAC cells" showed stronger phase coupling to local high gamma oscillations in load 3 then in load 1. At the same time, they were more closely coupled to the phase of remote theta oscillations recorded in ventromedial prefrontal cortex in load 3 as compared to load 1. Thus, more information maintained in working memory led to stronger coupling to fast local oscillations in the hippocampus as well as to slow remote oscillations in the frontal lobe. Moreover, spiking-timing of PAC cells differed as a function of memory load with spikes being more tightly coupled to the theta phase corresponding to the gamma power peak in load 3 then in load 1, as well as a function of picture category during memory encoding. While firing rates did not differ between experimental conditions, such theta phase shifts speak to the fact that PAC cells encode memory content using a phase rather than a firing rate code. Taken together, we identified neurons that relate their activity to ongoing interactions of theta and high gamma oscillations in the human hippocampus and frontal lobe. These interactions might be the neural marker of the ongoing coordination between frontal cognitive control and posterior stimulus processing that are necessary to hold information in mind for a brief period of time.

Title: Effects of variations in network features on characteristics of gamma bursts

Authors: *D. DOPP[1], M. STROUD[1], F. FENG[2], S. S. NAIR[3], Z. CHEN[4];
[1]Univ. of Missouri, Columbia, MO; [2]Electrical and Computer Engin., Univ. of Missouri-Columbia, Columbia, MO; [3]Electrical & Computer Engin., [4]Electrical Engin. and Computer Sci., Univ. of Missouri Columbia, Columbia, MO

Abstract: Effects of variations in network features on characteristics of gamma bursts
Daniel Dopp, Matthew Stroud, Feng Feng, Ziao Chen, Satish S. NairElectrical Engineering & Computer Science Dept., University of Missouri, Columbia, MO
Abstract Computational models to explore rhythmic activity in neuronal networks have used single cells that range in complexity from the integrate-and-fire and Izhikevich formulations defined by one or two

parameters to detailed biophysical models with over tens of parameters. Connectivity configurations have, similarly, varied from homogeneous to different heterogeneous types. Gamma oscillations (30-80 Hz) are expressed in many brain regions, where they are reflected in electroencephalogram (EEG) and local field potential (LFP) signals. In a recent study, we reported a large scale biophysical computational model of the basal amygdala (BL) that replicated several features of transient gamma oscillations seen in *in vivo* local field potentialLFP recordings from BL, via PING interactions involving principal cells (PNs) and fast-spiking interneurons (ITNs) (Feng et al., 2019).
The present modeling study uses the 1000-cell version of the amygdala model to explore the effects of variations in 'network features' including single cell model dynamics, heterogeneity in connectivity, and synaptic short-term plasticity, and neuromodulatory effects, on the genesis and characteristics of gamma. These characteristics include frequency of occurrence of bursts in the filtered LFP as well as frequency within a burst and burst duration. The genesis of burst will be explored via a temporal averaging approach that was recently found to reveal interesting insights. Preliminary results using the approach showed that average firing rates across the entire network model for afferents, PNs and FSIs were temporally correlated with the LFP. The time lags between the bursts revealed the causal connection between afferents, PNs and ITNs in this PING-type burst generation. Aligning the average firing rates using phase of significant cycles within bursts of the LFP revealed distinct phases of population activity for afferents, PNs and ITNs. How network features impact these and other characteristics of the genesis mechanism are being studied presently.

Title: The study of SLC6A1 and SCN1A gene hot spot mutation in families with idiopathic epilepsy

Authors: S. DUU[1], T. SURJAVKHLAN[2], T. AVIRMED[3], P. ICHINKHORLOO[2], ***J. JAMIYANSUREN**[2,4];
[1]Sch. of Med., Mongolian Natl. Univ. of Med. Sci., Dornogovi, Mongolia; [2]Dept. of Mol. biology and Genet., [3]Dept. of Neurol., Mongolian Natl. Univ. of Med. Sci., Ulaanbaatar, Mongolia; [4]Dept. of Biochem., Intl. Univ. of Hlth. and Welfare, Narita, Chiba, Japan

Abstract: Introduction. Epilepsy is a chronic neurological disorder characterized by recurrent and unprovoked spontaneous seizures, and is one of the most common neurological condition regardless of age group and gender. According to the WHO statistics, there are 50 million patients with epilepsy worldwide, with 5 million newly diagnosed cases each year. In addition, 50 percent of the diagnosed epilepsy is idiopathic and the role of the hereditary factors are essential. More than 500 genes related to epilepsy seizures have identified and they divided into ion channels and other types of genes. As for ion

channel genes, *SLC6A1* (Solute Carrier Family 6 Member 1) gene is located in the 3p25.3 locus, and encodes the voltage-dependent gamma-aminobutyric acid (GABA) transporter (GAT1). GAT1 is responsible for re-uptake GABA from the synaptic cleft. Therefore, one of major ion channel gene is *SCN1A*, located on 2q24.3 and encodes the voltage-gated sodium channel alpha 1 subunit (Nav1.1, alpha 1). Mutations in this gene lead to channel dysfunction and results epileptic seizures in patients. **Objective.** To determine hot spot mutations of *SLC6A1* and *SCN1A* mutations in families with idiopathic epilepsy. **Material and methods.** The study included six patients and their healthy four relatives, total 10 persons on voluntary basis to comply with ILAE criteria. Peripheral blood samples collected from each participants and DNA extracted using DNA extraction kit. DNA purity and concentration were measured using spectrophotometer. *SLC6A1* (c.889G>A and c.1369_1370 delGG) gene mutations detected by using allele specific PCR and confirmed by gel electrophoresis. *SCN1A* (530G>A and 1264A>G) mutations were detected by Sanger sequencing. **Results.** According to genealogical studies, except for the cases of children from the same mother, the disease inherited in every generation regardless of gender without regular pattern. In the DNA sequencing test, the c.889G> A mutation contained exactly the same G allele in 3 healthy and 5 cases with epilepsy. c.1369_1370 del GG mutation was identified in only one patient and did not contain deletion. The mean age of the participants was 23.5 for controls and 12.7 for patients. Pedigree analysis shows that epilepsy inherited by autosomal dominant type in this family. When, the *SCN1A* mutations were determined in these participants, the minor risk allele of 530G>A 1264A>G mutations were not identified. *SCN1A* 311T>C mutation was unable to analyze. **Summary.** In clinical genealogy, epilepsy inherited by autosomal dominant in the family. Hot spot mutations of *SLC6A1* and *SCN1A* are maybe not the cause of contributing factor of epileptic status for this family.

Investigación de Estudios Avanzados, South Headquarters, Mexico City, Mexico

Abstract: Abstract: Problem statement: In Mexico, 30% of epileptic patients are resistant to drug treatment. (Perez Almengor., et; al, 2015). Given the low response to current anti-epileptic drugs (AEDs) for the control of drug-resistant epileptic seizures, the use of cannabidiol (CBD) is a current alternative already used in patients who are resistant to conventional treatment, although CBD it is not part of the basic treatment. This molecule is metabolized mainly by the cytochrome family (CYP), due to this it is important to determine the type of polymorphisms that would better respond to CBD (Lakhan, R., et; al, 2011, Makowska, M., et; al, 2020). Knowledge about those CYP genetic variants that affect CBD metabolism can provide relevant information to the physician. (Consroe P., et; al, 1982, Jones NA., et; al, 2010) Aim: To analyze the association between CYP polymorphisms and the therapeutic response of CBD in Mexican patients with drug-resistant epilepsy. Results: We demonstrate a low-risk association in epilepsy drug-resistant patients with unknown etiology in rs17879239 variant of *CYP2C19* gene [OR= 1.30 (1.005 - 1.702); p=0.04]; however, although SNP rs16947 of *CYP2D6* gene associated with greater toxicity by AEDs administration, it was not a significant relevance. Conclusion: Risk association in variant rs17879239 of *CYP2C19* was demonstrated in our population with unknown etiology.

Title: Diet modifies allele-specific phenotypes in Drosophila carrying epilepsy-associated PNPO variants

Authors: *W. CHI[1], A. IYENGAR[2], W. FU[1], W. LIU[3], A. E. BERG[2], C.-F. WU[2], X. ZHUANG[1]; [1]Neurobio., Univ. of Chicago, Chicago, IL; [2]Univ. of Iowa, Iowa City, IA; [3]China Med. Univ., Shenyang, China

Abstract: Pyridox(am)ine 5'-phosphate oxidase (PNPO) catalyzes the rate-limiting step in the synthesis of pyridoxal 5'-phosphate (PLP), the active form of vitamin B6 required in the synthesis of neurotransmitters GABA and the monoamines. Pathogenic variants in *PNPO* have been repeatedly identified in patients with neonatal epileptic encephalopathy and early-onset epilepsy. These patients often exhibit different types of seizures and variable comorbidities, including developmental impairment and intellectual disability. It is unclear how seizure types and associated comorbidities are linked to specific *PNPO* alleles and to what degree diet can modify their expression. Furthermore, the molecular characteristics of *PNPO* variants have not been examined in model systems. Using CRISPR/Cas9, we

generated four knock-in *Drosophila* alleles, h^{WT}, h^{R116Q}, h^{D33V}, and h^{R95H}, in which the endogenous *Drosophila PNPO* (*sugarlethal*) was replaced by wild-type human *PNPO* cDNA and epilepsy-associated variants corresponding to R116Q, D33V, and R95H, respectively. We examined these knock-in flies at different levels. Collectively, we found a wide range of phenotypic variation in an allele- and diet-dependent manner. Specifically, the D33V mutation reduces the mRNA level, R95H reduces the protein stability, and R116Q alters the protein localization of *PNPO* in the brain. D33V and R95H mutations lead to partial and complete lethality during development, respectively and R116Q and D33V mutations shorten lifespan. At the behavioral level, h^{D33V}/h^{R95H} flies are hypoactive on all tested diets whereas h^{R116Q} homozygotes show diet-dependent behavioral outcomes. At the circuitry level, h^{D33V} homozygotes show rhythmic burst firing and h^{D33V}/h^{R95H} flies exhibit spontaneous seizure discharges. In h^{R95H} homozygotes rescued with PLP supplementation, we further uncovered that PLP deficiency abolishes development and causes extreme seizures in adults. Lastly, genetic and electrophysiological analyses demonstrate that h^{WT}/h^{R95H} flies are prone to seizures due to a dominant-negative effect of h^{R95H}. Together, this study demonstrates that human *PNPO* variants interact with diet to contribute the phenotypic variations; and that knock-in *Drosophila* model offers a powerful approach to systematically examine clinical manifestations and the underlying mechanisms of human PNPO deficiency.

Title: A Circadian Mechanism of Epilepsy Observed in PAR bZip Triple-Knockout Mice

Authors: *L. GOICOURIA[1], S. FEENEY[1], H. HIGASHIMORI[2], J. S. LIU[3];
[2]Sch. of Med., [3]Neurol., [1]Brown Univ., Providence, RI

Abstract: D site-binding protein (DBP), hepatic leukemia factor (HLF) and thyrotroph embryonic factor (TEF) are the 3 members of the PAR (proline and acidic amino acid-rich) subfamily of bZIP (basic region/leucine zipper) transcription factors. Epileptic tissue resected from pediatric patients with focal cortical dysplasia exhibits decreased expression of DBP, among other circadian rhythm proteins. Furthermore, in a genetic model of epilepsy in mice—in which the *Clock* gene is excised in excitatory neurons—there are decreased levels of DBP and HLF. Most importantly, excision of all 3 PAR bZip proteins in mice causes them lethal intractable seizures. The mechanistic cause of the seizures exhibited in the PAR bZip triple-knockout mouse is unknown. Immunohistological findings here represented and a unique circadian-based pattern observed in seizure frequency provide valuable insights into the possible mechanism of epileptogenesis in the PAR bZip triple-knockout mouse.

Title: Neuronal models to test compounds for beneficial or toxic effects relevant to pediatric epilepsy: quantification of synchronized activity via kinetic image cytometry

Authors: *P. MCDONOUGH[1], K. L. GORDON[2], C. G. RINES[1], R. C. B. BASA[1], C. HADLEY[1], D. RAKIC[1], J. H. PRICE[1,3];
[1]Vala Sci. Inc, San Diego, CA; [2]Vala Sci. Inc., San Diego, CA; [3]The Scintillon Inst., San Diego, CA

Abstract: Epilepsy, a common brain-disorder, affects ~3.5 million people in the US, including ~460,000 children. Epileptic seizures are episodes of abnormally increased and synchronized neuronal activity in the brain cortex which cause convulsions, repetitive movements/behaviors, and loss of consciousness. Seizures can result from metabolic imbalance, brain injury, drug toxicity, fever, and inherited mutations (primarily in genes encoding ion channels). Epilepsy in neonates and children (pediatric epilepsy) may lead to abnormal development, brain damage, and cognitive impairment (epileptic encephalopathy). Our goal is to develop high throughput screening assays, based upon hiPSC-neurons and glial cells, to test agents for beneficial effects relevant to pediatric seizures, as hiPSC-derived neurons may be relevant to fetal and neonatal CNS. We have utilized fluorescent indicators of intracellular calcium (Fluo-4) or voltage (FluoVolt), hiPSC-neurons plated in 384-well dishes, and Kinetic Image Cytometry (automated digital microscopy and cell-image analysis software) to quantify effects of 4-aminopyridine (4-AP) to elicit synchronized activity of the neurons. Coculture with astrocytes facilitates synchronized activity in response to 4-AP and we can quantify changes in the degree of synchronization and recruitment of neurons into active circuits via analysis of the kinetic signatures, on a cell-by-cell basis. Our assay system will enable testing of hiPSCs representing different genotypes and inclusion of additional cell types (e.g., hiPSC-microglial cells) to facilitate drug-discovery towards a pediatric epilepsies (e.g., Dravet Syndrome, Childhood Absence Epilepsy, Lennox-Gastaut Syndrome). The assay system will also enable elucidation of mechanisms relevant to adult forms of epilepsy and testing of candidate therapeutics for epileptogenic side effects (neurotoxicity).

Title: Dissecting the role of genetic modifiers on mTOR pathway activity in Tuberous Sclerosis Complex (TSC)

Authors: *P. SWAMINATHAN[1], H. FRY[1], S. KANESHAMOORTHY[1], V. NARAYANAN[2], S. RANGASAMY[1];
[2]Ctr. for Rare Childhood Disorders, [1]Translational Genomics Res. Inst., Phoenix, AZ

Abstract: Tuberous sclerosis complex (TSC) is an autosomal dominant disorder caused by heterozygous mutations in the TSC1 or TSC2 gene, resulting in dysregulation of the intracellular mammalian target of rapamycin (mTOR) signaling pathway. Neurocognitive phenotypes associated with TSC range in severity from seizures, cognitive impairment, developmental delay, and autism, to a milder phenotype. Phenotypic variability has been observed within single families where all affected members have the same TSC1 or TSC2 mutation. To investigate the molecular basis of phenotypic variability, we established primary dermal fibroblast cell lines from a severely affected child and their mildly affected parent, both of which carry a heterozygous germline TSC2 mutation [c.2621dupC (p. Tyr875fs)]. We evaluated the expression levels of different key players involved in the mTOR network via western blot analysis of fibroblasts from the parent-child pair and an unrelated control. Experimental observations indicated decreased phospho-Akt (Thr308) and augmented p70S6K1 levels in the child with severe phenotype compared to the mildly affected parent and control cells. Our biochemical results suggest impaired Akt phosphorylation to be a potential biomarker of mTOR signaling in cells from severely affected patients. Further genetic analysis between the parent-child pair exhibited heterozygous germline variants in other mTOR pathway genes such as EIF4G1, PIK3R3, and TNFRSF19 in the child. Our studies revealed differential mTOR activity in cells from patients with phenotypic variability in familial TSC, which could be influenced by genetic modifiers in the mTOR network.

Title: Fly seizure EEG: field potential activity in the Drosophila brain

Authors: *A. IYENGAR, C.-F. WU;
Univ. of Iowa, Iowa City, IA

Abstract: Hypersynchronous neural activity is a characteristic feature of seizures. Although many *Drosophila* mutants of epilepsy-related genes display clear behavioral spasms and motor unit hyperexcitability, field potential measurements of aberrant hypersynchronous activity across brain regions during seizures have yet to be described. Here, we report a straightforward method to observe local field potentials (LFPs) from the *Drosophila* brain to monitor ensemble neural activity during seizures in behaving tethered flies. High frequency stimulation across the brain reliably triggers a stereotypic sequence of electroconvulsive seizure (ECS) spike discharges readily detectable in the dorsal longitudinal muscle (DLM) and coupled with behavioral spasms. During seizure episodes, the LFP signal displayed characteristic large-amplitude oscillations with a stereotypic temporal correlation to DLM flight muscle spiking. ECS-related LFP events were clearly distinct from rest- and flight-associated LFP patterns. We further characterized the LFP activity during different types of seizures originating from genetic and pharmacological manipulations. In the 'bang-sensitive' sodium channel mutant *bangsenseless* (*bss*), the LFP pattern was prolonged, and the temporal correlation between LFP oscillations and DLM discharges was altered. Following administration of the pro-convulsant $GABA_A$ blocker picrotoxin, we uncovered a qualitatively different LFP activity pattern, which consisted of a slow (1-Hz), repetitive, waveform, closely coupled with DLM bursting and behavioral spasms. Our approach to record brain LFPs presents an initial framework for electrophysiological analysis of the complex brain-wide activity patterns in the large collection of *Drosophila* excitability mutants.

Title: Fornix deep brain stimulation lowers beta-amyloid levels in Alzheimer's disease patients.

Authors: *J. GERMANN[1], J. TOMASZCZYK[1], G. S. SMITH[2], K. YAMAMOTO[1], F. V. GOUVEIA[3], A. BOUTET[1], G. J. B. ELIAS[1], A. LOH[1], M. P. MCANDREWS[1], D. F. TANG-WAI[1], A. M. LOZANO[1];

Abstract: Alzheimer's disease (AD) is a highly prevalent neurodegenerative disease of aging. The pathological hallmarks of AD at autopsy are the accumulation of aggregated proteins and formation of extracellular amyloid-β (Aβ) plaques and intracellular neurofibrillary hyperphosphorylated tau tangles.

Amyloid and tau deposition can be quantified in vivo using positron emission tomography (PET). Clinically, AD is characterized by progressive memory impairment, and other cognitive deficits known to be caused by disturbances in widespread brain networks. Deep brain stimulation (DBS) is a neurosurgical therapy in which intracranial electrodes are employed to deliver current to specific brain structures modulating dysfunctional neural circuits. DBS targeting the fornix (fx-DBS) is being investigated for the treatment of AD. Active fx-DBS has been shown to alter neuronal activity, increase glucose metabolism, slow cognitive decline, and attenuate disease-related hippocampal atrophy in certain patients. Preclinical studies have demonstrated that stimulation of the fornix improves cognitive performance and reduces Aβ plaques in rodent models of AD. This open-label trial (ClinicalTrials.gov, NCT04856072) aimed to investigate if the disease-modifying effects of DBS can be observed in human fx-DBS patients. Cognitive performance (ADAS-cog) and imaging biomarkers (T1w MRI and Flutemetamol PET) were assessed in seven AD patients treated with fx-DBS at baseline (post implantation), at ~ 6months (1st follow-up (F/U)) and ~12 months (2nd F/U). The results show that fx-DBS significantly reduces PET-indexed brain-wide amyloid deposition. We observed an average decrease of 3% in patients undergoing active fx-DBS. Further analysis suggests this reduction is particularly pronounced in the first few months and subsequently drops off. This work suggests that fx-DBS has disease-modifying potential for the treatment of AD.

Title: Masupirdine (SUVN-502): A promising clinical candidate for the management of agitation in patients with dementia of Alzheimer's type

Authors: *R. NIROGI, P. JAYARAJAN, J. TADIPARTHI, A. SHINDE, R. BADANGE, A. MOHAMMED, V. GOYAL, V. BENADE, R. PALACHARLA, R. SUBRAMANIAN, J. RAVULA, S. JETTA;
Suven Life Sci., Hyderabad, India

Abstract: 5-HT_6 receptors are G-protein coupled receptor mainly localized in the brain regions primarily involved in cognition and behavior i.e., cortex, dorsal hippocampus and striatum. Evidence from the studies in animal models suggests that 5-HT_6 receptor antagonists may have a potential role in controlling neuropsychiatric behavior such as agitation. Masupirdine is a potent and selective 5-HT_6 receptor antagonist. Masupirdine was evaluated in a phase-2a proof-of-concept, 26-week, randomized, double-blind, placebo-controlled, multicenter, parallel groups study in moderate Alzheimer's disease (AD) patients in United States under active US IND. Subgroup analyses of phase-2a results were carried out to evaluate the effects of masupirdine on domains related to agitation/aggression on the Neuropsychiatric Inventory (NPI-12) scale. Masupirdine was also evaluated in resident-intruder task, an animal model for aggressive behaviors. Additionally, masupirdine was evaluated using brain microdialysis to assess its effects on the modulation of monoaminergic neurotransmitters in rats. In phase-2a clinical study subgroup analyses, masupirdine showed robust efficacy in agitation/aggression scores in subjects who had baseline symptoms of agitation/aggression. The effect sustained till end of 26 week treatment. Masupirdine was generally found to be safe and well tolerated. In preclinical animal models, masupirdine reduced the aggressive behaviour in resident intruder task and increased neurotransmitters with role in attenuating symptoms of agitation and aggression. Masupirdine showed clinically meaningful improvement in the neuropsychiatric symptoms associated with agitation/aggression in patients with AD, and reduced aggression in animal models. Masupirdine could be a differentiated therapeutic option for the management of agitation/aggression in Alzheimer's patients. Masupirdine is currently being studied for the management of agitation in patients with dementia of Alzheimer's type.

Title: Clinical development of SEMA4D blocking antibody, pepinemab, a novel potential treatment for neurodegenerative disease

Authors: *E. EVANS[1], T. FISHER[1], V. MISHRA[2], A. READER[1], E. SMITH[1], J. LEONARD[1], A. FEIGIN[3], E. SIEMERS[4], J. WITTES[5], M. ZAUDERER[1];
[1]Vaccinex, Rochester, NY; [2]Vaccinex Inc., Rochester, NY; [3]The Marlene and Paolo Fresco Inst. for Parkinson's and Movement Disorders, NYU Langone Hlth., New York, NY; [4]Siemers Integration LLC, Zionsville, IN; [5]Statistics Collaborative, Washington DC, DC

Abstract: Pepinemab (VX15/2503), a humanized IgG4 monoclonal antibody, blocks the binding of semaphorin 4D (SEMA4D) to its plexin receptors. SEMA4D is upregulated in diseased neurons and triggers glial activation. Downstream effects of chronic activation can aggravate neurodegeneration. Blocking antibody to SEMA4D has been shown to ameliorate pathology and symptoms of disease in preclinical models of Huntington's disease (HD), Alzheimer's disease (AD), multiple sclerosis, and Rett Syndrome. SIGNAL-HD (NCT02481674) is a completed Phase 2 placebo-controlled study of pepinemab in HD. SIGNAL-AD (NCT04381468) is an ongoing Phase 1b/2a placebo-controlled trial in AD that opened for enrollment in June 2021. Enrollment updates for SIGNAL-AD, as well as proof of concept safety, clinical, and biomarker data from the SIGNAL-HD trial will be presented. The SIGNAL-HD study included 301 subjects with late prodromal and early manifest (EM) HD, treated monthly by intravenous infusion for at least 18 months. Pepinemab was well-tolerated and detected in cerebrospinal fluid at the dose level targeted for biological efficacy. Co-primary efficacy measures consisted of a two-item HD cognitive assessment family including One Touch Stockings of Cambridge and Paced Tapping components of the HD-Cognitive Assessment Battery (HD-CAB), and clinical global impression of change (CGIC), a global measure of clinical meaningfulness. The primary endpoints did not achieve statistical significance in this study, however, positive trends in the direction of pepinemab benefit were observed and were supported by additional analysis of secondary and exploratory endpoints. Treatment benefits in clinical and imaging endpoints appeared to be restricted to the EM subjects. A treatment benefit was observed in 6/6 components of the HD-CAB cognitive assessment battery, with a significant HD-CAB composite score (p=0.007). In a posthoc subgroup analysis of EM subjects with somewhat more advanced disease (baseline TFC 11 vs TFC 12 and 13), treatment appeared to improve CGIC status (p=0.04). Effects on cognition were further supported by prespecified exploratory imaging endpoints, demonstrating that pepinemab treatment reduced brain atrophy (volumetric MRI; caudate p=0.017) and inflammation (TSPO-PET), and slowed or reversed decline in metabolic activity in 26/26 brain regions,

with 15/26 regions showing a significant positive treatment effect ($p \leq 0.05$) in FDG-PET imaging. Pepinemab did not achieve primary efficacy outcome measures in the SIGNAL study, but favorable safety profile and positive trends in cognition and imaging endpoints encourage continued development in HD and AD.

Title: Positive Clinical Outcomes of Posiphen in Two Phase 2a Studies—Alzheimer’s Disease and Parkinson’s disease

Authors: *C. FANG[1], M. MACCECCHINI[1], H. ZETTERBERG[2], M. CHEN[3], P. HERNANDEZ[4]; [1]Annovis Bio, Berwyn, PA; [2]Univ. of Goteborg, Goteborg, Sweden; [3]TCM group, Berkeley heights, NJ; [4]Ezy Med. Res., miami, FL

Abstract: Overexpression of neurotoxic proteins drives downstream events that dysregulate axonal transport, lead to inflammation, nerve cell death, and loss of function. By inhibiting the translation of amyloid precursor protein, tau and alpha-synuclein, our drug Posiphen has been shown in animal models to restore axonal transport, lower inflammation and protect nerve cells from dying. Posiphen preserved and restored full function in 7 animal models including Down Syndrome, Alzheimer’s disease (AD)

,stroke, traumatic brain injury, Parkinson's disease (PD), frontotemporal dementia, and blindness in acute glaucoma. Posiphen was proven safe in over 130 healthy and sick people [Maccecchini et al 2012]. To show that Posiphen reverses the toxic cascade and potentially shows efficacy in humans, we started two double-blind, placebo- controlled clinical phase 2a studies in AD and PD patients. In the first part of the study, we enrolled 14 AD and 14 PD patients (4 placebo and 10 treated with 80 mg posiphen QD). We took their blood, CSF and conducted safety evaluation and psychometric tests appropriate to the respective disease. The patients were treated for 25 +/- 2 days and had a second round of safety and psychometric tests. The plasma and CSF samples are being analyzed for markers of the toxic cascade leading to nerve cell death: AD and PD specific biomarkers, markers of axonal transport, inflammation, neurodegeneration and synapse health. The second part of the study is enrolling an additional 40 PD patients with the same study design to test the result on markers as well as on efficacy of different concentrations of posiphen. This second part will be completed and analyzed shortly. From the first part of the study, we are reporting statistically significant improvements in ADAS-Cog 11 in treated AD patients. In treated PD patients, we also see a strong trend in function improvements in the MDS-UPDRS. In both patient populations our drug statistically significantly improves speed, coordination, accuracy and attention in the WAIS coding test. We measured biomarkers and saw that inflammation was statistically reduced in AD and PD patients. The statistical significance holds whether the levels are compared within the same patients at 0 and at 25 days or between placebo treated and Posiphen treated at 25 days. Posiphen also reduced sAPPalpha, and beta, Tau, p-Tau and improved the Ab42/40 ratio. The other markers, such as aSYN oligomers, transport and synaptic markers are still being analyzed. In conclusion, we showed that Posiphen improves cognition in AD and motor function in PD patients and reverses the toxic cascade leading to nerve cell death.

Title: Longterm results of Alzheimer's disease treatment with TPS (Transcranial Pulse Stimulation)

Authors: *P. NOVAK[1], H. LOHSE-BUSCH[2];
[1]Storz Med. AG, Taegerwilen, Switzerland; [2]Rheintalklinik, Bad Krozingen, Germany

Abstract: Low intensity shockwaves proved to be efficient for the treatment of non-unions, tendon and muscular pain, wound healing, heart insufficiency, erectile dysfunction, aesthetic disorders and since 1990 also neurological indications. The working principle is the mechanical stimulation of biological processes called mechanotransduction resulting in increased cell metabolism, release of nitric oxide (eNO) and of numerous growth factors. There is also an anti-inflammatory effect, stimulation of stem cells and of the innate immune system.Transcranial Pulse Stimulation TPS) uses shockwave pulses for mechanical stimulation of the brain tissue. Detailed animal evaluation conformed the experience from years of shockwave applications in other medical disciplines that the treatment is safe. There have been no negative side effects observed.Six Alzheimer's disease patients have been treated with TPS since 2010. The treatment consists of a booster block of 6 treatment sessions within 2 weeks and one re-treatment session per month after 3 months follow-up. 6000 shockwave pulses with energy flux density of 0.2mJ/mm^2 are applied in one session. The CERAD score is typically improved by 10-17% within the first 3 months. The long-term data exists for more than 3 years. The results to date show that the monthly re-treatment is sufficient for maintaining the improvement for at least one year. Thereafter a further improved treatment protocol has to be developed. As can be derived on behalf of the available data, the booster block will have to be repeated approximately every 18 months.The current experience proves that the treatment is safe and effective. A two-center trial with Neurolith (Storz Medical) has been successfully completed with 35 patients and resulted in regulatory clearance in Europe. Still, further trials with larger number of patients are necessary. A placebo controlled, randomized trial is ongoing.

Title: Social Media Narratives around Genetic Testing for Alzheimer's Disease

Authors: A. TAHAMI[1], S. DOOGAN[2], ***N. FARID**[2], M. BRAY[1], E. KARAHAN[1], Q. ZHANG[1]; [1]Eisai, Woodcliff Lake, NJ; [2]Real Life Sci., Wayne, PA

Abstract: Background: Apolipoprotein E- ε4 (APOE-4) is a gene variation known to increase the risk for Alzheimer's disease (AD). Increasingly, people are discussing APOE-4 genotyping in AD on social media. The goal of this study was to compare barriers, planning, and rationale of decisions for genetic testing among the AD population and the general public.
Objective: To investigate the differences between conversations around genetic testing within the AD population compared to the general population.
Methods: We used the RLytics Natural Language Processing (NLP) platform to aggregate and analyze narratives from over 100 social media portals. The posts were extracted from AD-specific social media using the search terms "APOE" or "Genetic Testing" and included in the AD group.

Additionally, we extracted posts from non-AD-specific social media sites using only the “APOE” as a search term to exclude posts referring to non-AD-specific genetic tests. This group of narratives was included in the general population group.
RLytics used relational concept models to classify the ways in which medical conditions and functions were reported in raw text.
Results: A total of 3729 narratives were included in the study. The AD population had 2106 narratives from 169 users. Of which, 70 were caregivers, 54 were patients, and 92 were unclassified. 1623 narratives were posted by 673 users in the general public. Next, these narratives were categorized into low level categories and then eight high-level categories: 1. Unmet Needs, Education and Support 2. Financial Concerns 3. Logistics Challenges 4. Emotional Reactions 5. Genetic Counseling 6. Personal/Family Planning 7. Data privacy, Security, and Protection 8. Concerns or skepticism about the accuracy of test/test results. Analysis revealed that persons in the AD population showed similar trends to the general population in terms of education and costs. But they were more concerned about the eligibility for testing and privacy of results.
Conclusion: Social media narratives provide us meaningful insights about genetic testing in AD and associated patient journeys. The AD population showed a need for resources that provide more information around where they can get tested and the privacy implications that come with genetic testing. Whilst the general population sought general educational resources for genetic testing.

Title: Dual-task Intervention on Strength, Balance, and Executive Function Among Older Adults with Various Cognitive Levels

Authors: *N. VISNJEVIC[1], J. LEE[1], C. `. DAVIS[2], K. IP[2], J. IGNACIO[2], K. FAILDO[2], Y.-H. CHO[3], V. KRISHNAN[4];
[1]California State University, Long Beach Psychology, Long Beach, CA; [3]Psychology, [4]Physical Therapy, [2]California State Univ. Long Beach, Long Beach, CA

Abstract: Falls continue to be a leading cause of fatal and nonfatal injuries among older adults. Although dual-task (DT) interventions have shown to improve gait functionality in older adults (Agmon et al.,

2014), only limited studies have investigated the effects of dual-task intervention on muscle strength and clinical balance as a function of cognitive health in older adults (Elnaz et al., 2020). This study sought to investigate the effects of a DT training on strength, balance, and executive function in older adults with different levels of cognitive health. We hypothesized that both the mild, and cognitively impaired older adults will show larger improvement on strength, clinical balance, and executive function than would the older adults with no cognitive impairment from a DT intervention. Forty-one community-dwelling older adults (M_{age} = 76.46 ±7.88) participated in this study. Cognitive impairment was measured using the Montreal Cognitive Assessment (MoCA). Participants were classified as having no cognitive impairment (n = 17, MoCA ≥ 26), mild impairment (n = 13, 22 ≤ MoCA ≤ 25), and impairment (n = 11, MoCA < 22). Muscle strength was assessed using the Senior Fitness Test (SFT) with Arm curl, 30-second Chair Stand and 2-minute Step tests. Clinical balance was assessed with Fullerton Advanced Balance (FAB) Scale. Executive functioning was measured using the Trail Making Test (TMT). The intervention consisted of two sessions per-week (75 minutes per session) for eight weeks. Participants started with strength and balance exercises and then performed the same exercise while performing a cognitive task (e.g., word association, verbal fluency). Results of a two-way MANOVA indicated a marginally significant interaction of Time X Group on FAB only, Wilks λ=.863, $F(2, 38) = 3.016$, p =.061. Also, both FAB (Wilks λ =.227, $F[1, 38] = 129.235$, $p < .001$) and SFT (Wilks λ =.533, $F[3, 36] = 9.692$, $p < .001$), but not TMT, scores improved after the intervention for all groups. The level of cognitive impairment played a role such that the cognitively healthy group had higher FAB score ($p = .017$) and arm-curl score of SFT ($p = .055$) than the cognitively impaired group, and the cognitively healthy group had higher TMT score than each of the other two groups ($p < .0001$ for both).The DT intervention improved both balance and strength for all groups, providing evidence for the effectiveness of the DT intervention in reducing fall risks regardless levels of cognitive health. This result is particularly important for cognitively impaired older adults who have poorer balance and muscle strength than those who have no or mild impairment and thus are more prone to falls.

Title: Astrocyte injury subpopulations and fluid biomarkers validate acute neurotrauma MRI phenotypes in mild to moderate rat controlled cortical impact

Authors: *I. WANNER[1], A. TOBAR[1], S. ARREDONDO[1], J. LOPEZ[1], T. E. VAN METER[3], G. SHAW, Dr[4], N. VANDERVEER-HARRIS[2], A. PAYDAR[2], N. G. HARRIS[2];

[1]Semel Institute, IDDRC, BIRC, [2]Dept. of Neurosurgery, BIRC, UCLA, Los Angeles, CA; [3]Brain Box Solutions Inc., Richmond, VA; [4]Encor Biotechnologies Inc., Gainesville, FL

Abstract: This is a TOP-NT consortium project. Successful translation of preclinical research needs noninvasive classification tools to assess TBI in rat and human. To inform on context of use, biomarkers and neuroimaging need to reflect underlying injury phenotypes. Our objective was to achieve unbiased association of astrocyte injury-defined biomarkers (Halford et al., 2017) and volumetric MRI with quantitative histopathology. We used mild to moderate controlled cortical impact at 0.5-35 hours postinjury with sex, time, and region as covariates and randomly assigned sham (anesthesia, scalp incision; 8-24/group). We developed new rat and human compatible serum biomarker ELISAs for GFAP and aldolase C (ALDOC). Pan-astrocyte marker ALDOC stained gray matter astrocytes that were assessed for microstructural changes validated by morphometry. Immunofluorescence of ALDOC and immunoglobulins, for interstitial bleeding, were measured using standardized densitometry in juxtaposed areas of peak injury indicated by MRI. Unbiased MRI maps of individual injury burden, deviation (z=3.1) from the mean sham template, included deformation, T2*, diffusivity, kurtosis, modeled intra- and extracellular spaces. Undirected, multiple comparison-corrected (FDR $p<0.05$) bivariate regressions (R^2: 0.2-0.87) were done on outlier-removed datasets, a priori using marginal means (>3xSD) and posthoc by Mahalonobis distance (>3) and Cook's D (>1). Hyperacute serum ALDOC (0.5-4 hours) and serum GFAP associated with astrocyte decline. CSF GFAP correlated with pericontusional structurally compromised and ALDOC-depleted astrocytes. Astrocyte demise was associated with cortical gray matter volumes of T2* hypointensity (hemorrhage), mean kurtosis and decreased radial diffusivity. Astrocyte demise and blood extravasation covaried with increased acellular ALDOC proteinopathy. This novel astrocyte pathology was predicted by hyperacute rise in serum ALDOC and was proportional to gray matter increased FA and decreased radial kurtosis. White matter edema, volumes of elevated MD, covaried with CSF GFAP levels while gray matter brain swelling was linked to serum ALDOC elevation, matching predominant expression in fibrous (GFAP) and protoplasmic (ALDOC) astrocytes. Serum ALDOC elevation correlated with reduced gray matter microscopic diffusivities. These noninvasive measures of acute cytotoxic edema concur with compromised astrocyte subpopulations and blood-brain barrier breach, collectively reflecting damage to the neurovascular unit. This unique TBI endophenotype may support diagnostic monitoring of TBI and bidirectional experimental-clinical translation.

Abstract: Rodents interact with the environment mostly through their vibrissae, making them capable to recognizing objects and textures; afterwards, the sensory information is collected and processed when crossing ventral posterior medial nucleus and posteromedial nucleus of the thalamus and get to the barrel cortex (primary somatosensory cortex known as well as S1). A lesion in the cortex S1 in rodents produces a decrease in the amplitude of the record of Local Evoked Field Potentials (LEFP), as well to disturb the rodent's proprioception. In the present work we used male C57BL Black (24±4 grams) mice and we performed a radially symmetrical (0.5mm diameter) Penetrating Brain Injury (PBI) to track S1 LEFP amplitude during 30 days in mice treated with Tamoxifen and without treatment. Additionally, we added white gaussian noise to evaluate the stochastic resonance effect in both treated and not treated injured mice. We design a protocol which consist in two experimental groups: 1) mice lesioned with treatment (MWT n=10) and 2) mice lesioned without treatment (MWOT n=10). Tamoxifen was applied 3 continues days after injury (1mg/kg). The response of the LEFP was recorded to assess functional recovery before and after injury. Two electrodes were implanted on the surface of the cortex S1 for the recording of LEFP 3, 7, 14 and 30 days after the injury of both groups. In addition, the LEFP with white noise added to the record were also analyzed, which generates the effect of stochastic resonance (SR). The amplitude and the Signal to Noise Ratio (SNR) from LEFP´s recordings were analyzed with a signal analyzer self-designed script in MATLAB. After 30 days, the amplitudes of the LEFP´s were favored in both groups, the treated and no treated groups had a recovery. Animals treated with tamoxifen showed a statistically significant recovery ($p < 0.05$) in the amplitude and the SNR. Furthermore, the latency in the treated group was reduced 20%. We examine the statistical significance of the amplitude between the three conditions: Optimal Noise (ON), Zero Noise (ZN), and High Noise (HN) in both groups. An analysis uncovered significant differences between ZN and ON ($p<0.05$) and between ON and HN ($p<0.05$). Additionally, in the condition ON the latency was reduced 20%. In conclusion, Tamoxifen could help the functional recovery of the brain. These results are the first where is experimenting in a PBI protocol with SR.

Title: Mild Traumatic Brain Injury Impairs Episodic Memory in Rats

Authors: *G. D. NAH, M. ANTONOPOULOS, N. L. PORT, J. D. CRYSTAL;
Indiana Univ., Bloomington, IN

Abstract: Mild traumatic brain injury (mTBI) is the most common type of traumatic brain injury, and it leads to temporary memory impairment as well as a probable excitotoxic response in the brain, including the hippocampus. While many animal models of mTBI exist, it is difficult to fully replicate the injury seen in humans, and the effects of mTBI on the microenvironments of the brain are unclear. Additionally, few treatments specifically for mTBI currently exist. Notably, the Wayne State modified weight drop rat model of mTBI simulates many accurate elements of sport-related injuries, as well as the excitotoxic response in the hippocampus. Yet, this model has not previously been evaluated using a complex memory task. In this study, rats were trained in an odor-based item-in-context task which dissociates episodic and non-episodic memory. The animals then underwent either a weight drop or sham treatment using the Wayne State model. After the manipulation, animals continued in the item-in-context task. Episodic memory was moderately impaired in the injured rats, but not in the sham rats. Non-episodic memory was not impaired in either group. These findings are the first to document episodic memory impairment in an animal model of mTBI.

Title: Large-scale mapping of local field potentials associated with deficits in probabilistic reversal learning task in rats after traumatic brain injury

Authors: S. HULYALKAR[1], J. CRAMER[1], M. FRANCOEUR[1], *D. RAMANATHAN[1,2];
[1]UC San Diego, La Jolla, CA; [2]Mental Hlth., VA San Diego Healthcare Syst., San Diego, CA

Abstract: Behavioral flexibility describes the ability to respond flexibly to a changing environment. It is a key aspect of executive control, and is impaired after traumatic brain injuries. A probabilistic reversal learning (PRL) task is often used in both humans and animals to measure aspects of behavioral flexibility. In this task, responses are rewarded probabalistically (one response will be rewarded with an 80% probability and the other with a 20% probability). When subjects need to learn the reward contingencies and respond accordingly, reward contingencies are switched and subjects need to re-learn the new reward contingencies.
A bilateral frontal injury model in rats has been shown to recapitulate many executive function deficits, including this deficit in reversal learning. In this study, using distributed recordings of field potentials across brain targets, we have begun to characterize electrophysiological deficits associated with these impairments in behavioral flexibility after injury. Rats were given either a bilateral frontal traumatic brain injury or a sham-injury, followed by implantation of a neural probe that measures local field potentials across up to 32 brain sites. Our approach allows for an unbiased sampling of brain activity across visual,

limbic, motor, cognitive and reward related brain networks.
Following injury/implantation, animals were then trained on the PRL task for up to 3 months. We observed significant differences in performance on the task after the TBI injury, including differences in the number of reversals animals perform, and their tendency to repeat a rewarded trial (a key aspect of reinforcement learning). In association with these behavioral deficits, we observed clear differences in both reward processing within prefrontal and ventral striatal brain regions after the injury. Some of these changes normalized, but many remained. These electrophysiological deficits occurred in brain regions both adjacent and distal to the site of the injury.

Title: Use MRI to assess changes in dopaminergic function in adolescent mice acutely after mild traumatic brain injury

Authors: *Y. I. CHEN[1], S. CHAN[1], S. GENET[1], L. WU[2], K. K. KWONG[1], M. WHALEN[2];
[1]Athinoula A. Martinos Ctr. for Biomed. Imaging, [2]Pediatrics, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Major sequelae of mild traumatic brain injury (mTBI) in adolescence include attention deficit hyperactivity disorder (ADHD) symptoms and cognitive deficits. As cognitive deficits are linked to abnormal dopamine (DA) function in the brain, we aimed to examine DA function after repetitive closed head injury (rCHI) in mice. Here we showed the result in the acute phase after rCHI. We used BOLD fMRI and cerebral blood flow (CBF) to assess neuronal DA reactivity in responding to D-amphetamine (AMPH) to examine the DA transmission, to dihydrexidine (DHDD) and quinpirole (QUIN) to examine the D1- and D2-like receptor reactivity.
Method
rCHI model: Male C57Bl/6 mice (DOL 38) were subjected to weight drop (53 g, 46 in) daily for 3 days which produces deficits in Morris water maze and rotarod tests but no structure damages. Around 9 months, rCHI mice show hyperactivity phenotype.
MRI: Mice were imaged at a 9.4T Bruker MRI scanner. BOLD responses to ip challenge of AMPH 1mg/kg, DHDD 3mg/kg, or QUIN 2mg/kg were acquired via repetitive FLASH images (30 sec/time point for total of 65 min, DA ligand was injected at t = 15 min). pCASL was used to measure CBF at baseline and at 1 hour after drug challenge.
Results
BOLD results (Figure 1) AMPH led to significant BOLD increases ($p<0.05$) in nucleus accumbens (NAc) in rCHI (n=9) but significant decreases in sham mice (n=7). In thalamus, only rCHI mice showed

significant increase. QUIN led to significantly greater BOLD decreases in NAc in sham (n=6) than in rCHI (n=6) mice. DHDD led to bigger BOLD activated area in cortex in rCHI (n=7) than in sham mice (n=9).
CBF results (Figure 2) Both AMPH and DHDD led to significantly greater CBF decreases in rCHI (n=4) than in sham (n=5) mice ($p<0.01$) in the insular cortex, thalamus, and hypothalamus. DHDD led to significantly greater CBF decreases in Caudate/putamen in rCHI mice. QUIN had greater CBF decreases in cortex in rCHI mice (n = 5 / group).
Conclusion Although we anticipated DA function to deteriorate progressively and slowly after rCHI, we started to observe functional differences in key DA areas such as NAc and thalamus acutely after rCHI.

Title: Sex differences in recovery of fine motor function in a rhesus monkey model of cortical injury

Authors: *K. R. BOTTENFIELD[1], B. G. E. BOWLEY[1], M. A. PESSINA[1], M. MEDALLA[1,2], D. L. ROSENE[1,2], T. L. MOORE[1,2];

Abstract: Stroke disproportionately affects women over 65 who evidence increased severity of impairment and higher mortality rates than men. Human studies have explored risk factors that contribute to these differences in impairment and mortality, but additional research is needed to investigate sex differences in the rate and extent of functional recovery. In the present study, we used our rhesus monkey model of cortical injury and fine motor impairment to investigate sex differences in the rate and degree of motor recovery following injury. Aged male (n=4) and female (n=5) rhesus monkeys were trained on a task of fine motor function of the hand before undergoing surgery to produce a cortical lesion limited to the hand representation in the primary motor cortex. Post-operative testing began two weeks after the damage and continued for 12 weeks. All trials were video recorded and latency to retrieve a reward was quantitatively measured to assess the trajectory of post-operative response latency and grasp pattern compared to pre-operative levels. Results showed that in terms of recovery of fine motor performance, during the first five days of post-operative testing females returned to their pre-operative latency significantly faster than males ($p = 0.04$). In addition, females returned to their pre-operative finger-thumb grasp pattern significantly faster ($p = 0.04$) and more completely ($p = 0.004$) than males. Postmortem analysis showed no differences in lesion volume between males and females. To evaluate the possible role of estrogen, we compared pre-operative estrogen levels to all measures of recovery of function but found no significant relationship of estrogen levels to any recovery measures. To evaluate brain markers of recovery, immunohistochemistry experiments are underway to determine if there are sex differences in microglial mediated inflammation in the brain tissue. The findings of this study demonstrate the importance of including sex as a variable and the need to further explore the role of sex hormones that may differentially affect recovery outcomes in the primate brain.

Title: Widespread changes in cerebral cortical functional connectivity following mild, repetitive traumatic brain injury in the mouse

Authors: S. W. CRAMER[1], *L. S. POPA[2], S. HALEY[1], E. P. SCOTT[2], R. E. CARTER[2], J. DOMINGUEZ[3], J. D. ARONSON[2], L. SABAL[2], E. FLAHERTY[2], C. C. CHEN[1], S. B. KODANDARAMAIAH[3], T. J. EBNER[2];
[1]Neurosurg., [2]Neurosci., [3]Mechanical Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: Mild traumatic brain injury (mTBI) often results in brief loss of consciousness, impaired attention and concentration, memory problems, impulsivity, and headache without associated hemorrhage or structural pathology on CT imaging. Effects of repeated mTBI are cumulative and can lead to chronic traumatic encephalopathy, suggestive of global alterations in cortical networks. Using a transparent, morphological conformant polymer skull, we performed mesoscopic Ca^{2+} imaging to evaluate how mTBI alters patterns of interactions across the dorsal cerebral cortex. Transgenic mice (Thy1-GCaMP6f) were subjected to single injury directly to the motor cortex, for 3 consecutive days. Sham mice underwent the same injury protocol without cortical impacts. Histopathological examination of the brain following mTBI demonstrated ipsilateral elevation of GFAP (marker for reactive astrocytosis) and Iba1 (marker for microglial activation) signal at 24 hours post-injury with recovery after 48 hours post-injury. There was a transient microglial activation to mTBI, with reduced ramification ipsilateral to injury at 24 hours with recovery at 48 hours and beyond. Motor and cognitive effects performed using rotarod and Barnes maze, respectively, did not demonstrate deficits following TBI. On mice head-fixed to a freely moving disk we performed dual-wavelength mesoscopic Ca^{2+} imaging (7 mm x 7 mm field of view, 20 Hz) of the dorsal cerebral cortex during spontaneous behaviors. To assess for changes in cortical function, we used spatial independent component analysis to segment the hemodynamics-corrected mesoscopic Ca^{2+} imaging data into functional independent components (ICs) in sham and mTBI mice starting 2 weeks prior and up to 7 weeks post-injury. Correlations between IC time courses determined cerebral functional connectivity. We observed significant widespread, bilateral changes in functional connectivity between ICs immediately following impact that persisted for up to 7 weeks, far exceeding the changes observed in sham controls. Further analyses showed that the mTBI effects are driven by correlation decreases between specific nodes. We also observed an increase in the clustering of reduced correlations during the first three weeks post injury. These results suggest our repetitive mTBI mouse model produces a transient neuroinflammatory response, no identifiable alterations in cognitive or motor behavior but widespread, chronic alterations in cortical connectivity. The findings recapitulate salient features of human mTBI thus providing a means to study disease mechanisms and possible therapeutic interventions for traumatic brain injury.

Abstract: Traumatic brain injury (TBI) affects millions of people each year and constitutes a critical public health problem, yet has no standard approved therapeutics. In addition to increased inflammation following TBI, post-traumatic headache (PTH) is one of the most frequent adverse outcomes of TBI and may have detrimental effects on the quality of life for TBI patients. For this study we used the Closed Head Impact Model of Engineered Rotational Acceleration (CHIMERA), a recently developed technique that replicates the biomechanical mechanism of how humans sustain an impact TBI. To our knowledge, no CHIMERA studies have investigated the relationship between inflammation and PTH outcomes. Male Sprague-Dawley rats with an indwelling jugular vein catheter were exposed to 1x, 2x, or 3x repetitive CHIMERA impacts (~5-15 seconds between impacts). Catheter blood was collected 2, 4, and 6 hours after injury and 1, 2, 3, and 7 days after injury to determine the levels of plasma inflammatory cytokines. Brain tissue was collected at 7 or 14 days post-CHIMERA to determine effects on microglial and astrocyte activation. To determine the presence of PTH after CHIMERA, animals also underwent behavioral testing: (1) periorbital and hindpaw allodynia assessment by von Frey filament stimulation, and (2) photosensitivity by the light/dark box test. Animal weight and locomotor activity after injury were also monitored. Preliminary results indicate that repeated CHIMERA produced minimal allodynia, and short-term effects on weight loss and locomotor activity. Further analysis is in progress to determine CHIMERA effects on neuroinflammation and plasma cytokine levels in the same animals. Thorough characterization of clinically relevant rodent TBI models will enhance our understanding of the mechanisms of TBI that drive frequently experienced adverse symptoms and ultimately aid in the development of potential therapeutics.

Title: Quinpirole-mediated regulation via dopamine D2 receptors/Akt/GSK3-β signaling inhibits neurodegeneration in traumatic brain injury

Authors: M.-G. JO, S. ALAM, J.-S. PARK, M. IKRAM, H.-J. LEE, M.-W. KIM, M.-H. JO, *M.-O. KIM;
Div. of Applied Life Sci. (BK21 FOUR), Col. of Natural Sci., Gyeongsang Natl. Univ., Jinju, 52828, Korea, Republic of

Abstract: Brain injury is a significant risk factor for chronic gliosis and neurodegenerative diseases. Currently, no treatment is available for neuroinflammation caused by the action of glial cells following brain injury. In this study, we investigated the quinpirole-mediated activation of dopamine D2 receptors (D2R) in a mouse model of traumatic brain injury (TBI). We also investigated the neuroprotective effects of quinpirole (a D2R agonist) against glial cell-induced neuroinflammation secondary to TBI in adult mice. Our results showed suppression of D2R expression and deregulation of downstream signaling molecules in ipsilateral cortex and striatum after TBI. Quinpirole administration regulated D2R expression and significantly reduced glial cell-induced neuroinflammation via the D2R/Akt/glycogen synthase kinase 3 beta (GSK3-β) signaling pathway after TBI. Quinpirole treatment concomitantly attenuated increase in glial cells, neuronal apoptosis, synaptic dysfunction, and regulated proteins associated with the blood-brain-barrier, together with the recovery of lesion volume in the TBI mouse model. This study showed that quinpirole administration after TBI reduced secondary brain injury-induced glial cell activation and neuroinflammation via regulation of the D2R/Akt/GSK3-β signaling pathways. Our study suggests that quinpirole may be a safe therapeutic agent against TBI-induced Alzheimer's disease and Parkinson's disease.

Abstract: A spinal cord injury (SCI) scatters the communication between supraspinal centers and the spinal cord circuitry responsible for maintaining urodynamic functions. This loss of communication disrupts the coordination of detrusor muscle contractions and the necessary relaxation of the external urethral sphincter. Consequently, people with SCI experience constant incontinence, chronic urine retention, recurrent urinary tract infections, and other uro-renal complications. Here, we developed a conceptual and engineering framework to design an electrical spinal cord neuroprosthesis that targets circuitry in the spinal cord responsible for modulating the detrusor muscle and the external urethral sphincter. We first established a rodent model of chronic urodynamic dysfunction after SCI. Clinically-inspired assessments of urodynamic functions revealed a complete impairment of normal micturition and significant bladder overactivity that developed over time after injury. To identify the spinal segments most capable of modulating detrusor and external urethral sphincter contractions, we applied epidural electrical stimulation (EES) to each spinal segment, while measuring the activity of both muscles. We identified highly-specific hotspots over the lumbosacral spinal cord that, when stimulated with EES, enable contraction or relaxation of the detrusor and external urethral sphincter. Chemogenetic experiments revealed that EES induces detrusor contractions through a circuitry involving large-diameter parvalbumin neurons located in the dorsal root ganglia and excitatory interneurons within the urodynamic hotspots. We then combined CT scans, MRI sequences, and computational modelling to design a neuroprosthesis that targets urodynamic hotspots in the spinal cord. This neuroprosthesis was fabricated using e-dura technology. Closed-loop algorithms adapted the onset and amplitude of EES bursts to restore the coordination between bladder contraction and sphincter relaxation. The restoration of this coordination reduced bladder hyperreflexia and triggered micturition. These experiments provide a foundation to develop a neuroprosthesis to manage bladder dysfunction in people with SCI.

Title: Targeted neurotechnologies reverse autonomic dysreflexia after spinal cord injury

Authors: *J. E. SORIANO[1], R. HUDELLE[2], J. W. SQUAIR[1,2], S. AMIR[2], L. MAHE[2], M. GAUTIER[2], M. TSO[1], A. BICHAT[2], O. RIZZO[2], K. GALAN[2], Q. BARRAUD[2], S. P. LACOUR[2], J. BLOCH[3], A. A. PHILLIPS[1], G. COURTINE[2];

Abstract: Spinal cord injury (SCI) induces a syndrome called autonomic dysreflexia (AD), in which there is a dangerous onset of excessively high blood pressure. AD induces debilitating headaches and contributes to increased risks of stroke and heart disease. Recently, we developed a *neuroprosthetic baroreflex* based on epidural electrical stimulation (EES) of the thoracic spinal cord that controls blood pressure in closed-loop. We reasoned that the *neuroprosthetic baroreflex* may also have the capacity to treat AD. To study this possibility, we conducted a series of experiments to understand the circuitry underlying AD, and to determine whether this circuitry is compatible with the hypothesis that EES could prevent the development of AD. To enable these experiments, we established mouse and rat models of upper-thoracic SCI that lead to the development of AD over the course of four weeks. First, we asked whether the induction of AD triggers transcriptional activation of neurons in the lower thoracic spinal cord segments, since we previously identified these segments as the key hemodynamic hotspots required to restore hemodynamic stability. We found that AD elicited neuronal activity primarily in two regions: the hemodynamic hotspots in the lower thoracic spinal cord, and lower lumbar segments, where colorectal afferents are located. This activity coincided with an increased density of synaptic projections from lower lumbar segments to the hemodynamic hotspots in mice with SCI. Subsequent chemogenetic experiments revealed that AD is dependent on the activation of specific interneurons embedded within the hemodynamic hotspots. Likewise, chemogenetic inactivation of these interneurons in the hemodynamic hotspots blunted pressor responses induced by EES. We therefore surmised that chronic application of the *neuroprosthetic baroreflex*, called autonomic neurorehabilitation, could enable a circuitry remodelling that would prevent the development of AD. After two weeks of daily autonomic neurorehabilitation, AD decreased in intensity and eventually completely reversed. Future work will thus aim to establish a framework to develop a mechanistically-informed neuroprosthetic therapy for AD.

Title: Neuroprosthetic management of orthostatic hypotension in multiple system atrophy restores walking

Authors: *J. SQUAIR[1], M. BERNEY[2], M. CASTRO JIMENEZ[2], N. HANKOV[1], R. DEMESMAEKER[1], S. AMIR[1], A. PALEY[2], G. DUMONT[1], L. ASBOTH[2], F. BECCE[2], P. SCHOETTKER[2], G. WUERZNER[2], J. F. BALLY[2], G. COURTINE[1], J. BLOCH[2];

Abstract: Multiple system atrophy is an adult-onset, sporadic, rapidly evolving neurodegenerative disorder characterized by parkinsonian features (MSA-P), cerebellar features (MSA-C), or a combination of both. Central to the definition of MSA is the presence of autonomic failure, which manifests as orthostatic hypotension and/or urodynamic dysregulation. This hemodynamic instability is due to the degeneration of catecholaminergic neurons located in the rostral ventrolateral medulla and of sympathetic preganglionic neurons embedded in the thoracic spinal cord, among other relevant areas. We recently developed a *neuroprosthetic baroreflex* that leverages the ability of epidural electrical stimulation (EES) applied over the thoracic spinal cord to modulate the activity of sympathetic preganglionic neurons. We showed that EES activates sympathetic preganglionic neurons through the recruitment of large-diameter afferent fibers where they enter into the spinal cord. This *neuroprosthetic baroreflex* stabilized hemodynamics in humans with severe orthostatic hypotension due to cervical spinal cord injury. Although the etiology of orthostatic hypotension observed in individuals with MSA differs from those with spinal cord injury, both conditions disrupt the communication between brainstem vasomotor regulatory centres and sympathetic preganglionic neurons embedded in the thoracic spinal cord. Therefore, we reasoned that the neuroprosthetic baroreflex could manage orthostatic hypotension in patients with MSA, thereby enabling prolonged verticalization and walking. Here, we implanted this neuroprosthesis in a patient with MSA who presented with critical hemodynamic instability. The *neuroprosthetic baroreflex* restored sufficient hemodynamic regulation to enable the patient to stand and walk despite more than a year of immobility. While the therapeutic efficacy of the neuroprosthetic baroreflex in patients with MSA must be confirmed in a large-scale clinical trial, these results open the possibility that hemodynamic instability of patients with MSA may be managed effectively using bioelectronic medicine.

Abstract: A spinal cord injury (SCI) triggers a complex and progressive cascade of secondary injuries involving inflammatory cell infiltration and cytokine release, apoptosis, demyelination, excitotoxicity, ischemia and the formation of fibrotic scar and surrounding astrocyte scar border. How the individual types and subtypes of cells of the central nervous system coordinate to mediate this response remains incompletely understood. This lack of understanding hinders both our basic understanding of SCI biology as well as the development of new therapeutics. Here, we present a multi-omic atlas of spinal cord injury in mice at single-cell resolution. We applied single-nucleus transcriptomics, spatial transcriptomics, and single-nucleus ATAC-seq to profile 18 experimental conditions spanning the natural history of SCI. In total, we collected single-cell profiles from >600,000 nuclei from the lesion site. Cell type prioritization of the resulting dataset revealed distinct perturbation-responsive cell types and subpopulations across experimental conditions, allowing us to unravel variations in cellular phenotype associated with injury severity, sex, age, and pharmacotherapy. Spatial transcriptomics resolves the locations of SCI-associated cellular phenotypes on a spatiotemporal atlas of the lesion site as it evolves over the first months post-injury. This comprehensive single-cell atlas of SCI will open new avenues to understand and redirect disease pathobiology.

Abstract: Propriospinal neurons spontaneously form relay circuits which mediate function following incomplete spinal cord injury (SCI) and are therefore desirable to target for regenerative intervention following complete SCI. Propriospinal axons can be induced to regrow past anatomically complete SCI by following a developmentally inspired biological repair strategy which (i) upregulates neuron intrinsic

growth capacity, (ii) provides permissive substrate, and (iii) chemoattracts axons into and past injury sites. Yet, despite impressive growth, functional recovery remains elusive. Potential reasons for this include improper targeting of regenerating axons to their appropriate targets in the lumbar spinal cord, and a lack of persistence of regenerating axons at chronic timepoints post injury. In this study, we are examining methods to overcome these challenges by using additional spatially and temporally spaced hydrogel depots of glial derived neurotrophic factor (GDNF) to chemoattract axons to relevant targets in the lumbar spinal cord, and by using a lentivirus expressing GDNF to maintain these connections over time. Abstract: Epidural electrical stimulation of the lumbar spinal cord combined with neurorehabilitation (EES^{REHAB}) restored walking in nine people with chronic spinal cord injury (SCI). This recovery was associated with an unexpected reduction in the metabolic activity in the lumbar spinal cord, which might reflect an activity-dependent selection of specific neuronal subpopulations that become essential to walk after SCI. To identify these putative neurons, we modelled the technological and therapeutic features underlying EES^{REHAB} in mice. We applied single-nucleus RNA sequencing and spatial transcriptomics to elaborate a spatially-resolved molecular atlas of recovery in the spinal cord. A single population of excitatory interneurons located in intermediate laminae emerged as essential for recovery of walking. While these neurons were not necessary to walk before SCI, chemogenetic or optogenetic inactivation or targeted ablation demonstrated that they are essential to regain walking after SCI. In turn, chemogentically augmenting their activity instantly phenocopied the recovery of walking enabled by EES^{REHAB}. Together, these results identify a specific spinal neuron subpopulation that is necessary and sufficient to regain walking after SCI, and establish a molecular cartography framework that allows the identification of neurons underlying complex behaviours.

Abstract: Rehabilitation enabled by epidural electrical stimulation after spinal cord injury (EES^{REHAB}) leads to robust functional improvement. Here, we show that epidural electrical stimulation of the lumbar spinal cord combined with neurorehabilitation (EES^{REHAB}) restored walking in nine people with chronic spinal cord injury (SCI). This recovery was associated with a reduction of abnormal late muscle reflexes and of the metabolic activity in the lumbar spinal cord during walking. We hypothesized that this unexpected reduction reflects activity-dependent selection of specific neuronal subpopulations that become essential to walk after SCI. To identify these putative neurons, we modelled all the technological and therapeutic features underlying EES^{REHAB} in mice. We applied single-nucleus RNA sequencing and spatial transcriptomics to the spinal cord of these mice and then employed cell type and spatial prioritization to uncover the neurons involved in the recovery of walking. A single population of excitatory interneurons located in intermediate laminae emerged. These results identify a specific neuron subpopulation that is necessary and sufficient to regain walking after SCI, and establish a framework to identify the neurons producing complex behaviour using molecular cartography.

Title: Serotonergic input to the olfactory bulb modulates odor detection in rats

Authors: *O. ESCANILLA, A. AGGARWAL, B. COSTA, I. LEE, D. SCOTT, C. LINSTER; Neurobio. and Behavior, Cornell Univ., Ithaca, NY

Abstract: We examine the behavioral function of serotonin (5-HT) inputs for processing olfactory information in the first olfactory network, the olfactory bulb (OB). Previous data have suggested that 5-HT modulation in the OB acts both presynaptically on sensory input and enhances principal cell activation and dynamics. We use a simple non-associative behavioral paradigm, paired with local bulbar infusions of 1 µM 5-HT HCl, 5 µM 5-HT HCl and 200 µM of the 5-HT antagonist cinanserin HCl to probe the role of 5-HT in odor detection and discrimination. Rats are tested using an odor recognition paradigm similar to the one used in Hackett et al. (2015). During encoding, rats are presented with odor vials containing the carrier only (mineral oil). After a short delay, during the recall or recognition trials rats are presented with odor vials containing the carrier or an odor at one of 5 concentrations. Significant investigation of an odor signals that rats can detect this odor and differentiate from the carrier. We find

that manipulations of 5-HT signaling in the OB modulated the rats' odor detection performance in this task. These findings will be followed up with a reward motivated task, previously shown to enhance detection of low odor concentrations. We then show in a computational model of OB in which known cellular effects of 5-HT have been integrated that our observed behavioral results could be mediated by changes in overall dynamics and signal to noise ratio mediated by 5-HT receptor activation. We first reproduce cellular effects reported from brain slice experiments and then test how these would affect odor responses in vivo. We observe stronger and more synchronous activity in response to odor stimulation leading to changes in odor detection thresholds in the network. We have yet to implement the reported presynaptic effects on sensory inputs in addition to the cellular effects we added here.

Title: Selective attention to odors engages an olfactory-prefrontal network.

Authors: *H. L. CANSLER[1], E. E. IN 'T ZANDT[1], W. KHAN[1], M. MA[2], D. W. WESSON[1]; [1]Pharmacol. and Therapeutics, Ctr. for Smell and Taste, Univ. of Florida, Gainesville, FL; [2]Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Sensory perception is influenced by a variety of factors aside from the stimuli themselves, including cognitive states like attention. In olfaction, secondary olfactory structures, especially the tubular striatum (also known as the olfactory tubercle), display sharpening of odor-evoked activity during selective attention in both humans and rodents. Here, we used rats to identify interregional networks underlying the effects of attention on olfaction. First, we used multiple cell-type specific tracing approaches to establish that the TuS is a privileged recipient of dense input from the medial prefrontal cortex (mPFC). Retrograde tracing revealed a strong population of TuS-projecting glutamatergic neurons in the prelimbic and infralimbic regions of the mPFC. Through anterograde tracing with AAVs encoding synaptophysin-GFP or -mRuby into the prelimbic and infralimbic cortex, respectively, we found that these projections most densely target the TuS, yet only weakly target other olfactory regions. Next, we used multisite local field potential recordings in combination with an olfactory selective attention task developed by our lab to investigate the functional role of this pathway. We found that odor-directed attention drove elevated gamma band power in the olfactory bulb (OB) and mPFC. We also found that spectral coherence in the beta range between the OB-mPFC and the mPFC-TuS was higher when rats attempted an intermodal attentional switch, indicating a role for these pathways in flexible attention.

Coherence in the respiratory theta range between the OB-mPFC was also greatly upregulated during the intermodal attentional switch. Finally, we recorded sniffing to determine whether active sampling dynamics could explain these changes in respiratory theta coherence. We found that while rats precisely structure their sniffing to the task, their sampling strategies were inflexible, despite agile behavioral shifts in olfactory attention. This indicates that top-down (e.g., from mPFC) versus bottom up (from sniffing) mechanisms are likely responsible for the effects of selective attention on olfactory cortex activity. Overall, these results begin to reveal an olfactory attention network and bring us closer to understanding the circuits that underlie odor-directed attention.

Title: Neural dynamics underlying retronasal olfaction and the consolidation of olfactory memory

Authors: *R. HE[1,3], L. M. KAY[1,3], A. E. STUART[4,3], J. ZENG[2], M. XU[2];
[1]Dept. of Psychology, [2]The Col., The Univ. of Chicago, Chicago, IL; [3]Inst. for Mind and Biol., Chicago, IL; [4]St. John's Col., Annapolis, MD

Abstract: Retronasal olfaction refers to the process by which odorants enter the nasal cavity through the mouth, particularly during eating, and produce olfactory percepts. To understand the neura ldynamics underlying retronasal olfactory processing as it relates to reward, gustatory, and learning circuits, we implanted bipolar electrodes and recorded local field potential in the ipsilateral olfactory bulb, olfactory tubercle, piriform cortex, gustatory cortex and hippocampus. In addition to neural signals, we monitored nasal respiration and jaw muscle movement to track sensorimotor inputs during breathing and licking of reward stimuli. Fast neural oscillations in the olfactory system denote different stages of a retronasal odor discrimination Go/No-Go task, with gamma (40-110Hz) present in the pre-sampling period in the OB local network and beta (15-35Hz) later after odor sampling in a more global network. These are somewhat different from the patterns seen during orthonasal olfaction (odors which come into the nose through sniffing). The dynamical patterns measured with coherence depend on the presence of retronasal odorant, reinforcement type, and interaction with breathing and licking. We also report the behavior of these same circuits during pre- and post-training sleep to track consolidation at the systems level and better characterize sleep states using neural signals in the olfactory system.

Title: Basal forebrain GABAergic neurons are important for behavioral-state dependent sensory processing.

Authors: *K. BRANDEL-ANKRAPP[1], E. HANSON[2], B. R. ARENKIEL[3];
[1]Baylor Col. of Med. Dept. of Neurosci., Houston, TX; [2]Mol. and Human Genet., [3]Mol. & Human Genetis and Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Behavioral states including attention and arousal influence neuronal activity, affecting the processing of external stimuli and subsequent behavioral responses. This allows adaptation towards constantly changing contexts. In particular, top-down modulation of sensory regions from the basal forebrain (BF) allows flexibility in sensory processing. The BF contains various cell types including a heterogeneous population of GABAergic and cholinergic neurons projecting to the olfactory bulb. However, the role of GABAergic neurons in behavioral-state dependent sensory processing remains unclear. Here, we used fiber photometry and a genetically encoded calcium indicator to visualize GABAergic neuronal activity in the BF during an olfactory-cued discrimination task. We also chemogenetically manipulated BF GABAergic neuronal subtypes to observe how sensitivity and response bias are impacted by BF GABAergic signaling. We observe bidirectional response patterns in GABAergic neuronal activity which are time-locked to specific epochs of the behavioral task. Additionally, chemogenetically inhibiting BF GABAergic neurons significantly impacts task engagement and performance. Overall, we demonstrate a role for BF GABAergic neurons in modulating olfactory-guided behavioral responses.

Title: Neural Circuit Basis for Generating Spindle Oscillations in the Developing Olfactory System

Authors: *Z. ZHANG, D. C. COLINS, J. X. MAIER;
Neurobio. & Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: The brain changes throughout the life of an animal. Especially in early life, brains are structurally very different from adult brains and often considered "immature." However, animals must interact with their surroundings—process sensory input and transforming it into an appropriate behavioral output—as soon as they are born. We recently demonstrated that the neonatal olfactory system processes information in a stable manner: odor stimuli evoke spindle oscillations that are modulated by respiration and coherent between the olfactory bulb (OB) and piriform cortex (PC). The frequency of spindle oscillation remains stable between 10 and 20 Hz during the first two weeks of life, followed by a rapid increase of 20-30 Hz around postnatal day 15 (P15).
In work presented here, we investigated the circuit-level mechanisms underlying the generation of olfactory spindle oscillations. We recorded local field potential (LFP) activity simultaneously from OB and PC in awake rats ranging in age between P4 to P9 (n=27). Discrete Fourier transform (DFT) revealed that there was a significant information flow from bulb to cortex and cortex to the bulb in the spindle frequency range, suggesting that the generation of spindle oscillations relies on the feedback projections from the PC to OB. To investigate the causal effect of feedback projections on oscillatory activity, we recorded odor-evoked activity from the OB before and after pharmacological inactivation of the lateral olfactory tract through lidocaine injection (P5-P8, n=5). Inactivation caused a significant increase in oscillation frequency and shifted the temporal profile of oscillatory power relative to respiration. Thus, feedback projections modulate temporal and spectral characteristics of oscillations generated in the OB and may control different functional states of the neonatal olfactory system. Together, our results suggest that the neonatal olfactory system already exhibits adult-like circuit motifs, including net inhibitory feedback projections, capable of generating various complex activity patterns. Ongoing work is testing the relevance of these modes for neonatal odor perception behavior.

Title: Investigating the physiological and neural correlates of olfaction in infants

Authors: *L. K. SHANAHAN, L. B. MITHAL, S. OTERO, L. WAKSCHLAG, P. C. SEED, T. B. PARRISH, T. KAHNT;
Northwestern Univ., Chicago, IL

Abstract: The olfactory system serves critical functions in the earliest stages of human development. For instance, newborn infants show preference for maternal odors and are comforted by the scent of maternal breast milk. However, infant olfaction research is limited. Behavioral studies often rely on measures that are difficult to quantify (e.g., facial expression), and there are very few functional magnetic resonance imaging (fMRI) studies in this area. To address this gap, we exposed one-month-old infants to olfactory stimuli during fMRI. Infants were fed and swaddled prior to the scan to facilitate sleep, and they were fitted with (1) a custom nasal mask for odor delivery, and (2) a spirometer to measure breathing. Once asleep, infants were exposed to odors in blocks (5-seconds on/5-10-seconds off). Olfactory stimuli included two pleasant scents (ethyl hexanoate and isoamyl acetate) and two unpleasant scents (isovaleric acid and cyclopentanethiol). Preliminary breathing analysis suggests that odor valence may modulate respiration in infants, such that pleasant odors evoke a larger inhalation than unpleasant odors. fMRI data analysis is ongoing, and will shed light on the neural basis of olfaction in infants. Our work will promote a better understanding of the physiological and neural mechanisms underlying human olfaction at an early developmental stage.

Title: Mapping the human brain network for chemosensory perception

Authors: *A. BUSH[1], Z. A. KONS[1], A. HADANNY[1], T. PARKER[1], V. SARAVANAN[1], E. HOLBROOK[2], D. COELHO[3], R. CONSTANZO[3], M. RICHARDSON[1];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Massachusetts Eye & Ear Infirmary, Boston, MA; [3]Virginia Commonwealth Univ., Richmond, VA

Abstract: Background: Olfaction and gustation are chemosensory perceptions with a strong impact on quality of life and safety. However, the neurophysiological response to chemosensation has received less attention than other sensory modalities in humans. Here, we map the functional neuroanatomy and electrophysiology of olfactory and gustatory processing in the human brain. **Methods:** 13 epilepsy patients implanted by clinical indication with stereo EEG electrodes in areas with putative involvement in chemosensory responses performed an olfactory task. Participants were presented with 3 different smells and a blank using smell wands in block-randomized sequence and instructed to indicate detection of a smell (or certainty that none was present) with a keypress. After each trial, participants identified the stimulus with a multiple-choice question. 11 of these patients subsequently performed a similar gustation task using waterless taste strips. Timing of stimulus onset was recorded from video EEG review. **Results:** No olfactory or gustatory stimulus was identified more reliably than the others as assessed by a mixed-

effects model. However, olfactory stimuli reported as pleasant by each participant were identified more reliably than those reported as neutral. Response times and the fraction of correctly identified stimuli were variable across participants, but reproducible patterns were observed between individual stimuli. Cortical electrode coverage included the piriform cortex (7 [37]; # patients [# electrodes]), entorhinal cortex (7 [42]), middle insular area (7 [23]), posterior insular area (7 [20]), frontal opercular area (6 [17]), posterior orbitofrontal cortex (5 [18]) and perirhinal ectorhinal cortex (5 [14]). Time-frequency analysis of Local Field Potentials from these regions revealed stimulus-specific increases in low-gamma and broad-band gamma power following olfactory and gustatory stimulus presentation. Different cortical regions showed preferential activation in response to specific chemosensory modalities, including a stronger olfactory gamma response in the piriform cortex, entorhinal cortex, orbitofrontal cortex, and stronger gustatory gamma response in the insula, though significant overlap was observed. **Conclusions:** This study shows evidence of increases in gamma-band activity during olfactory and gustatory processing in humans, consistent with other sensory modalities and previous reports in animal models. Mapping the cortical chemosensory network in humans is an important step to explore the feasibility of neuroprosthetic devices for olfaction and gustation.

Title: State-dependent linearisation of mixture responses in the olfactory bulb

Authors: A. M. ADEFUIN, J. REINERT, S. LINDEMAN, ***I. FUKUNAGA**;
Okinawa Inst. of Sci. and Technol. Grad. Univ., Okinawa, Japan

Abstract: One of the common challenges for sensory systems is to analyse complex signals from the environment and to segregate them into relevant and irrelevant parts. For the olfactory system, there is a unique difficulty associated with this task, due to a widespread nonlinear summation of component signals. Nonlinear summation is present at various stages of processing, including in the olfactory nerve input, and persists to the olfactory cortex, making it unclear whether the olfactory system can accurately analyse mixture responses. Here, we investigate how mice represent and utilise binary mixtures of odours, using a combination of behavioural and imaging experiments.
To probe how well mice are able to analyse binary mixtures, we trained head-fixed mice to perform Go/No-Go task, where water reward was associated with ethyl butyrate presentations (target odour), either as a single odour or in binary mixtures. The other odours in the panel comprised simple esters and other, structurally unrelated compounds. Odours were presented at relatively high concentrations, namely 1-5% of the saturated vapour, to increase the overlap in activity patterns. A two-photon imaging of

GCaMP6f from the apical dendrites of Tbet-expressing neurons showed the masking indices to range from 0.5 to 0.9, with methyl butyrate having the largest overlap with ethyl butyrate. An analysis of the behavioural data confirmed previous findings, where mice tend to make more mistakes when the stimulus contained odours with high masking indices. However, short training, the behavioural accuracy improved significantly, demonstrating the ability of the system to improve on the binary mixture analysis, even when the components evoke highly overlapping activity patterns.
To investigate possible mechanisms, we observed the activity of olfactory bulb output neurons in Tbet-Cre::Ai95D mice with a two-photon microscope. Contrary to previous reports from anaesthesised preparations, in mice performing the odour detection task, we found the overall summation to be relatively linear, with just 16.3% of ROIs (33/202 ROIs, 5 mice) showing significant deviation from linear summation. When the same mice were later anaesthetised with ketamine/xylazine, this proportion increased to 41.8% (43/103 ROIs). Investigating the mixtures in untrained but awake and engaged mice revealed that the majority of the above, state-dependent difference is explained by wakefulness, even though a small difference remained, accompanied by a residual difference in sniff patterns.
Altogether, our results demonstrate that the property of mixture representations in the olfactory system is highly state-dependent.

Title: The olfactory epithelium response to Herpes Simplex Virus 1 infection

Authors: *L. MERLE, C. S. NIEMEYER, B. D. BAXTER BOLT, A. GENTILE POLESE, J. HASSELL JR, A. N. BUBAK, M. A. NAGEL, D. RESTREPO;
Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Olfactory deficits related to viral infection have been highlighted during the COVID-19 pandemic. The sense of smell relies on the detection of odorant molecules by olfactory sensory neurons (OSNs) in the olfactory epithelium (OE). The OE lies within the nasal cavity and is constantly exposed to airborne pathogens. In addition, the OE constitutes a direct route of entry to the brain since OSNs axons project to the olfactory bulb (OB). However, viral infections of the OE do not necessarily result in encephalitis. This implies that the OE likely mounts robust inflammatory / immune responses that enable clearance of viruses and prevent direct spread to the brain. The OE includes different cell types that could contribute to fight against viruses. Microvillous cells (MVCs) are part of a family of TRPM5-expressing cells found in the airways and the intestine that respond to virus and bacteria, and we recently published a transcriptional analysis that revealed that MVCs express high levels of transcripts involved in immunity,

inflammation, and viral response. Here we investigated the OE response to infection with Herpes Simplex Virus 1 (HSV-1), a virus shown to promote Alzheimer's disease (AD). Mice were intranasally inoculated with HSV-1 strain McKrae (10^6 PFU, 15 µL in each nostril) and sacrificed 5 days later for tissue collection. At this timepoint, RT-qPCR revealed the presence of HSV-1 DNA in the OE and OB. Immunostainings showed sparse HSV-1 antigen presence in the OE and no HSV-1 antigen was detected in the OB. Iba1 staining suggested increased monocytes/microglia recruitment in the OE and OB. HSV-1 infection of 5xFAD mice (a mouse model of AD) appeared to increase amyloid-beta presence in the OE. We also used mice expressing channelrhodopsin under the ChAT promoter to investigate whether MVCs could play a role in triggering an antiviral response in the OE. Repeated optogenetic activation of MVCs induced an increase in the number of Ki67-positive cells in the basal side of the OE, suggesting increased proliferation of horizontal basal cells. We hypothesize that the OE response to HSV-1 prevents its spread through OSNs axons to the OB, and MVCs could play an antiviral role by interacting with olfactory stem cells.

Abstract: When listening to music, our brain constantly attempts to predict the sounds that will follow. Consequently, we often end up humming, singing along or tapping our foot to the beat, and find pleasure in listening to pieces we know very well. However, the nature and brain basis of musical predictions or expectations remain poorly understood. Concretely, we do not know the extent to which these expectations arise from a representation of the sensory properties of sounds or from a more cognitive and culturally shaped learning of the statistics of musical pieces and styles. Here, we employed computational modelling and MEG data to investigate the neural correlates of melodic expectations. We compared the performance of a cognitive model of music statistical learning (IDyOM) and a sensory model based on pitch distance, in predicting neural responses to sounds in listeners with different cultural backgrounds

and levels of musical expertise (N = 150). For this, an encoding model based on regularized linear regression was used. Our results show that, across listening conditions, datasets and types of listeners, the pitch distance model outperforms statistical learning models. Furthermore, in exploratory analysis, a Gaussian predictive coding model reproduced the relationship between pitch distance and neural activity, thereby pointing to a potential neurophysiological mechanism based on prediction errors. Our work suggests that sensory expectations play a prominent role in shaping neural responses to musical sounds.

Title: Measuring fatigue in children with hearing loss

Authors: *B. ADAMS, S. THORNTON, I. WIGGINS, G. NAYLOR, P. KITTERICK;
NIHR Nottingham Biomed. Res. Ctr., Nottingham, United Kingdom

Abstract: Children with hearing loss appear to experience a greater level of fatigue than children with normal hearing (NH). This effect has been observed using self-report questionnaires in children with bilateral hearing loss (BHL) and more recently, in children with unilateral hearing loss (UHL). These questionnaires have often been designed for use in children with other chronic health conditions and only the Vanderbilt Fatigue Scale (VFS) measures listening-related fatigue. Little is known about the validity of any of these measures for use in children with hearing loss. The current objectives were to: (1) examine the sensitivity of these measures to distinguish fatigue levels in children with and without hearing loss; and (2) determine the extent to which each questionnaire measure unique aspects of fatigue. The study is still open to recruitment; to date 75 children aged 6-16 (31 NH; 18 UHL; 26 BHL) have completed the PedsQL™ Multidimensional Fatigue Scale (MFS), the VFS and the PROMIS Pediatric Fatigue Scale. They also completed the PedsQL™ Core and the HearQL questionnaires, which measure general and hearing-related quality of life respectively. Physical Activity Energy Expenditure (PAEE) was also measured using the Children's and Young Person's Physical Activity Questionnaire. Analyses of mean scores identified greater fatigue in children with hearing loss, and qualitatively similar levels of fatigue in children with UHL and BHL, regardless of which measure of fatigue was used. The Kaiser-Meyer-Olkin measure indicated that the strength of the relationships among variables was high, and a preliminary principal component factor analysis was performed. Of the two factors with eigenvalues >1, the first accounted for 86% of the variance and correlated with all fatigue and quality of life measures, and the second primarily accounted for variance in the physical activity measure explaining a further 14% of the variance. These results suggest that both generic and hearing-related measures of fatigue may be assessing similar constructs. The strong correlations between fatigue measures and both generic and hearing-related quality of life questionnaires may also indicate that these constructs may not be specific to fatigue. Alternatively, it is possible that fatigue impacts children with hearing loss in a similar way to

children with other physical chronic diseases, and that impact has a strong association with poorer quality of life. The disassociation between fatigue and PAEE suggests that current measures are assessing forms of fatigue that are distinct from physical tiredness.

Title: Grey matter thickness covariance in hearing and deaf cats using ultra-high field MRI

Authors: *S. G. GORDON[1], S. G. LOMBER[2];
[2]Physiol., [1]McGill Univ. Integrated Program in Neurosci., Montreal, QC, Canada

Abstract: Grey matter thickness derived from high-resolution magnetic resonance images is a useful non-invasive method of characterizing a macroscopic property of the cerebral cortex. When combined with an atlas of the species in question, these measurements can be used to distinguish anatomically relevant regions of thinning or thickening in an experimental or disease group from healthy controls. In this investigation we sought to examine if high-resolution MRI could be used to assess differences in cortical thickness covariance across regions between the brains of deaf cats and those of hearing controls. In this study we scanned 29 normal hearing and 26 deaf cats at 0.5mm isotropic resolution to look for areas of differing thickness using regions of interest (ROIs) from a digital cat brain atlas. All animals were examined in adulthood and deafness was induced during the first postnatal month by systemic administration of ototoxic drugs). Thickness maps were obtained using the Advanced Normalization Tools (ANTs) software package and this data was then processed in MATLAB. Age and gender were regressed out of the raw thickness values independently for each group, and all subjects' values were normalized to the mean of that group. These corrected regional thickness values were then correlated against each other for each pair of ROIs across all subjects within each group. After correcting for False Discovery Rate (FDR) using the Benjamini-Hochberg method, significant covariances were compared within and across the two groups. Plots of covariance vs. Euclidean distance between the ROI pairs were similar across hearing and deaf subjects, with each group showing increased significant covariances at very short distances (&gt5mm apart) and a more consistent distribution out to the extremes (~35mm). The mean covariance for bilaterally homologous ROIs were found to be significantly higher than for non-homologous ROI pairs in both groups. Numbers of significant covariances within and across sensory modalities differed between groups, with a notable result being an increase within the auditory modality in the deaf group as compared to the hearing group. Results from this work point to a change in the structural covariance across the cat brain following deafness, supporting the plasticity of the brain seen in past tracer and behavioral studies. While overall the covariance of ROIs in the hearing and deaf brain

remain similar, there are marked differences when looking at the regional and modal levels that require further analysis. Funding was provided by CIHR.

Title: Diffusivity differences in the feline cerebral cortex following early-onset deafness

Authors: *A. SACCO, S. GORDON, S. LOMBER;
McGill Univ., Montreal, QC, Canada

Abstract: Following sensory deprivation, such as deafness, sensory-specific brain areas will reorganize to optimize processing, relying more heavily on remaining modalities - a phenomenon known as compensatory plasticity. For instance, following visual deprivation, higher-order visual areas adapt to process tactile stimuli, providing somatosensory enhancement to visually-deprived individuals. Considering the consequences of plasticity following visual deprivation, what changes occur throughout the brain following the loss of auditory input? Previous studies have examined microstructural alterations due to deafness using various techniques including behavioral paradigms, electrophysiology or imaging protocols. However, a more recent method is diffusion tensor imaging (DTI), which reveals differences in cerebral water diffusion, but nearly all prior investigations have studied these microscopic changes in humans rather than animals. The purpose of the present study was to extend microstructural investigations to cats - an animal model which is well studied for both auditory processing and hearing loss. Using DTI, diffusivity scalars including fractional anisotropy (FA) and mean (MD), axial (AD) and radial diffusivity (RD) were derived for 27 adult hearing control and 19 adult deaf cats (deafness onset in the first postnatal month), and compared across 155 grey and 21 white matter regions. All processing was accomplished using FSL and ANTs, followed by Wilcoxin rank sum and Benjamini-Hochberg statistical tests in MATLAB. Results indicate structural plasticity in various regions throughout the deaf brain in both tissue types, noted by a significant change in scalar value. As a general pattern, regions with significant scalar differences demonstrated an increased AD, RD and/or MD value in deaf felines compared to hearing, with substantially more white matter tracts affected than grey matter regions. Grey matter regions affected in the cat were the perirhinal cortex and frontalis agranularis, and white matter tracts affected include the corpus callosum, superior longitudinal fasciculus, and more. Overall, this is the first study to examine DTI alterations following auditory deprivation in cats, and it demonstrates that early-deafness incites plasticity throughout the brain well beyond auditory cortex.Funding was provided by CIHR.

Title: Neural mechanisms underlying reduced discriminability of speech in noise at high sound intensities

Authors: *C. G. HUANG, N. A. LESICA;
Ear Inst., Univ. Col. London, London, United Kingdom

Abstract: Hearing loss is a widespread global problem with an economic impact as well as individual detriments to those affected, decreasing overall quality of life. It is known that hearing loss causes distortions in the neural code, which subsequently leads to misinterpreted neural representations of complex sounds as information ascends the auditory pathway. As a result, perception of complex sounds such as speech is compromised. This problem is further complicated by the fact that sound intensity level varies in natural settings, both in quiet and in noisy backgrounds, and plays a critical role in speech perception. Therefore, we aimed to investigate how speech sounds heard at various intensity levels are represented and processed in the inferior colliculus (IC), using an established noise-induced hearing loss model in the Mongolian Gerbil, *Meriones Unguiculatus*. We hypothesized that the neural representation of speech at different sound intensity levels will vary and that this representation will change in noise-induced hearing loss. Specifically, we predicted that there will be strong effects of temporal masking in the boundaries between consonant and vowels in syllables, and that these effects will be most pronounced at higher intensity levels and in hearing loss conditions. To test this prediction, we recorded the responses of neurons in the central nucleus of the IC and assessed responses using a variety of information quantification techniques. We found that the neural discrimination between consonant classes at high intensity levels became worse in normal hearing animals in noisy conditions. In animals with hearing loss, however, consonant discrimination plateaued at high intensity levels in noisy listening conditions. Furthermore, when we introduced gaps between syllable elements, we observed an improvement in discriminability in both control and hearing loss conditions at high intensity levels, showing a mitigation of the masking effect between elements. Through improved understanding of the neural mechanisms that contribute to impaired perception with noise-induced hearing loss, we may be able to identify new directions for improved hearing aids and potential therapeutic treatments in the future.

Title: The Role of Envelope and Temporal Fine Structure in Auditory Neural Coding of Timbre in Normal and Impaired Hearing

Authors: *A. SIVAPRAKASAM[1], H. BHARADWAJ[1,2], M. HEINZ[1,2];
[1]Weldon Sch. of Biomed. Engin., [2]Speech, Language, and Hearing Sci., Purdue Univ., West Lafayette, IN

Abstract: A common psychoacoustic feature of both speech and music is *timbre*: defined as the "character or quality" of sound that allows it to be distinguished from others with the same pitch and intensity. Because of our inherent ability to perceive timbre we can distinguish between different instruments or voices, even when they play or sing the same note. However, the neurophysiological basis for our perception of timbre is enigmatic. It is not well-understood how biological and neurological deficits in the auditory periphery impact our coding and perception of timbre-related cues. To provide insight on this question, we developed a framework to investigate how auditory nerve (AN) coding of envelope (ENV) and temporal fine structure (TFS) features of stimuli with distinct timbre is affected by a flat 40 dB hearing loss. The first stimulus group consisted of recorded bassoon, flute, violin, and banjo sounds with the same pitch (A4). The second group consisted of *spiccato* and *martele* articulations recorded on the violin. A third group consisted of 4 synthetic instrument sounds with harmonic magnitudes estimated from the first group, and temporal envelopes modeled using sinusoidal amplitude modulation or (in the banjo) a decaying exponential. The AN response to each stimulus was simulated using a previously described 2018 AN-fiber model by Bruce, Erfani, and Zilany. ENV and TFS spectra were computed for auditory neurons with characteristic frequencies (CFs) at the first 7 harmonics of A4 using alternating-polarity peristimulus time histograms (apPSTHs). The original stimuli were processesed through a gammatone filterbank and the Hilbert analytical signal was used to extract ENV and TFS of the filtered stimuli. As CF increased, TFS magnitude-squared coherence between the AN model and filterbank was increasingly reduced in the hearing impaired simulations, despite a compensatory 40 dB volume increase. Mean ENV coherence within a low-frequency band (0-440 Hz) was enhanced in impaired vs non-impaired responses at low CFs, but diminished at CF>1320 Hz. Despite these general trends, the magnitude of these effects greatly varies depending on instrument and articulation. This implies that with hearing loss, one's ability to rely on timbre to differentiate instrumental sounds may not be consistent for every sound source. This framework can be further applied to study more sound sources, including speech, and may be paired with behavioral and neurophysiological experiments to explore individual differences in perception that arise from peripheral differences in etiology. All relevant code and figures may be found at: https://github.com/sivaprakasaman/Timbre_SfN_2021.

Title: Probing hierarchical prediction errors under different prediction precisions in auditory sequences: an ERP study

Authors: *Y.-Y. HUANG[1], F. B. KERN[1], C.-T. WU[1,2], Z. C. CHAO[1];
[1]Intl. Res. Ctr. for Neurointelligence (IRCN), The Univ. of Tokyo, Tokyo, Japan; [2]Sch. of Occup. Therapy, Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Perceiving sensory inputs from our external world highly depends on our internal model of prior experience. According to the predictive-coding theory, such perception is achieved by two bidirectional and interdependent processes operating across multiple hierarchies: top-down predictions which are generated through learning the probabilistic structure of sensory inputs, and bottom-up prediction errors which are the residuals between the predicted and actual inputs and which are sent back to update the predictions. However, it remains unclear how prediction errors are modulated by different prediction precisions established in a hierarchical structure of auditory sequences. In this study, we recorded 64-channel EEG in 30 subjects during an auditory local-global oddball paradigm, where auditory sequences with local regularity (tone-transition probability, TP) and global regularity (sequence probability, SP) were manipulated. We used 8 different auditory blocks, each consisting of 3 different sequences delivered with controlled probabilities, and established predictions with 8 different precisions. Prediction-error signals were quantified as the differences between event-related potential (ERP) responses to oddball stimuli and those to standard stimuli. Two ERP components were evaluated: mismatch negativity (MMN) and P300 which are thought to reflect lower-level and higher-level prediction-error processes, respectively. By using regression analysis, we found that the peak amplitude of MMN negatively correlated with TP, while the peak amplitude of P300 positively correlated with both TP and SP. Furthermore, regressing prediction-error signals at each time point against TP and SP showed that the signals in the early stage (128 to 190 ms) were correlated with TP, and the signals in the late stage (222 to 242 ms) were correlated with both TP and SP. These key findings support a hierarchical interpretation of the predictive-coding theory where prediction errors propagate across hierarchies modulated by that level's prediction precision. Our study also opens the door to potential future research examining atypical prediction precisions in individuals with mental illness.

Title: Vowel Encoding In The Human Superior Temporal Gyrus

Authors: *I. BHAYA-GROSSMAN[1,3], Y. OGANIAN[1], E. F. CHANG[2];
[2]Neurosurg., [1]Univ. of California, San Francisco, San Francisco, CA; [3]Univ. of California, Berkeley, Berkeley, CA

Abstract: Understanding natural speech requires listeners to map the continuous acoustics of vowel sounds onto discrete categories, compensating for variability in vowel production within and across speakers. Vowel identity is mainly determined by the central frequencies of the first two spectral peaks in the sound signal, the first (F1) and second (F2) formants. Behavioral experiments have shown that the auditory perception of vowels is non-linearly warped in continuous F1-F2 space towards the prototypes of each vowel category. Neuroscience research has suggested that cortical areas on the superior temporal gyrus (STG) responsive to speech encode the relative spectral location of F1 and F2. It remains unclear, however, how such a representation supports the warped perception of vowel categories. We exploited the spatial and temporal resolution of high-density intracranial recordings using natural speech and artificial vowel sound stimuli to study how neural representations at the local and population level encode the identity of vowel sounds. In Experiment 1, native speakers of Spanish (n = 7) listened to naturally produced Spanish sentences, while we recorded neural activity from the STG. Local neural populations in the STG were sensitive to either one or both formants, with a majority encoding both F1 and F2. Formant tuning resembled a nonlinear sigmoidal function, with heightened sensitivity to a narrow section of the full formant range. Formant tuning also shifted to adjust for speakers with different formant ranges. Decoding analyses showed that while neural responses recorded from a single electrode contact did not reliably discriminate between vowel categories, category representations did emerge at the population level when the range of F1 F2 encodings spanned the entire vowel formant space. Population level responses to vowel instances from the same category clustered together, as predicted by behavioral perceptual warping. The formants produced in natural speech are limited and as a result, Experiment 1 did not let us test whether neural activity in the STG is speech specific. To address this, in Experiment 2, native speakers of English (n = 8) listened to artificial vowel sounds with formant combinations extending beyond those encountered in natural speech. We found that the neural representation of formants did extend beyond the natural vowel formant space. Our results reveal that vowel-discriminating neural populations on STG are best characterized by complex, nonlinear two-dimensional formant receptive fields. When presented with human speech, these neural populations work in concert to encode vowel category and category boundary information.

Title: State-dependent contributions of inhibitory transcriptomic subtypes to the activity of mouse visual cortex

Authors: S. BUGEON, T. HAULING, M. DIPOPPA, J. DUFFIELD, D. NICOLOUTSOPOULOS, I. PRANKERD, D. ORME, A. RITOUX, H. PENG, Y. ISOGAI, M. CARANDINI, K. D. HARRIS; Univ. Col. London, London, United Kingdom

Abstract: [Introduction] Cortical computations rely on microcircuits that involve multiple neuronal subtypes. While cortical neurons have been classically subdivided into broad subtypes (i.e. Vip, Sst and Pvalb positive interneurons), transcriptomic analysis has revealed more subpopulations of finely distinguished cortical neurons (Tasic et al., *Nature* 2018). [Methods] To decipher the functional properties and network activity of these fine cell types in primary visual cortex (V1), we applied post-hoc in situ transcriptomic analysis to cortical neurons after imaging their activity in vivo. We first recorded the activity of V1 neurons using two-photon calcium imaging in head-fixed, freely running mice, during visual stimulation. The visual stimuli comprised drifting gratings, sparse noise, and natural scenes. After these recordings, we collected consecutive brain slices and used landmarks to register them to a reference z-stack obtained in vivo. We then matched individual cells between the in vivo recordings and the brain sections. These brain sections were then processed for post-hoc transcriptomic analysis using in situ sequencing (Qian et al., *Nature Methods* 2020), a multiplexed single-RNA detection procedure that characterizes the expression of 73 genes at the single cell level. Based on this gene expression, we assigned a transcriptomic cell type to the recorded cells. [Results] To confirm that this procedure can reveal the functional properties of transcriptomic cell types, we first reproduced findings on the size tuning of the main V1 cell types, and their modulation by running (Dipoppa et al., *Neuron* 2018). We then explored finer distinctions among inhibitory transcriptomic subtypes. These could be arranged in a genetic continuum based on the first principal component of gene expression, and the position of a cell type in this continuum predicted how its spontaneous activity correlated with running. Transcriptomic subtypes also responded differently to other behavioral variables (eye saccades, running onset etc.) and to network events associated with bursts of activity in Sst cells. Finally, the visual response of given excitatory cell subpopulations could be predicted solely based on which interneuron subtypes they correlate with during spontaneous activity. [Conclusions] This method provides a high-throughput approach to characterize the in vivo activity of fine transcriptomic cortical cell types, revealing a striking role for the great diversity of interneurons subtypes in following the animal state gradient and shaping visual response according to it.

Title: Ndnf interneurons in layer 1 gain-modulate whole cortical columns according to an animal's behavioral state

Authors: *K. COHEN-KASHI[1], E. TSIVOURAKIS[1], D. KUSHINSKY[1], D. APELBLAT[1], S. SHTIGLITZ[1], E. ZOHAR[1], M. SOKOLETSKY[1], G. TASAKA[2], A. MIZRAHI[2], I. LAMPL[1], I. SPIEGEL[1];

Abstract: Processing of sensory information in neural circuits is modulated by an animal’s behavioral state, but the underlying cellular mechanisms are not well understood. Focusing on the mouse visual cortex, here we analyze the role of GABAergic interneurons that are located in layer 1 and express Ndnf (L1 NDNF INs) in the statedependent control over sensory processing. We find that the ongoing and sensory-evoked activity of L1 NDNF INs is strongly enhanced when an animal is aroused and that L1 NDNF INs gain-modulate local excitatory neurons selectively during high-arousal states by inhibiting their apical dendrites while disinhibiting their somata via Parvalbumin-expressing interneurons. Because active NDNF INs are evenly spread in L1 and can affect excitatory neurons across all cortical layers, this indicates that the state-dependent activation of L1 NDNF INs and the subsequent shift of inhibition in excitatory neurons toward their apical dendrites gainmodulate sensory processing in whole cortical columns.

Title: Connectivity and function of chandelier cells in mouse primary visual cortex

Authors: *K. SEIGNETTE, N. JAMANN, R. PORNESO, L. DE KRAKER, C. VAN DER TOGT, E. RUIMSCHOTEL, P. NEERING, M. W. SELF, M. H. P. KOLE, C. N. LEVELT;

Abstract: The mammalian cortex contains a large variety of inhibitory interneurons. The functions of many of these interneuron subsets are slowly becoming clear. However, one particular subtype of interneuron remains elusive: the chandelier cell. Chandelier cells are a unique GABAergic cell type that exclusively targets the axon initial segment of pyramidal neurons. Although chandelier cells were first identified decades ago, their exact function in the cortical network remains a mystery. Here, we studied connectivity, plasticity and function of chandelier cells in mouse primary visual cortex (V1). We made use of a novel genetic approach to label V1 chandelier cells for chronic two-photon calcium imaging and optogenetics in mice performing a behavioral task in a virtual tunnel. We further employed viral tracing and electrophysiology to study their connectivity with pyramidal cells. Our findings suggest that chandelier cells predominantly encode feedback information and that they target a subpopulation of pyramidal cells to modulate feedforward and feedback information streams in the cortical network.

Title: Excitatory cortical inputs produce distributed suppression via recurrent mechanisms described by a balanced network model

Authors: *J. F. O'RAWE, Z. ZHOU, P. K. LAFOSSE, A. LI, H. C. GOLDBACH, M. H. HISTED;
NIMH, NIH, Bethesda, MD

Abstract: Local recurrent connections in the cortex are numerous and strong, yet their role in computation is not well-understood. Here we study the influence of recurrent connections in awake mouse V1 by probing network response to strong excitatory drive.
We first observed with two-photon cellular imaging that intense visual inputs created a salt-and-pepper pattern of suppressed and excited neurons. We then stimulated excitatory neurons optogenetically and

measured responses using both electrophysiology and calcium imaging at the 2-photon cellular level and widefield population level. When cortical excitatory cells are excited directly, we found suppressed cells in a similar salt-and-pepper pattern as with strong visual input. Though excitatory neurons were recruited a few milliseconds before inhibitory neurons, as expected (Excitatory latency: median 5.4 ms, inhibitory 7.9 ms, U = 1256, $p < 0.01$), excitatory and inhibitory cell populations relaxed to similar steady-state firing rates (mean difference t (134) = -0.21, $p = 0.83$), with some cells elevated and some suppressed. Further, the elevated and suppressed cells relaxed to their steady states with similar dynamics (Elevated steady state median latency: 39.9 ms, suppressed: 40.5 ms, U = 801, $p = 0.32$), suggesting a network mechanism where strong excitatory input drives the network to a new fixed point. Suppressed cells were highly intermixed even at the center of stimulation, though widefield imaging revealed a surround that is on average suppressed at ~500 microns away from the center of stimulation. A moderate- or strongly-coupled balanced-state cortical model with heterogeneous local connectivity can account for the results. Cortical inhibition-stabilized networks produce paradoxical suppression when inhibitory cells are stimulated. Here, we also found paradoxical suppression of excitatory cells, but via a different mechanism. The widespread yet distributed pattern of single-cell suppression arises from individual cells receiving different amounts of recurrent input from the excitatory and inhibitory network, not population-level changes in the mean excitatory and inhibitory rates. Together, these results show recurrent connectivity in mouse visual cortex can have dramatic effects on responses to input.

Title: Spatially specialized dendrites support orientation tuning in mouse visual cortex

Authors: *L. F. ROSSI[1], N. GHANI[2], C. REDDY[1], K. D. HARRIS[3], M. CARANDINI[1];
[1]Inst. of Ophthalmology, [2]Sainsbury Wellcome Ctr., [3]Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: [Introduction] A longstanding hypothesis holds that the orientation selectivity of a neuron in primary visual cortex (V1) is related to the spatial pattern of the neuron's dendrites (Colonnier, J Anat, 1964). This hypothesis has eluded confirmation (Anderson et al, Nat Neurosci, 1999), but seems consistent with recent evidence that presynaptic inputs to a V1 neuron favor an elongated region of cortex coaxial with the neuron’s preferred orientation (Niel & Scanziani, Annu Rev Neurosci, 2021). We thus asked whether we could causally relate the shape of a neuron’s dendritic tree to the neuron’s orientation

selectivity and to the retinotopy of the surrounding cortex. [Methods] We applied 2-photon calcium imaging to record the orientation tuning and retinotopy of V1 populations using GCaMP, with sparse L2/3 pyramidal neurons labelled with a red fluorescent protein. We reconstructed the dendritic arbors of the red cells from structural z-stacks. We estimated the visual position of each dendritic segment from their path through the retinotopic map of V1. We then recorded longitudinally from the same neurons after pruning up to half of their total length of basal dendrites using laser dendrotomy (Park, Nat Commun, 2019). In one group of neurons we pruned 'parallel' dendrites which extended co-axially with the neuron's preferred orientation, and in a second group of neighbouring neurons, we pruned instead dendrites that extended orthogonally to the preferred orientation. [Results] Parallel dendrotomies significantly reduced responses to both the preferred ($p < 0.001$) and the orthogonal orientations ($p < 0.05$). On average, these effects were captured by a strong divisive scaling and a mild subtractive shift of the tuning curve. By contrast, orthogonal dendrotomies did not significantly change responses to either orientation. Changes in preferred orientation were not significantly different between the two groups (16 ± 4 deg, $p = 0.6$). Pruning larger portions of the parallel dendrites, but not of orthogonal dendrites, further reduced the responses ($R = 0.73$, $p<0.001$). [Conclusions] These results suggest a causal link between the dendritic architecture and the function of V1 neurons: by extending towards, and receiving more of, the appropriate co-tuned inputs, spatially specialised dendrites may provide a morphological substrate to establish orientation selectivity.

Title: Binocular receptive field match in primary visual cortex

Authors: *F. OLIANEZHAD, J. JIN, J.-M. ALONSO;
Dept. of Biol. Sci., SUNY Optometry, New York, NY

Abstract: The primary visual cortex integrates convergent thalamic inputs from both eyes to generate binocular receptive fields. The receptive fields from the two eyes have to be precisely matched to process stimuli at the focus plane but also mismatched to extract information about visual depth. To quantify the precision of the binocular receptive-field match, we performed multielectrode recordings in cat visual cortex and measured visual responses to static stimuli and moving bars separately through each eye. The orientation selectivity (OS) and direction selectivity (DS) of each cortical site were calculated as (P-NP)/P, where P and NP are maximum responses to preferred and non-preferred stimuli. The ocular dominance (OD) and light-dark polarity dominance (PD) were calculated as (X-Y)/(X+Y), where X/Y are

maximum responses driven by contralateral/ipsilateral eyes (OD) or light/dark stimuli (PD). The binocular match in orientation preference was very accurate across cortical sites with diverse orientation selectivity and ocular dominance (OS ≥ 0.1, OD = -1 to 1, r = 0.96, mean orientation difference = 2.82 ± 17.87 degrees, n = 541 cortical sites). The binocular match in direction preference was also very accurate in cortical regions with high direction selectivity (DS ≥ 0.4, OD = -1 to 1, opposite/same direction preferences: 0/148 cortical sites). However, cortical regions with less direction selectivity included a small subset (7%) that had opposite direction preferences for contralateral and ipsilateral eyes (DS ≥ 0.2, OD = -1 to 1, opposite/same: 21/292 cortical sites). The orientation and direction selectivity were also binocularly matched but the correlations across eyes were weaker than for orientation preference (OS: r = 0.52, C/I means = 0.72/0.70; DS: r = 0.51, C/I means = 0.45 /0.44; OD = -1 to 1 and n = 541 for both). The response latency to static stimuli was binocularly matched but the average was ~2 msec faster for the contralateral than ipsilateral eyes (OD = -1 to 1, r = 0.44, n = 495, C/I means = 32.1/34.3 msec, p = 0.0003, Wilcoxon test). Finally, light-dark polarity dominance was also correlated across eyes. However, the correlation was strongest at cortical regions with high binocularity (OD = -0.1 to 0.1, r = 0.50, n = 92, C/I means = -0.16/-0.10) and became weaker in regions dominated by one eye (OD = -1 to 1, r = 0.19, n = 495, C/I means = -0.10/-0.10). We conclude that binocular receptive fields in primary visual cortex are precisely matched in orientation preference, direction preference, orientation/direction selectivity, response latency, light-dark polarity, and the match is most accurate at cortical regions with high stimulus selectivity and binocularity.

Title: Border ownership selectivity in neurons across layers of macaque V1 measured with high-density Neuropixels recordings

Authors: *S. ZHU[1,2], X. CHEN[2], T. MOORE[1,2];
[1]Howard Hughes Med. Inst., Stanford, CA; [2]Stanford Univ. Sch. of Med., Stanford, CA

Abstract: It is known that neurons in visual cortex integrate visual information from far beyond their classical receptive fields (RFs). One example is the encoding of border-ownership in early macaque visual cortex, particularly in area V2, where the responses of almost half of the orientation-selective neurons signal the side to which an object's edge belongs. At present, it remains unclear to what extent neurons at earlier processing stages, particularly those across different layers in V1, signal border ownership. To address this question, we examined the responses of large populations of macaque V1 neurons to standard border ownership test stimuli. Neuronal activity was recorded using high-density, linear array Neuropixels probes (384 channels). In each session (N = 8), Neuropixels recordings were

largely confined to single cortical columns with RF eccentricities spanning between 4º and 8º, and in each session the neuronal RFs of recorded neurons were highly overlapping. Border ownership test stimuli consisted of solid white or black objects (4º or 8º squares) on a black or white background, respectively. The orientation of the object varied in 45º steps, and in each trial, one of the object's edges fell within the RFs of the neuronal population. As in previous studies, border ownership was quantified as the difference in neuronal responses to edges with identical orientation and local contrast but belonging to opposite sides of the object. Across recording sessions, we found that ~10% of V1 neurons responded differently to objects appearing on different sides even though orientation and local contrast remained constant within the RF. Neurons exhibiting border ownership selectivity were found within all cortical layers, including input layer 4C. We further measured the degree to which local populations of V1 neurons (n = 10) across layers could signal border ownership by testing the performance of a binary decoder in identifying the side to which the object's edge belonged. We found that the performance of the decoder exceeded chance level for populations of neurons across all cortical layers and occurred within ~70 ms in layer 4C. These results suggest that border ownership signals are present at the earliest stages of visual cortical processing.

Title: Mapping visual experience-dependent functional connectivity of feedback projections in the visual cortex of Fmr1 KO mice using channelrhodopsin-2-assisted circuit mapping

Authors: *X. CHENG, S. NAREDDULA, Y. TANG, A. A. CHUBYKIN;
Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN

Abstract: Fragile X syndrome (FXS) is the most common form of inheritable autism spectrum disorders (ASD), which is often characterized by intellectual disability and visual learning deficits. Previous studies have described disrupted excitatory to inhibitory (E/I) balance, impaired short-term plasticity (STP), and altered functional connectivity in Fmr1 KO mice, the model of FXS. The feedback projections from higher visual areas to the primary visual cortex (V1) have been implicated in the regulation of cognitive processes such as prediction, attention, and visual learning. However, the mechanism of this regulation and how it is changed in FXS is poorly understood. To gain more insight into this process, we developed a new perceptual experience paradigm leading to the emergence of familiarity-specific theta oscillations. We measured the strength and properties of the long-range synaptic connections between the mouse higher visual area, lateromedial area (LM), and V1 in wildtype (WT) and Fmr1 KO mice, pre-and post-visual experience, using channelrhodopsin-2-assisted circuit mapping (CRACM). We have discovered that the strength of the connectivity from LM to the superficial layer II/III of V1 decreased in WT mice after the visual experience but did not change in Fmr1 KO mice. In contrast, the synaptic connections

from LM to the deep layer V of V1 were stronger after visual experience in Fmr1 KO compared to WT mice. Interestingly, some of the synaptic properties of the feedback projections in Fmr1 KO mice appeared to improve following visual experience, such as the synaptic E/I and the paired-pulse ratios as a measurement of STP. Our findings provide first measurements of the inter-areal synaptic connectivity before and after visual experience in WT and Fmr1 KO mice and suggest that visual training may potentially serve as a promising therapeutic intervention for ASD.

Abstract: Animals must continuously coordinate multiple needs, such as hunger and thirst, and rank them against competing opportunities like mating. Despite a long-known crucial role of the lateral hypothalamus (LH) in the regulation of hunger and thirst, the neuronal mechanisms enabling the representation and orchestration of multiple innate behaviors are not yet understood.
Here, we report how two functionally orthogonal neural populations of the lateral hypothalamus (LH) encode competing rewards and enable their appropriate prioritization even against acute metabolic pressure. Using a combination of deep-brain Ca^{2+} imaging in freely behaving mice and cell type-specific activity manipulations, we show that both leptin receptor-expressing ($LepR^{LH}$) and neurotensin-expressing (Nts^{LH}) populations track individual food consumption, water consumption and social interaction to selectively and flexibly promote their prioritization, and to regulate distinct anticipatory and consummatory phases of need fulfilment.
We provide a mechanistic understanding how the complementary control of innate drives by distinct, cooperating neuronal populations enables the flexible fulfilment of orthogonal needs according to current opportunities and gated by physiological demands.

Title: Characterization of the parasubthalamic nucleus (PSTN) as an appetite suppression center

Authors: J. KIM, **G. KROMM**, J. SPERBER, K. HAN, L. HEUER, M. NEWMAN, O. BARNHILL, S. LOOMIS, T. LEGAN, F. GULAMALI, *M. CARTER;
Williams Col., Williamstown, MA

Abstract: Food intake behavior is regulated by a network of appetite-inducing and appetite-suppressing neuronal populations throughout the brain. The parasubthalamic nucleus (PSTN), a relatively unexplored population of neurons in the anterior hypothalamus, has been hypothesized to suppress appetite because of its connectivity with other anorexigenic neuronal populations and the fact that these neurons express Fos, a marker of neuronal activation, following a meal. However, the individual cell types that make up the PSTN are not well characterized, nor are their roles in food intake behavior. Here we identify two distinct PSTN subpopulations, those that express tachykinin-1 ($PSTN^{Tac1}$ neurons) and those that express corticotropin-releasing hormone ($PSTN^{CRH}$ neurons), and use a panel of genetically encoded tools to show that $PSTN^{Tac1}$ neurons play a causal role in appetite suppression in mice. Both populations increase activity following a meal and in response to administration of the anorexigenic hormones amylin, cholecystokinin (CCK) and peptide YY (PYY). Optogenetic and chemogenetic stimulation of $PSTN^{Tac1}$, but not $PSTN^{CRH}$ neurons, is sufficient to reduce food intake. Furthermore, chemogenetic inhibition of $PSTN^{Tac1}$ neurons reduces the appetite-suppressing effects of amylin, CCK, and PYY. $PSTN^{Tac1}$ and $PSTN^{CRH}$ neurons project to distinct downstream brain regions, and stimulation of $PSTN^{Tac1}$ neural projections to the anorexigenic parabrachial nucleus is sufficient to reduce food intake. Taken together, these results reveal the functional roles and connectivity of the cell types that make up the PSTN, demonstrating an anorexigenic role for $PSTN^{Tac1}$ neurons in food intake behavior.

Title: Organ specific, wireless optogenetic gastric implants for multiplexing interoception dynamics

Authors: *W. KIM[1], B. C. JARVIE[2], Z. KNIGHT[2], **S. PARK**[1];
[1]Electrical and Computer Engin., Texas A&M Univ., College Station, TX; [2]Univ. of California at San Francisco, San Francisco, CA

Abstract: Optogenetics also has the potential to transform the study of the peripheral nervous system, but the complex anatomy of the peripheral nervous system (PNS) poses unique challenges for the focused delivery of light to specific tissues. In principle, it is possible to target peripheral tissues with light by using a wired fiber optic that exits the animal via the back or rectum, analogous to the intracranial fiber optics commonly used in the brain. However, the abdominal visceral differs from the brain in that it lacks a stable interface for securing large fiber optics and preventing motion. An alternative approach is to implant a wireless probe that internalizes the light source, thereby bypassing physical constraints associated with fiber optic cables. Strategies for such wireless, radio frequency (RF)-powered devices have recently been described, but it remains a major challenge to achieve long-term, organ-restricted illumination without impeding normal behavior or physiology. Recently, we have developed a new class of implantable wireless devices and demonstrated their applicability to study the vagus nerve. This new wireless optogenetic implant delivers light to nerve endings from inside the stomach via a pre-curved tether. This intragastric light delivery enables illumination of stomach innervating nerves with much greater specificity than μLEDs affixed to the organ surface and allows for simultaneous/independent control of multi-channels in a single platform device. It could in principle be extended to study other organs such as intestine. The optogenetic implants maintained functionality up to 1 month *in vivo*. With this approach, we induced appetite suppression in Calca(calcitonin gene-related peptide)-Cre mice by activating vagal nerve endings in the stomach of a freely behaving animal. We used adult male mice (C57/BI6 background) for this experiment. Animal model demonstrations of their utility in optogenetic studies of viscerosensory neural pathways in Calca-Cre mice revealed novel research findings that activation of Calca neurons innervating non-stretch receptors can inhibit appetite. This suggests that our wireless gastric optogenetic implants can be used for the study of peripheral sensory pathways, and the proposed wireless device will create many opportunities for future work in optogenetics and related behavioral science.

Title: Using mesoscale imaging of neural activity to map circuits controlling food intake behavior and circuit reorganization following consumption of high-fat diet.

Authors: *T. B. OUELLETTE, K. M. S. O'CONNELL;
The Jackson Lab., Bar Harbor, ME

Abstract: Neurons expressing agouti-related peptide (AgRP) in the arcuate nucleus of the hypothalamus (ARH) are central regulators of hunger and their activity reflects metabolic need. It has been shown that AgRP neuronal activity is rapidly modulated by sensory detection of food (Betley et al., 2015; Chen et al., 2016; Garfield et al., 2016) and that consumption of high-fat diet (HFD), even for brief periods, changes excitability of AgRP neurons (Wei et al., 2015), but the location of presynaptic afferents and mechanisms for this change in excitability remain largely uncharacterized. These unidentified presynaptic inputs may represent untapped targets for therapeutic intervention to address pathological overeating. Our limited understanding of CNS driven feeding behavior is in part due to having incomplete understanding of these circuits. Additionally, the impact of diet and obesity on plasticity within these circuits is largely unknown, further obstructing a clear understanding of the role of CNS dysfunction in diet-induced obesity (DIO). We hypothesize that diet-induced plasticity in presynaptic inputs to AgRP neurons contributes to aberrant sensations of hunger, futhering pathological overeating and the progression of DIO. In this study, we used an unbiased approach to fluorescently label neurons brain-wide using transgenic mouse lines: Ai14;Arc^{CreERT2} and Ai14;Fos^{CreERT2} (referred to as ArcTRAP and FosTRAP, respectively). In these mice, the immediate early gene (IEG) *Arc* or *Fos* (which are well-defined as molecular markers of neuron activity) drive expression of Cre recombinase following administration of 4-hydroxy-tamoxifen (4-OHT), thereby permitting the permanent labeling of activated neurons using Cre-dependent expression of the reporter tdTomato. Expression of *Arc* and *Fos* is not uniform across the brain, necessitating the use of two separate transgenic lines to observe activity in regions where one of the two is absent. In this study we compared activity patterns of both sexes during low or high metabolic need states (sated, or overnight fasted) and during a satiated state following 2 days of HFD consumption. This unbiased approach allows us to identify novel brain regions involved in the CNS response to metabolic need state, and observe large-scale circuit plasticity during development of DIO.

Abstract: The zona incerta (ZI) is a predominantly GABAergic hypothalamic region, but some ZI GABA neurons co-express dopamine. ZI GABA neurons are implicated in behaviors underlying fear, feeding, sleep, hunting, and motor control, and while GABA and dopamine may be released from the same neuron, it is not known if ZI dopaminergic signaling mediates functions similar to GABA. To elucidate the potential roles of dopaminergic signaling from the ZI, we identified the projection targets of ZI neurons expressing tyrosine hydroxylase (TH) in a *Th-cre* mouse line. We first validated the *Th-cre* mouse line via a *Th-cre;L10-Egfp* reporter mouse and by performing *in situ* hybridization for *Gfp* and *Th* mRNA, followed by immunohistochemistry for TH. We determined the colocalization of *Gfp* with either *Th* mRNA hybridization and/or TH immunoreactivity (TH-ir). Overall, about one quarter of *Gfp*-labeled cells co-expressed *Th* mRNA and TH-ir (26%) but the majority expressed *Th* mRNA only (62%). The remaining *Gfp* cells (10%) did not express TH-ir or *Th* mRNA, and this ectopic *Gfp* expression was more prominent towards the lateral ZI, defined as the region of the ZI lateral to the mammillothalamic tract and fornix. Interestingly, 96% of *Gfp* cells in the medial ZI co-expressed *Th* mRNA and a few medial ZI *Gfp* cells (4%) were ectopic. We therefore delivered a Cre-dependent adeno-associated virus (50-75 nl) encoding either tdTomato or mCherry over the medial ZI to label the fiber projections of medial ZI *Th-cre* or *Th-cre;L10-Egfp* neurons. In both cases, we observed widespread fiber projections from medial ZI TH neurons throughout the brain. The projection sites that expressed consistent labeling were within the bed nucleus of the stria terminalis, paraventricular nucleus of the thalamus, nucleus reunions, and the periaqueductal grey. Similarities between these two injection cases using different viruses and mouse lines may reflect robust projection targets of dopaminergic neurons in the medial ZI. However, we also noted brain region differences between these two injection cases with regards to the pattern and density of fiber projections; for example, in the lateral septum, anterior hypothalamic area, and superior colliculus. These may be ascribed to differences in injection volume or the transfection of *Th-cre* cells outside the medial ZI. Interestingly, the projection targets of medial ZI TH neurons are also consistent with the known roles of GABA ZI neurons. Given that *Th-cre* ZI neurons are also GABAergic, future work will determine if they may innervate downstream targets by GABA and/or dopamine release.

Abstract: Maintaining an adaptive body weight requires integrating hunger signals and nutrient status to influence hedonic and metabolic needs. The cerebellum integrates external and internal sensory feedback to fine-tune functional outputs, and recent work has linked the cerebellum to motivated behavior. Therefore, we tested the hypothesis that food modulates cerebellar activity using whole-brain task-based fMRI. Activity in the deep cerebellum responds to food cues, and this activity is dysregulated in individuals that never experience satiation (Prader Willi syndrome patients). To better understand the neuronal subtype identity and function of the deep cerebellum in food intake regulation, we conducted single-nucleus RNA sequencing, activity-dependent gene expression analyses and neural manipulation studies in rodents. Transcriptomic profiling, targeted recombination in active populations strategy and *in situ* hybridization uncovered the molecular identity and spatial organization of neurons in the anterior deep cerebellar nuclei (aDCN) activated by food intake and intragastic infusion of nutrients. Chemogenetic activation of these aDCN neurons suppressed food intake. We next examined how aDCN activity influences feeding associated neural circuits. We found that dopamine signaling in the nucleus accumbens and not activity in the hypothalamic agouti-related peptide expressing neuron is modulated during aDCN mediated food intake reduction. Our findings suggest that food intake activates cerebellar output neurons leading to a surge of striatal dopamine that stops eating by attenuating the reward value of additional consumption. Taken together, our study reveals that cerebellar output neurons is a critical and evolutionarily conserved neural node that puts a "brake" on food intake to promote satiation.

Title: Complementary regulation of innate behaviours by distinct cell populations in the lateral hypothalamus

Authors: *R. FIGGE[1,2], H. E. VAN DEN MUNKHOF[1,2], A. PETZOLD[1,2], T. KOROTKOVA[1,2];
[1]Inst. for Vegetative Physiol., Univ. of Cologne, Cologne, Germany; [2]Neuronal Circuits and Behaviour Group, Max Planck Inst. for Metabolism Res., Cologne, Germany

Abstract: The lateral hypothalamus (LH) integrates metabolic signals and maintains energy homeostasis by modulating feeding through an intricate interplay between a neurochemically and functionally diverse neural populations. Our research is focused on GABAergic cell populations in the LH, which regulate multiple innate behaviours. Specifically, we investigated molulation of consumptive and exploratory behaviours by leptin receptor-expressing (LepR) and neurotensin-expressing (Nts) neurons in the LH. Using opto- and chemogenetics, as well as subsecond unsupervised analysis of behaviour using Motion Sequencing (MoSeq), in sated and food-deprived mice, we found that these cell populations exert opposite effects on social interaction. Further, LepR and Nts neurons complementary regulate feeding, drinking, and locomotion in a state-dependent way. Our study reveals neuronal mechanisms of adaptive need fulfillment in the presence of multiple natural rewards.

Title: The Impact of Acetylcholine on Basolateral Amygdala Macrocircuits

Authors: *E. K. TANTRY[1], J. ORTIZ-GUZMAN[2], M. KOCHUKOV[3], B. R. ARENKIEL[4];
[1]Rice Univ., Houston, TX; [2]Mol. and Human Genet., Baylor Col. of Med., Fresno, TX; [3]Mol. and Human Genet., [4]Mol. & Human Genetis and Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Neural circuits governing food intake have been widely studied. However, our current understanding hinges on a binary hypothalamic neuronal model that fails to address more adaptive feeding behaviors underpinning variable environmental conditions. Previous work in our lab posits an extra-hypothalamic circuit involving the cholinergic-rich diagonal band of Broca (DBB) and the valence encoding basolateral amygdala (BLA). To further analyze this circuit, we used a projection-defined approach to characterize the cellular composition of the BLA. We utilized a stereotactic frame for bilateral injections of channelrhodopsin and tdTomato containing viruses into the DBB,

and either the nucleus accumbens (NAc) or the lateral hypothalamic area (LHA), respectively. The latter regions were selected due to their established involvement in regulating food intake. We determined projection profiles of BLA cells using channelrhodopsin assisted circuit mapping (CRACM) and optogenetics, and found that the majority of neurons projecting to the LHA exclusively possess fast-acting nicotinic synapses, whereas most neurons expressing slow-acting muscarinic synapses project exclusively to the NAc. The contrasting nature of these receptors indicates that there are more dynamic neural regions involved in orchestrating complex hedonic feeding behaviors.

Title: Elucidating the neural circuit that balances sugar and water ingestion in Drosophila melanogaster

Authors: *A. J. GONZALEZ-SEGARRA, K. E. SCOTT;
Univ. of California, Berkeley, Berkeley, CA

Abstract: All organisms need to acquire nutrients from their environment to survive. In particular, water and sugar ingestion are vital to sustain many metabolic needs. Ingestion of sugar and water is tightly regulated by internal signals, such as thirst, hunger, and satiety, to maintain homeostasis. Although generally considered separately, interactions between these internal nutrient signals are important to coordinate competing needs. Recent studies have identified four neurons called Interoceptive Subesophageal zone Neurons (ISNs) in *Drosophila melanogaster* that respond to endogenous hunger and thirst signals to oppositely regulate sucrose and water ingestion. Upon activation, ISNs increase sucrose ingestion but decrease water ingestion. While the key molecular pathways that lead to ISN activation have been identified, it is still unknown how ISN activity translates to a behavioral response. To examine how competing needs are coordinated by the nervous system, we identified and characterized the neural circuit downstream of the ISNs. Using a genetic approach for trans-synaptic circuit tracing, we labeled approximately 30 candidate downstream neurons. To gain genetic access to these neurons, we compared them to a novel neuron collection that labels single cell-types in the Subesophageal Zone and identified 30 candidate postsynaptic neurons based on neurite proximity to the ISNs. A behavioral activation screen was performed on these candidate neurons to determine their involvement in feeding, which yielded 4 candidate postsynaptic neurons which are involved in sucrose and water ingestion. Interestingly, activation of some of these neurons altered both sugar and water ingestion, while other neurons only altered sugar ingestion or water ingestion. Further functional imaging experiments, where we optogenetically activate the ISNs and measure candidate downstream neuron activity, are needed to

determine if these neurons are in fact postsynaptic to the ISNs. This study will provide insight into how the nervous system organizes competing internal needs to drive opposing behavioral responses.

Title: Is respiratory sinus arrhythmia a marker for stress and anxiety during a stressor?

Authors: *M. KHAITOVA[1], B. FAN[2,1], S. MYRUSKI[3], Q. LIN[1], T. A. DENNIS-TIWARY[1,2]; [1]Hunter Col. - The City Univ. of New York, New York, NY; [2]The Grad. Ctr. - The City Univ. of New York, New York, NY; [3]The Pennsylvania State Univ., University Park, PA

Abstract: Anxiety disorders are the most common mental health diagnosis, and have been linked to reduced capacity to regulate the stress response. Respiratory sinus arrhythmia (RSA) reflects heart rate variability due to respiration changes, and reflects parasympathetic nervous system (PNS) activity. Suppressed RSA is associated with decreased PNS activity and represents an adaptive physiological response to stress, as the sympathetic nervous system engages during a stressor to help individuals cope. Few studies, however, have investigated associations between RSA suppression measured during a standardized lab stressor and behavioral signs of anxiety. This study aims to examine these associations by measuring self-reported anxiety, RSA, and behavioral indices of anxiety during a standardized lab stressor, the Trier Social Stress Test (TSST). The TSST has been shown to increase cortisol levels and heart rate in previous research. Participants self-reported anxiety symptoms, then completed the TSST, while electrocardiogram (ECG) was simultaneously recorded. Anxious behaviors were coded from videotaped TSST observations. RSA suppression during stressor versus baseline was quantified from ECG data, with more negative scores indicating greater suppression. Anxiety severity was measured using the Hamilton Anxiety Rating Scale (HAM-A). We tested the hypothesis that individuals with high versus low anxiety severity will show reduced RSA suppression during the TSST, which in turn will predict increased frequency of anxious behaviors. This research is exploratory. Anxiety level and anxious behaviors during the TSST were not significantly correlated, $r(98) = -.030$, $p = .768$. Similarly, anxiety level and RSA suppression during the TSST were not significantly correlated, $r(96) = -.031$, $p = .761$. The moderation analysis using regression revealed a trend, $\Delta R^2 = .0461$, $F(1, 87) = 4.2191$, $p = .0430$, albeit in a direction opposite to that hypothesized: those reporting greater anxiety severity evidenced fewer anxious behaviors during the TSST when they showed low levels of RSA suppression. Findings highlight the need for additional examinations of the associations between physiological and behavioral responses during a stressor among anxious individuals.

Title: State-trait anxiety and State-trait depression in Mexican twins

Authors: *T. V. ROMÁN-LÓPEZ[1], X. J. LÓPEZ-CAMAÑO[1], Z. X. ESPINOSA-VALDÉS[2], E. I. ORTEGA-MORA[2], U. CABALLERO-SÁNCHEZ[2], E. CHIU-HAN[1], D. RAMÍREZ-GONZÁLEZ[1], O. ALDANA-ASSAD[3], E. Internacional de Investigación sobre el Genoma Humano, Univ. Nacional Autónoma de México, Querétaro, Mexico; [4]QIMR Berghofer Med. Res. Inst., Brisbane, Australia

Abstract: Monozygotic (MZ) and dizygotic twin studies estimate the variability in a trait is due to environmental or genetic factors, this is known as heritability. Specifically, the heritability of traits as anxiety has been estimated around 7.4% for the population of European ancestry and 14% in Latin-American population living in the United States, which suggests that each population must be studied in a specific manner and that it is not possible to directly translate results between populations. The aim of this study was to correlate symptomatology of anxiety and depression in MZ and DZ Mexican twins, as a first step to calculate the heritability of these traits in a Mexican population. A sample of 108 (n=42 MZ pairs and n=12 DZ pairs) twins answered (through the website of the Mexican Twin Register, TwinsMX https://twinsmxofficial.unam.mx/) the State-Trait Anxiety Inventory (STAI) and 100 (MZ n=39 pairs; DZ n=11 pairs) of them, the State-Trait Depression Inventory (STDI). These instruments allow evaluating the state, defined as how a person currently feels, it is a measure of the feelings at the time of evaluation, and it can be understood as a transient measure. On the other hand, the trait describes how people usually respond to day-to-day life, which implies a more stable set about her/his cognition and behavior; this measure is related with temperament. As a result of this study was observed a significant correlation for Anxiety-Trait in MZ twins ($r_s=0.57$; $p<0.01$), but not in DZ ($p=0.75$). By contrast, for Anxiety-State there were no significant results for MZ ($p=0.054$) nor DZ ($p=0.76$). Meanwhile, for Depression-Trait there was a significant correlation for MZ ($r_s= 0.58$; $p<0.01$) but not for DZ twins ($p = 0.37$). For Depression-State, there was a significant correlation for both MZ ($r_s= 0.52$; $p<0.01$) and DZ ($r_s = -0.78$; $p<0.01$). Trait results for Anxiety and Depression, in MZ twins, but not in DZ, suggest that this symptomatology is probably associated with greater genetic contribution. Nevertheless, the results for state for anxiety and depression are still not conclusive, a greater sample will be necessary to improve statistical estimations,

including the heritability index. Overall, this study shows the necessity of having twin data in the Mexican population to strengthen the knowledge of mental health traits, such as anxiety and depression symptomatology.

Title: Differences between affective-cognitive empathy and overload in informal caregivers of patients with chronic diseases

Authors: *A. CABALLERO VELARDE[1], A. MONTIEL RIVERA[2], E. ACOSTA-MARI[2], S. ZAMORA-LUGO[2], R. L. CASTILLO LOPEZ[3], T. CIBRIAN-LLANDERAL[2];
[1]Facultad de Psicologia, Univ. Veracruzana, Xalapa, Veracruz, Mexico; [2]Neurociencias Afectivas, Inst. de Neuroetologia, Univ. Veracruzana, Xalapa, Veracruz, Mexico; [3]Ctr. Estatal de Cancerologia "Dr. Miguel Dorantes Mesa", Xalapa, Veracruz, Mexico

Abstract: It is known that patients with chronic diseases present physical and psychological affections, these complications can also affect informal caregivers (IC) directly and indirectly, generating changes in the quality life, care overload, cognitive and affective alterations, etc. This can occur at the initial time of diagnosis or during the disease, so it is relevant to know the variations that IC can present. The objective of this work was to identify the differences between the levels of empathy and overload in three IC groups of patients with cancer, psychiatric and lupus. A comparative, observational and cross-sectional study was carried out, with a sampling by convenience; where a total of 116 IC participated, 37 from the “Centro Estatal de Cancerología *Dr. Miguel Dorantes Mesa*”, 26 of the “Instituto Veracruzano de Salud Mental *Dr. Rafael Velasco Fernández*” and 53 at the “Hospital de Especialidades *Antonio Fraga Mouret* La Raza”. The Davis Interpersonal Reactivity Index (IRI), the Zarit Caregivers Burden Interviews (ZBI) and the Reading the Mind (RME) tests were applied. For statistical analysis, independent samples were taken with Mann-Whitney U test and intragroups were compared with the Kruskal-Wallis test, using the SPSS program. The results show a majority participation of women (71.6%), there were no differences between sex. Differences were found in RME ($p = 0,003$), where IC of patients with lupus obtained higher scores compared to those of cancer, also in IRI-Perspective Taking scale ($p = 0.048$) IC with psychiatric patients obtained higher scores compared to those with lupus, and finally at ZBI ($p = 0.030$) IC of patients with

lupus obtained higher scores compared with IC of cancer. It concludes that there are differences between IC according to the type of disease of the patient. So, it is pertinent to implement prevention and catalytic strategies for IC in patients with chronic diseases.

Title: Weaker resting-state ventromedial PFC-amygdala connectivity is associated with mindfulness meditation induced depressive mood reductions

Authors: *L. KHATIB[1], V. OLIVA[1], G. RIEGNER[1], G. POSEY[3], J. DEAN[1], J. BAUMGARTNER[1], Y. JUNG[4], R. KRAFT[3], J. BIRENBAUM[2], F. ZEIDAN[1];
[2]An, [1]UCSD, San Diego, CA; [3]Wake Forest Univ., Winston-Salem, NC; [4]Univ. of California, Davis, Davis, CA

Abstract: Negative mood is associated with stronger functional connectivity between brain mechanisms supporting low-level affective reactivity (amygdala) and self-related affective processing [ventromedial prefrontal cortex (vmPFC)]. Mindfulness meditation, a practice premised on sustaining non-reactive attention to the present moment, reduces acutely evoked stress, anxiety and pain through greater PFC recruitment. Mindfulness also reliably reduces amygdalar activity in the presence of a stressor. However, it remains unclear if and how brief mindfulness training reduces dysphoric mood. The proposed study employed fMRI to examine if mindfulness-induced reductions in depressive mood would be associated with vmPFC-amygdala resting state functional connectivity.
Forty healthy participants were randomized to four, 20-minute sessions of mindfulness meditation training or book listening (n=20/group). The Center for Epidemiological Depression (CES-D) scale was administered before and after respective trainings. Resting state fMRI scans were acquired after completion of the interventions. Participants were instructed to "rest with eyes closed" during continual innocuous 35°C stimulation to the right calf (Medoc, Inc).
A 2 (group) X 2 (pre vs. post-intervention) ANOVA (SPSS v26) examined if mindfulness training produced greater reductions in depressive mood when compared to the controls. Within and between-group seed based functional connectivity analyses [FSL (Center for FMRIB, University of Oxford, Oxford, UK); randomise] between the bilateral amygdala (xyz coordinates right = 26, 0, -22; left = -24, -4, -18) and vmPFC (xyz = 36, -1, -14) were conducted. Residualized CES-D scores were then entered as

regressors to test if mindfulness-induced depression changes were associated with amygdala-vmPFC connectivity and if this relationship differed between groups.
Brief mindfulness training significantly reduced depressive mood (-15%) when compared to the book-listening regimen (+23%; $p < .05$, $\eta = .10$). The relationship between dysphoric mood changes and vmPFC-amygdala connectivity varied by group ($p < .05$). Mindfulness meditation-related reductions in depressive mood were associated with weaker vmPFC-amygdala resting state connectivity in meditators ($p < .05$) but not controls ($p = .55$). We provide novel evidence that 4 days of mindfulness training improves depressive mood. Further, at rest, lower depressive mood was associated with weaker vmPFC-amygdala connectivity and suggests that mindfulness may enhance psychological resilience to dysphoria in healthy individuals by reducing affective self-related appraisals.

Title: Detrended fluctuation and coherence under emotional burnout formation (Exhaustion stage)

Authors: *S. TUKAIEV[1], D. HARMATIUK[2], A. POPOV[2], M. MAKARCHUK[1];
[1]Inst. of Biol. and Med., Taras Shevchenko Natl. Univ. of Kyiv, Kyiv, Ukraine; [2]Dept. of Electronic Engin., Igor Sikorsky Kyiv Polytechnic Inst., Kyiv, Ukraine

Abstract: The neurophysiological mechanisms of emotional burnout remain insufficiently studied. It was found that EEG changes during burnout differ from biomarkers of depression and chronic fatigue syndrome. To establish the EEG markers of burnout was our aim. 182 volunteers, first-third year students from the Taras Shevchenko National University of Kyiv aged 18 to 24 years participated in this study. The EEGs were recorded during the resting state (3 min, closed eyes condition) monopolarly using EEG 23-channel system Neurocom. To establish EEG correlates of emotional burnout during rest state we used a special software written in Python 3.6 to implement Power Spectral Density calculation, the interhemispheric and intrahemispheric average coherence and Detrended Fluctuation Analysis (DFA). We analyzed separate artifact-free EEG segments in all frequency bands from 0.2 to 45 Hz. Psychological testing was performed before the registration of EEG. To determine the formation of emotional burnout Boyko's "Syndrome of emotional burnout" Inventory was used. The Exhaustion phase of emotional burnout was formed in 13 participants, and it was under development in 47 participants. In background EEG activity during the development of the exhaustion variations in EEG spatial synchronization were observed in low- and high-frequency EEG components. Development of exhaustion includes breaking of parietal-occipital links (alpha2,3-subbands) and formation of interhemispheric prefrontal, anterior frontal, and frontal links (alpha1,2-subbands). There were interruptions of coherence in the beta1 (interhemispheric frontal-frontal and parietal-parietal links) and beta2 subbands (right interhemispheric frontal link). DFA describes the long-term temporal correlations in the cortex, which are involved in

different aspects of brain functioning. We detected a high resting state DFA scaling exponent values (up to 0.90-0,95) under exhaustion development in the theta1 (left prefrontal area), theta2 (right frontal area), alpha3 (posterior regions), beta2 (left temporal region). Obtained values of DFA exponent and average coherence suggest the exhaustion formation is accompanied by the changes in visual and verbal processing, emotional processes (discretion and analysis).

Abstract: Introduction: Comorbid psychological disorders are common in patients with epilepsy. Issues in emotion processing are postulated to underlie psychological disorders, yet they remain understudied in epilepsy research and clinical care. The goal of this exploratory study is to assess emotion conflict processing in epilepsy. We hypothesized that adolescents with epilepsy would exhibit a blunted response to emotional conflict both in behavior and brain function compared to typically developing (TD) individuals. **Methods:** Six adolescents with epilepsy and nine age- and gender-equivalent controls (aged 10-18) underwent a magnetoencephalography recording (MEG, 306-channel VectorView system) during an emotional face-word Stroop task. Images of faces were presented with emotion words written across them that were either congruent or incongruent with the facial expression. Response times were calculated by congruency. Event-related fields (ERFs) were calculated across a period of 1000 ms before and after motor response by group, condition (i.e., congruent, incongruent), and for the difference field (i.e., incongruent-congruent). Global Field Power (GFP) was estimated for sensors covering different brain regions. Minimum Norm Estimates (MNE) were estimated per condition and group. Additionally, depression severity was assessed using the 9-item Patient Health Questionnaire and investigated in relation to response times and MEG findings. **Results:** TD participants responded faster for congruent than incongruent stimuli ($t = 5.5$, $p < .05$). Contrarily, participants with epilepsy had similar response times across conditions ($t = 2.2$, $p > .05$). GFP revealed an over activation in the left temporal lobe from 0 ms to 200 ms post-response for patients with epilepsy, compared to TD individuals ($F = 7.6$, $p < .05$). MNE localized this activation to the left inferior temporal lobe. Depression severity was positively correlated to emotion conflict response time ($r = .5$; $p < .05$) and GFP values in the left temporal lobe ($r =$

.6; $p < .05$). **Discussion:** This preliminary study is the first to report potential blunted emotion conflict processing in an adolescent epilepsy sample using MEG. Differences in post-response activity in the left temporal lobe may be related to differences in post-response monitoring or conflict adaptation processes in epilepsy. Extending research on depression and emotion processing, the relationships between emotion conflict processing and depression level in the current study may suggest depression to play a modifying role in the ability to react to and regulate emotional conflict in those with epilepsy.

Title: Neighborhood safety is associated with anxiety symptoms and variation in emotion processing neurocircuitry in children

Authors: *B. BORG, H. MARUSAK;
Wayne State Univ., Detroit, MI

Abstract: While the literature has long established the relationship between the environment and mental health, less is known about the neural correlates underlying these associations. Emotion-related disorders, such as anxiety, commonly begin during childhood and adverse environments, such as living in dangerous neighborhoods, can increase risk for anxiety. Moreover, how children perceive their environment is a determinant for their overall health. This study aims to understand the relationships among perceived neighborhood safety, anxiety, and emotion processing neurocircuitry in a large, demographically diverse sample of children. The current study used cross-sectional baseline survey and functional magnetic resonance imaging (fMRI) data from 11,878 9-year-old children from the Adolescent Brain Cognitive Development study (48% female; 65% White, 15% Black). Children self-reported on their neighborhood safety using the Youth Neighborhood Safety/Crime Survey. Child anxiety was estimated using the Child Behavior Checklist. The primary neuroimaging outcome variables were blood oxygen-level dependent response in emotion processing brain regions of interest (ROIs) during an emotional n-back task: amygdala, hippocampus, dorsal anterior cingulate cortex (dACC), and the insula. We estimated neural response via mean beta weights in each ROI to (1) threatening v. neutral faces, (2) positive v. neutral faces, and (3) overall response to emotional faces. Regression models examined whether neighborhood safety predicted anxiety symptoms and neural response in ROIs, and if neural responses, predicted anxiety. Overall, lower neighborhood safety was associated with greater anxiety

symptoms in children. Children living in less safe neighborhoods also demonstrated greater left amygdala and right hippocampus reactivity to emotional faces and to positive faces, and lower dACC and insula reactivity to emotional faces. Lower insula reactivity was also associated with higher anxiety, but insula reactivity did not mediate the association between neighborhood safety and anxiety. Given the role of the amygdala and hippocampus in emotion reactivity, and the dACC and insula in top-down emotion regulation, lower neighborhood safety may be associated with greater emotion reactivity and poorer top-down regulation. These results demonstrate that neighborhood safety predicts anxiety and variation in emotion processing neurocircuitry in children. These findings also have public health implications and future interventions aiming toward neighborhood safety may be a promising approach for improving mental health and moderating neurodevelopment in children.

Title: The neurophysiological markers of social anxiety

Authors: T. HSU[1,3], T.-R. HUANG[2,3], ***S.-M. HSU**[1,3];
[1]Imaging Ctr. for Integrated Body, Mind and Culture Res., [2]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan; [3]MOST AI Biomed. Res. Ctr., Taipei, Taiwan

Abstract: Social anxiety involves excessive fear and anticipation of social situations. The identification of the associated yet reliable neurophysiological signatures may facilitate early detection and prevention of the potential risk resulted from this symptom. This study adopted the well-established Trier Social Stress Test to induce psychosocial anxiety, in which participants were requested to perform a self-presentation speech that would be subsequently evaluated. Simultaneously, participants' (n=19) magnetoencephalography activities were recorded and anxiety levels was assessed using the State Anxiety Inventory (SAI)**.** As revealed from the SAI scores, participants' anxiety levels increased from the baseline to the task instruction stage and then slightly dropped during the task preparation stage. By exhaustively examining the common social anxiety-related biomarkers reported in previous literature, we observed a significant relation, across the above three stages, between the behavioral SAI scores and the delta/theta power over the frontal location, the alpha/low beta (14-20 Hz) power over the frontal/parietal locations or the frontal alpha power asymmetry. These findings reveal multifaceted and complex neural patterns that mediate social anxiety.

Title: Affective components of a preclinical fibromyalgia model

Authors: *C. ARGENBRIGHT[1], C. A. SALCIDO[2], T. AGUIRRE[1], P. FUCHS[1];

Abstract: Fibromyalgia (FM) is a highly represented pain disorder that is well understudied. FM animal models have provided knowledge surrounding the biological mechanisms of FM through the replication of physical symptoms, but often forego assessment of emotional comorbidities like anxiety. The purpose of this study was to investigate the efficacy of an acidic saline preclinical model of FM in replicating anxiety-like behaviors of approach/avoidance, while also assessing pregabalin in alleviation of FM-related pain affect. In a sample of 48 female rats, decreased mechanical thresholds for acidic saline compared to controls were found, suggesting model efficacy. Further, mechanical thresholds increased with the administration of pregabalin, indicating efficacy in treating FM related pain. Escape/avoidance behavior data revealed FM condition with a saline control treatment showed increased escape/avoidance behavior. There were, however, no differences between conditions in measures of velocity or distance travelled within the open field (OF) paradigm. As expected, animals reared more at baseline OF measures, than at post-injection 1 and post-treatment, but there were no differences observed in rearing behavior between conditions. These results indicate that while the acidic-saline model of FM was effective in lowering mechanical thresholds, it may not be as efficacious in replicating typical anxiety behavior in an OF paradigm.

Title: Investigating the neural mechanisms of interval timing using electroencephalography.

Authors: *H. MCCONE[1,2], J. S. BUTLER[4,3], R. G. O'CONNELL[1,2];
[1]Sch. of Psychology, [2]Trinity Col. Inst. of Neurosci., [3]Discipline of Physiology, Sch. of Med., Trinity Col. Dublin, Dublin, Ireland; [4]Sch. of Mathematical Sci., Technological Univ. Dublin, Dublin, Ireland

Abstract: Accurately reproducing time intervals in the range of hundreds of milliseconds to seconds is critical for everyday human behaviours such as playing music and sport. To probe the neural mechanisms underlying interval reproduction in this range, we recorded electroencephalography (EEG) while participants completed a time interval reproduction task. We examined two EEG signatures: the centro-parietal-positivity (CPP), which is an established signature of sensory evidence accumulation during perceptual decisions, and the Contingent Negative Variation (CNV), which is a fronto-central negative potential that is linked to anticipation and temporal decision making. The data used for the analyses were from nine students (5 female) with a mean age of 21 years (range: 19-23 years). The task consisted of two parts. In the first part of each trial, participants were presented with a time interval represented by a single, continuous auditory tone and were instructed to estimate its duration. Following a brief gap of variable duration, participants were presented with a short cue tone and reproduced the time interval by clicking a mouse button at the time they estimated the interval had elapsed. We found that participants' response times increased with interval duration and deviated from veridical towards the mean of the underlying time interval distribution. To examine the relationship between the EEG signatures and response times, we separated trials within participants, within interval conditions, into three response time bins and computed within participant average waveforms for each response time bin. We found that the slope of the CNV in the lead up to response significantly varied across response time bins (F (2,16) = 6.94, p = .006). Additionally, a linear mixed effects model indicated that single-trial estimates (5794 trials) of CNV slope significantly predicted response time independent from interval duration (standardized b = 0.07, 95% CI = [0.05, 0.09], p < 0.001), with a shallower CNV slope leading to a longer response time. By contrast, we did not find a gradually building positive CPP prior to response, or at any other point in the task. These findings suggest that variations in time reproductions are related to variations in CNV slope prior to response. The CNV may represent a motor plan for reproducing intervals or an urgency signal that emphasises the need to respond before a certain point in time. The absence of the CPP suggests that its role in decision making may be contingent on external sensory input and does not extend to internal representations of evidence such as the passing of time.

Title: Cognitive effort exertion enhances electrophysiological responses to rewarding outcomes

Authors: *M. BOGDANOV[1], H. RENAULT[1], S. LOPARCO[2], A. WEINBERG[1], R. OTTO[1];
[1]Psychology, [2]Integrated Program in Neurosci., McGill Univ., Montreal, QC, Canada

Abstract: A body of recent work has examined many of the neural mechanisms underlying cognitive effort-related discounting of anticipated rewards. However, studies investigating whether prior effort exertion increases or decreases the subjective value of obtained rewards have reported inconsistent findings. Here, we provide a more nuanced account of how cognitive effort affects subsequent reward processing in a novel task designed to assess effort-induced modulations of the Reward Positivity (RewP), an event-related potential characterized by larger responses to monetary gains than to losses. To probe individual differences, we also measured participants' effort discounting rates and RewP responses in absence of effort manipulations. We found that RewP amplitudes for both gains and losses were significantly elevated in trials requiring more versus less cognitive effort, suggesting that people ascribed more value to high-effort outcomes. Time-frequency analysis revealed that these effects were mirrored in delta band activity, but not in theta band activity. Examining individual differences, we found that participants who are more tolerant of cognitive effort exertion did not exhibit the canonical gain/loss difference in the delta band after low effort exertion, possibly suggesting that these participants experience reward received from easy tasks as less valuable. Together, our findings provide evidence that cognitive effort exertion can increase the subjective value of subsequent outcomes and further suggest that individual differences in effort sensitivity may modulate this effect.

Title: The influence of priors in encoding and accumulating sensory evidence in a decision-making task

Authors: *K. WALSH[1], D. P. MCGOVERN[2], R. G. O'CONNELL[1];
[1]Trinity Col. Inst. of Neurosci., Trinity Col., Dublin, Ireland; [2]Psychology, Dublin City Univ., Dublin, Ireland

Abstract: In recent years, there have been significant efforts to better understand how sensory expectations influence perceptual processing. Yet, many questions remain about the stages of information processing that exploit sensory priors and the mechanisms that best capture their influence on decision formation. Traditionally, priors have been represented in decision-making models with static biases in the rate of accumulation (drift biases). However, some have proposed that these biases may change dynamically across the duration of a trial. Here, we sought to address this question, using EEG to capture distinct electrophysiological signatures of three fundamental stages of perceptual decision-making: the encoding of sensory evidence, evidence accumulation, and motor preparation. Over the course of 4-6 sessions, subjects (n = 12) performed a two-alternative contrast discrimination task, consisting of discrete trials featuring two superimposed leftward- and rightward-tilted gratings, which gradually changed in

relative contrast. The task incorporated task-informative cues, designed to establish a prior expectations about the upcoming stimulus, and pulses of sensory evidence delivered at variable onsets. This allowed us to detect differences in the influence of prior-consistent and prior-violating sensory evidence at different stages of the decision-making process. Priors were found to influence both behavioural and neurophysiological indices of this process. Current analyses seek to clarify if these effects result from constant or dynamic biases shaping decision formation.

Title: Dissociating neural mechanisms of recognition memory and decision criterion using dense sampling fMRI

Authors: *E. LAYHER, T. SANTANDER, V. BABENKO, M. GROSS, M. B. MILLER;
Univ. of California Santa Barbara, Santa Barbara, CA

Abstract: When making a recognition memory judgment, individuals must determine whether the familiarity strength of an item surpasses the decision criterion to identify it as previously studied (‘old’) or novel (‘new’). Since recognition judgments encompass both memory *and* decisional processes, it is difficult to dissociate neural mechanisms associated with each. In a dense sampling fMRI study within a single individual, we systematically manipulated discriminability and decision criteria at four levels each to better dissociate activity underlying familiarity, the criterion, or both. During study phases the participant viewed a series of scene images that either appeared one, three, six, or nine times to modulate discriminability at test. A payment manipulation modulated the criterion at test, where the participant earned four cents for a correct response, lost either one or eight cents for a critical error, but received no penalty for a noncritical error. In the conservative criterion conditions incorrect ‘old’ responses represented the critical errors, whereas incorrect ‘new’ responses served as critical errors in the liberal criterion conditions. This created a fully crossed four discriminability by four criterion design in which the 16 test conditions appeared in separate test blocks (e.g. the lowest discriminability and most conservative criterion condition consisted of 20 old images studied once and 20 new images, where incorrect ‘old’ responses resulted in an eight cent penalty). The participant conducted the full task during fMRI scanning on 31 consecutive days, to obtain enough power to assess how each manipulation affects frontoparietal activity within an individual. In whole-brain analyses comparing old versus new responses in each test condition, we found widespread frontoparietal regions that became more active as the decision criterion became more conservative (e.g. anterior insula, dorsolateral prefrontal cortex, and superior parietal lobule) or more liberal (e.g. angular gyrus and medial prefrontal cortex), independent of the discriminability condition. In contrast, changes in discriminability revealed spatially sparser increases

in frontoparietal activity as memory performance increased, such as anterior regions of the dorsolateral prefrontal cortex. Most of the widespread frontoparietal activity observed in the old versus new response contrast is attributable to the decision criterion. Whole-brain fMRI analyses appear to be rather insensitive to changes in discriminability when controlling for the decision criterion.

Dublin, Dublin, Ireland; [6]Neurosurg. / Neurol., Hofstra Northwell Sch. of Med., Manhasset, NY

Abstract: Making choices on the basis of perceptual information involves a dynamic flow of events that includes (but is not limited to) encoding the sensory input, evaluating the sensory evidence in favor of the options, and performing the appropriate action. Single-unit recordings in non-human primates have characterized neural activity across frontoparietal regions supporting the formation of perceptual choices through a process of evidence accumulation over time. In humans, scalp EEG work has identified neural signals consistent with this process, however the generators of these signals are not yet clear. Human intracranial EEG provides a unique opportunity to study the time-resolved unfolding of neural activity with increased spatial precision, and to therefore capture the heterogeneity of decision-related neural responses and disentangle their underlying sources. Here, we recorded data from presurgical epilepsy patients implanted with intracranial electrodes while they performed one or more of three possible perceptual decision tasks. A visual speeded response task asked participants (N=18) to judge the direction (up vs. down) of random-dot motion stimuli and report their choice with a button press. To probe for stimulus-independent choice related activity, we used an auditory analogue of this task where participants (N=15) discriminated the dominant pitch (high vs. low) of mixed tone auditory stimuli. Finally, to evaluate decision related signals that might arise independently of motor requirements, a subset of participants (N=8) performed a version of the visual direction discrimination task whereby choices were reported vocally after a randomized delay. Using a data-driven dimensionality reduction approach, we were able to identify functionally dissociable task-correlated components in the neural activity that showed unique temporal dynamics, spatial distribution, and relationship with decision behavior, in line

with a cascade of neural events supporting the decision process, and consistent with previous observations in the non-human primate brain. Our results highlight the complementary value of iEEG to scalp EEG and invasive animal studies to investigate the neural substrates of perceptual decision making.

Title: Distinct frequency bands synchronize distributed feedback tuned neuronal populations in the human brain

Authors: *I. SKELIN[1], H. ZHANG[2], M. R. PAFF[3], E. A. BUFFALO[5], R. T. KNIGHT[6], J. LIN[4]; [2]Biomed. Engin., [1]Univ. of California Irvine, Irvine, CA; [3]Univ. of California, Irvine, Orange, CA; [4]Dept. of Neurol., Univ. of California, Irvine, Irvine, CA; [5]Univ. of Washington, Seattle, WA; [6]Univ. of California Berkeley, Berkeley, CA

Abstract: Adaptive behavior requires utilization of action outcome feedback, which could be present at the level of neuronal populations, reflected in the high-frequency activity (HFA; 70-200 Hz). The Wisconsin Card Sorting Task (WCST) contains 12 possible rules, across 3 different dimensions (color, shape and texture), with unpredictable rule switching. This experimental model is suitable for investigating the neural and behavioral dynamics underlying feedback signaling during rapid rule acquisition and switching. We recorded intracranial electroencephalographic (iEEG) signal from the temporal and frontal lobe in 16 subjects undergoing pre-surgical evaluation of epileptic foci, during performance on WCST (32 datasets; 983 electrodes). The HFA feedback tuning (HFA significantly associated with trial outcome) was present in 12.4% of local populations, distributed across all the recorded structures (amygdala, hippocampus, orbitofrontal and anterior cingulate cortices). Next, we assessed the noise correlations between the feedback-tuned electrode pairs and found significantly higher noise correlations during the time periods when HFA in both populations contained feedback information. Finally, we hypothesized that HFA noise correlations are driven by low-frequency synchrony. To test this hypothesis, we computed the Spearman correlations between the pairwise noise correlation time-courses and low-frequency connectivity (phase-locking value; PLV) for the feedback-tuned populations. PLV dynamics was significantly associated with noise correlations in two distinct, feedback-dependent bands: beta range (25-30 Hz) during correct and ~2 Hz during incorrect trial feedback periods. These results provide evidence for outcome-based oscillatory mechanisms integrating distributed feedback information in the human brain.

Title: EEG signatures of decision formation in motion direction estimation

Authors: *E. A. CORBETT[1], P. L. SMITH[2], H. MCCONE[1], S. KELLY[3], R. G. O'CONNELL[1]; [1]Trinity Col. Inst. of Neurosci. and Sch. of Psychology, Trinity Col. Dublin, Dublin, Ireland; [2]Melbourne Sch. of Psychological Sci., Univ. of Melbourne, Melbourne, Australia; [3]Sch. of Electrical and Electronic Engin., Univ. Col. Dublin, Dublin, Ireland

Abstract: In perceptual decisions with continuous outcomes, response variability may be influenced by categorical biases as well as attentional fluctuations. Here we investigated whether directional biases and trial-to-trial variability in accuracy were reflected in EEG signatures of decision formation in a random-dot-kinematogram direction estimation task. Six participants reported the perceived direction of motion from 18 stimulus directions spanning 360º using a joystick. Two levels of coherence of the dot motion stimulus were interleaved, and modulated at a frequency of 15Hz generating a steady-state visual motion evoked potential (SSVMEP) in the EEG signal reflecting the strength of sensory evidence encoding. We also measured the centroparietal positivity (CPP), thought to reflect the evidence accumulation process. Both the SSVMEP (466 ms post-stimulus) and CPP (200-333 ms) were strongly modulated by coherence (linear mixed effects (LME) models with random intercepts for participants, excluding minority of trials with errors > 120º in all EEG analyses; both $p<.001$). The SSVMEP ($p=.01$) and CPP ($p=.045$) signals were both significant predictors of response accuracy (LME model with fixed effects for coherence, CPP and SSVMEP, with random intercepts).
Participants' responses displayed varying amounts of idiosyncratic directional biases. We jointly fit individuals' response angles and response times with the circular diffusion model, including a mixture component with a zero-drift process in low coherence trials to account for encoding failures. We accounted for directional variation through stimulus biases using the similarity-choice method of Smith et al (2020), in which the drift rate is the vector sum of the encoded metric (true stimulus direction) and categorical (participant-favoured directions) representations of the stimulus. We then averaged the SSVMEP and CPP for each direction and coherence level to examine their relationships with the directional drift rate estimates. Drift rate was a significant predictor of the CPP ($p=.001$, LME model with fixed effects for coherence and drift rate, with random intercepts), but not the SSVMEP ($p=.49$). Taken together, these results suggest that while directional biases may be reflected in neural processes of evidence accumulation, the modulation of the sensory-level SSVMEP signal reflects trial-to-trial influences on response accuracy unrelated to directional biases.

Title: Neurally informed insights into speed-accuracy adaptations in older adults

Authors: *C. JUDD, J. DULLY, E. A. CORBETT, R. G. O'CONNELL;
Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland

Abstract: When instructed to prioritise speed over accuracy in decision making, older adults tend to make smaller adjustments to their choice behaviour compared to younger adults. Behavioural modelling suggests this may be due to less pronounced adjustment of decision bounds across conditions and a general preference for a more cautious response style. However, this work has relied on standard models which overlook important algorithmic elements and adjustments that have been identified in recent neurophysiological research. The current study aims to leverage neurally-informed modelling to investigate aging's effects on speed-accuracy adaptation. 30 older adults and 30 young adult controls completed a random dot-motion task, while electrical brain activity was recorded through EEG. Neural data indicated significantly greater pre-stimulus motor preparation in the young group which was not present in the older group ($F(1)=7.571$, $p=0.008$). A cross-over effect of condition on sensory processing signals was also observed, with higher sensory encoding signal amplitudes (SSVEP) under speed pressure in older adults, while the signal was stronger under accuracy pressure in the young group ($F(1,56)=9.672$, $p=0.003$). Concurrent drift-diffusion modelling indicated age differences in the setting and dynamic adjustment of decision bounds. This work is using neural signals to constrain model parameters, seeking to reconcile the two data streams to create a parsimonious and biologically grounded model of the impact of ageing on speed-accuracy adaptations in older adults.

Title: Two distinct patterns of EEG activity emerge during value-based choice, neither related to evidence accumulation

Authors: *R. FRÖMER[1], M. R. NASSAR[2], B. V. EHINGER[3], A. SHENHAV[1];
[2]Metcalf Hall, [1]Brown Univ., Providence, RI; [3]Univ. of Stuttgart, Stuttgart, Germany

Abstract: Research into value-based choice and its neural correlates often centers on a unitary process subsuming the accumulation of evidence about one's options until a choice is made. The centro-parietal positivity (CPP) is one putative index to this evidence accumulation process. At odds with a unitary view, our previous fMRI research suggests two distinct forms of evaluation during value-based choice: (1) overall appraisal of one's options, and (2) comparing between those options for the current choice. Here we test whether these processes are also temporally dissociable, with appraisal-related processes tied to the time one's options appear and choice-related processes tied to the time a decision is made. In light of this dissociation, we reevaluate the CPP as an index of evidence accumulation.We recorded EEG while participants (N = 39) made choices between consumer goods, previously rated individually. Afterward, participants rated their overall appraisal (liking) of each set, how anxious they felt making the choice, how confident they were in this choice. Using PCA, we reduced the dimensionality of measures to two components, broadly indexing variance associated with the appraisal of items (e.g. overall value and set appraisal) and choice between items (e.g. value difference and confidence). We used those components as regressors for stimulus- and response-locked EEG activity.As predicted, activity locked to the onset of the stimuli correlated with our appraisal-related PC, and activity locked to (and preceding) the response with our choice-related PC. Neither activity pattern was consistent with canonical indices of evidence accumulation. However, we show that typical CPP evidence accumulation patterns can emerge artificially as stimulus and response locked effects occur closely in time. Confirming this, we demonstrate in an independent dataset that signatures of evidence accumulation commonly observed in the CPP vanish when accounting for such overlap through joint modeling of stimulus and response-locked activity. Our results provide further evidence that neural activity during value-based choice does not reflect a unitary choice process. Neither of the spatiotemporally distinct patterns associated with appraisal and choice conformed with canonical signatures of evidence accumulation. They might instead reflect affective and metacognitive appraisals of one's options and (latent) choice. Our findings call for caution when interpreting neural correlates of choice value, a critical re-examination of putative EEG evidence accumulation signals, and for taking a broader, more integrative perspective on value-based choice.

Title: Representations of the subjective value of cognitive effort

Authors: *G. E. STEWARD, V. S. CHIB;
Johns Hopkins Univ., Baltimore, MD

Abstract: Many of our daily tasks require us to evaluate how cognitively effortful they feel. We often use these effort judgements to prioritize tasks -- which to take on, and which to leave for another day. Despite the ubiquity of cognitive effort judgement, it is not well understood how we make decisions involving cognitive effort at the levels of brain and behavior. We used a combination of functional magnetic resonance imaging and a behavioral decision-making task for prospective cognitive effort, in the form of working-memory, to understand how healthy human participants represent the subjective nature of cognitive effort in the brain.
We had participants make choices as to whether to undergo a low-effort cognitive task for $1 or a variable higher-effort cognitive task for variable reward while undergoing an fMRI scan. The cognitive effort task took the form of the N-Back working memory task, with increasing N representing increasing working memory load and increasing cognitive effort. The choice paradigm used was designed to be robust, with considerations for balanced order randomization and choice difficulty over time.
We found that participants probability of acceptance of the more effortful option increased with increasing reward and decreased with increasing effort level. We found that individuals varied the point at which they began accepting high effort options for reward, indicative of individual differences in subjective valuation of cognitive effort. Subsequent analysis will examine brain regions with activity associated with participants subjective preferences for cognitive effort and reward.

Title: Widespread gamma suppression in exploratory decision-making

Authors: *K. JUREWICZ[1], S. KOENIG[2], R. MCGOVERN[2], M. C. PARK[2], D. P. DARROW[2], B. EBITZ[1], A. B. HERMAN[2];
[1]Univ. de Montréal, Montreal, QC, Canada; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: In complex and changing environments, the best option is not always known in advance or stable over time. Under these circumstances, organisms have to balance two goals: exploiting options

with a known, good value versus exploring alternatives that might turn out better. Exploring and exploiting require such different computations that we might expect to see large changes in brain activity between periods of exploration and exploitation, but we have only recently developed methods to clearly differentiate these goal states. Here, we examined neural activity across distributed intracranial recordings while humans made both exploratory and exploitative choices.
Ten epileptic patients performed a sequential decision-making task, choosing between three available options whose values changed gradually and independently over trials. A hidden Markov model (HMM) was used to model exploration and exploitation as the latent states underlying behavior, which allowed us to label choices as exploratory or exploitative. The patients contributed signals from over 1000 subdural electrocorticographic (ECoG) and/or depth electrodes, distributed across a wide range of brain regions, with the most dense coverage of prefrontal, temporal, and (para)hippocampal regions.
Exploration produced widespread suppression of local field potential power in the gamma band (~60-120 Hz), when compared to exploitation state. Gamma suppression was identified in most of the recording electrodes and was sustained throughout the trial, across decision-making and reward-processing epochs. This effect was highly specific to the gamma band and could not be explained by the lower reward rate in explore than exploit trials.
Gamma oscillations index the intensity of local neuronal activity and widespread differences in gamma local field potentials have been previously identified in cognitive tasks, with higher gamma activity when mnemonic demands are higher. In this context, the profound whole-brain gamma suppression we observed in exploration could suggest that distributed information maintained for exploitative choices is less available during exploration. This could facilitate the discovery of new options through overcoming historical biases.

Title: Does the timing of a decision cue based on neural activity modulate the decision outcome? A real-time EEG study

Authors: *M. SCHULTZE-KRAFT, H. STEINRÜCK, J.-D. HAYNES;
Bernstein Ctr. for Computat. Neurosci. Berlin, Berlin, Germany

Abstract: The relationship between voluntary, spontaneous motor decisions and preceding neural activity has been studied for decades, yet the question whether this relationship is causal remains debated. In

humans, movements executed at freely chosen time points ("when" decisions) are preceded by a negativation of the electroencephalogram (EEG) over motor areas, the so-called readiness potential (RP) (Shibasaki & Hallett, 2006). Similarly, when people are instructed to decide whether to execute a rapid or a delayed movement at an externally cued time point ("whether" decisions), rapidly executed movements are preceded by signals similar to RPs (Filevich et al., 2013). This suggests that neural signals preceding spontaneous movements and those preceding cued, free-choice rapid movements are closely related. Using a novel experimental paradigm, we tested whether the presence of such RP-like events (RPLEs) at the time of a free-choice cue in a motor task has an effect on the subsequent decision. In an initial experimental stage, we instructed participants (N=18) to perform self-paced movements in single trials and trained a brain-computer interface (BCI) on the recorded RPs. In the main experimental stage, participants were presented with a visual cue in each trial and instructed to spontaneously decide to quickly execute a movement, or not to move. The cues were elicited in real-time by the BCI either upon detecting the presence or the absence of an RPLE in the ongoing EEG. We hypothesized that participants would decide more often to execute a movement when the decision cue was elicited by an RPLE than when no RPLE was present. We found no evidence for an effect of EEG signals at the time of the cue on participants' decisions. This negative result can have several reasons. First, although offline analyses show that the EEG preceding the two types of cues indeed reflected the presence or absence of RPLEs, the accuracy of a BCI in detecting RPLEs in real-time is limited by the noisy nature of EEG. Second, it could be that the similarity between EEG signals preceding "when" and "whether" decisions is spurious. Finally, RPLEs may simply not modulate the outcome of "whether" decisions. Future advancements of our real-time paradigm will help disambiguate these findings.

Title: Neuronal mechanisms of dynamic social competition

Authors: *Y. JIANG, M. L. PLATT;
Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: People naturally engage in social interactions involving competition or negotiation in which they continuously update mental models of other agents. To understand the neurobiology of these dynamic interactions, we studied humans and monkeys playing a virtual competitive soccer game in which the numbers of moves and counter-moves were unconstrained. This game combined a classic zero-sum matching penny scheme with a timing game by requiring players to optimize both movement sequence and temporal control of their final move to win. Using this game we uncovered a wide range of strategic performance in humans that was correlated with various socio-cognitive traits including mentalizing capacity. Remarkably, performance of monkeys was well within the human distribution in all facets. Next, we recorded neuronal activity in macaque mid-superior temporal sulcus (mSTS), the putative simian homolog of the human temporo-parietal junction (TPJ)--a brain area engaged in strategic social interactions guided by mentalizing. Two distinct neuronal populations with different tonic firing rates and residing within different depths in the mSTS showed opposing activity patterns throughout the virtual soccer game. One population encoded self over opponent movements during gameplay, and encoded loss over win after gameplay. The second population encoded opponent moves during gameplay and win over loss after gameplay. Both populations retained information about trial history and behaved similarly when monkeys played attacker or defender. Together, these activity patterns are well-suited to support the complex, dynamic interactions between players in this game, and by extension natural pairwise social interactions. To test this idea, we inactivated mSTS with muscimol, and observed a significant decrease in players' strategic flexibility and responsiveness as a result. These findings suggest mSTS evaluates strategies to fit the current social context and endorse the hypothesis that it is the primate homolog of human TPJ.

Title: Identification of functional subdivisions within the rodent medial prefrontal cortex during decision making

Authors: G. W. DIEHL, A. D. REDISH;
Neurosci., Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Anatomical work has long identified heterogeneity within the rodent medial prefrontal cortex (mPFC) suggesting distinct subdivisions of anterior cingulate (ACC), prelimbic (PL), and infralimbic (IL) cortices. However, it remains unknown if these anatomical differences are reflected functionally, or how multiple functional subregions may interact in support of behavior.
We trained rats to perform a complex economic decision making task (Restaurant Row) that required

multiple cognitive processes such as sensory descrimination, value assessment, and cognitive override, which have been closely associated with the mPFC. We used silicon probes to record ensemble activity from the full dorso-ventral extent of the mPFC during behavior and precisely localize each unit. This experimental approach allowed us to monitor neural activity patterns across multiple portions of the mPFC simultaneously during decision making to directly test for the existence of functional subdivisions and interactions between them.
Leveraging the precise anatomical information afforded by silicon probes, we developed a novel analytic approach that related functional activity patterns across pairs of mPFC cells according to their specific positions along the mPFC dorso-ventral axis. This analysis revealed distinct functional domains with the mPFC and allowed us to define independent subregions. The boundaries between these subregions closely matched anatomical data, providing a direct link between the functional and anatomical domains. Integrating functional and anatomical profiles yielded four distinct subregions, Acc, IL, and dorsal (dPL) and ventral (vPL) prelimbic cortex. All four subregions exhibited unique but complementary activity profiles. ACC and dPL were involved in active decision making with dPL providing a general decision signal and ACC signalling an override of the default choice. vPL and IL provided more state based signals, either marking transition points in the task (vPL) or maintaining and updating information about the current state (IL).
Finally, examination of network interactions revealed that functional connectivity within mPFC is graded, with the strength of influence dissipating with increasing anatomical distance. Followup ensemble analysis between subregions pointed to the existence of two complementary modes of information transfer: A strong connectivity that relayed information stepwise across adjacent regions from dorsal to ventral mPFC, and a weaker, longer range connectivity from ventral to dorsal mPFC which may provide updates about changes to task conditions for consideration in future decisions.

Title: Optogenetic manipulation of the rodent medial prefrontal cortex disrupts the transition from deliberative to procedural decision processes on a delay discounting task

Authors: A. E. MCLAUGHLIN, K. SEELAND, A. SHEEHAN, *A. D. REDISH;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Rats show a preference for smaller, immediate rewards over larger, delayed ones, a phenomenon known as delay-discounting. Rats were trained on a spatial delay discounting task (Papale et al 2012 CABN) where they repeatedly faced two choices while running laps on a figure-8 maze: a smaller-sooner reward offered immediately or a larger-later reward offered after a variable delay that

increased in time (+1s) each lap it was selected and decreased each lap it wasn't (-1s).
Well-trained rats typically show three behavioral phases: investigation, characterized by alternation between options, titration, characterized by a repeated preference for one side or the other (adjustment laps) which titrates the delay to a preferred delay, and exploitation, characterized by alternation between options which holds the delay constant. These phases can be identified by changes in behavioral characteristics such as path stereotypy, pause and re-orient behavior at choice points (vicarious trial and error, VTE), and changes in adjustment and alternation laps, suggesting these phases are indicative of transitions between deliberative and procedural decision processes. The medial prefrontal cortex (mPFC) has been identified as a central component in the mediation between these decision-making processes. 15 rats underwent in-vivo optogenetic manipulation of the mPFC during the spatial delay discounting task. Comparisons between rats with active (n=8, AAV5-CaMKIIa-ChR2-mCherry) and inactive (control, n=7, AAV5-CaMKIIa-mCherry) virus revealed a significant deficit in the active group's ability to transition to automated, procedural decision processes. Both groups learned the task equally well after transfection, but before the experimental phase in which light activated the optogenetic receptors; however, differences appeared with extended exposure to the task after light administration. Interestingly, we did not find trial-by-trial changes due to light delivery, but instead found long-term changes that arose after the first delivery of light to the transduced rats. Control rats showed developing procedural responses as they gained experience with the task, but active rats did not, continuing to express adjustment laps throughout each session. Active animals also exhibited fewer instances of VTE compared to the control group after the first delivery of light to mPFC. These results suggest that VTE may be an important component in learning to transition from deliberative to procedural decision modalities and that this transition may be mediated in part by the medial prefrontal cortex in rats.

Title: Distinct representations across the medial-to-lateral rodent orbitofrontal cortex in an economic decision-making task

Authors: *P. J. CUNNINGHAM, G. W. DIEHL, A. D. REDISH;
Neurosci., Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: The rodent orbitofrontal cortex (OFC) plays a diverse role in value-based decision making. Emerging evidence suggests functional heterogeneity along the medial-to-lateral axis of the OFC. We examined information-processing from the medial (MO), ventral (VO), and lateral (LO) subregions simultaneously while rats made value-based decisions in the Restaurant Row (RRow) neuroeconomic

task.
Rats serially encountered four “restaurants” offering distinctly flavored food delivered after a randomly chosen delay (ranging from 1- 30 s) to earn their daily food intake within a one-hour time budget. Each restaurant contained an offer zone (OZ) and a wait zone (WZ). Entry into the OZ triggered a tone indicating the delay to reward for that offer. In the OZ, rats could either “accept” the offer by entering the WZ or “skip” it by proceeding to the next restaurant. In the WZ, the delay to reward counted down and rats could either wait through the delay and earn reward (“earn”) or leave the WZ prior to earning reward (“quit”). Neural ensembles were recorded simultaneously from MO, VO, and LO with 3 silicon probes each as rats (n=5) made value-based decisions in RRow.
We found dissociable information processing in LO, VO, and MO ensembles. LO firing increased in the moments preceding reward delivery, whereas VO and MO firing decreased after reward delivery. Despite these contrasting firing patterns, each subregion contained information about the currently offered reward type at reward delivery time. VO ensemble firing differentiated skip/accept decisions in the OZ by increasing firing rate only when a skip decision was made. Indeed, VO ensembles contained more mutual information about the current OZ decision (accept vs. skip) than LO or MO ensembles. This result suggests that VO ensembles represent accept/skip OZ decisions at the decision moment more than LO and MO ensembles. In contrast, LO ensemble firing rate differentiated quit/earn decisions by increasing prior to leaving the restaurant only when a quit decision was made. These results suggest that accept/skip and quit/earn decisions depend on different evaluation processes which are likely mediated by VO and LO respectively.
Finally, VO ensemble firing increased when leaving a restaurant regardless of whether the rat left by quitting the WZ, or by proceeding to the next restaurant after post-reward lingering. This result suggests that VO ensembles likely participate in deciding to leave a reward-associated location to search for reward elsewhere. Overall, these results suggest distinct information-processing characteristics across the medial-to-lateral OFC at various learning and decision moments in a neuroeconomic task.

Title: Neuronal encoding in LIP during abstract categorical decisions based on multiple visual features

Authors: *P. MOGHIMI, A. A. SILVA, D. J. FREEDMAN;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Primates have a remarkable ability to group visual stimuli into arbitrary learned categories, which often involves integrating multiple features such as shape, motion and color. Previous studies have

shown that neurons in the lateral intraparietal area (LIP) of monkeys encode the learned category membership of visual stimuli, and that inactivation of LIP impairs category judgements. In previous studies of categorization in LIP, stimuli were typically categorized by a single visual feature—direction of motion. The current study asks whether LIP's role in categorization of visual motion is but one example of a more general role in visual categorization. We investigated whether and how neuronal populations in LIP participate in categorizing visual stimuli when categorical decisions require integrating two visual features—motion direction and color. We trained one monkey to perform a double-feature categorization task where it was required to assign a random-dot motion stimulus into one of two categories based on both their direction of motion and color. Each trial began with fixation, after which an array of colored, coherently moving dots appeared. After 700ms, two targets appeared, each associated with one category. The animal indicated category of the stimulus by making a saccade to one of the two targets. Six motion directions (36° apart) and six colors (ranging from red to yellow) were combined to generate a set of visual stimuli, and a category boundary was defined which required the monkey to take into account both features in order to categorize the stimulus. During the task, we recorded from LIP in 16 sessions, and completed preliminary analysis of 41 single units from four sessions. The monkey's accuracy was 83% for conditions away from the category boundary and 64% for conditions close to the category boundary on included sessions. We used three-way nested ANOVA ($p=0.05$) to assess selectivity of each neuron for both features and the abstract category of the stimulus. A majority (30/41) of LIP neurons were selective for at least one of two features (14 and 16 neurons selective for direction of motion and color, respectively). Interestingly, five neurons were selective for both features, suggesting integrative encoding of the two features. Two neurons were category selective, of which one was selective for both features and one was not selective for either feature. These results indicate that LIP neurons integrate multiple features to perform this categorization task. Ongoing work is examining the nature of stimulus and categorical representations in LIP during this task, to gain insight into how integrative representations support the animal's decisions.

Title: Distinct roles of the superior colliculus and the lateral intraparietal area in decision formation and termination

Authors: *G. M. STINE, E. M. TRAUTMANN, D. JEURISSEN, M. N. SHADLEN;
Zuckerman Inst., Columbia Univ., New York, NY

Abstract: Many decisions arise through an accumulation of evidence to a terminating threshold. Previous work has shown that the lateral intraparietal area (LIP) represents the accumulation of evidence when monkeys make decisions about the direction of random dot motion (RDM) and express their decision with an eye movement. However, LIP is interconnected with several other brain regions that also display decision-related activity, such as the superior colliculus (SC). SC and LIP are strongly interconnected and share several functional similarities, including subsets of neurons that display spatially selective, persistent activity. Whether SC's role in the decision process is similar to or fundamentally different from that of LIP is unclear.

We used newly-developed, primate neuropixels probes and v-probes to record simultaneously from retinotopically-aligned populations of neurons in LIP and SC as a monkey performed a reaction-time, RDM task. LIP neurons represented the accumulation of noisy motion-evidence on single trials (e.g. drift-diffusion). In contrast, SC neurons did not reflect evidence accumulation—including neurons with persistent activity in a memory-guided saccade task (i.e. prelude neurons). SC neurons generated an all-or-none burst of activity immediately preceding the saccade. In addition, single-trial analyses revealed that this saccadic burst was often preceded by non-saccadic bursts of activity, which were not apparent in trial-averages. Both types of bursts were associated with a sharp increase in LIP activity. Saccadic bursts tended to occur when LIP had also achieved a higher level of firing rate, suggesting that the conjunction of a sharp increase and elevated activity in LIP facilitates a burst in SC large enough to generate a saccade.

We hypothesized that this saccadic burst terminates the decision process. Consistent with this, we found that unilateral inactivation of SC induced (1) a coherence-dependent increase in reaction times for contralateral choices, (2) an ipsilateral choice bias, and (3) an increase in overall sensitivity, the combination of which is diagnostic of a higher terminating threshold for contralateral choices. Recordings in LIP during SC inactivation showed a prolonged build-up of activity, further suggesting that commitment to a contralateral choice required more accumulated evidence. We conclude that LIP and SC play fundamentally different roles in the decision process—LIP represents the accumulation of evidence whereas SC is involved in implementing the decision threshold—and we pose a novel neural mechanism for terminating an ongoing decision process.

Title: Neuropixel recordings in macaque area LIP reveal drift-diffusion dynamics on single trials

Authors: *N. A. STEINEMANN[1], G. M. STINE[1], E. M. TRAUTMANN[1], A. ZYLBERBERG[1], M. N. SHADLEN[1,2];
[1]Neurosci., Columbia Univ., New York, NY; [2]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: The concept of a dynamic firing rate, *r(t)*, is elemental to principles of computational systems neuroscience. Yet it is elusive, or latent, because single neurons produce spikes separated by silent interspike intervals. *r(t)* is thus estimated by averaging across repetitions, on the assumption that the neuron is a member of a larger population that represents r(t) on a single trial. With few exceptions, such populations have been inaccessible to electrophysiology, either because they lie deep in sulci or because they are intermingled among a heterogeneous population. This is especially problematic for the study of stochastic dynamic processes, such as decision making, where a decision variable, *V(t)*, is itself stochastic. On a trial i, $V_i(t)$ is thought to represent the cumulative sum of random samples—the momentary evidence, x_t—as in discrete drift-diffusion. Averaging across repetitions renders only a ramp: a line with slope $\langle x \rangle$, termed the drift rate. The diffusion component of $V_i(t)$ is latent. Two monkeys indicated the net direction of dynamic random dots by making a saccadic eye movement to a left or right choice target when ready. We recorded simultaneously from 54-191 neurons in the lateral intraparietal area (LIP) using high density, multichannel, primate neuropixel probes (IMEC/HHMI-Janelia). We focused on groups of 7-18 neurons (sample-population) with response fields that overlap a common choice target. We hypothesized that these neurons are a subset of a larger population that represents the animal's decision variable, $V_i(t)$. We found that mean firing rates from sample populations, $S_i(t)$, approximate drift-diffusion processes on single trials. (1) The variance of S(t), across trials, increases linearly over time. (2) Values of $S_i(t)$ at the beginning of the decision are correlated with decision outcome (choice and response time), consistent with temporal integration, and (3) this correlation is nullified when controlling for sample-population activity at later time points, consistent with the Markov property of diffusion. (4) When the decision ends with an eye movement to the choice-target in the common response field, $S_i(t)$ achieves a stereotyped level 50-100 ms before saccade initiation, consistent with the hypothesis that decision termination is accomplished via a threshold applied to . The observation of diffusion dynamics on single trials provides direct support for a neural mechanism long suspected to underly perceptual decisions arising through evidence accumulation.

Title: To blame or not? Modulating third-party punishment with the framing effect

Authors: *J. YANG[1,2], R. GU[3,4], J. LIU[2], F. CUI[1,2];
[1]Shenzhen Univ., Shenzhen, China; [2]Shenzhen Key Lab. of Affective and Social Neurosci., Shenzhen, China; [3]Inst. of Psychology, CAS Key Lab. of Behavioral Sci., Beijing, China; [4]Univ. of Chinese Acad. of Sci., Beijing, China

Abstract: People as third-party observers, without direct self-interest, may punish norm violators to maintain social norms. However, third-party judgment and the follow-up punishment might be susceptible to the way we frame (i.e., verbally describe) a norm violation. We conducted a behavioral and functional magnetic resonance imaging (fMRI) experiment to investigate the above phenomenon, which we call "third-party framing effect". Our task design combined the "social framing" task with third-party punishment. Participants observed an anonymous perpetrator deciding whether to keep her/his economic benefit while exposing a victim to a painful shock(described as "shocking others" in harm frame condition and "not helping others" in the help frame condition), then they had a chance to punish that perpetrator at their own cost. Our results showed that the participants were more willing to execute third-party punishment under the harm frame compared to the help frame, manifesting as a framing effect. In Behavioral Experiment, self-reported anger toward perpetrators mediated the relationship between empathy toward victims and the framing effect. In fMRI Experiment, we found that the mid-cingulate cortex (MCC), and insula were both significantly sensitive to the main effect of frame; the functional connectivity between these regions could significantly predict the framing effect size. Also, insular activation mediated the relationship between mid-cingulate cortex activation and the framing effect. Overall, this study reveals that third-party punishment is susceptible to decision frames, which may help understand why moral standards and moral actions could be flexible and relativistic. Besides, our findings may broaden the understanding of the framing effect in general.

Title: The effect of topology on adaptive strategies that arise from a conflict between deliberative and procedural decision-making.

Authors: *U. MUGAN[1], P. J. CUNNINGHAM[1], P. S. REGIER[2], S. AMEMIYA[3], A. D. REDISH[1]; [1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [3]Circuit and Behavioral Physiol., RIKEN Ctr. For Brain Sci., Saitama, Japan

Abstract: Prior research suggests that decision-making arises from a conflict between systems driven by dissociable neural circuits. Navigation studies reveal that deliberative strategies are characterized by pause-and-re-orientation behaviors (vicarious trial and error, VTE) and hippocampal (HC) goal-directed representations, while procedural responses are characterized by regularity in paths taken (path stereotypy) and dorsolateral striatal (DLS) task-bracketing (increased firing at the start and end of ballistic trajectories).
To examine the role of environmental structure on the balance between these decision-making strategies, we re-analyzed previous data from a contingency-switching task, taking into account a new measure of topological complexity, which quantifies the difficulty of the central path. This new measure uses an abstract representation of the task space to calculate its graph entropy, which quantifies the structural feature of the environment (Mugan and MacIver, 2020).
The task consisted of a spatial maze with a changeable central path that led to a high cost choice point (CP). Three different reward contingencies were used: turning left for reward at CP, turning right for reward at CP, or alternating choices. The reward contingency changed roughly half way through the session. Neural ensembles (n = 50 sessions) were recorded from DLS (6 rats) or HC (5 rats). The proportion of VTE events per session increased with central path and topological complexity. Neurophysiological correlates of deliberative decision-making also changed with environmental complexity. In HC, theta cycles were more symmetric in environments with high central path complexity. These theta cycles included more time spent in the ascending phase of the theta cycle—hypothesized to contain nonlocal representations. Both sharp wave ripple (SWR) overall rate and individual duration increased with central path complexity. SWRs have been implicated in planning, consolidation, and the mental exploration of navigational possibilities. More complex environments likely require a higher cognitive memory load, which could lead to more and longer SWRs. In contrast, path stereotypy decreased with central path and topological complexity, consistent with theories that environmental complexity slows the development of procedural automation. Task-bracketing effects (preferential firing in DLS at the start and end of a lap), emerged more slowly in environments with complex central paths. These data suggest that rats are more likely to use deliberative decisions in environments with more topological complexity.

Title: A two-step decision task to measure confidence in economic choices

Authors: *K. M. ROTHENHOEFER[1], W. R. STAUFFER[2];
[2]Neurobio., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Decision confidence is the belief that a choice is correct. This concept has been widely used to perform psychometric measurements of confidence in perceptual judgements. However, the application of confidence measures to economic choices is more challenging because 'correct' and 'incorrect' are not well defined. To address this limitation, we modified a recently published, two-step choice task that showed confidence in the first judgment was used as a prior in the second judgment (Lisi, Mongillo et al. 2021). In our version of the task, the first decision was an economic choice and we applied first- and second-order stochastic dominance (FOSD and SOSD, respectively) rules to the animals' utility function to categorize the choices as better or worse. The second decision was a perceptual judgment about the net direction of motion in a Random Dot Kinetogram (RDK). We trained NHPs that better choices were followed by motion stimulus to the right, whereas worse economic choices were followed by motion stimulus to the left. When the monkey indicated the correct direction of motion, it was rewarded with the amount chosen in the economic decision, otherwise it received no reward. Because monkeys rarely choose worse options, we masked the stimuli during the economic choice; we only revealed both options after the choice was made. On half the trials, by design, the animal chose the better option, and on the other half the worse option. In preliminary data, we observed an effect of the first (economic) choice on the second (perceptual) choice. When the difference between the reward options was large, for example when selecting between 0.75 and 0.15 mls, the monkeys indicated the correct motion, right or left, on the second choice with greater than 95% accuracy. However, when the difference was smaller, for example between 0.55 and 0.35 mls, the behavior diverged. When the animal chose the better option, it correctly indicated rightward motion >95% of the time. When it chose the worse option, on the other hand, it correctly indicated leftward motion only ~55% of the time. The different performance on the RDK stimulus - for lower value choices - was not value based: the animal performed much better when the outcome was 0.15 mls than when it was 0.35 mls. Rather, their psychophysical judgements appeared highly dependent on the value differences between the options in the economic choice. Further testing is underway to explore this paradigm, but the preliminary results are consistent with the notion that the confidence in the economic choice was used as a prior in the perceptual judgment. If confirmed, this task will provide a method to measure the trial-by-trial confidence in economic choices.

Title: Rhesus macaques demonstrate economic deliberation in the 'knapsack task'

Authors: *T. HONG[1,2,3], W. STAUFFER[3,4,5,6,7];
[1]Program in Neural Computation, [2]Neurosci. Inst., Carnegie Mellon Univ., Pittsburgh, PA; [3]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [4]Syst. Neurosci. Ctr., [5]Dept. of Neurobio., [6]Ctr. for Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [7]The Brain Inst., Pittsburgh, PA

Abstract: Value optimization is a defining principle of economic choices. To uncover the psychological and neural processes underlying value optimization, we developed a behavioral task based on the 'knapsack problem'. Given several items, each with a value and weight, the objective of the knapsack problem is to maximize value within a specified weight limit. We adapted the knapsack task for non-human primates (NHPs), by equating weights with juice reward values. We presented the animal with multiple items - visual cues that each predicted a different sized reward. The animal could select any subset of the items by using a touchscreen. In each trial, the animal received the total reward value of the chosen subset, unless the chosen subset exceeded the virtual knapsack size limit, in which case no reward was provided. Task performance was higher when a virtual knapsack displayed on the screen to provided visual feedback on the value of chosen items. The animal performed well above chance and achieved at least 75% of the optimal reward value on approximately half of all trials. We defined each unique set of items as an 'instance,' and we estimated the difficulty of instances according to the number of feasible solutions. Crucially, the performance was sensitive to instance difficulty: the selected subsets were closer to optimal on easier instances, compared to more difficult ones. Response time showed the same trend: the animal took longer to choose the total subset on difficult instances, and took longer on individual selections when the probability of exceeding the limit was higher. Selection-by-selection analysis revealed that the animals employed a 'satisficing' threshold and, moreover, that threshold was lower when the instance was more difficult. Finally, as the instances became more difficult, the chosen solutions became more stable. This increased stability observed on difficult trials suggests an underlying algorithm for value optimization. Overall, these results lay the foundation for uncovering behavioral algorithms for optimal reward seeking and their neural implementation.

Title: Assessing the influence of reward and attention on value-based decision-making

Authors: *N. T. MUNET[1], L. A. MECKLER[1], Z. BALEWSKI[1], J. D. WALLIS[1,2];
[1]Helen Wills Neurosci. Inst., [2]Dept. of Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: During decision-making, attention is a powerful mechanism to select which option to evaluate and filter out irrelevant information about alternatives. However, just as attention can influence value computations, the reverse is also true: attention paradigms often use reward to manipulate attentional allocation, demonstrating that value can guide attention. This raises the question of how attention and value computations dynamically interact to guide decision-making processes. Prior work from our lab shows that value-encoding ensembles in orbitofrontal cortex (OFC) alternate between encoding the value of chosen or unchosen options during a value-guided choice task. This serial encoding of option values may reflect attentional filtering of OFC's inputs, or it may serve as a basis for value-guided attention as value information is transmitted from OFC to attention-related regions in lateral prefrontal cortex (LPFC). To distinguish these possibilities, we trained macaques on a task that combined attention and value-based decision-making paradigms in interleaved blocks, allowing us to potentially train attention and value decoders on prefrontal ensemble activity and examine how these processes interact. Here we present a behavioral analysis of the attention and value-based decision-making components of our task, which validate the task's suitability for dual-decoding experiments. In value-based decision-making blocks, we fit subjective value models to stable choice behavior and found that the amount and probability of reward are integrated with similar weights to yield abstract subjective values for each option. To investigate how these subjective values are learned, we fit reinforcement learning (RL) models to choices as animals learned to map novel stimuli onto a set of nine unique reward contingencies. Model comparison showed that animals learn novel stimulus-outcome associations quickly and efficiently, in a manner that can be approximated with a model-free RL algorithm. Moreover, we found that animals treat reward information similarly on free and forced choice trials, supporting previous evidence that subjective value generalizes between free and forced trials. On attention blocks spatial cuing yielded a robust attentional effect on change detection accuracy and reaction times. Together, our results confirm the distinct effects of reward and attention on overt choice behavior and validate our task's suitability for future decoding experiments that will analyze the relationship between neural signals of attention and value during decision-making.

Title: Interhemispheric orbitofrontal communication during value-based choice

Authors: *T. W. ELSTON, Z. Z. BALEWSKI, J. D. WALLIS;
Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: Contralaterality describes how sensory and motor functions pertaining to one half of the body are carried out by the opposite half of the brain. For example, the left hemisphere's motor cortex controls the musculature of the right side of the body. Here, we asked whether pre-choice, deliberative processing in the orbitofrontal cortex (OFC) of monkeys making value-based choices would also exhibit lateralization. Once monkeys learned to decide between options varying in both the amount and probability of yielding a juice reward, we lowered multiple, multi-channel probes bilaterally into OFC, allowing us to record from up to 240 neurons simultaneously. Our behavioral task was explicitly designed for a decoding approach. We included single-picture, forced choice trials to ensure that all value levels were regularly sampled and used these trials to train linear discriminant classifiers, one for each hemisphere, in each session. We tested our decoders on both a held-out set of forced-choice trials and free-choice (two picture) trials. We found that when the more valuable option was on the left, the right OFC carried information about the value that would be chosen earlier than the left OFC (and vice versa). This effect depended on the animal deliberating between two options: we found no evidence of lateralized value processing during forced choice trials. Interestingly, the time-courses of the decoder states in each hemisphere became correlated during pre-choice deliberation, suggesting that deliberative choice may involve coordination between the hemispheres. In support of this view, we found a spectral signature of lateralized value processing in the local field potential: increased alpha-band (8-14Hz) interhemispheric coherence was associated with lateralized value processing. We found that alpha coherence was elevated during free (as compared to forced) choice trials. This effect was also evident at single-trial resolution: individual trials with more lateralized responses in ensemble decoding were associated with greater alpha coherence. These results suggest a previously unappreciated role for interhemispheric coordination during value based choice and potentially reveal alpha coherence as a mechanism facilitating that coordination.

Title: Fast decision representation in caudate nucleus during value-based choices

Authors: *Z. BALEWSKI[1], E. B. KNUDSEN[2], J. D. WALLIS[3];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Helen Wills Neurosci. Inst., [3]Univ. of California Berkeley, Berkeley, CA

Abstract: Decades of research in humans and animals have identified brain regions and circuits critical to value-based decision making. However, the dynamics of value computation are difficult to study because the decision process is opaque and varies from trial to trial. In this experiment, we decoded choice

behavior at the level of single trials in a two alternate forced choice task. We identified fast, stereotyped value signals in the head of the caudate nucleus (CdN), in contrast with the variable value representations found in orbitofrontal cortex (OFC). We hypothesize that these signals reflect parallel value processes that both contribute to the ultimate choice. We trained two monkeys on unique juice reward outcomes predicted by 16 pictures. The subjects freely viewed pairs of pictures and used a lever to choose between them. Both performed the task with high accuracy but relatively slow response times (RT; subject 1: 666 ms, subject 2: 454 ms). We performed large-scale acute single-unit recordings simultaneously in the head of the caudate nucleus (CdN) and the orbitofrontal cortex (OFC), averaging 27 (subject 1) and 103 (subject 2) units from each region per session. We observed strong prediction of choice direction from the CdN population using a linear decoder trained on firing rates in sliding time windows. Prediction strength peaked around 180 ms after trial onset. While the strength of the peak correlated with picture value and RT, the timing of the peak was independent of RT. This fast signal was also highly correlated with the timing and direction of the first saccade, which was overwhelmingly directed to the chosen picture. These observations are consistent with fast, automatic value processing. In contrast to the stereotyped dynamics of CdN, the value representation in OFC appeared to be idiosyncratic across trials. We successfully replicated our previous results (Rich & Wallis, Nat Neuro 2016), which showed that OFC representation flip-flopped between the pair of available picture values over the course of an entire trial and was predictive of response time. We found no evidence that the OFC representation was influenced by eye movements or CdN population dynamics. Representations in both regions predicted choice behavior but were not correlated with each other. Important open questions remain about how and when distributed value signals like these are integrated into motor actions.

Title: Neural mechanisms of hidden state inference

Authors: *C. FORD[1], J. D. WALLIS[2];
[1]Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA; [2]Univ. of California Berkeley, Berkeley, CA

Abstract: Understanding the world requires making inferences about the hidden causes, or belief states, generating our observations. Converging evidence from rodent, human, and computational models suggests that the orbitofrontal cortex (OFC) represents these states by contextualizing relevant information. The hippocampus (HC) may also contribute to this process by representing a cognitive map of the current task environment, linking observations, actions, and outcomes. Given their strong anatomical and functional connections, OFC and HC likely work together to drive inferential learning and decision-making behavior. However, the neural mechanisms of these processes remain unknown. Here,

we trained a male monkey (Macaca mulatta, 6.5 years old, 10.8 kg) on a probabilistic reversal learning task where state inference is required for optimal choice behavior. Reversals were triggered by meeting a set of learning criteria. On average, he triggered 18 reversals per session (n = 6), and was able to quickly detect and adapt to state changes, informing decisions on trials where reward contingencies had not yet been directly experienced. Given this evidence that he acquired a working knowledge of task structure, we simultaneously recorded single-unit neuronal activity from OFC (n = 287) and HC (n = 418) during task performance to examine how task state representations are stored, updated, and used to drive decision-making. The majority of units we acquired across both OFC and HC were sensitive to task state, implicating both regions in state inference. To analyze neural state representations with single-trial resolution, we trained a linear discriminant analysis (LDA) algorithm to classify task state for each trial, given activation patterns in OFC or HC synced at different trial events. We observed that, while task state can be decoded in HC across an entire trial, it can only be reliably decoded in OFC after choice options are visible. This suggests that state representations stored in HC are passed to OFC during decision-making, where they are ultimately used to guide behavior.

Title: Replay events in primate hippocampal neurons encoding an abstract cognitive map

Authors: *E. B. KNUDSEN, J. D. WALLIS;
Univ. of California, Berkeley, Berkeley, CA

Abstract: The ability to learn the relationships that govern and mediate interactions with the world is a key component of flexible behavior. In rodents, representation of physical spaces takes the form of a place map, encoded by place neurons in the hippocampus. Consolidation of prior routes or mental rehearsal of prospective routes are supported by replay events, temporally-compressed sequential activations of the place neurons that tile the space. In primates, we recently found that abstract spaces are also instantiated in hippocampal neurons. These ‘value place’ neurons map the cognitive dimensions defined by a value-based learning task. Although human work has hinted at replay-like phenomena in non-invasive neural signals, whether value place neurons participate in replay events during cognition remains an open question. We investigated hippocampal neuronal activity collected from two monkeys making decisions within a value space defined by the reward probabilities of three visual stimuli for evidence of replay.
We first found that sharp wave ripples (SWRs), high (150-300 Hz) frequency oscillations in the local field potential that coordinate prospective and retrospective activity, tended to occur predominantly

during two task epochs: when subjects were fixating a central target prior to the onset of visual stimuli, and when subjects received the outcome of their choice. We investigated SWRs for the presence of replay-like activity by correlating pairs of value place neurons recorded simultaneously. During the fixation epoch, forward ordered correlations were roughly twice as prevalent as reverse ordered, consistent with subjects anticipating the expected value of the choice options. During the outcome epoch, forward and reverse ordered events were more evenly balanced. We also observed differences in the prevalence of forward and reverse replay across the course of the value trajectory, with forward replay more prevalent when the animal begins moving through the value space, and reverse ordered events more common during the later stages of the traversal. Together, these results provide the first direct evidence of the compressed sequential activation of hippocampal neurons encoding the relational structure of a cognitive parameter, and furthers the idea that a representational cognitive map, instantiated at the level of individual hippocampal neurons, enables sophisticated flexible behaviors.

Title: The Role of PDE11A4 in Social Isolation-Induced Changes in Intracellular Signaling and Neuroinflammation

Authors: *K. PILARZYK[1], M. P. KELLY[2], L. D. PORCHER[1], R. FARMER[1];
[1]Univ. of South Carolina- Sch. of Med., Columbia, SC; [2]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Phosphodiesterase 11A (PDE11A), an enzyme that degrades cyclic nucleotides (cAMP and cGMP), is the only PDE whose mRNA expression in brain is restricted to the hippocampal formation. Previously, we showed that chronic social isolation changes subsequent social behaviors in adult mice by reducing expression of PDE11A4 in the membrane fraction of the ventral hippocampus (VHIPP). Here we seek extend these findings by determining 1) if isolation-induced decreases in PDE11 require chronic social isolation or if they occur acutely and are sustained long-term, 2) if isolation-induced decreases occur uniquely in adults (i.e., not adolescents), and 3) how the loss of PDE11A4 signaling may increase neuroinflammation. We find that both acute and chronic social isolation decreases PDE11A4 expression in adult but not adolescent mice. This decrease in PDE11A4 is specific to the membrane compartment of the VHIPP, as it does not occur in either the cytosolic or nuclear compartment of the VHIPP nor in any

compartment of the dorsal HIPP. The effect of social isolation on membrane PDE11A is also selective in that PDE2A and PDE10A expression remain unchanged. Isolation-induced decreases in PDE11A4 expression appear to be functional as social isolation elicited changes in PDE11A-relevant signal transduction cascades (i.e., decreased pCamKIIα and pS6-235/236) and behavior (i.e., increased remote long-term memory for social odor recognition). Interestingly, we found that isolation-induced decreases in membrane PDE11A4 correlated with increased expression of interleukin-6 (IL-6) in the cytosolic fraction, suggesting pro-inflammatory signaling for this cytokine. This effect on IL-6 is consistent with the fact that *Pde11a* deletion increased microglia activation, although it left astrocytes unchanged. Together, these data suggest that isolation-induced decreases in PDE11A4 may alter subsequent social behavior via increased neuroinflammatory processes in adult mice.

Title: Serotonin 1B/1A receptor activation impairs behavioral flexibility in C57BL/6J mice

Authors: B. OLIVER, A. PAHUA, M. BURDETTE, S. SANCHEZ, P. FLORES, *D. AMODEO; California State Univ. San Bernardino, San Bernardino, CA

Abstract: Obsessive compulsive disorder (OCD) is defined as insistent urges, persistent thoughts, and/or repetitive behaviors that are difficult to inhibit. Pharmacologically induced alterations to the serotonergic system have been shown to directly induce OCD-like behaviors (Shanahan et al., 2009; Ho et al., 2015). The serotonin 1B/1A receptor (5-HT1B/1A) agonist RU24969 has been shown to induce OCD-like behaviors in rodents (Ho et al., 2015; Shanahan et al., 2009; Woehrle et al., 2013), in addition to inducing working memory deficits (Woehrle et al., 2013). Several studies examining increased 5-HT1B/1A activation use relatively high doses of RU24969, usually between 1 to 10 mg/kg (Ho et al., 2015; Shanahan et al., 2009; Thompson & Dulawa, 2019; Woehrle et al., 2013). OCD symptoms include excessive habit formation that can inhibit goal-directed learning (Gillan & Robbins, 2014) and behavioral flexibility (Grutter & Pitteger, 2017). The current study examines the effects of systemic 5-HT1B/1A receptor agonist RU24969 (vehicle, 0.01, 0.1 or 1.0 mg/kg) treatment on behavioral flexibility using a spatial 80:20 probabilistic reinforcement reversal learning task. Before acquisition, all mice were treated with vehicle. Before the reversal phase, mice were injected with RU24969 and the reinforcement contingencies were reversed to examine how many trials were required for mice to reach learning criterion. Learning criterion was met when mice made six consecutive correct choices. As previously demonstrated, all groups performed similarly on acquisition of the initial spatial discrimination. On reversal, female mice treated with 1.0 mg/kg RU24969 required significantly more trials to reach criterion. Instead, all doses (0.1, 0.1 & 1.0 mg/kg) of RU24969 significantly increased trials needed to reach reversal learning criterion. This impairment was driven by a specific increase in perseverative type errors, suggesting RU24969 treatment impaired the ability to initially inhibit the previously learned

spatial discrimination. Further analysis shows that RU24969 did not increase trials per minute, demonstrating that RU24969 was not sedative. In sum these findings indicate that acute systemic 5-HT1B/1A receptor activation significantly impaired reversal learning performance.

Title: Effects of pharmacological substances on long term potentiation in rodent hippocampal slices: an ex vivo model of episodic-like memory.

Authors: *K. WALKER[1], E. ESNEAULT[1], T. FRERET[2], C. ROUX[1];
[1]Porsolt S.A.S., Le-Genest-Saint-Isle, France; [2]Univ. de Caen Normandie, Caen, France

Abstract: Memory capacity relies on adaptive and long-term modifications in synaptic strength, a process known as synaptic plasticity. NMDA-dependent long-term potentiation (LTP) is a form of synaptic plasticity, considered to be the main support for memory processes. Hippocampal formation plays a key role in the memory process and was historically the first brain region where LTP experiments were performed.
Our study aims to evaluate the effects of well-known pharmacological substances, to investigate the memory process on LTP recordings. Both pro- and a-mnesic agents were investigated. D-AP5, an NMDA-antagonist, and scopolamine, a muscarinic antagonist, were used as LTP blockers. The pro-cognitive agent Rolipram was used as an LTP enhancer.
Transverse hippocampal slices were obtained from male Wistar rats. Extracellular recordings were performed at the apical dendritic layer of the CA1 area. Field excitatory postsynaptic potentials (fEPSPs) were elicited by electrical stimulation of afferent Schaeffer collaterals located in the *stratum radiatum*. A Theta-burst stimulation protocol was used to mimic naturally occurring brain oscillations observed during spatial learning tasks. fEPSPs were recorded for 15 min for baseline levels and another 60 min after induction of LTP.
D-AP5 (50 and 100µM) prevented the induction of LTP, while the LTP magnitude remained unchanged with scopolamine treatment (10µM), when compared to control slices. Conversely, the LTP magnitude was significantly enhanced when Rolipram (0.1µM) was added to the perfusion bath.
These results highlight the potential to modulate LTP by pharmacological substances acting at different synaptic levels inducing and/or maintaining LTP. D-AP5 is commonly used to assess NMDA-dependent features of LTP. Rolipram, through inhibition of type 4 phosphodiesterase, leads to an increase of cAMP, a key regulator of the signaling cascade involved in the persistence of LTP. Here we show that pro-cognitive properties of a substance could be linked to LTP enhancement. While scopolamine is considered the gold standard to induce memory deficits in rodents, the weak cholinergic tone in hippocampal slices may explain the absence of an observed effect.

These results suggest that LTP recordings represent a reliable tool for predicting the effects of new molecules on memory-related electrophysiological features. This model is also useful for providing new insights into the mechanisms underlying the effects that are observed in pre-clinical cognitive tests.

Abstract: Fear memories can be attenuated by targeting their reconsolidation, which is differentially regulated by medial prefrontal cortex (mPFC) subregions. The major non-psychotomimetic component of the Cannabis plant, cannabidiol (CBD), can disrupt fear memory reconsolidation through cannabinoid type-1 (CB1) receptor signaling in the brain. Here we aimed to investigate whether CBD-induced reconsolidation impairments involve the activation of CB1 receptors in the anterior cingulate (AC), prelimbic (PL), and infralimbic (IL) cortices. Adult male Wistar rats were fear conditioned in context A. A brief context A re-exposure was performed on the next day to induce memory labilization, then animals were infused with vehicle (VEH) or the CB1 receptor antagonist AM251 into the AC, PL, or IL cortex and systemically treated with VEH or CBD. Animals were re-exposed to conditioned Context one day later (Test A) to assess the potential pretreatment and treatment effects on memory reconsolidation. In experiment 1 (n = 9-12/group), CBD-treated animals presented less freezing time than controls during Test A (VEH/VEH: 77 ± 6%; VEH/CBD: 51 ± 4%). CBD effects were prevented by AC cortex CB1 receptor antagonism (AM251/VEH: 82 ± 5%; AM251/CBD: 80 ± 7%). In experiment 2 (n = 8-9/group), PL cortex CB1 receptor antagonism prevented the CBD effects on reconsolidation (VEH-VEH: 85 ± 4%; VEH/CBD: 43 ± 7%; AM251/VEH: 72 ± 6%; AM251/CBD: 74 ± 7%). In experiment 3 (n = 8-9/group), CB1 receptor blockade in the IL cortex also prevented CBD effects (VEH-VEH: 70 ± 6%; VEH/CBD: 42 ± 9%; AM251/VEH: 78 ± 5%; AM251/CBD: 66 ± 6%). In experiment 4 (n = 7-11/group), we sought to determine wheter CBD injections in different mPFC subregions can mimic the effects of systemic treatment. Animals treated with CBD intra-AC or intra-PL presented less freezing during test A than controls (AC-VEH: 70 ± 9%; AC-CBD: 48 ± 4%; PL-VEH: 82 ± 5%; PL-CBD: 45 ± 6%), whereas intra-

IL CBD treatment didn't produce effects compared to controls (IL-VEH: 70 ± 9%; IL-CBD: 62 ± 8%). Present results suggest that activation of CB1 receptors along the mPFC dorsoventral axis is necessary for the impairing effects of CBD on memory reconsolidation. Furthermore, CBD infusion into the AC or PL cortex is sufficient for mimicking the systemic effects of CBD on reconsolidation.

Title: Acquisition of extinction requires microglia activity in adult rats

Authors: *R. BUENAOBRA, N. FERRARA, A. ROSENKRANZ;
Rosalind Franklin Univ. of Med. and Sci., Grayslake, IL

Abstract: Title: Acquisition of extinction requires microglia activity in adult rats**Authors:** Reggie, Nicole C. Ferrara, & J. Amiel Rosenkranz**Dept/Inst:** Cellular and Molecular Pharmacology/RFUMS Anxiety and stress-related disorders induced by trauma are characterized by maladaptive fear responding as a result of dysregulated associations between predictive aversive stimuli and the aversive event. This often results in a loss of context-appropriate emotional responding, which can be treated with exposure therapy. The mechanisms underlying exposure therapy are similar to extinction learning, where fear responses can be reduced through repeated presentations of the associated conditional stimulus (CS) in the absence of the aversive stimulus. A new memory, extinction memory, results from extinction learning and is then in competition with the fear memory for behavior. While this approach to reducing fear has many benefits, fear responding can return in circumstances outside of the context in which extinction was learned, known as renewal. Therefore, there is great therapeutic potential for understanding the processes through which renewal occurs to minimize the return of fear following extinction. There are several brain regions that interact and are essential for encoding fear and extinction processes, such as the prefrontal cortex, amygdala, and ventral hippocampus. During extinction, prefrontal cortical activity driven by the ventral hippocampus can reduce amygdala activity, ultimately resulting in a lower fear response. There are many factors that can regulate neuronal activity in this circuit to permit extinction and one relatively understudied are microglial cells, the resident immune cells of the CNS. Microglia participate in neural inflammation and regulate synaptic activity in various immune states that change with stress exposure. Here, we investigated the way in which microglia contribute to the behavioral and neural process of extinction. Our data demonstrate that suppression of microglia with minocycline prior to extinction diminish fear response to the CS and results in heightened fear during a renewal test. Ongoing work is investigating the relationship between microglia activity during extinction and activity in extinction circuitry. These results suggest that there is a relationship between fear extinction and renewal and microglia, where activation of microglia can in turn regulate fear inhibition.

Title: Development and characterization of a rat model of post-finasteride syndrome

Authors: *A. AHIRE, R. SASIBHUSHANA, K. MRUDULA, B. SHANKARANARAYANA RAO; Natl. Inst. of Mental Hlth. and Neuro Scie, Bengaluru, India

Abstract: Development and Characterization of a Rat Model of Post-Finasteride Syndrome R. Sasibhushana, Ashutosh Ahire, K. Mrudula, B. S. Shankaranarayana Rao, **B.N. Srikumar**Department of NeurophysiologyNational Institute of Mental Health and Neuro Sciences (NIMHANS), Bengaluru, IndiaEmail: kumarasri@nimhans.ac.in
The enzyme 5α-Reductase (5α-R) catalyzes the formation of dihydroxytestosterone, which is involved in male pattern hair loss and benign prostatic hyperplasia. Finasteride inhibits 5α-R and is used to treat both these conditions. Several clinical studies show that chronic finasteride treatment induces persistent depression, suicidal thoughts and cognitive impairment. The neurobiological mechanisms underlying the effects of finasteride are not clearly understood. In an effort to address this, we are developing an animal model of finasteride-induced depression and cognitive dysfunction. We subjected male/female rats to repeated finasteride administration over a period of 7 or 10 days. We evaluated depression, anxiety and cognitive function in several paradigms. Repeated finasteride administration resulted in increased immobility in the forced swim test, decreased grooming in the splash test, decreased open arm exploration in the elevated plus maze and impaired social interaction. Further, the antidepressant effect of fluoxetine was diminished following finasteride administration. Memory was impaired in the radial arm maze task and cognitive flexibility in the attentional set-shifting task was also decreased following finasteride administration. When the allopregnanolone levels were examined in the frontal cortex and hippocampus, we observed a decrease following finasteride administration. Finasteride administration (100mg/Kg, s.c.) also significantly decreased AChE activity in the frontal cortex and hippocampus. In summary, our results indicate that repeated finasteride administration induces treatment-resistant depression-like behavior, co-morbid with anxiety and cognitive dysfunction, potentially through cholinergic and neurosteroid mechanisms. These results provide insights into the involvement of neurosteroids in depression and cognitive function and has potential for development of novel therapeutics to treat neuropsychiatric diseases.**Keywords:** finasteride, treatment-resistant depression, anxiety, finasteride, neurosteroid, cognition

Title: The effects of Ouabain treatment on adult hippocampal neurogenesis

Authors: *A. M. M. ORELLANA[1], N. M. S. PORT´S[1], J. A. LEITE[2], J. A. M. NETO[1], C. SCAVONE[1], E. M. KAWAMOTO[1];
[1]Pharmacol., Univ. of São Paulo, São Paulo, Brazil; [2]Dept. of Pharmacol. - Inst. of Biomed. Sci., Federal Univ. of Goiás, Goiânia, Brazil

Abstract: Neurogenesis is a very complex process that provides the integration of new functional neurons into developed brain circuitry. This process occurs mostly in two brain regions that have a permissive neurogenic microenvironment. In this neurogenic niche, stem cells coexist with differentiated astrocytes that secrets support factors for the maintenance and development of new neurons, adult neurons and other cell types. Furthermore, the proximity to endothelial cells facilitates the contact of stem cell clusters with signal transduction modulators such as mitogens (EGF, bFGF, IGF), morphogens (Wnt, Shh, Notch, Eph), and neurotrophins (BDNF), among others. Although the entire process of neurogenesis is not yet fully understood, at least in the hippocampus it seems to be important for the formation and maintenance of functional hippocampal circuitry and thus for memory and learning. It has been proposed that Ouabain (OUA), a cardiotonic steroid, in non-inhibitory concentration, can bind to Na,K-ATPase and trigger many signaling pathways. A previous study reported that, in rat hippocampus, OUA could activate signaling pathways such as CREB, Wnt/β-catenin and NFκB in neurons, increasing BDNF levels, hippocampal neuronal dendritic branching and leading to a spatial long-term memory improvement in rats. Therefore, the main purpose of this study is to verify whether OUA affects hippocampal adult neurogenesis. Methods: Newborn Wistar rats from both genders were purchased from the Animal Facility at Institute of Biomedical Sciences, USP. Their hippocampus were used for the primary culture of neural precursor cells (NPCs). The protocol was approved by the Ethics Committee from University of São Paulo (CEUA 74/2017). Immediately after being plate, cells were exposed for 7 days to medium (DMEM/F12, supplemented with B27, bFGF 10 ng/mL e EGF 10 ng/mL, penicillin and streptomycin 10%) containing OUA 10 nM or aCSF (Control). Neurospheres developed during this period. After neurospheres dissociation, NPCS were plated and maintained for more 7 days with aCSF or OUA 10 nM in the medium

(DMEM/F12, supplemented with B27, penicillin/streptomycin 10% and NGF 20 ng/mL) to start differentiation. Immunofluorescence, flow cytometry, viability assays and Western Blot were performed, all with samples from 6 independent cell cultures. Results: Preliminary results suggest that: (i) OUA 10 nM is not toxic for NPCs; (ii) OUA didn´t alter the NPCs´proliferation rate and (iii) OUA increases immature neurons percentage in the culture after 14 days, compared to control.

Title: Tropomyosin-related kinase B receptor agonism rescues the long-term spatial memory impairment seen in mice lacking new oligodendrocytes

Authors: *F. HEATH, H. JOHANSEN-BERG;
Wellcome Ctr. for Integrative Neuorimaging, Univ. of Oxford, Oxford, United Kingdom

Abstract: Myelin in the central nervous system (CNS) is produced by oligodendrocytes (OLs) and the adult rodent brain retains the ability to produce new myelinating OLs through the differentiation of oligodendrocyte precursor cells (OPCs). The ability to produce new myelinating OLs is important for learning and memory, with recent evidence suggesting that disrupting oligodendrogenesis leads to behavioural impairments in long-term spatial memory. Further, there is growing evidence that brain derived neurotrophic factor (BDNF) may have a pro-myelinating effect in the CNS. However, whether the influence of BDNF on processes of myelination has any impact for learning and memory is unclear. Here we investigated the effect of BDNF tropomyosin-related kinase (Trk) B receptor agonist 7,8-dihydroxyflavone hydrate (DHF) administration on spatial learning and memory via newly formed OLs. Mice with a conditional knock-out of OPC myelin regulatory factor ($MyRF^{-/-}$) were tested in the Morris water-maze (MWM). $MyRF^{-/-}$ mice and their hemizygous siblings ($MyRF^{-/+}$) underwent seven days of MWM training. Immediately following each training session they were systemically administered DHF or vehicle. The long-term memory of the mice was assessed 28-days later. Following behavioral testing histology was undertaken to stain for anti-adenomatous polyposis coli clone CC1 and 5-ethynyl-2' -deoxyuridine (EdU). GFAP-TK mice that have inhibited adult neurogenesis were also tested in the MWM under the same conditions as the MyRF mice. We found, using analysis of variance, that long-term spatial memory was impaired in $MyRF^{-/-}$ mice compared with $MyRF^{-/+}$ and that systemic administration of DHF immediately following training rescued this memory impairment. We also found that DHF administration during training partially rescued the number of $EdU^{+}/CC1^{+}$ cells in the corpus callosum. The memory of the GFAP-TK mice was unaffected, suggesting this finding is not associated with adult neurogenesis. In

conclusion, these findings show that newly formed oligodendrocytes are required for long-term spatial memory consolidation and that this effect is facilitated by BDNF signaling via TrkB receptors.

Title: Inbred mouse strains differ in adolescent ethanol-induced learning deficits

Authors: *L. R. SEEMILLER, L. R. GOLDBERG, T. J. GOULD;
Penn State Univ., University Park, PA

Abstract: Ethanol impairs learning and memory, and these effects can be greater among adolescents. This study investigated how other factors, specifically genetic background and sex, may influence learning outcomes after ethanol exposure in adolescent mice. Adolescent (PND 38 +/- 3) male and female inbred mice from different strains were treated with saline or ethanol (1.5 g/kg) 15 minutes prior to fear conditioning training. Contextual and cued fear retention were tested one day later. Blood ethanol content (BEC) was also assessed 15 minutes after 1.5 g/kg ethanol treatment to investigate the role of ethanol metabolism in strain differences. We found significant effects of drug and strain on contextual learning. Analysis of BEC data suggested that these effects were not likely related to strain differences in ethanol metabolism. Overall, we demonstrated that genetic background contributes to differences in contextual learning after ethanol administration to adolescent mice.

Title: Neural correlates of success and failure to swallow foods that may act as reinforcers of Aplysia feeding

Authors: *J. P. GILL[1], H. J. CHIEL[2], A. J. SUSSWEIN[3];
[1]Biol., [2]Biology, Neurosciences, Biomed. Engin., Case Western Reserve Univ., Cleveland, OH; [3]Bar-Ilan Univ., Ramat-Gan, Israel

Abstract: *Aplysia* that try and fail to swallow food learn that the food is inedible, and subsequently respond less to that food. By contrast, *Aplysia* that successfully consume food learn that the food is edible, and later respond more to the food. Lip stimulation inducing bites but no attempts to swallow has no long-term consequences.
To provide insight into how animals differentiate success and failure to swallow, and bites initiated by lip stimulation, extracellular nerve recordings coupled with video recordings of feeding behaviors were obtained in freely behaving animals while the lips of *Aplysia* were stimulated with food, and were fed edible and inedible foods. One possibility is that edible foods elicit attempts to swallow, whereas inedible foods elicit a mixture of swallows and rejection responses that push food out of the mouth. Swallowing and rejection are readily distinguished by different patterns of neural activity. However, inedible food overwhelmingly induced attempts to swallow, rather than rejection responses, with very occasional rejection responses observed.
Previous data have shown that the esophageal nerve (EN) has a role in learning that food is edible or inedible. In particular, bilaterally severing the EN blocks the ability to learn that food is inedible, and stimulation of one branch of the EN paired with lip stimulation acts as a positive reinforcer of feeding. Activity of the EN during successful and failed attempts to swallow was compared to activity in response to lip stimulation eliciting bites. Recordings from the trunk of the EN showed significant increases of large spike activity when animals successfully swallowed food, and significant decreases in activity when animals failed to swallow food, suggesting that increased activity is a correlate of successful swallowing, and decreased activity is a correlate of failure to swallow. During all types of feeding responses, EN activity decreased during retraction, with respect to activity during protraction, or during the interval between the end of retraction and the start of the next protraction, suggesting that EN activity during success or failure occurs in the seconds after swallowing, as a consequence of food entering or not entering the gut.

Title: Functional dissection of recurrent feedback signaling within the mushroom body network of the Drosophila larva

Authors: *R. LYUTOVA-HRISTOVA;
Univ. of Regensburg, Regensburg, Germany

Abstract: Behavioral adaptation to environmental changes is crucial for animals' survival. The prediction of the outcome of one owns action, like finding reward or avoiding punishment, requires recollection of past experiences and comparison with current situation, and adjustment of behavioral responses. The process of memory acquisition is called learning, and the *Drosophila* larva came up to be an excellent model organism for studying the neural mechanisms of memory formation. In *Drosophila*, associative memories are formed, stored and expressed in the mushroom bodies. In the last years, great progress has been made in uncovering the anatomical architecture of these brain structures, however there is still a lack of knowledge about the functional connectivity.
Dopamine plays essential roles in learning processes, as dopaminergic neurons mediate information about the presence of rewarding and punishing stimuli to the mushroom bodies. In the following work, the function of a newly identified anatomical connection from the mushroom bodies to rewarding dopaminergic neurons was dissected. A recurrent feedback signaling within the neuronal network was analyzed by simultaneous genetic manipulation of the mushroom body Kenyon cells and dopaminergic neurons from the primary protocerebral anterior (pPAM) cluster, and learning assays were performed in order to unravel the impact of the Kenyon cells-to-pPAM neurons feedback loop on larval memory formation.
In a substitution learning assay, simultaneous odor exposure paired with optogenetic activation of Kenyon cells in fruit fly larvae in absence of a rewarding stimulus resulted in formation of an appetitive memory, whereas no learning behavior was observed when pPAM neurons were ablated in addition to the KC activation. I argue that the activation of Kenyon cells may induce an internal signal that mimics reward exposure by feedback activation of the rewarding dopaminergic neurons. My data further suggests that the Kenyon cells-to-pPAM communication relies on peptidergic signaling via short neuropeptide F and underlies memory stabilization.

Title: Aversive massed training in Aplysia uncouples normally co-expressed behavioral changes by inducing long-term feeding suppression in the absence of long-term sensitization

Authors: R. T. MUELLER, M. L. WAINWRIGHT, *R. MOZZACHIODI;
Life Sci., Texas A&M Univ. Corpus Christi, Corpus Christi, TX

Abstract: Following exposure to aversive stimuli, an organism budgets its behaviors by enhancing defensive responses and reducing appetitive behaviors. In response to aversive training, *Aplysia* co-expresses sensitization of defensive withdrawal reflexes and feeding suppression across different training protocols and with common temporal domains (Acheampong et al. 2012; Shields-Johnson et al. 2013). However, a recent regimen of prolonged food deprivation was shown to uncouple the above training-induced behavioral changes, with sensitization prevented and feeding suppression still expressed but attenuated (Mac Leod et al. 2018). These findings raised the question of whether other protocols could induce feeding suppression in the absence of sensitization. Therefore, in this study, we examined whether massed training, which does not induce long-term sensitization (LTS; Wainwright et al. 2002), could still induce long-term feeding suppression (LTFS) at 24 h, compared to a multiple-day spaced training, which leads to the co-expression of LTS and LTFS (Mac Leod et al. 2018). Both protocols consist of 16 trials, each made of 10-s trains of electrical shocks to the animal's body wall. However, the delivery pattern is remarkably different: in spaced training, 4 trials are delivered per day (30-min inter-trial intervals) for 4 consecutive days, whereas in massed training, 16 trials are administered every 30 min in one day. Four groups of 10 animals each were utilized: massed-trained (M-T), massed-untrained (M-UT), spaced-trained (S-T), and spaced-untrained (S-UT). The untrained animals were handled as the trained animals but did not receive any shock. To remain blind to the condition of the animals, the experimenter was kept unaware of their training history. For each group, the duration of the defensive tail-siphon withdrawal reflex and the number of bites in response to a food stimulus were measured prior to (pre-test) and 24 h after the conclusion of aversive training (post-test). Statistical significance was determined using the Kruskal-Wallis test followed by the Student-Newman-Keuls post-hoc comparisons (Mac Leod et al. 2018). Results revealed that both S-T and M-T animals expressed LTFS at 24 h. Notably, LTFS in the M-T group was statistically indistinguishable from LTFS measured in the S-T group, thus, indicating that LTFS was fully expressed in the M-T animals, even in the absence of LTS. These findings indicate that massed training is another protocol that leads to the expression of feeding suppression in the absence of sensitization, suggesting that these behavioral changes may act independently from one another and may be modulated by different mechanisms.

Title: Characterization Of Serotoninergic Pathways In The Brain Of Octopus maya

Authors: *P. GARCÍA-ANDALUZ, H. SÁNCHEZ-CASTILLO, D. GONZÁLEZ-NAVARRETE, F. VERGARA OVALLE;
UNAM, Mexico City, Mexico

Abstract: Serotonin (5-HT) is a highly conserved neurotransmitter among species and its study has been considered crucial for understanding the physiological mechanisms underlying behavior and cognition. Importantly, research on physiologically distant species from mammals like invertebrates has strongly contributed to the overall perspective of 5-HT's role in an organism but also has presented an opportunity to study the evolutionary development of complex nervous systems and the emergence of cognition. Even though the presence of 5-HT has been previously identified in the brain of octopuses, its mechanism and role on cognition hasn't been described yet. Therefore, in this study, we evaluated the presence and distribution of 5-HT and its receptor 5-HT1A in the brain of Octopus maya. Through an immunolabeling technique, we were able to observe 5-HT and 5HT1A-like immunofluorescence (Inf) in the optic, olfactory, vertical, sub-vertical, superior frontal, inferior frontal, sub-frontal, posterior buccal, buccal, anterior basal, precommissural, medial basal, dorsal basal, palliovisceral, posterior pedal, anterior pedal, post-brachial and, pre-brachial lobes; as well as 5HT1A-like Inf in the posterior chromatophore, vasomotor, and siphon lobes and brachial nerve. These results show a possible conserved participation of 5-HT on information integration, learning, memory, axonal regeneration, inhibitory modulation of neurotransmitters, and homeostatic regulation of vertebrates and some invertebrate animals. Hence, this is the first direct evidence of the presence of a serotonergic receptor and a possible underlying mechanism for synaptic plasticity in the octopod nervous system.

Title: Effects of Injury on Nociceptive Operant Conditioning

Authors: J. DOHN[1], J. HOYNOSKI[1], ***B. BURRELL**[2];
[1]Basic Biomed. Sci., [2]Basic Biomed. Sciences/Center for Brain & Behavior Res., Univ. of South Dakota, Vermillion, SD

Abstract: The capacity to learn to avoid damaging or potentially damaging stimuli represents an important component of nociception. The goal of this project is to observe how prior injury affects nociceptive operant conditioning. In *Hirudo verbana* (medicinal leech) 40 needle pokes (25 gauge needle) were delivered to the posterior sucker at one minute intervals. Initially, the animal's response to these stimuli were reflexive withdrawals, but repeated stimulation the magnitude of these reflexes diminished and were replace by preemptive evasion behaviors. These evasion behaviors consisted of hiding the posterior sucker under the rest of the body or locomotion to avoid the needle poke. Prior injury to the posterior sucker on the same day as training (Day 1) enhanced nociceptive operant conditioning in *Hirudo* in two ways. First, there was an increase in level of locomotion-based evasion compared to non-injured animals. A second difference was that injured animals required fewer stimuli (pokes) to transition to evasion behaviors, indicating rapid/more efficient conditioning. In non-injured *Hirudo*, 34% required >20 pokes to begin evasion behaviors with the remaining animals requiring <20 pokes. In injured *Hirudo*, 100% required <20 pokes to reach evasion criterion (in fact the all animals tested required <15 pokes). In animals that underwent operant conditioning 7 days after injury no change in the level of evasion behaviors was observed compared to non-injured animals. However, these injured animals again required fewer stimuli to begin evasion behaviors, with 83% requiring <20 pokes to reach criterion. These findings suggest that prior injury can facilitate learning to avoid further nociceptive stimuli. The enhancement on Day 1 likely represents a sensitization effect, while the enhancement observed on Day 7 may represent a form of priming. The mechanisms that contribute to this sensitization vs. priming effect may have implications in the study of chronic pain.

Abstract: The vertical lobe (VL) in the *Octopus vulgaris* brain is a major structure involved in learning and memory. The VL demonstrates a robust activity-dependent NO-mediated LTP (Turchetti-Maia et al 2018), which is important in memory acquisition (Shomrat et al 2008). Our anatomical knowledge of the VL considerations is limited to the work of Young and Gray in the 1940-70's. To better understand the computational functions of the VL, the current study used volume electron microscopy (EM) to produce the first detailed synaptic-level wiring diagram of VL. The VL was fixed, serially sliced at 30 nm, imaged with a Scanning Electron Microscope at 4 nm per pixel and aligned into a traceable 3D image stack (260x390x30µm). Based on morphology, connectivity, and EM profiles, we have identified new components of the VL circuitry and provide detailed descriptions of 7 key cellular components (only 3 were previously characterized). The synaptic outputs of axons from the Superior Frontal Lobe (SFL), forming the main input to the VL, were reconstructed. This showed that the VL is segregated into two distinct interconnected feedforward networks that utilize two distinct populations of interneurons: a very large (~$22X10^6$) population of non-bifurcating simple amacrines (SAM) that are highly selective as they receive only one SFL input via an extremely large SFL synapses, and a newly identified, much smaller population (~$500X10^3$) of bifurcating complex amacrines (CAM), which integrate synaptic inputs from multiple SFLs and neighboring SAMs. Both the SAMs (likely excitatory, cholinergic) and CAMs (conceivably inhibitory) converge on the dendritic processes of the VL large efferent neurons (LNs). We also describe an overlay of two extrinsic highly organized modulatory systems which are likely involved in reward/punishment signaling (Shomrat et al 2010). While the organization of the SAMs in a feedforward fan-out fan-in organization is similar to other feedforwarded classification/association networks, the parallel CAM integrates global activity (SFLs+SAMs) and may provide an inhibitory input for balancing the excitatory SAMs inputs. Another surprising result is the unprecedented way in which "sensory features" are represented at the $22x10^6$ one-to-one SFL-to-SAM monosynaptic connections. As this synaptic structure undergoes LTP we suggest that SFL-to-SAM connection has an exclusive role as a "temporary memory-module". Overall, our results demonstrate morphological and network wiring novelties that have evolved independently in octopuses to subserve their highly advanced learning and memory.

Title: Network Ca^{2+}-activity correlation of memory reactivation in a mushroom body-like brain center of the crab Neohelice granulata

Authors: *F. J. MAZA[1], F. J. URBANO[1,2], A. DELORENZI[1,2];
[1]IFIByNE-CONICET-Universidad de Buenos Aires, Ciudad Autónoma de Buenos Aires, Argentina;
[2]Dept. de Fisiología, Biología Mol. y Celular, FCEN-UBA, Ciudad Autónoma de Buenos Aires, Argentina

Abstract: High order brain centers play key roles in sensory integration and learning. In arthropods, although much is known about insect high-order associative centers, the mushroom bodies, much less is known about the putative equivalent structures in crustaceans, the hemiellipsoid bodies. Getting both structural and physiological evidence to support the hypothesis that crustaceans possess structures equivalent to the mushroom bodies that play a role in associative memories has proved challenging. In the true crab Neohelice granulata, this high order brain center exhibits, for instance, dopaminergic innervation and elevated expression of proteins necessary for memory processes (Maza et al. 2020, doi 10.1002/cne.24960). Moreover, plasticity in hemiellipsoid bodies` neuronal activity reflects, in the short term, the context dependent attribute of memory (Maza et al. 2016, doi 10.1073/pnas.1612418113). The Neohelice memory paradigm consists in a long-term, context-specific, decrease in the escape response toward an iterative visual danger stimulus presentation. We used in vivo calcium imaging to test whether crab hemiellipsoid bodies' neuronal activity is associated with memory reactivation in the long-term (24 h after training). Long-term training effects were tested by presenting the reminder known to trigger the reconsolidation process (a shift in setup illumination in the training context) and, next, the visual danger stimulus. We found hemiellipsoid bodies' spontaneous activity, which does not differ between trained and naïve animals (n=5-6). However, after the training-context presentation, the trained animals disclosed an increase in the event rate, suggesting memory reactivation changes the activity state of the hemiellipsoid body. Similar to the behavioral changes, when animals were tested with the visual danger stimulus, trained animals showed a significantly lower evoked calcium transient. Results suggest that hemiellipsoid bodies play a role in contextual associative long term memory processes.

Title: A neuromarker of narrative comprehension abilities in constructing causal structures

Authors: *J. PARK[1,2], H. SONG[4], W. SHIM[1,2,3];
[1]Ctr. for Neurosci. Imaging Research, IBS, Suwon-si, Korea, Republic of; [2]Dept. of Biomed. Engin., [3]Dept. of Intelligent Precision Healthcare Convergence, Sungkyunkwan Univ., Suwon-si, Korea, Republic of; [4]Dept. of Psychology, Univ. of Chicago, Chicago, IL

Abstract: Narrative comprehension requires a process of extracting information from individual events and inferring their coherent causal structures. In this study, we examined the neural signatures that predict individual differences in each comprehension process and characterized the features of narratives that are critical for comprehension using a natural language processing (NLP) approach. After watching a movie consisting of temporally scrambled events in an fMRI scanner, subjects recounted the original story. In a separate behavioral experiment, a group-aggregate measure of the subjective degree of comprehension at each moment of the movie was obtained from an independent group of subjects. We computed individuals' comprehension scores for the amount of recalled information (content score) and the accuracy of reordering the temporal sequence of recalled events (ordering score) by comparing the similarity in the semantic content between the original movie annotations and each subject's recall using a topic modeling method (Heusser et al., 2021). We then developed a model to predict each individual's content and ordering scores based on whole-brain functional connectivity patterns (Shen et al., 2017). Separate predictive models were built based on two periods in the movie—the moments at which the group measure of the degree of comprehension was either high or low. We found that the functional connectivity patterns during movie watching could predict the content score, regardless of which moments of the movie were used for the model. In contrast, the ordering score could only be predicted when the functional connectivity patterns at high comprehension moments were used. To further examine the characteristics of narratives that are critical for comprehension, we estimated the coherence of each annotated sentence in a narrative using the pre-trained deep language model BERT (Devilin et al., 2018). We found that the degree of comprehension at each moment of the movie could be predicted by the narrative coherence between the current and past sentences, as estimated from the next sentence prediction task. Together, these results suggest that individuals' abilities to encode the semantic information of events and construct a coherent causal structure across them can be predicted differentially via large-scale functional connectivity. Our findings also suggest that the predictability of future events estimated from an NLP model can computationally characterize the causal relationships in narratives that are associated critically with human narrative comprehension.

Title: The contributions of vision and body-movements to memory for locations in real-world environments

Authors: *A. MULLER[1], J. GARREN[2], M. PETERSON[1], A. EKSTROM[1];
[1]Psychology, [2]Univ. of Arizona, Tucson, AZ

Abstract: Vision has long been associated with encoding and retrieving items from memory although its contributions to active navigation are unclear. Similarly, body movements are critical to learning spatial layouts though it is unclear how much they contribute to memory. This issue has been difficult to address due to constrains in virtual reality navigation experiments, a lack of free ambulation experiments in humans, and the difficulty of performing eye tracking in freely moving participants. The current research aimed to address these concerns by pairing mobile eye tracking with a navigation and memory task in a real-world environment. 17 participants stood stationary to encode the layout of 8 objects attached to the walls (4 objects on 2 walls) for 30 seconds. Then, they were either asked to remain still while the researcher removed the objects from the wall or they were guided around the room blindfolded and instructed to remove the objects. After the objects were collected, the participants placed the objects back in their original positions on the wall from either the same location as encoding or on the opposite side of the room. Placement error scores were calculated by comparing the positions of objects at encoding and replacement and converting those scores to error estimates in centimeters. A Friedman's test of differences among repeated measures was performed to assess differences in accuracy in our 4 conditions (walking condition: walking around the room to collect objects, remaining stationary while the research collects the object; replacement orientation: replace objects from same location as during encoding, replace objects from the opposite side of the room). We found a significant difference for the height of the placed object ($\chi 2(3) = 10.92$, $p = .01$). Post-hoc analysis using a Nemenyi-Wilcoxon-Wilcox all-pairs test revealed that placement error was significantly larger when participant did not walk around the room and replaced objects from the opposite than when participants did not walk around the room and replaced objects in the same location ($p = .002$). This was also true when comparing participants not walking around the room and replacing from the same viewpoint than when participants walked around the room and replaced objects from the opposite side of the room ($p = .04$). There were no significant differences in placement error among conditions for horizontal placement error ($\chi 2(3) = 6.20$, $p = .10$). Our finding suggest an advantage for body-movement (ambulation) in generalizing viewpoints. Future analyses will investigate how eye movements, particularly "scanpaths" contribute to memory from the same and different viewpoints.

Title: One-shot learning of paired associations by a reservoir computing model with Hebbian plasticity

Authors: *M. G. KUMAR[1], C. TAN[5], C. LIBEDINSKY[2], S.-C. YEN[3], A. Y. Y. TAN[4];
[1]Integrative Sci. and Engin. Programme, [2]Dept. of Psychology, [3]Innovation and Design Programme, [4]Dept. of Physiol., Natl. Univ. of Singapore, Singapore, Singapore; [5]Inst. for Infocomm Res., Singapore, Singapore

Abstract: One-shot learning can be achieved by algorithms and animals, but how the latter do it is poorly understood as most of the algorithms are not biologically plausible. Experiments studying one-shot learning in rodents have shown that after initial gradual learning of associations between cues and locations, new associations can be learned with just a single exposure to each new cue-location pair. Foster, Morris and Dayan (2000) developed a hybrid temporal difference - symbolic model that exhibited one-shot learning for dead reckoning to displaced single locations. While the temporal difference rule for learning the agent's actual coordinates was biologically plausible, the model's symbolic mechanism for learning target coordinates was not, and one-shot learning for multiple target locations was not addressed. Here we extend the model by replacing the symbolic mechanism with a reservoir of recurrently connected neurons resembling cortical microcircuitry. Biologically plausible learning of target coordinates was achieved by subjecting the reservoir's output weights to synaptic plasticity governed by a novel 4-factor variant of the exploratory Hebbian (EH) rule. As with rodents, the reservoir model exhibited one-shot learning for multiple paired associations.

Title: Temporal Proximity Does Not Influence Behavioral Integration of Spatial Memories across Experiences in humans

Authors: *X. FANG[1], K. ALSBURY-NEALY[1,4], Y. WANG[2,5], S. A. JOSSELYN[5,2,1,3], P. W. FRANKLAND[5,2,1,3,6], M. L. SCHLICHTING[1], K. D. DUNCAN[1];

Program, Canadian Inst. for Advanced Res., Toronto, ON, Canada

Abstract: Linking memories across related experiences is crucial to the extraction of commonalities that can inform decision making in novel situations. Rodent work using fear conditioning (Cai et al., 2016; Rashid et al., 2016) has shown that memories are more likely to be integrated, as evidenced by the generalization of freezing behavior across contexts, when they are encoded close (within a few hours) as compared with far apart (>18 hours or one week) in time. Such behavioral generalization is a result of allocation of related memories to overlapping sets of neurons. However, the scope of this phenomenon is unclear; both whether temporal proximity—i.e., the length of delay between related experiences—similarly affects the integration of reward-motivated learning and whether it has a similar impact on human behavior as it does in rodents. Here, 134 participants searched for rewards in two similar virtual environments (created using OpenMaze; https://openmaze.ca), learning the rewarded zone of each in a separate session. Across environments, the two rewarded zones were adjacent to one another, making it possible to merge memories about reward locations. The delay between sessions was either 30 minutes, 3 hours, or 27 hours. We measured memory integration three days later by comparing search paths across similar environments. Based on previous rodent work, we hypothesized higher search path similarity—reflecting an integration of related memories into the same mental map—across similar environments experienced at shorter delays. We found that participants successfully formed spatial memories about reward locations by the end of each learning session. In the final test, while participants were most likely to search in the rewarded zone of each environment, we also observed evidence for integration: When participants searched in an incorrect location, they were more likely to search in the rewarded zone from the related environment as compared with a never-rewarded zone. Critically, however, Bayesian analysis yielded strong evidence that memory integration was not modulated by temporal proximity, in contrast to previous work. One possible explanation for this finding is that humans are more inclined to adopt strategic solutions, making their memories less sensitive to temporal proximity. While future work is needed to uncover the neural mechanisms contributing to such species differences, our findings provide preliminary evidence that species-specific mechanisms could underlie memory integration in certain tasks.

Title: The neural and cognitive markers of enhanced processing of asymmetric musical scales

Authors: *C. PELOFI[1], M. REZAEIZADEH[3], M. M. FARBOOD[2], S. A. SHAMMA[3];
[1]Ctr. for Language Music and Emotion, [2]Steinhardt, New York Univ., New York, NY; [3]Inst. for Systems Res., Univ. of Maryland, College Park, MD

Abstract: Music is produced and enjoyed in every known human culture, past and present. Despite its rich diversity across cultures, musical systems exhibit recurrent features, and the extent to which these "universals" result from cognitive and neural constraints is still debated. Here, we focus on the asymmetry of scales, a robust universal feature (Savage et al., 2015) which corresponds to the fact that the discrete pitches used in melodies are separated by intervals of different sizes. This intervallic asymmetry has been posited to help orient listeners in a tonal space representation (Brown, 1981). Here we use a combination of behavioral and EEG measures to assess the cognitive benefits associated with asymmetry in scales. Melodies are generated using an artificial grammar based on a first-order Markov chain and derived from either an asymmetric or symmetric hexatonic (i.e. six-tone) scale. After an exposure phase presenting a corpus of melodies derived from the grammar, listeners' performances on detecting syntactic violation in a set of new melodies are measured behaviorally and contrasted for asymmetric and symmetric scales. Behavioral results demonstrate enhanced performances in detecting syntactic irregularities for melodies derived from the asymmetric scale. EEG results mirror these findings: ERPs associated with distinct probabilities of note transitions suggest that neural responses better encode the grammar of melodies of the asymmetric scale. Besides, a set of linear decoders trained on classifying neural processing of grammatical structure shows enhanced accuracy in the context of the asymmetric scale. By highlighting the cognitive underpinning of a music universal, this study provides an account of the trade-off between diversity and stability across musical cultures and opens a new avenue in the investigation of cross-cultural musical learning.

Title: Learning context-dependent temporal associations across time-scales

Authors: *C. M. SMITH, A. C. SCHAPIRO, S. L. THOMPSON-SCHILL;
Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: How does the brain encode temporal contingencies at different time-scales? A cortical hierarchy of sensitivity to order information at different time-scales has been observed using naturalistic paradigms (Hasson et al. 2015). We seek to develop a statistical learning paradigm that can be used to map cortical and hippocampal temporal gradients. Human participants (pilot N=32, replication ongoing) played a game similar to "whack-a-mole" in which they clicked on a target image when it appeared in one of 9 locations. The task was performed in 8 different contexts, differentiated by the background and target image. Across contexts, the order of locations where the target might appear changed systematically, at either a short or long time-scale. At a short time-scale we manipulated the order of pairs of locations in which the target appeared. At a longer time-scale, we manipulated the higher order set of locations that appeared in the first vs. second half of the game. Participants were periodically asked to predict the upcoming target location. They later performed similarity judgements comparing the games based explicitly on their order properties. Preliminary data suggest context dependent sensitivity to order information at both short and long time-scales. Figure shows that sensitivity to high and low level order information among good learners (separately assessed) is numerically above chance. To our knowledge, this is the first time it has been shown that humans can learn hierarchically nested order information at different time-scales in a statistical learning paradigm. Neural network modeling results and plans to collect fMRI and EEG data will be discussed.

Title: Effects of presentation order on learning hierarchical structure

Authors: W. ALEXANDER, R. GALLAGHER;
Florida Atlantic Univ., Boca Raton, FL

Abstract: It is generally accepted that prefrontal cortex is organized along a hierarchical rostrocaudal abstraction gradient: caudal regions represent concrete task information, while rostral regions maintain information related to abstract rules and context. While the existence of an abstraction gradient is well-supported by empirical investigation, it is less clear how the information signaled by a stimulus is identified as being either concrete or abstract in the first place. A recent model of prefrontal cortex, the *Hierarchical Error Representation* (HER) model, suggests not only how hierarchically organized regions in prefrontal cortex interact to support behavior, but also how humans learn to identify abstract and concrete cues in the first place. According to the HER model, relative levels of abstraction amongst information sources are determined by their temporal proximity to a response as well as by the degree to which the cue on its own reduces uncertainty about identity of the correct response. A key prediction of the model is that manipulating the order in which structured information is presented produces differences in performance: learning rate and accuracy will increase when a cue that more effectively reduces response uncertainty is presented immediately prior to a response. We tested this prediction by having subjects perform a task in which they were required to learn the correct response to repeated sequences of two images. In one condition ('Concrete First'), stimuli that were more effective at reducing uncertainty about response identity were presented first, while in a second condition ('Abstract First'), these stimuli were presented immediately prior to a response. As predicted by the HER model, subjects learned more slowly and with lower terminal accuracy in the Concrete First condition. Drift-diffusion modeling of behavioral data aligned to the onset of the second cue shows that subjects integrated information more quickly in the Abstract First condition than in the Concrete First condition, consistent with a role for context information in modulating the processing of concrete information rather than directly driving behavioral responses. Taken together, these results provide additional insight into how hierarchically structured information is identified, represented, and used to inform behavior.

Title: Supplementary motor area first predicts reaction time in stereotyped word articulation in large-scale intracranial EEG

Authors: *L. BULLOCK[1], K. FORSETH[1], N. TANDON[1,2,3];
[1]UT Hlth. Sci. Ctr. Houston, Houston, TX; [2]Texas Inst. for Restorative Neurotechnologies, Houston, TX; [3]Mem. Hermann Hosp., Houston, TX

Abstract: Intracranial recordings provide unparalleled insights into the dynamics of word production. However, these data are limited by sparse coverage of brain areas, and the derivation of a whole brain map of speech production is confounded by varied responses across individuals, along with the semantic, lexical, and phonological confounds intrinsic to the generation of a range of words. To control for this, we performed intracranial recordings in a large cohort (n = 134, 25,000+ electrodes) while they articulated a single multisyllabic word, 'scrambled' (average 66/person). Global mean broadband gamma activity (BGA), derived using a surface-based mixed-effects multilevel analysis (SB-MEMA), was used to create a 4D representation of cortical dynamics during production of this single-word. BGA changes in supplementary motor area (SMA), pre-SMA, precentral sulcus, and inferior frontal sulcus reached significance earliest, followed by central sulcus and IFG. To assess contributors to RT variability, we modelled it as a function of BGA across trials at time points across the pre-articulatory window. Activity in the SMA was the earliest predictor of RT, reaching significance just 250ms after stimulus onset. In contrast, activity in other early-onset ROIs, such as IFS and precentral sulcus, were not predictive of RT until 300ms after stimulus onset. In a final set of analyses, we use linear mixed-effects modeling of RT to show a priming effect: The second of two consecutive SCRAMBLED trials had a lower RT. We tested each active electrode in each ROI for BGA divergence between the two conditions. 13 of 637 recording sites showed a 'preference' for either the PRIMED or UNPRIMED conditions. Taken together with the finding that SMA predicts RT earliest, the sparse cortical effects we see suggest that RT decreases in the PRIMED condition may be primarily driven by SMA-mediated cortical-basal ganglia-thalamus loops, that are initiated sooner for PRIMED trials as they require a re-execution of a motor program. Overall, this work highlights the key role of the SMA in speech initiation and timing.

Title: Impaired monitoring on intact repreaentational function mediates auditory verbal hallucinations

Authors: *F. YANG[1,2], C. ZHANG[3], **X. TIAN**[4,2,1];
[1]Sch. of Psychology and Cognitive Science,East China Normal Univ., Shanghai, China; [2]NYU-ECNU Inst. of Brain and Cognitive Sci., Shanghai, China; [3]Shanghai Mental Hlth. Ctr., Shanghai, China; [4]Neural and Cognitive Sci., New York Univ. Shanghai, Shanghai, China

Abstract: Speech production requires efficient monitoring. Impairment in the monitoring functions may misattribute inner speech to stimulus induced perception and result in auditory verbal hallucinations (AVHs). We hypothesize that auditory representation can be induced by a motor signal (*efference copy, EC*) that contains detailed speaking contents; whereas motor signal (*corollary discharge, CD*) monitors and determines the source of internally induced auditory representation by the *EC* signal. Specific in patients with AVHs, *EC* that induces auditory representation is relatively intact but *CD* that monitors the induction process is impaired so that the internally evoked auditory responses are incorrectly attributed as externally induced and hence yields AVHs. To test our hypothesis, we carried out an electroencephalography (EEG) experiment with a delayed articulation paradigm. Nineteen schizophrenic patients with AVHs and sixteen schizophrenic patients without AVHs were instructed to make different types of preparation before speaking according to visual cues. One visual cue consisted of symbols that did not contain any linguistic information. Participants were asked to prepare to speak without knowing what to say *(general preparation GP* that would induce *CD).* Another visual cue was syllables. Participants were asked to prepare to speak a specific syllable *(specific preparation, SP* that would induce *EC).* Auditory syllables were presented during the last 400ms of each preparation stage to investigate the nature of the motor signals by testing how distinct preparation stages modulate the perceptual responses to the auditory probes. In both schizophrenic patients with AVHs and without AVHs, *general preparation* did not inhibit auditory neural responses, contrasting with suppression results in normal participants (Li, Zhu & Tian, 2020). The absence of inhibition during *general preparation* suggests the impairment of *CD* in patients. Whereas *specific preparation* modulated auditory representation but different between patients with and without AVHs. Specifically, in patients without AVHs, the modulation effect was consistent with normal participants where *specific preparation* enhanced auditory neural responses to the sounds congruent with what prepared. Whereas in patients with AVHs, the modulation was in an opposite direction as observed in normal participants, indicating the malfunctioned *CD* on monitoring the intact *EC*. These results suggest that the interplay of distinct
functional motor signals balances the computational demands between executing and monitoring the top-down mental operations.

Title: A speech planning circuit for interactive language use

Authors: *G. A. CASTELLUCCI[1], C. K. KOVACH[2], M. A. HOWARD, III[2], J. D. GREENLEE[2], M. A. LONG[1];
[1]Neurosci. Inst., NYU Langone Med. Ctr., New York, NY; [2]Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA

Abstract: During conversation, people take turns speaking by rapidly responding to their partners while simultaneously avoiding interruption. Such interactions display a remarkable degree of coordination, as typical gaps between turns are ~200 ms - approximately the duration of an eyeblink. These response times are considerably shorter than those observed in simple word production tasks, indicating that speakers often plan their responses while listening to their partners. Although a distributed network of brain regions has been implicated in speech planning, the neural dynamics underlying the specific preparatory processes which enable rapid turn-taking are poorly understood. Here we use intracranial electrocorticography to precisely measure neural activity as participants perform interactive tasks, and we observe a distinct class of cortical dynamics associated with speech planning. We localize these preparatory responses to a frontotemporal circuit that is anatomically segregated from regions involved in speech perception and production, and we find the core of this network to be comprised of language-critical caudal inferior frontal cortex (i.e., 'Broca's region') and caudal middle frontal gyrus - a region not normally implicated in speech planning. Using a series of motor tasks, we then show that this planning network is selectively active when preparing speech but largely unrecruited when planning nonlinguistic orofacial and manual actions. Finally, we uncover planning-related circuitry in natural conversation that is nearly identical to the network mapped with our interactive tasks, and we find this circuit to be most active prior to participant speech during unconstrained turn-taking. Therefore, we have identified a speech planning network central to natural language generation during social interaction.

Title: Leveraging brain encoding models to predict individual differences in behavior

Authors: *J. WILLIAMS[1], L. WEHBE[2,3];
[1]Computat. Biol., [2]Machine Learning, [3]Neurosci. Inst., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: To increase our understanding of the brain-behavior relationship we want to understand how individual differences in brain function are associated with differences in behavior. Recent neuroimaging studies have shown that individual differences in functional connectivity (FC) are predictive of behavior. FC tells us when two brain areas are connected and activated together. This is an important part of understanding which areas are interacting, and has allowed researchers to identify networks related to different cognitive processes (i.e., vision, language). However, this knowledge does not include what kind of information different areas are processing and passing to each other, which might also be predictive of individual differences in behavior. To better understand individual differences in processing information a complementary approach to FC is to identify where differences in information processing exist and what information is processed in these areas. Encoding models have enabled researcher to build complex maps of the information underlying processes such as vision or language. However, encoding models are typically used in studies with lots of data from a few participants, which would prevent them from leading to insights about individual differences. We propose a framework to leverage encoding models to identify individual differences in stimulus processing. We evaluate our framework on the fMRI blood-oxygen-level-dependent (BOLD) responses collected when 176 participants (104 female, age 22-37) watched an hour of naturalistic video clips, and when they performed a tightly controlled motor task for 7 minutes. This data was provided as part of the Human Connectome Project (HCP). We use encoding models, to estimate the BOLD response of each area from the stimulus features. We find that encoding model predictive performance, correlation between actual and encoding model predicted BOLD response, is feature-space and task specific. Next we interrogate the relationship between brain function and behavior, by using the individual differences in predictive performance to predict cognitive behavior measures in the HCP. We find that predictive performance predicts the vast majority (12/15) of cognitive behavior measure scores significantly higher than chance (one-sided permutation test, alpha = 0.05, FDR corrected), and that these predictive capabilities are feature-space and task specific. These results argue that encoding models can be a powerful tool for studying individual differences that is complementary to FC and can reveal specific differences in how brain areas process information and how these differences relate to behavior.

Title: Spatiotemporal brain dynamics of sentence reading

Authors: *O. WOOLNOUGH[1], E. MURPHY[1], P. S. ROLLO[1], C. DONOS[1], S. DEHAENE[2], N. TANDON[1];
[1]UTHealth, Houston, TX; [2]INSERM-CEA, GIF/YVETTE, France

Abstract: Reading a sentence entails inferring meaning from combinations of multiple lexical objects, allowing us to derive complex meaning. Studies of cortical activity underlying semantic and syntactic operations implicate inferior frontal gyrus (IFG) and middle temporal gyrus (MTG), yet the relative contributions of these regions to sentence comprehension remains controversial. We used direct intracranial recordings from IFG and MTG in the left hemisphere, in a large cohort, to map spatiotemporal neural correlates of multi-word semantics and sentence structure building. 29 patients undergoing implantation of intracranial electrodes for localising pharmaco-resistant epilepsy silently read Sentences, Jabberwocky sentences, Unstructured word lists, and Pseudoword lists, presented in rapid serial visual presentation. Broadband gamma activity (70-150Hz) was extracted from electrodes across the left hemisphere (n>2,500) and subjected to linear mixed effects modelling to dissociate the impact of sentence structure, word frequency and lexicality on recorded activation. Contrary to predictions from prior studies, we found that sentence structure did not lead to a simple monotonic increase in activation across the duration of the sentence, relative to word lists. Instead, we observed an initial suppression of activity for sentences, coinciding with formation of a phrase structure at word 2, followed by a progressive increase in activity along the rest of the sentence. This pattern was identical for electrodes in MTG, anterior IFG and medial frontal operculum. Ventral visual cortex, parietal cortex and posterior IFG did not show modulation by sentence structure. Lastly, a tuning to word frequency was observed across ventral occipitotemporal cortex, appearing earliest in mid-fusiform cortex, and preceding frequency tuned responses in IFG and traditional visual word form regions by around 200 ms. Our work suggests that the neural correlates of sentence structure comprehension. primarily care about an accumulation of semantic rather than syntactic information. Both IFG and MTG demonstrate comparable sensitivity to sentence structure. The IFG is sensitive to lexical properties of single words, subserving an item-specific representation, while MTG appears to be involved in the generation of abstract, structural inferences. Our work provides crucial insight into the integration of individual words into complex semantic concepts and highlights the critical need for large cohort studies of sentence processing utilising methods that provide high spatiotemporal resolution.

Title: Prefrontal mediation of the reading and language network in first-grade predicts longitudinal reading comprehension growth

Authors: *K. ABOUD, A. N. BURGESS, L. CUTTING;
Vanderbilt Univ., Nashville, TN

Abstract: Early developmental predictors of long-term reading comprehension (RC) have primarily focused on behavioral and neural measures related to reading and language. However, recent studies have revealed that executive brain areas, such as the dorsolateral prefrontal cortex (dlPFC), play a critical role in in the integration of word and text reading processes. In the current study, we aimed to determine how executive versus reading and language network (RLN) connectivity patterns relate to early RC (first grade) and later RC growth (from second to third grade). We hypothesized that within-network RLN connectivity would be associated with RC at all time points, but executive interactions with the RLN would be particularly predictive of later RC growth. We examined n = 44 first graders as they read words in the MRI. We then employed a longitudinal design to examine first-grade neural predictors of RC growth in first, second, and third grades. Specifically, we were interested in the role of executive versus the RLN in early and later RC performance. Functional connectivity analysis revealed that first-grade coupling in the canonical RLN, but not executive areas, was significantly predictive of first-grade out-of-scanner RC ability. However, RC growth from second to third grade was predicted by RLN connectivity as well as left dlPFC mediation of within-network RLN coupling. These findings mirror previous studies on reading intervention that show similar executive mediation of the RLN as a significant pre-intervention predictor of reading intervention response. Our results reveal that early executive support of the RLN is a critical part of longitudinal RC development, suggesting that the development of an executive "scaffold" of reading processes may be an important component of early reading practice. Future studies should track executive-RLN interactions across development and bridge findings to inform intervention.

Title: Higher order thinking and neuroplasticity

Authors: *M. ORKODASHVILI;
Vanderbilt Univ., Tbilisi, Georgia

Abstract: The paper looks into the influence of the so-called *higher order thinking* on the development of neuroplasticity in monolingual, bilingual and multilingual brains. *Higher order thinking* involves understanding of linguistic units and linguo-pragmatic means with non-literal meanings such as certain abstract notions (often of polysemantic nature), metaphors, and humor. The paper analyzes the effects of the recognition of abstract notions, metaphors, and humor in monolingual, bilingual and multilingual individuals on the development of their cognitive capacities. It is hypothesized that transferring, explaining and understanding abstract notions, metaphors, and humor across languages is more difficult than transferring, explaining and understanding simple and concrete concepts or actions (e.g. concrete nouns and verbs denoting simple actions). As a result of systematic mental exercise, subjects develop three important advantageous features of cognitive capacity: 1) quicker response time to understanding expressions and statements with non-literal meanings; 2) multitasking ability of understanding and reacting (or proacting) to simultaneous multiple tasks such as simultaneous translation and interpretation; and 3) quicker context anticipation. All three advantages indicate higher brain plasticity. The study so far has come to the following findings:a) bilinguals and multilinguals are 85-95 milliseconds quicker in recognizing and understanding non-literal meanings as opposed to monolinguals;
b) monolinguals are 45-55 milliseconds quicker understanding complex texts after being exposed to the metaphoric expressions for a while; c) subjects who have been exposed to metaphoric expressions and texts report the ability of performing two tasks at a time such as simultaneous translation in multiple languages more often than those who have not been exposed to such non-literal expressions; d) furthermore, in the process of reading a new text, the subjects who have been exposed to metaphoric expressions, anticipate the subsequent words, actions or concepts from the context with 78 % precision, as compared to those who have not been exposed to such expressions and who reveal only 22 % precision of anticipation.

Title: Distributed and joint representation of linguistic feature hierarchy in the human auditory cortex

Authors: *M. KESHISHIAN[1], S. AKKOL[2], J. L. HERRERO[3], S. BICKEL[2], A. D. MEHTA[2], N. MESGARANI[1];

[1]Columbia Univ., New York, NY; [2]Hofstra Northwell Sch. of Med., Manhasset, NY; [3]The Feinstein Inst. For Med. Res., Manhasset, NY

Abstract: How the human auditory cortex represents and transforms the sound pressure waveforms produced by a speaker to enable speech recognition remains unclear. Here, we used direct neural recordings from implanted electrodes in the auditory cortex of fifteen neurosurgical patients as they listened to thirty minutes of natural speech. We used a multivariate regression framework to predict neural responses from various acoustic and linguistic features of speech and measured the variance explained by each feature. We found an explicit and distinct neural encoding of multiple levels of linguistic processing, including the acoustic, phonetic, phonotactic, lexical-phonemic and lexical-semantic features. Grouping neural sites according to their encoded linguistic features revealed several patterns of joint feature encoding, where the representations of higher-level features were added to the representation of lower-level features. Anatomical and functional localization of linguistic encoding showed a gradual emergence of low- to high-level features from primary to non-primary auditory cortical areas. Furthermore, we observed a temporal order in the appearance of these features, where encoding of higher-level features was correlated with neural response latency and the response time-lag for higher-level features was higher than lower-level features across the population. This joint, anatomically distributed, and temporally ordered appearance of various levels of linguistic features shines a light on what hierarchical processes enable the human auditory cortex to extract meaning from the speech sounds.

Title: Investigating the Cerebellar Connectivity of Language Processing: A DTI Feasibility Study

Authors: *I. THAKKAR[1], L. ARRAÑO-CARRASCO[1], R. ZUNINO-PESCE[1], B. CORTÉS RIVERA[2], F. MERY-MUÑOZ[1], M. RODRIGUEZ-FERNANDEZ[1], A. LEEMANS[3], C. MENDEZ-ORELLANA[1]; [1]Pontificia Univ. Católica de Chile, Santiago, Chile; [2]Univ. Santo Tomás, Santiago, Chile; [3]UMC Utrecht, Utrecht, Netherlands

Abstract: BOLD activations in the cerebellum contralateral to language-dominant cortical regions during a verbal fluency task were first shown in Hubrich-Ungureanu et al., 2002, pointing at the cerebellum's role in language processing. In our previous studies, these activations were observed in both left- and right-handed healthy subjects and brain tumor patients (Mendez Orellana et al., 2014), and during semantic and phonological association tasks (Thakkar et al., 2021). White matter tracts connecting the frontal lobe to the contralateral cerebellum have been observed in tractography studies (Keser et al., 2015;

Oh et al., 2016). Here, we investigate the feasibility to reconstruct white matter tracts directly connecting the contralateral cerebellum specifically with cortical ROIs involved in the dorsal stream of language processing, i.e. the inferior frontal gyrus (IFG), and the supramarginal and angular gyri (SMG, AG).
We use the ExploreDTI Toolbox (Leemans et al., 2009) to demonstrate the presence of these tracts in healthy subjects (n = 14, age-range = 20 - 70 years, mean age = 42.43 years, females = 6, left-handed = 4). With tracking settings used in Keser et al., 2015, we perform whole-brain tractography for all subjects. We identify cortical ROIs in each hemisphere for each subject and analyze tracts from the contralateral cerebellum to the contralateral ROIs separately. In our preliminary analyses, we observe fiber tracts from the contralateral cerebellum in 6 subjects extending to IFG, in 11 extending to SMG, and in 7 extending to AG.
This warrants further investigation in tractography parameters to consistently construct these pathways that may be sustaining the contribution of the cerebellum in language processing in both healthy and brain tumor cohorts. This is crucial due to the occurrence of false positives and crossing fibers in tractography (Jeurissen et al., 2013). We will quantify diffusion properties of these tracts with respect to their functional properties to aid surgical planning in brain tumor patients and shed light on the current model of language processing.

Title: Sex-dependent impact of prenatal cannabinoid exposure on neonatal and adolescent neuropsychiatric outcomes

Authors: *M. G. NASHED[1], R. HUDSON[1], M. H. SARIKAHYA[1], K. LEE[2], S. R. VANIN[2], D. B. HARDY[2], S. R. LAVIOLETTE[1];

Abstract: Objective/Rationale: Recent reports suggest that the prevalence of cannabis use during pregnancy is upwards of 35% in North America, with a rise in use mirrored by increasing legalization and the perception of safety. This project utilizes a rat model of prenatal cannabinoid exposure to assess neonatal and long-term neuropsychiatric liability of in utero exposure. Delta-9-tetrahydrocannabinol (Δ9-THC; the psychoactive component of cannabis) and cannabidiol (CBD; a non-psychoactive component of cannabis) were assessed separately and in combination.
Methods: Pregnant Wistar rat dams were administered daily intraperitoneal (i.p) injections between gestational days (GD) 6 and 20. Dams received vehicle, 3mg/kg Δ9-THC, 30mg/kg CBD, or a combination of 3mg/kg Δ9-THC plus 30mg/kg CBD. In a subset of dams, fetal and placental weights were measured at GD19. Pup body and brain weights were measured at postnatal day (PND) 1 and PND21. Male and female adolescent offspring underwent behavioural testing to assess neuropsychiatric and cognitive domains. The open field test (OFT) and elevated plus maze (EPM) were used to assess anxiety-related behaviours. Cognition was assessed through temporal order novel object recognition (tNOR) and the social memory task.
Results: Δ9-THC and CBD administration did not impact maternal food intake, weight, or litter size. However, Δ9-THC, CBD, and combination treatment all resulted in decreased fetal weight and fetal:placenta ratio at GD19, suggesting placental insufficiency. At PND1, brain and body weight measures were indicative of asymmetrical fetal growth restriction (FGR) for Δ9-THC offspring, and symmetrical FGR for Δ9-THC/CBD combination offspring. At PND21, no differences in brain weights were observed for either male or female offspring in any treatment group, suggesting postnatal catch-up growth. During adolescence, sex-specific neurobehavioural effects emerged. For male offspring, all treatments (Δ9-THC, CBD, and combination) impaired object recall in the tNOR, with no significant effects observed in emotional tasks (EPM and OFT). For female offspring, CBD exposure was associated with anxiety-like behaviour in the EPM, and all treatments (Δ9-THC, CBD, and combination) impaired social recall in the social memory task.
Conclusion: We demonstrated that in utero exposure to Δ9-THC and CBD are associated with impairments in fetal development, as well as sex-specific deficits in adolescent neuropsychiatric and cognitive outcomes. This project will contribute to informing public attitudes and regulatory policies on the use of cannabinoid-based products during pregnancy.

De Buenos Aires, Facultad de Medicina, 1ra Cátedra de Farmacología, Ciudad Autónoma de Buenos Aires, Argentina; [4]Inst. de Biología Celular y Neurociencias (IBCN, UBA-CONICET), Ciudad autónoma de Buenos Aires, Argentina

Abstract: Human adolescents usually consume ethanol (EtOH) for recreational purposes in social gatherings, bars and concerts, places where they are also often exposed to noise of high intensity. According to published animal experimental data, both stimuli presented separately might generate an imbalance in hippocampal (HC) oxidative system that could underlay HC-dependent behavioral alterations. Thus, the aim of this work was to test the effects of EtOH intake followed by noise exposure on the oxidative state of the HC in adolescent rats.Wistar rats of both sexes (28-days-old) were subjected to voluntary 10% EtOH intake using the “two-bottle choice drinking-in-the-dark” paradigm, during 4h/d, for 4 days. After the last session, rats were exposed to noise (95-97 dB, 2h). Finally, HC was dissected to assess the levels of reactive oxygen species (ROS) and catalase activity (CAT) through biochemical techniques as well as the antioxidant enzyme glutaredoxin-1 (Grx-1) through western blot analyses.Results showed an increase in ROS levels after EtOH intake and a decrease in Grx-1 levels after noise exposure in the HC of female rats, when compared with sham animals. In contrast, a decrease in ROS levels after noise exposure was found in males HC. When EtOH intake was followed by noise exposure, a significant decrease in ROS levels was found, both in males and females HC and an increase in Grx-1 was found only in males HC. Finally, non-significant differences were observed in CAT among groups in comparison to sham animals, either in females or males.These findings suggest that EtOH intake and noise exposure might affect HC oxidative state in a sex-dependent way. When both stimuli were presented separately, female rats appear to be more sensitive to EtOH, whereas males showed changes only when exposed to noise. However, when both agents were presented together, both sexes seem to be equally affected, suggesting that the combination of both stimuli might unmask any effects that would not have been observed with each agent individually. Finally, the finding of an increase in Grx-1 levels when ROS levels are decreased, observed only in males, might reveal a relevant role for this enzyme aimed to compensate for an oxidative imbalance triggered by the environmental stressors.

Title: Developmental exposure to cannabidiol via intraperitoneal injection or passive inhalation is without substantial behavioral consequences on locomotor behavior, anxiety, and spatial learning in mice

Authors: H. STEVENSON[1], T. MCGILLIS[1], J. K. WAGNER[1], K. REED[1], F. MCGUINNESS[1], S. ARVILA[1], M. BROOKS[1], J. JONES[1], B. RISCH[1], R. BUDINICH[1], E. GAMBELL[1], ***J. S. KAPLAN**[2]; [1]WESTERN WASHINGTON UNIVERSITY, BELLINGHAM, WA; [2]WESTERN WASHINGTON UNIVERSITY, Bellingham, WA

Abstract: Cannabidiol (CBD) is a non-intoxicating phytocannabinoid with rapidly escalating popularity for the treatment of numerous off-label conditions including pain, anxiety, depression, hyperactivity, and autism spectrum disorder. Since CBD consumption is generally well-tolerated in adults, the impression of CBD's high safety profile has contributed to an increase in prenatal, early childhood, and adolescent exposure through the placenta, breastmilk, and oral consumption. Yet, the impact of CBD exposure on brain development across different developmental stages is unknown. As the number of CBD-related clinical trials in children and adolescents continues to grow, it has become increasingly important to characterize the long-term consequences of developmental CBD exposure. Here, we tested the effect of CBD exposure during several developmental time periods in male and female C57BL/6J mice on locomotor behavior in the open field, anxiety behavior on the elevated plus maze, and spatial memory on the Barnes Maze using two different exposure methods: intraperitoneal injection (i.p.) and passive CBD vapor inhalation. We first validated the acute anxiety-reducing efficacy of our CBD compounds in adult mice and used these doses to determine our developmental exposure levels. Twice daily 20 mg/kg CBD i.p. injections during the equivalent adolescent period (25-45 days) had no detrimental effects on locomotor behavior or anxiety in adulthood but improved the rate of learning on the Barnes Maze compared to vehicle-treated mice. Two weeks of twice daily passive inhalation sessions of CBD (33.3 mg/ml; 6 3-second hits delivered across 30 minutes) during the perinatal window (7 days prenatal to 7 days postnatal), early postnatal (P7-20), and (P14-27), and adolescent period (P28-41) were without detrimental behavioral effects on these three core assays. We conclude that prolonged adolescent CBD exposure in mice does not have substantive negative impacts on a range of behaviors in adulthood and may even improve the rate of learning when administered under certain stressful experimental conditions. These findings do not detract from the progression of clinical studies investigating CBD’s therapeutic potential in an adolescent population.

Title: Downregulation of parvalbumin expression in the ventral hippocampus during adolescence causes long-lasting impairments in prefrontal cortex function in adults

Authors: *S. DUBE, A. OROZCO, K. Y. TSENG, A. CABALLERO;
Dept. of Anat. and Cell Biol., Univ. of Illinois At Chicago, Col. of Med., Chicago, IL

Abstract: The upregulation of the calcium-binding protein parvalbumin (PV) in fast-spiking GABAergic interneurons is necessary for the maturation of GABAergic function and the adjustment of the excitatory-inhibitory (E-I) balance observed in the prefrontal cortex (PFC) during adolescence. Similarly, the developmental increase in the PV expression in the ventral hippocampus (vHC) during adolescence may refine hippocampal activity and output to downstream structures. Notably, a downregulation of PV in both HC and PFC has been observed in post-mortem brains of schizophrenia patients, suggesting that inadequate levels of PV result in a disruption of inhibitory transmission within these structures. Since the vHC is a main afferent to the medial PFC, we hypothesized that downregulation of PV expression within the ventral hippocampus during adolescence would lead to hippocampal overactivity that ultimately disrupts the activity of the PFC in adults. To test this hypothesis, we delivered a PV shRNA vector directly into the ventral hippocampus to reduce PV expression during adolescence and examined its impact on PFC-dependent behaviors during adulthood. The results indicate that animals with reduced PV expression in the vHC had an impaired level of extinction in trace fear conditioning, a behavioral paradigm that relies on intact PFC-vHC connectivity. In addition, PV shRNA-treated animals displayed an impairment in sensory-motor gating as measured by reduced pre-pulse inhibition (PPI) of acoustic startle reflex (ASR). These results indicate the downregulation of PV expression in the vHC during adolescence is sufficient to disrupt prefrontal function, providing a useful translational model to study the effects of ventral hippocampal hyperactivity in neuropsychiatric disorders.

Title: Social and neuronal alterations in adult male rats following adolescent intermittent ethanol exposure

Authors: *T. T. TOWNER, D. T. APPLEGATE, L. P. SPEAR, E. I. VARLINSKAYA, D. F. WERNER;
Binghamton Univ., Binghamton, NY

Abstract: Adolescence is a sensitive developmental period during which alcohol use is often initiated. Furthermore, adolescents are also known to consume alcohol in high quantities, often at binge levels or even high-intensity drinking. Our lab has repeatedly found that adolescent intermittent ethanol (AIE) exposure in rats during postnatal days (P) 25-45 results in long-lasting social impairments, specifically in males. The goal of the current study was to further assess these AIE-induced sex-specific social alterations through the measurement of prelimbic (PrL) and infralimbic (IL) neuronal activation associated with exposure to a social stimulus. Based on previous findings and preliminary data, we hypothesized that AIE males would display social anxiety-like alterations accompanied by enhanced PrL neuronal activation in comparison to water-exposed males. Using a Sprague-Dawley cFos-LacZ transgenic rat, we intermittently exposed male adolescents (P25-45) to ethanol (4 g/kg, 25% v/v) or water via intragastric gavage for a total of 11 exposures (n = 13 per group). In adulthood (P70), rats were tested using a modified social interaction paradigm, and brains were collected approximately 60 minutes following the social interaction. Every sixth section of the PrL and IL were then subjected to β-galactosidase (β-gal) enzymatic histology, allowing for the identification of recently activated neurons, with β-gal used as a cFos proxy. We found that AIE exposure induced a social avoidance phenotype, as evidenced by a significantly lower social preference coefficient in AIE-exposed males relative to water-exposed controls. In contrast to our prediction, AIE males tended to have lower neuronal activation in the PrL although this effect of AIE was not statistically significant. No difference in IL activation was evident between water- and AIE-exposed males. Importantly, frequency of social investigation behavior was positively correlated with PrL neuronal activation in water-exposed rats, a relationship not evident in AIE-exposed rats. These data suggest that under normal circumstances the PrL cortex may be involved in the regulation of social behavior, however the involvement of the PrL may be dysregulated by AIE exposure. Further assessment of neuronal activation in other brain regions that modulate social behavior are underway as well as the inclusion of females to confirm whether these are sex-specific changes. Future studies will be focused on the inactivation of the PrL, thus allowing for a better understanding of the functional role of the PrL in AIE-induced social impairments.

Univ. of Western Ontario, London, ON, Canada

Abstract: Sustained cannabis consumption during adolescence has been widely associated to cognitive impairments and enhanced risks for anxiety/mood disorders at adulthood. In particular, clinical and preclinical evidence has demonstrated that chronic exposure to the main psychoactive component Δ-9 tetrahydrocannabinol (THC) induces profound hippocampal (Hipp) morphological maladaptations and dysregulations of its glutamatergic signaling. Notably, several studies have reported a functional dissociation in physiological and pathological state between anterior and posterior Hipp subregions, identified as ventral (vHipp) and dorsal (dHipp) in rodents. Hence, in this study we investigated whether adolescent THC exposure induces different long-lasting abnormalities in vHipp and dHipp function. Adolescent male rats were treated from postnatal day (PND) 35 to 45 with increasing doses of THC (PND 35-37 2.5 mg/kg, PND 38-41 5 mg/kg, PND 42-45 10 mg/kg, i.p., twice a day) or vehicle. At adulthood (PND 75), a battery of behavioral tasks was carried out to assess cognitive performances and anxiety. Moreover, a detailed molecular examination in dHipp and vHipp was performed using Matrix-Assisted Laser Desorption/Ionization Imaging Mass Spectrometry (MALDI-IMS) and Western Blots techniques. Lastly, neural activity of glutamatergic cells was investigated in dHipp and vHipp with *in vivo* electrophysiological recordings. We report that adolescent THC exposure induced long-term anxiety and remarkable impairments in memory processing, concomitant with a wide range of molecular modifications. Specifically, IMS relative quantification revealed a significant decrease of dopamine levels in both, dHipp and vHipp, while GABA levels were decreased only in dHipp and no differences were detected in glutamate levels. In addition, protein analyses pointed out an opposite trend for NMDA2B, which was reduced in dHipp and enhanced in vHipp. Consistently, mGlu2/3 was increased in vHipp. Chronic THC exposure did not affect dopamine receptor as well as GAD67 and mTOR expression levels, in both dHipp and vHipp. Finally, chronic THC exposure led to a reduction in spontaneous electrical activity of glutamatergic neurons in dHipp, while no differences were found in vHipp. Overall, our findings provide evidence that THC exposure during adolescence impact differently dHipp and vHipp function, which dysconnectivity may underlie the cognitive and affective pathological outcomes of cannabis consumption.

Title: Characterization of resting state networks in awake adolescent and adult squirrel monkeys

Authors: *W. YASSIN[1,4], F. B. DE MOURA[1,4,2], S. L. WITHEY[1,4], L. CAO[1], J. STOVER[1], S. J. KOHUT[1,4,2], B. D. KANGAS[3,4], J. BERGMAN[3,4];

Abstract: Resting state networks (RSNs) are increasingly used as candidate biomarkers for neuropsychiatric disorders. Such biomarkers could serve as objective measures for novel therapeutic interventions where there is a strong need for translational research using well-controlled animal models. Squirrel monkeys offer advantages over macaques due to their smaller size and ease of handling, and marmosets due to being closer phylogenetically and neurobiologically to humans. This study aimed to characterize the RSNs of awake squirrel monkeys and report the characteristics of those networks from a developmental perspective.Twenty-seven squirrel monkeys (N=12 adolescents [6 male/6 female] approx. 2.5 years and N=15 adults [7 male/8 female] approx. 9.5 years) were gradually acclimated to awake scanning procedures. Whole-brain fMRI images were acquired with a 9.4T scanner. Quality control was evaluated using MRIQC and visual inspection. Modified FSL software pipeline was used for preprocessing and group level independent component (IC) analysis (30 ICs) to detect RSNs that were identified by 3 independent observers. ICs representing noise were excluded, resulting in 16 ICs corresponding to physiologically meaningful networks. In adolescents, the sensory motor network (SMN) was found in 2 ICs; one contained the bilateral supplementary motor areas (SMA), primary motor cortex (M1), anterior parietal cortex (APC), posterior parietal cortex, and parietal ventral area and secondary somatosensory area (PV/S2), the other contained the bilateral M1, APC, and premotor cortex (PMC). In adults, the basal ganglia included the head of the caudate, globus pallidus and putamen. Two single region ICs were identified: one limited to the bilateral cingulate cortex and another limited the thalamus. In the SMN, one IC included the PMC, M1, APC and PV/S2, and the other contained the PMC, M1, APC, and SMA. In adolescents and adults, the visual network was found in 6 of the 16 ICs. Four of the 6 included the bilateral primary visual area (V1), left and/or right V1 IC. The default mode network was found in 2 ICs that contained the anterior precuneus, posterior cingulate cortex and inferior parietal cortices. An inferior temporal cortex activation was also seen bilaterally. The prefrontal cortex (PFC) was found in 3 ICs, all localized to bilateral PFC. A cerebellar component covering the entire structure was also observed.
We report consistent and stable squirrel monkey RSNs previously identified in humans, rodents, and other non-human primate species. This data demonstrates a developmental trajectory of several networks that either varies or remains conserved depending on the RSN of interest.

Title: The Role of Puberty on Brain and Physical Development: A Longitudinal Study in Adolescent Male Rhesus Macaques

Authors: Z. KOVACS-BALINT[1], J. RAPER[1], R. RICHARDSON[1], R. HONG[1], E. MORIN[1], M. PINCUS[1], L. LI[1], M. A. STYNER[2], E. FECZKO[3], E. EARL[4], D. A. FAIR[3], J. BACHEVALIER[1], ***M. SANCHEZ**[1];

Abstract: Studies investigating the drastic cognitive, emotional, hormonal and neural changes during adolescence are crucial to understand the vulnerability for psychopathology during this developmental phase. The goal of this study was to investigate the role of pubertal maturation on developmental changes in stress, emotional and cognitive control neurocircuits and physical growth using a translational nonhuman primate model. We collected longitudinal data from 10 male macaques between pre-puberty (23 months) and early adolescence (peri-puberty: 32, 34 and 37 months of age). Testicular volume and physical growth measures (body weight, height) were collected at each timepoint. Structural and resting-state functional MRI scans were acquired at 23 and 34 months using a 3T MRI scanner to examine developmental changes in amygdala (AMY), hippocampus (HIPPO), prefrontal cortex regions (PFC, based on Brodmann Areas -BAs-) and intracranial volumes (ICV), as well as functional connectivity (FC) between these regions of interest (ROIs). We hypothesized that pubertal maturation would be a better predictor than chronological age for developmental changes in physical growth and in brain ROI volumes and FC. Testicular size and physical growth measures showed significant increases from pre- to peri-puberty (RMANOVA, $p<0.1$), but also high individual variability. Structural brain maturation - measured as ICV, AMY, HIPPO and dorsolateral PFC (BA9, 32) volume increases - was also detected, with hemispheric differences in the AMY and HIPPO (RMANOVA, $p<0.5$). Increased FC between left HIPPO and orbitofrontal cortex (BA11), but decreased FC in the right hemisphere (RMANOVA, AGExHEMISPHERE: $F(1,9)=6.897$, $p=0.028$) were detected. Interestingly, pubertal maturation (measured as testicular volume increases) was associated with only a few brain and physical changes: body weight increases (Pearson's r: 0.674, $p<0.05$) and with the whole PFC's volume decrease (Pearson's r: -0.865, $p<0.05$). Despite individual variability in physical growth and structural and functional brain changes, our results suggest that early pubertal maturation may trigger pruning-related remodeling in the PFC. We expect that other neural circuits critical for emotional and stress regulation and cognitive control will show pubertal-dependent maturation during later adolescence stages. Since our subjects are still young and some have not truly reached puberty yet -in male macaques it happens around 3-4 years-, we expect to see more drastic changes associated with pubertal progression (testicular growth, testosterone levels) and stronger associations with brain maturation at later ages.

Title: Does morphine exacerbate complement dependent synaptic pruning to modify social development?

Authors: *D. NDAMBUKI[1], A. KOPEC[2];
[2]Neurosci. and Exptl. Therapeut., [1]Albany Med. Col., Albany, NY

Abstract: Does morphine exacerbate complement dependent synaptic pruning to modify social development?Introduction: Morphine analgesics are administered annually to approximately 1 million adolescentseach year. Adolescent morphine treatment increases the risk of developing morphine-use disorder laterin life by 30%. Mechanisms to describe this increased vulnerability have primarily focused on the effectsof morphine on opioid receptors. However, little in the literature describes morphine induced-neuroinflammation. Morphine, additionally, is an agonist for the pattern recognition receptor Toll-likereceptor 4 (TLR4). TLR4 is enriched in microglia in the brain. Adolescence is a sensitive period forbehavior development. In pre-clinical models, adolescence is a period for sex-specific social behaviordevelopment via complement dependent synaptic pruning in the nucleus accumbens (NAc); aneuroimmune developmental process. Synaptic pruning is a function of microglia.**Hypothesis:** We hypothesize that adolescent morphine exacerbates complement dependent synapticpruning in a sex-specific manner leading to altered adult social behavior.**Methods:** Rats receive adolescent morphine during sex-specific complement dependent synapticpruning periods of the NAc. Afterwards adolescent synaptic pruning and adult social behavior arequantified.**Results:** Early data suggests that morphine modifies social behavior during the NAc complementdependent synaptic pruning period in a sex-specific manner.**Discussion:** This suggests that the NAc complement dependent synaptic pruning period is a criticalperiod for social behavior development.

Title: Application of electromagnetic field in alleviating aging-induced and diabetes-caused behavioral alterations in the neruonal motor system.

Authors: *J.-W. GAO;
Chung Yuan Christian Univ. Dept. of Biomed. Engin., Taoyuan, Taiwan

Abstract: Abstract Naturopathic medication is the newest approach to cure or prevent diseases, including adjusting the daily routine, physical therapy, or natural supplements. The theoretical mechanism is to prevent or slow the disease by reducing the body's free radical, oxidative stress, or inflammatory response. The magnetic field belongs to physical therapy and is usually driven by electric current to produce electromagnetic fields. It is a non-invasive and painless therapy with high patient acceptance. Previous studies have shown that electromagnetic fields stimulate bone cell repair to treat bone fractures, have an anti-inflammatory effect, and are commonly used to treat arthritis or eye inflammation and swelling. Thus, we want to know if low-frequency electromagnetic fields (MF) can improve the effects of disease-induced inflammation or oxidative stress on the nervous motor system. We adopted two disease models that usually cause neuron inflammation or oxidative stress, which are diabetes and aging. The diabetes animal model was achieved by using transgenic mice (KS.Cg-m+/+Leprdb/J (db/db) mice, db/db mice), and the aging animal model was accomplished by subcutaneous application of D-galactose (100 mg/kg) to the Sprague Dawley (SD) rats. The mice were divided into four groups: control (C57BL/6JNarl mice), control with MF, db/db, and db/db with MF; the SD rats were divided into three groups: control, D-gal, and D-gal with MF. The MF groups are exposed to a 1.8 mT magnetic field for 30 minutes per day. The diabetic animal model group was exposed to MF for 22 weeks, and the aging animal model group was treated for 28 weeks while aging is inducing at the same time. Motor neuro-behavior assessments are conducted every four weeks. In the diabetes animal model, we found that the performance of locomotor ability is significantly improved, especially in the lower limb. The tissue staining of muscle slicing also showed significant increases in the area of muscle fibers. Moreover, rising in the number of white blood cells due to diabetes has also improved in MF treated group. In the aging animal model, we found that MF improves the effectiveness of abnormal motor behavior caused by aging. Accordingly, it is assumed that MF can protect the nervous motor system by regulating oxidative pressure and immune response, thus maintaining normal muscle function.

Title: HED-3G tool ecosystem for machine-actionable event annotation

Authors: *D. TRUONG[1], *D. TRUONG[2], *D. TRUONG[1], S. MAKEIG[2], A. DELORME[2], K. A. ROBBINS[3];
[1]UCSD, La Jolla, CA; [2]Inst. for Neural Computation, UCSD/INC/SCCN, La Jolla, CA; [3]Computer Sci., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Current standards for storing and sharing neuroimaging data such as BIDS (Brain Imaging Data Structure) focus on dataset-level organization and only mandate the inclusion of minimal metadata. However, BIDS allows a much richer specification of machine-actionable experimental event description using Hierarchical Event Descriptors (HED). The HED system has recently undergone a major developmental revision, to HED-3G (K. Robbins, this meeting). HED-3G introduces a more user-friendly way of annotation, greatly increasing the usability of the framework. It also enables the documentation of experiment structure, including tasks, condition variables, and temporal structure as related to experimental events. HED-3G introduces the concept of Library Schemas that allows the expansion of HED to cover all types of time-series data experiments without obfuscating (or bloating) the base schema (S. Makeig, this meeting).
Our working group has been developing a collection of tools to support HED-3G, a key component to making the standard usable and *widely adopted*. Validation tools, which ensure consistency and compliance of dataset annotation, have been updated to support new features of HED-3G and have been integrated into analysis software such as EEGLAB in MATLAB. The graphical user interface tool CTagger guides users through the annotation process, providing hints and shortcuts to expedite event annotation. The EEGLAB *HEDTools* plug-in incorporates CTagger to annotate and perform HED-based analysis on EEGLAB datasets and studies.
HED-3G not only provides a more holistic and detailed way of understanding shared data, but also supports the prospect of automatically aggregating and jointly analyzing data from collections of HED-annotated datasets across laboratories, studies, and data repositories. HED-enabled data discovery requires ongoing development of HED tools for data, tools and compute resources such as the NEMAR portal (*nemar.org*) to OpenNeuro (*openneuro.org*). An important planned component is integration of HED tools with the metadata handling mechanisms of Datalad, the data management software layer underlying current major data portals including OpenNeuro. Future developments also include HED-enabled analysis tools for HED-enabled multiple regression, event-related context analysis, and advanced statistical and machine learning methods suitable for application to large-scale neuroimaging data.

Title: The use of Hierarchical Event Descriptors with fMRI

Authors: *M. J. M. DENISSEN[1], M. PAWLIK[1], A. N. RAVENSCHLAG[1], N. A. HIMMELSTOß[1], S. HAWELKA[1], S. MAKEIG[2], K. A. ROBBINS[3], F. HUTZLER[1];

Abstract: Data-sharing is becoming a more common practice in neuroscience. Currently, the majority of shared neuroimaging data consist of fMRI recordings. Many of these datasets include task-based fMRI, where participants engage with controlled sensory stimulation following task instructions. A major flaw is that these datasets are often minimally annotated. While these experiments can include complex events and event combinations, descriptions are often generalized on the level of conditions, at best allowing users to replicate the original analysis but leaving little opportunity to use more of the information about brain dynamics supporting cognition contained in the data to its full extent. The Hierarchical Event Descriptor (HED) system provides detailed and machine-actionable descriptions originally developed to describe neuroimaging experiments recording M/EEG data. HED has been applied successfully to EEG data to facilitate analysis across multiple datasets. Its current release (3G) provides a user-friendly environment for annotation of events using a sparse, human-readable tagging system (K. Robbins, this meeting), and several available tools facilitate annotation (D. Truong, this meeting). Applying HED to fMRI data is straightforward as fMRI and EEG experiments follow a similar structure. Despite the differences in the measured signals, both have similar requirements for analysis. By applying HED annotation to fMRI datasets researchers cannot only improve its reusability, but also benefit from the continuous development of HED-enabled tools that aid in developing and/or automatize parts of the data-analysis. Methods for fMRI analysis are developing rapidly; the use of multivariate rather than standard univariate analysis methods is increasingly common. Such experiments are particularly well suited for reanalysis, since they engage many aspects of cognition that can be linked to brain activity. Detailed information about these experiments, experiment events, and time structure is needed to use these valuable datasets to their full potential, and is also vital for helping researchers find relevant datasets in continuously growing databases. Applying the same HED standard to describe events and structure of fMRI and M/EEG experiments will also allow researchers to better connect results from these datasets on the basis of the underlying brain processes they record. Standardized, machine-actionable descriptors for data are vital to accelerating knowledge accumulation. HED-3G provides a framework for detailed description that is not only useful and necessary for M/EEG datasets, but equally so for fMRI data.

Title: Meta- and mega-analysis of electroencephalographic data via the Neuroscience Gateway using the BIDS/HED framework in EEGLAB

Authors: *A. DELORME[1], D. TRUONG[1], S. SIVAGNANAM[2], K. YOSHIMOTO[1], K. A. ROBBINS[3], S. MAKEIG[4], A. MAJUMDAR[5];
[2]San Diego Supercomputer Ctr., [1]UCSD, La Jolla, CA; [3]Computer Sci., Univ. of Texas at San Antonio, San Antonio, TX; [4]Inst. of Neural Computation, UCSD/INC/SCCN, La Jolla, CA; [5]San Diego Supercomputer Ctr., Univ. of California San Diego, La Jolla, CA

Abstract: EEGLAB is an interactive Matlab toolbox for processing continuous and event-related EEG, MEG, and other electrophysiological data incorporating independent component analysis (ICA), time/frequency analysis, artifact rejection, event-related statistics, and several useful modes of visualization of the averaged and single-trial data. EEGLAB integrates the Brain Imaging Data Structure (BIDS) standards and HED (version 3G) system for event annotation, allowing meta-analysis across a large corpus of datasets. The advantages of using the BIDS standards for analysis use and reuse are several. First, they do not rely on a complex database schema; they simply store data and relevant metadata in text and binary files within an ordinary file folder structure. Second, BIDS text files are both human and machine-readable, making it easier for new users to examine. BIDS data may be imported directly into EEGLAB for processing as an EEGLAB study (a group of related EEG datasets). BIDS allows defining time-marked data events using dedicated text files that can contain detailed event information using the Hierarchical Event Descriptor (HED) system that is currently being upgraded to its third generation (HED-3G). Here we demonstrate an EEGLAB pipeline processing multiple BIDS-formatted, HED-3G-annotated datasets made publicly available on OpenNeuro.org and NEMAR.org. The pipeline imports BIDS datasets, preprocesses the data and extracts data epochs of interests based on HED tags in common across (here) BIDS-formatted datasets from different experiments and laboratories. We then process the data using the Neuroscience Gateway (nsgportal.org) platform using the EEGLAB nsgportal plug-in. The Neuroscience Gateway (NSG) project facilitates neuroscientist access to and use of National Science Foundation (NSF) funded high performance computing (HPC) resources. As a simple demonstration, we compute a 'target' event-related potential containing a P300 positivity, by averaging event-related data epochs collected from more than one experiment. We discuss the planned incorporation of BIDS and HED tools in the NEMAR.org data, tools, and compute resource.

Title: Brain Imaging Data Structure (BIDS) compatible Hierarchical Event Descriptor (HED) library schema for clinical (i)EEG data annotation

Authors: *T. PAL ATTIA[1], K. A. ROBBINS[3], S. MAKEIG[4], D. Q. TRUONG[5], B. H. BRINKMANN[2], G. A. WORRELL[2], D. HERMES[1];
[1]Multimodal Neuroimaging Laboratory, Dept. of Physiol. and Biomed. Engin., [2]Bioelectronics Neurophysiol. and Engin. Laboratory, Dept. of Neurol., Mayo Clin., Rochester, MN; [3]Computer Sci., Univ. of Texas at San Antonio, San Antonio, TX; [4]Inst. of Neural Computation, UCSD/INC/SCCN, La Jolla, CA; [5]Gettysburg Col., San Diego, CA

Abstract: Sharing data in standardized, reproducible formats enables powerful mega-analysis that advances neuroscience and informatics. In particular, in the clinical setting of epilepsy research which must deal with many different data formats acquired and analyzed using various software packages, the standardization of clinical terminology holds great potential. The Brain Imaging Data Structure (BIDS) has moved these standardization efforts forward for neuroimaging data. Within BIDS, there are clearly defined extensions for combining many different data types acquired in neuroimaging studies. The Intracranial Electroencephalography (iEEG) extension standardizes the data and metadata storage and the description of events during an iEEG recording. Additionally, BIDS has accepted the Hierarchical Event Descriptors (HED) system for detailed data and experiment event annotations. The new HED-3G schema library concept gives researchers the option to extend the base HED schema vocabulary by supporting the use of specialized vocabularies to describe events of specific interest to their field adequately. In this study, we developed a HED schema library for the Standardized Computer-based Organized Reporting of EEG (SCORE). SCORE is a textual description now implemented in commercial software for annotating EEG and ictal clinical events using standardized terms to create a standardized report. Our SCORE implementation in HED tackles these textual reports' lack of machine readability and makes SCORE available for and machine-readable by open-source software. To further make epilepsy terms available within BIDS, we use the HED convention to enrich BIDS datasets with epilepsy classification and seizure onset zone terms. These efforts, including a HED schema library for the SCORE standard to annotate events and features, including epilepsy classification and seizure onset zone, support the machine-readability of clinical annotation. These tools can be used by many researchers worldwide alongside other standard machine-readable formats for data sharing using standard definitions, to reduce errors in clinical evaluations, and to perform advanced mega-analyses, ultimately advancing the understanding of the human brain.

Title: Extending HED-3G event annotation using Library schemas

Authors: *S. MAKEIG[1], D. Q. TRUONG[2], A. DELORME[3], K. A. ROBBINS[4];
[1]Inst. for Neural Computation, UCSD, La Jolla, CA; [2]Dept. of Electrical and Computer Engin., [3]Inst. for Neural Computation, Univ. of California San Diego, La Jolla, CA; [4]Computer Sci., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: A major current gap in standards for storing and sharing any neuroimaging time series data is a system for detailed description of experiment events. The Hierarchical Event Descriptor (HED) system, first proposed a decade ago by Nima Bigdely-Shamlo (2012), has recently undergone a major developmental revision to HED-3G (K. Robbins, this meeting), whose architecture and syntax is now based on a root schema (set of supported terms) and syntax, plus a provision for extending the annotation vocabulary established by the root schema using specialized HED Library Schemas. HED Library schemas are designed to eliminate the need for the root HED schema to grow unwieldy, and to promote incorporation of maximally efficient and accepted sets of terms for use by the relevant research communities who build and maintain them. Thereby, HED-3G can be made suitable for annotating all types of time-series data and experiments. For example, annotations of neuroimaging datasets recording brain activity during performance of language tasks will require terms such as noun, verb, dependent-clause, etc., defined in a Language library schema. One HED library schema under development incorporates terms from the international standard SCORE vocabulary for clinical reporting of human scalp EEG data features (T. Pal Attia, this meeting), including terms such as ‘sleep spindle’, ‘interictal spike’, ‘alpha burst’, etc. Four more HED library development projects are now planned or underway: one for experiments involving viewing Moving-Pictures, a second for annotating events in Story-Narratives (presented in either text, audio, or audiovisual formats), a third for annotating Spatial-Relationships, and a fourth for describing Task-Design. Other research community areas needing development include: Human-Anatomy, Health-Disease, Human-Kinematics, Rodent-Kinetics, Sport, Virtual-reality, Music, Driving, etc. HED-3G is designed to work efficiently with data stored per the BIDS (Brain Imaging Data Structure) or other archiving frameworks. As the amount of shared, well-annotated neuroimaging data accumulates, the foreseen rewards of identifying new information by applying machine learning and related methods to large, inhomogeneous neuroimaging data collections can be realized. Leveraging this technology to apply statistical machine learning methods to large collections of well-annotated neuroimaging data, cognitive neuroscience researchers should be able to identify yet unknown patterns of behavior-related brain dynamics and apply the results in healthcare and other application areas.

Title: Rapid spatiotemporal analysis of astrocytic calcium dynamics using deep learning

Authors: *J. BONATO[1,2], S. CURRELI[1], S. ROMANZI[1,3], T. FELLIN[1], S. PANZERI[4,1];
[1]Italian Inst. of Technol., Genova, Italy; [2]Dept. of Pharm. and Biotech., Univ. of Bologna, Bologna, Italy; [3]Univ. of Genova, Genova, Italy; [4]Dept. of Neural Information Processing, Ctr. for Mol. Neurobio., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Astrocytic intracellular calcium dynamics convey key information about both local synaptic function and distributed activity of neuronal networks. However, available methods to analyze astrocytic calcium data are slow and they extensively rely on user-defined parameters, limiting reproducibility and scalability of the workflow and preventing closed loop experimental approaches. Moreover, automated segmentation methods for the analysis of neuronal calcium signals cannot be readily applied to the segmentation of astrocytic calcium dynamics, because of the intrinsic anatomical and functional differences between neurons and astrocytes. Therefore, the development of a fast, precise, and fully automated image segmentation method to analyze astrocytes calcium dynamics is of utmost importance. Here, we present Rapid Astrocytic Spatio-Temporal Analysis (RASTA), a novel software for spatiotemporal semantic segmentation of astrocytes. RASTA combined deep learning algorithms with feature engineering of calcium data and operated without human intervention. In two-photon calcium imaging movies from *in vivo* recordings, RASTA achieved fast and precise identification of astrocytic cell somata, processes, and cellular domains showing correlated calcium dynamic. We validated RASTA on multiple two-photon imaging datasets against human manual annotation, obtaining near-human performance in astrocyte detection and segmentation. Moreover, when detecting and segmenting astrocytic regions of interests RASTA performed better compared to state-of-the-art algorithms for the analysis of astrocytic and neuronal calcium imaging data. Overall, RASTA is an end-to-end analytical tool providing fast, automated, and accurate semantic segmentation of astrocytes two-photon imaging data, which will facilitate the analysis of astrocytic calcium signals *in vivo* and will enable new experimental approaches.

Title: Comparison of manual, semi-automatic and fully automatic counts of immunostained neurons in mouse brains

Authors: *P. A. DELGADO[1], K. B. SANCHEZ[1], A. ANDERSON[1], R. H. PATEL[1], S. S. ALAHMARI[1,2,3], D. B. GOLDGOF[2], L. O. HALL[2], P. R. MOUTON[1,2];

Abstract: Enhanced morphometric methods allow for accelerating hypothesis testing and preclinical drug studies focused on neurological disorders and mental illnesses. In this study, we assessed the performance of fully manual, semi-automatic and fully automatic methods for quantifying total number of neurons in digital images from an anatomically well-defined region of the mouse brain. Stacks of digital images 1-um apart (disector stacks) were automatically collected at systematic-random locations in the neocortex (NCTX) of NeuN-immunostained sections from the Tg4510 transgenic mouse model of tauopathy (n=3) and age- and sex-matched littermate controls (n=3). Manual stereology-based estimates of total neuron number in NCTX were done by trained technicians counting (clicking on) neurons while scanning through the digital planes of each disector stack [i.e., manual optical disector (MOD)]. These MOD counts provided the gold standard for assessing the performance of 5 methods applied to extended depth of field (EDF) images created from the same disector stacks, including two automatic methods [deep learning (DL) and adaptive segmentation algorithm (ASA)]; two semi-automatic methods (DL, ASA) each followed by manual correction for over-counts (false positives) and under-counts (false negatives); and one Active DL approach in which images from automatic DL counts were user-corrected and the corrected images used for further training of the DL model. Manual counts on disector videos created from disector stacks were compared for accuracy, inter-rater agreement and throughput efficiency to neuron counts using MOD on the same disector stacks. Overall, there was a significant 61% difference in mean total number of NeuN-immunostained neurons in NCTX of Tg4510 mice compared to non-Tg controls ($p < 0.02$). The DL-based semi-automatic and fully automatic methods showed comparable results, but with >5x and >10x enhanced efficiency, respectively, as compared to neurons counts using the MOD. At an optimal speed of 1 frame per second, disector videos allowed for neuron counts with 100% agreement to the MOD method in less than half the time. We conclude that DL-based stereology counts of immunostained neurons on digital images can achieve comparable results to manual stereology on digital images with substantially higher efficiency and without the need for labor-intensive, subjective manual counting by well-trained technicians. An added benefit of digital images for stereology studies is that a record of cells counts is created for validation, training, and archival purposes.

Abstract: There is a large and growing need for computer-assisted methods to accelerate the testing of hypotheses associated with neuroinflammation in normal aging, neurological disease, neurotoxicology, and other conditions. The combination of artificial intelligence-based deep learning (DL) and unbiased stereology provide an innovative strategy for accurate, reproducible, and high-throughput quantification of stained biological structures in tissue sections. Previous work emphasized the automatic optical fractionator: automatic detection (cell-level segmentation) with fractionator-based estimation of total cell number at high magnification (100x). Here we use DL to automatically classify global changes in total number of Iba-1 immunostained microglial cells based on training with cell densities at low magnification (20x). Specifically, we tested if a DL model could predict high verses low total number of microglial cells in the neocortex (NCTX) of the Dp16 mouse model of Down syndrome (i.e., trisomy Hsa21) in which the APP gene is overexpressed versus sex- and age-matched littermate controls. A computerized stereology system (Stereologer, SRC Biosciences, Tampa, FL, USA) was used to quantify relatively high (n=7) or low (n=7) total number of microglia cells using the ordinary (manual) optical fractionator at 100x magnification. Second, we imaged a minimum of 380 low magnification fields of microglia cells at systematic-random locations in a minimum of 15 sections through NCTX of each brain (2660+ total images with low and high mean cell densities). After center cropping to remove lens distortion and regions outside the NCTX, the images were used to train a DL model evaluated by cross validation using n=6 cases of each group for training with 1 case from each group for validation. All training images were labeled according to the total microglial estimate in NCTX (i.e., global label). For automatic classification, if the DL model predicted over half the images from a brain belonged to one class (high or low density), the brain was assigned to that class. The findings showed the DL model correctly predicted the global class (high vs. low number) of microglial cells in 80% of the cases (i.e., 11 of 14 correct, 78.6%) based on microglial cell densities in low magnification images. Thus, a DL model trained with low magnification images of microglia cells can automatically predict two extremes (low vs. high) for the total microglial cell number in NCTX without cell-level segmentation or manual stereology at high magnification. Further accuracy and a more robust model are expected after training with more low-, middle-, and high-density images from additional animals.

Title: A Novel Automatic Approach for Total Neuron Counts using the Unbiased Disector Method

Authors: *P. DAVE[1], D. GOLDGOF[1], L. O. HALL[1], Y. KOLINKO[2], K. ALLEN[1], S. ALAHMARI[3], H. MORERA[1], G. DENHAM[1], S. GALVEZ[1], A. BECKER[4], R. ALBAY[4], W. C. MOBLEY[4], P. R.

Ctr., Charles Univ., Pilsen, Czech Republic; [3]Dept. of Computer Sci., Najran Univ., Najran, Saudi Arabia; [4]Univ. of California at San Diego, San Diego, CA; [5]Stereology Resource Ctr. (SRC Biosciences), Tampa, FL

Abstract: Disector-based stereology methods provide an unbiased approach for quantifying the number of well-stained biological objects in tissue sections. Artificial intelligence (AI) may be used to automate these approaches for improved efficiency, repeatability, and reduced error and subjectivity due to human factors. Current state-of-the-art methods for AI-based cell quantification rely on Extended Depth of Field (EDF) images created by converting a disector volume containing a z-axis stack of digital images (disector stack) into a synthetic 2D image showing all stained objects (neurons) at their maximal plane of focus. A limitation of all cell counting methods (AI or non-AI) on EDF images is the possibility of under-counts due to masking, i.e., overlapping cells or smaller cells occluded by larger cells in the z-plane. Here we propose an automatic disector-based approach using a multichannel input and multichannel output (MIMO) U-Net deep learning (DL) model. The MIMO model avoids masking errors by automatic z-axis scanning through the individual planes of each disector stack combined with cell counts obtained using the optical disector principle and unbiased counting rules. Each focal plane (image) in a disector stack serves as an input channel to the DL model and each segmented cell is counted only once (in its best focus plane) as output. Like the manual optical disector, the MIMO approach automatically counts each cell through a known tissue volume without bias due to the cell's size, shape, or orientation. We applied the MIMO model to counting neurons in tissue sections through the neocortex (NCTX) of the Dp16 mouse model of Down syndrome (i.e., trisomy Hsa21) in which the APP gene is overexpressed versus sex- and age-matched littermate controls. The results show similar counts to manual disector counts of the same disector stacks by multiple experts, with higher repeatability and improved throughput efficiency than manual counts. Furthermore, the proposed approach is highly efficient in terms of computational cost and training data requirements. Moreover, it requires no additional expert time for Ground Truth preparation as compared to the state-of-the-art AI-based cell counting. We present results for the total number of NeuN-immunostained neurons in the mouse NCTX together with results for tuning the same model for automatic counts of another population of immunostained neurons (ChAT-immunostained neurons in the basal forebrain). Thus, automatic quantification of immunostained neurons using a combination of DL and unbiased stereology can be achieved with comparable or enhanced accuracy compared to manual counts using disector-based methods.

Title: Enhancements to the NWB Data Standard and Software Ecosystem for Neurophysiology

Authors: *R. LY[1], P. M. BAKER[2], B. DICHTER[3], A. TRITT[1], M. AVAYLON[1], S. GHOSH[4], L. NG[2], O. RUEBEL[1];
[1]Lawrence Berkeley Natl. Lab., Berkeley, CA; [2]Allen Inst. for Brain Sci., Seattle, WA; [3]CatalystNeuro, Benicia, CA; [4]MIT, Cambridge, MA

Abstract: Neurodata Without Borders (NWB) is a community-driven data standard that provides neuroscientists with a common format to share, archive, use, and analyze neurophysiology data. NWB supports a wide range of neurophysiology data and metadata, including from intracellular and extracellular electrophysiology and optical physiology experiments. After the initial release of NWB 2.0 in 2019, we have made significant enhancements to the standard and software ecosystem. First, to enhance FAIR data sharing, we have extended NWB to support the integration of ontologies and

controlled vocabularies. Users can now associate metadata/data in an NWB file, such as the subject's species and genotype, with persistent identifiers in external ontologies, such as the NCBI Taxonomy database and the Mouse Genome Informatics database. Second, we have extended NWB to formalize the description of the hierarchical organization of intracellular electrophysiology experiments. Users can now store metadata about simultaneous and sequential recordings, repetitions, and experimental conditions in a structured tabular way in NWB. Third, because neurophysiology data is often large, downloading complete NWB files from online archives can be expensive and ultimately hinder reuse of valuable data. To address this challenge, we have developed new methods for streaming select data and metadata from NWB files stored in the cloud. Users can now open NWB files from S3 data stores (e.g., the DANDI data archive) remotely using standard NWB APIs, and then load selected slices of large NWB data arrays from the DANDI S3 bucket for interactive exploration, visualization, and analysis in the cloud, without having to download the entire file. Finally, we present our progress toward dissemination and integration of NWB across the neurophysiology community, and our vision for NWB over the next five years.

Title: Modeling Patch-seq experiment data using ontologies in NWB

Authors: *P. M. BAKER[1], R. LY[2], M. AVAYLON[2], A. TRITT[2], P. RAY[1], T. GILLESPIE[3], O. RUEBEL[2], L. NG[1];
[1]Allen Inst. for Brain Sci., Seattle, WA; [2]Computat. Res. Div., Lawrence Berkeley Natl. Lab., Berkeley, CA; [3]Neurosci., UCSD, La Jolla, CA

Abstract: The term 'Patch-seq' refers to the combined application of whole-cell patch clamp recording and single-cell RNA-sequencing (scRNA-seq) to individual cells which can additionally include high resolution morphological imaging and reconstruction. Patch-seq links cell structure and function; correlates cell phenotype with gene expression profiles; and automation of the technique has facilitated large-scale collection of data for cell census and atlasing efforts such as the BRAIN Initiative Cell Census Network (BICCN: https://biccn.org). Patch-seq datasets shared online, including those at the BICCN and through the Allen Institute online portal (https://portal.brain-map.org), are of great value to the broader community. To enable reuse, it is essential to conform with FAIR principles through the use of common controlled vocabularies, integration of consensus knowledge in the form of ontologies, and robust links to definitions, reagents, protocols, and associated datasets through persistent identifiers (PIDs). Neurodata Without Borders (NWB: https://nwb.org) is a unified data format that provides a comprehensive standard for storing electrophysiological data including the intracellular recordings generated by Patch-seq. As a

community standard for data and metadata storage, NWB is committed to adhere to the FAIR principles for data sharing. Rigorous descriptions of experimental methods and other metadata are critical for facilitating the uses of publicly shared data, including replicating protocols, applying novel analysis techniques, and enabling dataset comparison and search. In this work we extend the NWB standard to include links to the external resources and PIDs that are a critical component of FAIR data sharing, with the goal of facilitating the reuse of large datasets such as the Patch-seq data stored at the DANDI archive (https://dandiarchive.org). We implemented schema extensions to NWB to support integration of external resources and PIDs and will demonstrate their use with examples from Patch-seq datasets hosted at DANDI. The new schemas include data structures for storing genotype metadata including animal strains, gene loci, and alleles that are essential for describing experimental subjects. We also extended NWB to use a recently developed stimulation ontology to support rigorous description of the stimulus waveforms used in these experiments. Finally, we show how spatial location metadata (coordinates, structural annotations, and anatomical terms) from reference atlases can be stored in NWB.

Title: Induced pluripotent stem cell-derived neural organoids generated on synthetic hydrogels for assessment of neural inflammation and toxicity

Authors: *J. ZIMMERMANN, W. RICHARDS, S. VISURI, C. LEBAKKEN;
Stem Pharm Inc, Madison, WI

Abstract: While animal models have value in drug discovery and toxicology applications, they also have many limitations including translation, cost, and ethical concerns. There is a critical need to develop advanced neural microphysiological systems (MPS) that complement or reduce the use of animal models. Most current *in vitro* models, however, do not adequately reflect the complexity of non-neural cell types and cell-cell interactions found within neural tissue. To address these limitations, Stem Pharm has developed synthetic hydrogels that enable the formation of complex, reproducible iPSC-derived neural organoids containing microglia and vascular cells. Organoids are generated in 96-well plates and ready for screening within one month and high intraclass correlation and low coefficients of variation are observed between biological replicates through RNA-seq analysis. The organoids are cell-type diverse; single-cell RNAseq analysis demonstrates organoids are comprised of multiple neuron types, astrocytes, microglia, and endothelial cells. Microglia express over 95% of core signature gene sets of primary human microglia and microglial activation within organoids was validated through stimulation with

lipopolysaccharides, interferon gamma, TGFβ & IL-10, or IL-4 & IL-13 to activate inflammatory or alternatively activated phenotypes. To demonstrate application for toxicology screening, organoids were subjected to a screen of known neurotoxins: chlorpyrifos, an organophosphate insecticide; lead acetate, known to cause developmental defects; valproic acid (VPA), an anti-convulsant; and PLX-3397 a CSF-R inhibitor. Transcriptional data and differential expression (DE) analysis between treatment groups was utilized to identify gene ontology (GO) sets affected by compound treatment. We detected perturbations in expected pathways including neural development, axon guidance, and mitochondria upon exposure to chlorpyrifos, depletion of microglia with PLX-3397 treatment, and response to metal ion and toxin and metallothionine production to lead treatment. Lead and VPA treatment also resulted in downregulation of GO sets involved in inflammatory and innate immune responses and microglial-specific genes, demonstrating the importance of using multicellular systems to assess toxicities. These preliminary data demonstrate the promising application of Stem Pharm's neural organoids for toxicology screening in complex multicellular systems and broader potential for facilitating translation between pre-clinical and clinical discovery and development.

Title: Human iPSC-derived brain organoids regional specification in a mesofluidic device

Authors: *S. SCUDERI[1], T.-Y. KANG[2], A. JOURDON[1], L. YANG[2], A. LEVCHENKO[2], F. M. VACCARINO[1,3];
[1]Child Study Ctr., [2]Biomed. Engin. and Yale Systems Biol. Inst., [3]Neurosci., Yale Univ., New Haven, CT

Abstract: Morphogen gradients play a critical role in directing cell fate specification during development but are not yet implemented by current *in vitro* human organoid models. Among these, the WNT and SHH are crucial for the development of posterior and ventral regions in the brain. Human brain organoids recapitulate early cellular and molecular mechanisms of brain development as well as histological features (e.g. ventricle-like structures), but they lack spatial topographical organization. Here we introduce a new method to model early neural tube patterning by using human induced pluripotent stem cells (iPSC)-derived organoids exposed to continuous and spatially defined gradients inside a mesofluidic chamber (5c-orthoDev). We hypothesized that the introduction of oriented signaling centers over a culture system of brain organoids would allow the organized specification of their identity in a distance-dependent manner. Our gradient patterning device has the advantage of not relying on externally driven

flow, but only on short-range diffusion, simplifying the approach and offering a wide range of applications. We also developed a compatible hydrogel matrix which ensures both the spatial stability of the organoids exposed to orthogonal gradients and allows their transfer in standard open cultures after the regionalization. We demonstrate that this brain-on-a-chip platform serves to spatially control cellular fate decisions. We used a potent activator of Wnt signaling, CHIR99021, and, on a perpendicular axis, the canonical ventral morphogen SHH in our 5c-orthoDev device to generate brain organoids spatially defined not only along the antero-posterior axis, as demonstrated by gene networks specific for forebrain (FOXG1, LHX2, SIX3), midbrain (WNT1, EN1) and hindbrain (GBX2, IRX3), but also along the dorsal-ventral axis as demonstrated by dorsal (GLI3, PAX6) and ventral markers (DLX1, NKX2.1 and NKX6.1). This practical and versatile device will facilitate research on factors and molecular cascades that mediate primary brain and neural tube patterning, as well as secondary organizing centers formation, like the isthmic organizer. Finally, the ability to separatly obtain multiple brain regions, at once, in a simple protocol will further facilitate the generation of assembloids and the investigation of the connectome in normal and diseased iPSC lines.

Title: Generation of cerebral organoids from dental pulp stem cells to model neurodegeneration

Authors: A. GUTIERREZ-MALACARA, M. SILVA-LUCERO, G. LOPEZ-TOLEDO, *M. CARDENAS-AGUAYO;
Physiology, Sch. of Med., Natl. Autonomous Univ. Mexico, Ciudad de Mexico, Mexico

Abstract: Introduction: Cerebral Organoids (CO) are a recently described 3D-cell cultures that shows more complex process in an *in vitro* environment as compared to monolayers. CO mimic molecular changes seen in diseases such as Alzheimer´s disease. Most of the CO are generated from Induced Pluripotent Stem Cells (iPSC) or human Embryonic Stem Cells (hESC). However, Dental pulp Stem Cells (DPSCs) could be a suitable source to generate CO, with the advantage, to model neurodegeneration when obtained from affected patients. DPSCs have proved to be capable of differentiating into several phenotypes, including neuronal. The aim of this study was to differentiate DPSCs obtained from a healthy donor into an organoid-like structure with a neuronal phenotype. **Methods:** The DPSCs were obtained by dissociation of the dental pulp of a healthy 46 years old female, with a colagenase-dispase mix at 37ºC, isolated and cultured. The cells phenotype was characterized by Western-Blot, RT-PCR and

immunofluorescence staining. We placed the DPSC into low-adherence wells for 6 days in a DMEM/F12 + thiazovivin 50 mM, bFGF 4ng/mL, FBS 20%, Glutamax 200x, MEM-NEAA 1:100, 2-mercaptoethanol 100 µm and murine LIF 10 µg/mL until cell aggregation into embryoid-like structures. Thereafter, neural induction was carried out in DMEM/F12 + N2 1%, Glutamax, MEM-NEAA and heparin 1 µg/mL for 48 hours, and then transferred into a Geltrex matrix to form droplets which were placed into a cerebral organoid differentiation medium composed by DMEM/F12, Neurobasal medium 50%, N2 1%, ITS 0.01%, Glutamax 1x, MEM-NEAA 1%, penicillin-streptomycin 1x, 2-mercaptoethanol and B27 without retinoic acid 1x. Finally, the obtained cerebral organoid-like structures were immunostained against MAP2, NeuN, β-III Tubulin and Tau. **Results:** We characterized the DPSC phenotype by detecting pluripotential markers: OCT4, Actin, Nanog, mesenchymal markers: CD105, CD73 and the neuronal marker: β-III Tubulin which is always present in the DPSCs lineage, as well as the lack of hematopoietic markers: CD14, CD34 and CD45. We obtained CO-like structures from de DPSCs after 35 days of the differentiation protocol and detected NeuN, Map2, β-III Tubulin and Tau. **Conclusion:** Our results suggest a potential use of DPSCs CO to model neurodegenerative disease, instead of iPSC or hESC with the benefits of a simple and less expensive protocol, thus DPSCs could reflex the molecular changes associated to aging, such as DNA damage, free radicals, shortening of telomeres an micro RNA's regulation mechanisms that cannot be studied using hESC. Further studies need to be done to fully characterize this model and its potential clinical applications.

Title: Myelination and inflammation cortical network platform for high content screening: 3D MICro-brains

Authors: M. VAN DER KROEG[1], S. BANSAL[1], V. WONG[2], D. A. EGAN[2], S. A. KUSHNER[1], *F. M. S. DE VRIJ[1];

Abstract: Recent developments in induced pluripotent stem cell (iPSC) technology make it possible to implement cell-type-specific human cell culture models for research and drug development. Here, we present a 3D model with human neural networks that recapitulate the complex structure of the frontal brain in early development. These micro-brains (3D MICro-brains) reduce the modelling of the frontal cortex to a millionth of the normal brain volume. The platform contains all major brain cell types: functional neurons and glia in layered radial structures, along with astrocytes, myelin-producing oligodendrocytes and microglia. The 3D MICro-brain differentiation protocol is based on our recently

published widely recognized protocol to derive functionally mature synaptic networks of human iPSC neurons. Briefly, iPSCs are differentiated to form neural progenitor cells (NPCs) using an embryoid-based method creating NPCs with a frontal cortical identity. Importantly, this protocol was specifically designed to create both neuronal and glial cell types from a common iPSC-derived forebrain neural progenitor, without the need for rodent astrocyte co-culture. The result is a neural network that is fully derived from a single individual. We have now expanded this protocol to develop functional adherent cortical organoids in standard 384-well plates. These cortical organoid cultures develop spontaneously from NPCs and show radial outgrowth, including neurodevelopmentally timed formation of segregated cortical layer markers, highly reminiscent of early human neurodevelopment of the cerebral cortex. We have now further enhanced this model by implementing human iPSC-derived myelinating oligodendrocytes and functional microglia that fully integrate into the structures, creating the 3D MICro-Brain platform that is suitable for the study of myelination and inflammation in human adherent cortical brain organoids. Due to its scale and reproducibility, the 3D MICro-brain platform is ideally suited for automated high-content (HC) imaging. Together with Core Life Analytics, we have developed a robust and practical HC workflow that combines automated microscopic imaging, image analysis and advanced data analytics for phenotypic studies. This platform will be useful for toxicological and nutritional screening, as well as therapeutic target and drug development.

Abstract: Brain organoids are in vitro three-dimensional (3D) self-organized neural structures, which have been used for several applications, including the study and mimicking of brain development, the modeling of neuronal disorders and their employment in preclinical drug screening tests. A fine in vitro modulation of specific molecular cues enabled the generation of a broad range of cerebral organoids,

either resembling macro brain identities (e.g. whole-brain organoids) or specific brain regions (e.g. cortical organoids). So far, organoids were obtained from human induced pluripotent stem cells (hiPSCs) but the high batch-to-batch variability, long differentiation time (10-20 weeks), and high cost required for production limit their use for standardized large-scale studies. We developed, for the first time, a highly standardized, reproducible and fast (5 weeks) murine brain organoid model starting from multipotent neural stem cells (NSCs) isolated from embryonic subgranular zone (SGZ). Global transcriptome, protein expression, and cell metabolism data showed that murine brain organoids progressively differentiate trough defined early, intermediate, and mature stages. During differentiation, brain organoids acquire a self-organized neural structure with a compact and interconnected neuronal layer at its edge. Functional neuronal properties measured by electrophysiological techniques (patch-clamp and MEA recordings), transsynaptic tracing and calcium imaging analysis revealed that organoids own functional neurons organized in 3D networks with synaptic connections. Furthermore, we validated the potential of murine brain organoids to acquire a specific brain-region signature; by adding the morphogen WNT3a, we were able to generate brain organoids enriched in neurons with CA3 hippocampal region signature. Overall, our results showed the establishment of a novel fast, robust and reproducible murine 3D in vitro brain model that may represent a useful tool for high-throughput drug screening and disease modelling. The possibility to obtain functional mouse hippocampal organoids could be further exploited as an innovative cell source for transplantation procedures and regenerative purposes in pathological conditions, such as epilepsy.

Abstract: Cortical organoids, three-dimensional neuronal cell cultures derived from human induced pluripotent stem cells, have recently emerged as promising models of human brain development and dysfunction. However, lack of oxygen and nutrients often renders the organoid core necrotic, interfering with further maturation. Therefore, organoids have been implanted into mouse brain, where they were vascularized, which enabled further growth and development, including generation of functional synapses between xenograft and host neurons (Mansour, et al., 2018, Nat Biotech 36: 432-41). This approach enables longitudinal studies, for which effective multimodal recording technologies are crucial. Here, we demonstrate multimodal monitoring of human cortical organoids transplanted into mouse cortex using transparent graphene microelectrode arrays and two-photon imaging. We implanted single organoids into the retrosplenial cortex of adult NOD/SCID mice, placed a graphene array bonded to coverglass on top of implant and surrounding host cortex, and monitored the implant using electrophysiology and two-photon imaging over 11 weeks. We performed recordings of both local field potentials and multi-unit activity during spontaneous activity and in response to sensory stimulation. As the implantation site is close to visual cortex, we were able to record electrical activity in host cortex and organoid implant in response to photic stimulation of the contralateral eye. Low-pass filtered signals followed the stimulation frequency, but we also observed a stimulus-locked frequency component at ~80 Hz. In high-pass filtered data, we observed spontaneous activity in host and implant and responses to individual light pulses, likely reflecting multi-unit activity. Isoflurane anesthesia of the host led to stronger suppression of ongoing gamma activity in the organoid implant than in surrounding host cortex. In two-photon imaging with intravascular Alexa 680-Dextran, we observed vessel regrowth within the implantation site. Imaging of organoid implants transduced with fluorescent protein-encoding adeno-associated virus before implantation showed sustained transgene expression over 11 weeks. We performed immunohistochemistry at the end of the study; staining of human cell nuclei revealed some variability in xenograft size across animals while staining of endothelial cells confirms vascularization of the implant. This novel combination of stem cell and neurorecording technologies provides a unique opportunity for comprehensive evaluation of the development, maturation, and functional integration of human neuronal networks within the mouse brain.

Title: Generating Neural Organoids with Anatomically Distinct Identities

Authors: *R. MOTAHER, J. TANCREDI, M. DERR, A. IBRAHIMI, B. SCOTT, R. E. JOSEPHSON, S. SHIN;
Res. and Develop., Thermo Fisher Scientific, Frederick, MD

Abstract: While organoid development is not new technology, generating neural organoids with specific developmental identities in an efficient manner remains a challenge. Previously we reported a protocol to generate organoids with hindbrain and midbrain specific identities using our established kit. Here we report a protocol to generate organoids with forebrain specific identity. While most protocols in circulation require over 40 days to generate neural organoids, we established a novel protocol to obtain cortical organoids with forebrain specific identity, within 28 days. Large scale PSC culture either in defined medium (Essential 8, Essential 8 Flex), or in enriched medium (StemFlex, StemScale) can be differentiated into a forebrain phenotype and maintained either in 2D or 3D configuration using this protocol. Our protocol is specifically designed to overcome the hurdle of excessive cell death during differentiation, especially for PSC cultured in defined media. In addition, this protocol utilizes fewer steps to obtain mature organoids, with fully optimized conditions designed to promote healthy and observable growth at each stage. First, PSCs are induced to form spheroids in PSC medium to reach 300-400 microns. Next, spheroids are specified to develop a forebrain identity in a two-step induction media. Finally, forebrain spheroids are differentiated to form mature cortical organoids with forebrain specific identity in Neuronal Maturation Medium. To confirm the phenotype, we designed a gene expression panel to verify forebrain, midbrain and hindbrain regions. After generating region specific organoids with respective phenotypes, their relative gene expression profiles were compared using this custom designed Taqman qPCR panels. In addition, to verify electrophysiological integrity of the neural organoids, we examined the ability of the differentiated forebrain organoids to fire action potentials. Our protocols demonstrate rapid, healthy growth of organoids grown from PSC cultured in multiple media systems, with mature organoids forming in as little as 21 days using a simplified protocol. This protocol completes a series generating organoids with specific developmental identities: forebrain, midbrain and hindbrain, verified by immunohistochemistry, qPCR panel testing and electrophysiology.

Title: Chronic optical stimulation of sparsely transfected cortical circuits induces homeostatic plasticity and neural clustering.

Authors: *B. LIU, M. J. SEAY, D. V. BUONOMANO;
Neurobio., UCLA, Los Angeles, CA

Abstract: Cortical computations emerge from the dynamics of neurons embedded in complex cortical circuits. Up-states are one of the best studied examples of emergent neural dynamics at both the experimental and computational levels. Typically, Up-states are defined as transient global dynamic regimes in which all neurons in a circuit are co-active and fire at a constant firing rate. This self-sustained firing is maintained by recurrently connected excitatory neurons, which, critically, is held in check through strong inhibition. Relatively little is known, however, about how Up-states can arise in a self-organizing manner, nor is it known if different subnetworks, or clusters can exist and differentially contribute to Up-states. Here we first show that chronic optical stimulation (24 - 48 hrs) of cortical organotypic networks in which most excitatory neurons express Channelrhodopsin2 (ChR2) produces a homeostatic downregulation of Up-state frequency. In chronically stimulated but sparsely transfected slices, paired recordings revealed differential activity patterns during Up-states in $ChR2^+$ and $ChR2^-$ neurons (3.2 ± 3.0 and 0.3 ± 0.5 Hz, respectively). These cell-specific changes in Up-state firing were associated with decreases in intrinsic excitability of the $ChR2^+$ neurons, and an apparent decrease in connectivity between $ChR2^+ \leftrightarrow ChR2^-$ pyramidal neurons. Furthermore, there was a decrease in the correlation of activity between $ChR2^+$ and $ChR2^-$ neurons, compared to controls. These results indicate that while Up-states are a global network-wide phenomenon, different populations of pyramidal neurons can exhibit different levels of activity during Up-states depending on their stimulation history. Computational models suggest that Up-states reflect bistable regimes, in which during the Up-state component, all neurons exhibit a steady-state firing rate (representing a fixed-point attractor). By incorporating the observed changes in intrinsic excitability into a two-population model we observed that changes in the gain and threshold of intrinsic excitability were sufficient to account for the decrease in Up-state frequency. Ongoing simulations with multi-unit models suggest that intrinsic changes in a subpopulation of neurons are sufficient to account for the observed decrease in firing rate of the $ChR2^+$ cluster. Together our results suggest that imposing differential correlations through chronic optical stimulation can generate partial decoupling of cortical subnetworks, potentially leading to neural clustering.

Title: Endocannabinoid Adaptation During Homeostatic Scaling Down

Authors: *M. YE[1], S. MONROE[2], S. M. GAY[1], M. L. ARMSTRONG[3], D. YOUNGSTROM[1], F. URBINA[1], S. L. GUPTON[1], N. REISDORPH[3], G. H. DIERING[1];

Abstract: Homeostatic regulation of neuronal activity in response to hyperexcitation is critical to maintaining network stability and functional signaling. Endocannabinoids (eCBs) are bioactive lipids synthesized in the post-synaptic compartments in response to neuronal activities to activate pre-synaptic cannabinoid receptor CB1. Therefore, the eCB system is well suited to coordinate pre- and post-synaptic activity. However, the role of the eCB system remains elusive in homeostatic adaptation to neuronal hyperexcitation. We induced hyperexcitation in cultured rat cortical neurons with chronic bicuculline treatment (BCC), known to induce homeostatic scaling down. We combined western blotting with targeted lipidomics to investigate biochemical changes during neuronal adaptation to hyperexcitation over 48 hours. Neurons adapt to hyperexcitation by downregulating total fatty acid amide hydrolase (FAAH), upregulating N-acylethanolamines (NAEs) and surface CB1. We used multi-electrode array and live-cell imaging (iGluSnFR) to investigate spontaneous synchronous network activities. CB1 antagonism suppresses spontaneous glutamatergic network events. Our data shows that coordinated adaptation of the eCB system supports homeostatic plasticity.

Title: Role of transmitter plasticity in fear generalization

Authors: *H. LI[1], W. JIANG[1], C. CHEN[2], D. W. CLEVELAND[2], N. C. SPITZER[1];
[1]UC San Diego, Kavli Inst. for Brain and Mind, La Jolla, CA; [2]Dept. of Cell. and Mol. Med., Univ. of California San Diego; Ludwig Inst., La Jolla, CA

Abstract: Fear is an essential emotion for survival. Acquired fear responses can be specific to the cue or context associated with an aversive stimulus (conditioned fear) and/or spread to other environmental cues or contexts (generalized fear). Fear generalization can be harmful when fear responses are exaggerated and inappropriate to the threat of a novel environment. However, little is known about the cellular and circuit mechanisms by which fear is generalized. We have studied the transmitter plasticity underlying fear generalization in the adult mouse brain. Two weeks after intense footshock stress, a subset of serotonergic (5-HT) neurons in the lateral wings of the dorsal raphe (lwDR) of shocked mice were found to have switched their co-transmitter from glutamate/VGLUT3 (vesicular glutamate transporter type 3) to GABA/GAD67 (glutamic acid decarboxylase 67). Strikingly, by examining post-mortem human brain tissue, we found a similar switch from VGLUT3 to GABA in the 5-HT^{lwDR} neurons of PTSD subjects

compared to age-matched controls. To investigate whether the loss of VGLUT3/glutamate and gain of GAD1/GABA occur in the same neurons, we used a VGLUT3-Cre transgenic mouse line crossed with a Rosa-mCherry reporter line to permanently label VGLUT3+ neurons. We found more mCherry+GAD67+VGLUT3- neurons in shocked mice compared to controls, demonstrating the occurrence of the transmitter switch in single neurons. To study the causal relationship between the transmitter switch and generalized fear, we used Cre-dependent adeno-associated viruses (AAVs) to express exogenous VGLUT3 and/or suppress expression of GAD1 in 5-HT^{lwDR} neurons and tested their impacts on the stress-induced fear responses. Our data show that expression of exogenous VGLUT3 partially reduced generalized fear and expression of GAD1 entirely erased it. We then investigated whether fluoxetine, a selective serotonin reuptake inhibitor (SSRI) that is a first-line pharmaceutical treatment for fear disorders, affects transmitter switching and fear. Our results show that prompt delivery of fluoxetine right after the shock blocks both the glutamate-to-GABA switch in the lwDR and generalized fear responses. When the delivery of fluoxetine was delayed, e.g. starting two weeks after the shock, no effect was seen. We are now using AAVs to create a similar switch in the 5-HT^{lwDR} neurons to determine whether this will suppress the effect of fluoxetine in blocking the switch and fear generalization. This study is expected to identify brain plasticity underlying fear generalization and provide mechanistic understanding of the action of a pharmacological treatment for fear disorders.

Title: Homeostatic-like potentiation of the aversive habenulo-raphe pathway in an animal model of post-stroke depression

Authors: *S. MAILLÉ[1], S. D. GEDDES[1], D. LEMELIN[2], S. ASSADZADA[2], J.-C. BEIQUE[2];
[2]Cell. and Mol. Med., [1]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Stroke is one of the leading causes of death and adult long-term disability across the world. Despite increasingly efficient rehabilitation programs, stroke survivors experience an unusually high incidence of depressive symptoms which, beyond the emotional suffering, also undermine recovery outcomes by reducing patient motivation levels. Human and animal studies have linked the incidence of post-stroke depression to the extent of prefrontal cortex (PFC) damage. We hypothesized that PFC stroke promotes the development of depressive phenotypes by triggering maladaptive network remodelling in mood-related networks. The PFC and the epithalamic lateral habenula (LHb) are limbic structures that send powerful, top-down axonal projections to the serotonergic dorsal raphe nucleus (DRN), a key

neuronal hub for mood regulation. We used viral, optogenetic and electrophysiological strategies to outline the functional architecture of the PFC and LHb projections to DRN. We found that an endothelin-1-mediated stroke in PFC triggers a time-dependent remodeling of the glutamatergic input from the LHb to DRN 5-HT neurons. This remodeling resulted in an increased AMPAR/NMDAR ratio, insertion of GluA2-lacking AMPARs and an increased quantal size and faster decay kinetics of quantal excitatory postsynaptic currents. Because the LHb-DRN pathway is believed to encode emotional features such as aversion and anticipation of threat, a maladaptive, homeostatic-like upregulation of this pathway may contribute to the depressive symptomology following stroke.

Title: Disruption of developmental synaptic plasticity contributes to hypersynchrony of the visual circuit in a mouse model of infantile neuronal ceroid lipofuscinosis

Authors: *K. KOSTER[1], E. FLORES-BARRERA[1], T. NGUYEN[1], A. NIQULA[1], L. NORIEGA-GONZALEZ[1], S. COLOGNA[1], K.-Y. TSENG[2], A. YOSHII[3];
[1]Univ. of Illinois at Chicago, Chicago, IL; [2]Anat. and Cell Biol. / Neurosci., Univ. of Illinois At Chicago - Col. of Med., Chicago, IL; [3]Dept of Anat. & Cell Biol., UIC, Chicago, IL

Abstract: Developmental synaptic plasticity is the basis for long-term brain function and hinges on the function of postsynaptic α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs). Protein palmitoylation is an understudied reversible lipid posttranslational modification that regulates the trafficking of many synaptic proteins, including all AMPAR subunits (GluA1-4) and the postsynaptic scaffold A kinase anchor protein 5 (Akap5). While understanding of palmitoylation has recently improved, less is known about protein depalmitoylation. Importantly, mutation of the depalmitoylation enzyme palmitoyl-protein thioesterase 1 (PPT1) causes Infantile neuronal ceroid lipofuscinosis (CLN1), a devastating pediatric neurodegenerative disorder characterized by seizure and death by age 5. However, how synaptic protein depalmitoylation by PPT1 regulates developmental plasticity and how its loss causes neurodegeneration in CLN1 is not understood. Here, we studied visual cortex plasticity in the *Ppt1*$^{-/-}$ mouse model to decipher how lack of protein depalmitoylation drives neuronal dysfunction in CLN1, with a particular focus on synaptic scaling, a form of homeostatic plasticity important for regulating neuronal population excitability. *Ppt1*$^{-/-}$ cultured neurons fail to downscale synapses and respond excessively to induction of synaptic upscaling, incorporating an increased number of calcium-permeable (CP)-AMPARs at synapses compared to wild-type (WT) cells. Amplified recruitment of CP-AMPARs was correlated with increased GluA1 palmitoylation solely in *Ppt1*$^{-/-}$ upscaled neurons. Further,

inducing synaptic upscaling in the visual cortex by dark rearing *Ppt1*$^{-/-}$ animals exacerbated CLN1 progression. Performing a palmitoyl-proteomic screen revealed excessive palmitoylation of Akap5, protein kinase A, and calcineurin, which regulate synaptic scaling of CP-AMPARs, in *Ppt1*$^{-/-}$ visual cortical synaptosomes. Akap5-calcineurin signaling is also linked to a neuroinflammatory response via nuclear factor activated in T-cells (NFATc3). Not only was this pathway sensitized in *Ppt1*$^{-/-}$ cultured neurons, but neuroinflammatory activation of microglia was accelerated in dark reared (upscaled) *Ppt1*$^{-/-}$ visual cortices. To evaluate the contribution of disrupted synaptic scaling to the visual circuit, we performed *in vivo* two-photon calcium imaging in awake mice. Intriguingly, layer 2/3 excitatory cortical neurons were hypersynchronous in *Ppt1*$^{-/-}$ animals. Together, these data point to a crucial role for protein depalmitoylation in developmental plasticity mechanisms whose disruption leads to circuit level dysregulation in CLN1.

Title: Dysregulation of protein metabolism in Angelman Syndrome

Authors: *F. ARIA, K. PANDEY, C. M. ALBERINI;
New York Univ., New York City, NY

Abstract: Angelman syndrome (AS) is a neurodevelopmental genetic disorder characterized by intellectual disability, speech and motor defects, sleep problems, and seizures. The mechanisms by which the genetic defects result in AS symptoms are still poorly understood, despite, in most cases, they appear to be linked to the loss of function of the maternal copy of ubiquitin-protein ligase E3A (UBE3A) which is located on the maternal chromosome region 15q11-13. By focusing on the hippocampus, a region critical for memory consolidation, here we show that maternal deletion of Ube3a (Ube3a m-/p+) in mice, which in fact reproduce most core symptom of AS, is accompanied by significant alteration of a hallmark mechanism of synaptic plasticity: the stimulus-dependent increase of *de novo* protein synthesis coupled to autophagic flux. We found that compared to wild type control mice (WT), AS mice have: i) a significant increase in hippocampal de novo protein synthesis, measured by *in vivo* Surface Sensing of Translation (SUnSET), ii) an accumulation of proteins involved in autophagy including LC3B, p62 and LAMP1, and iii) a blunted autophagic flux, in both basal conditions and following contextual fear conditioning (CFC) learning. Furthermore, while, as expected, CFC learning led to an increase in the levels of the immediate early gene (IEGs) ARC, c-FOS and EGR-1 proteins in the hippocampus of WT mice, it failed to do so in AS mice, which also had an accumulation of IEG proteins in basal condition. Take together these data

lead us to conclude that AS is characterized by a significant accumulation of proteins and a stalled autophagic flux with consequent defect of protein metabolism homeostasis, also known as proteostasis. We suggest that this proteostasis alteration is a major neurological problem that leads to AS symptoms.

Title: Activity-dependent cytoskeleton associated protein is regulated by the autophagy pathway

Authors: *K. PANDEY, F. ARIA, C. M. ALBERINI;
New York Univ. Ctr. For Neural Sci., NEW YORK, NY

Abstract: Learning increases autophagy and this increase requires *de novo* translation. Autophagy is an evolutionarily conserved protein degradation mechanism that, through lysosomes, removes damaged organelles or proteins but is also important for recycling cytosolic components. Recent studies have shown that autophagy is critical for long-term memory formation. Previously, we found that learning-induced autophagy is coupled to the *de novo* protein synthesis evoked by learning (Pandey, K., Yu, X. W., Steinmetz, A., and Alberini, C. M., Autophagy, 1-22, 2020. doi: 10.1080/15548627.2020.1775393). The target molecules of this learning-induced autophagy remain to be identified. Using episodic learning paradigm in rats, here we show that learning-induced increase of the immediate early gene activity-dependent cytoskeleton associated protein (ARC/ARG3.1 thereafter ARC) in the dorsal hippocampus colocalizes with microtubule-associated protein 1 light chain 3 beta (LC3B), a protein that is recruited to the autophagosomal membrane and considered a typical marker of autophagic vesicles. Pharmacological inhibition of autophagy and lysosomal pathways or targeted molecular disruption of critical regulators of autophagy, which are known to impair long-term memories, led to a significant accumulation of ARC protein without changing its mRNA level. In addition, a reporter system generally employed to measure autophagic flux, which was engineered to express ARC, revealed that learning leads to ARC transport along an intracellular compartment that traffics from basic to acidic compartments, suggesting that ARC undergoes autophagic flux. Collectively, these data suggest that the autophagy pathway, which is activated in response to learning, regulates ARC protein degradation.

Title: Fmrp phosphorylation leads to enhanced granule assembly and clustering

Authors: *Y. J. YOON[1], L. NUNEZ[1], D.-W. HWANG[1], S. KHAROD[1], R. H. SINGER[2];
[2]Anat. & Structural Biol., [1]Albert Einstein Col. of Med., Bronx, NY

Abstract: Fragile X syndrome is the leading single-gene cause of autism and the most common form of inherited intellectual disability. While we understand the genetic mechanism of fragile X mental retardation (*FMR1*) gene silencing and the resulting loss of fragile X mental retardation protein (FMRP) expression, what is not clearly defined is how FMRP function is regulated. Previous biochemical and genetic evidence suggested that phosphorylation of serine residue 499 (S499) was key to FMRP function in repressing protein synthesis. However, what was less clear was how phosphorylation of S499 could impart FMRP function in the context of the intracellular milieu. To address this question, we have generated FMRP fluorescent reporters (GFP-FMRP and Halo-FMRP), along with the phospho-deficient and phospho-mimic mutants, S499A and S499D, respectively, to visualize the intracellular dynamics of FMRP. Analysis of our imaging results show that the S499A mutant exhibits smaller and more motile granules when compared to the wildtype GFP-FMRP or the S499D mutant reporter. Also, the S499A mutant showed reduced clustering relative to the wildtype and S499D counterparts, suggesting that the phosphorylation of S499 is necessary for FMRP granule formation and persistence at dendritic spines. Our high resolution approach can detect measurable differences in the dynamics of FMRP granules between the wildtype and mutant FMRP reporters and can advance our understanding of FMRP granule dynamics in live neurons.

Title: Activity-induced proteomics dynamics in different cell types following PTZ-induced seizure and visual experience in mouse

Authors: *Y. XIE, L. SCHIAPPARELLI, Y. MA, P. SHARMA, J. CHANG-WEINBERG, A. MAXIMOV, J. YATES III, H. CLINE;
Scripps Res. Inst., San Diego, CA

Abstract: Proteome dynamics induced by sensory stimulation differ among neuronal cell types. Being able to temporally dissect the changes of cell-type specific proteomics in a given brain region allows the discovery of novel protein candidates associated with developmental plasticity and disease progress. To analyze acute proteomics dynamics in genetically defined neuronal cell types, we applied metabolic labeling with the non-canonical amino acid Azidonorleucine (ANL) in a transgenic mouse line (JAX#028071; Alvarez-Castelao B, 2017), where a mutant methionine tRNA synthetase ($MetRS^{L274G}$) is knocked-in in a cre-dependent manner. We used the Direct Detection of Biotin-containing Tag (DiDBiT, Schiapparelli L, 2014) method in the sample preparation and mass spectrometry pipeline, which ensured high fidelity in filtering out background signal. With this system, we performed a 'proof of principle' proteomics analysis in $MetRS^{L274G}EMX^{Cre}$ mice, following brain-wide neuronal activation by pentylenetetrazol (PTZ). EMX^{Cre} is expressed predominantly is excitatory neurons. First, we demonstrated that constitutive expression of $MetRS^{L274G}$ from embryonic stage didn't elicit any major pathological changes in cortical lamination, cell population or mouse behavior. Second, we showed that intraperitoneal injection of ANL acutely before PTZ-induced neuronal activation successfully identified >1500 biotin-labeled newly synthesized proteins with our pipeline, the majority of which are annotated to excitatory neurons, as expected. Among these, the synthesis of ~100 proteins was significantly regulated by activity. Bioinformatic analysis showed that the significantly regulated dataset was enriched in components pertaining to synaptogenesis as well as chromatin and cytoskeleton remodeling. Building on this 'proof-of-principle' experiment, we are testing for acute proteomic dynamics in the visual cortex induced by visual input at P28 and P56. We identified >2000 proteins in the excitatory proteomics 12-hour post visual experience in both sexes. >200 protein was significantly regulated by visual experience. The hits in P28 and P56 only share ~25% overlap, which suggests different regulatory program in the visual critical period and in adult. We are also exploring the inhibitory proteomics induced by visual experiences at different ages. By comparing activity-dependent proteomics in these neuronal cell types, we will be able to gain more insight into the molecular regulations of critical period and adult visual plasticity.

Title: Differential location of Golgi apparatus proteins in adult hippocampal dendrites

Authors: *D. LAL[1], K. E. PANNONI[2], L. CAMPBELL[2], S. FARRIS[3];
[1]Virginia Tech. Carilion Sch. of Med., Roanoke, VA; [2]Ctr. for Neurobio. Res., Fralin Biomed. Inst. at VTC, Roanoke, VA; [3]Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: Local protein translation affords neurons the ability to differentially regulate cellular functions in distinct compartments by controlling when and where mRNA translation occurs. The endoplasmic reticulum (ER) and Golgi apparatus (GA) are responsible for synthesizing and "tagging" secretory and transmembrane proteins (i.e., glycosylation) for their final destinations, respectively. An unresolved issue in local translation is whether the GA or a separate processing pathway is present in dendrites to process transmembrane proteins. Mutations in GA proteins have been implicated in autism spectrum disorders (ASD) where dysregulation of protein synthesis at synapses can lead to disease (Giannandrea et al, 2010). Early studies identified polyribosomes and ER in adult dendrites in vivo using electron microscopy (Steward & Levy, 1982 & Pierce et al, 2000). GA and trans Golgi network were similarly identified in adult dendrites using electron microscopy with immunogold staining for organelle markers (Pierce et al, 2001). In contrast, more recent studies using developing neurons in culture found no evidence of the GA in dendrites using confocal microscopy, and instead identified a separate processing pathway through which proteins are trafficked from dendritic ER to the membrane by recycling endosomes (Bowen et al, 2017). Thus, it remains unclear whether the GA is present in distal dendrites to locally process proteins for destined for the membrane.
To address whether GA proteins are localized in dendrites, we used transgenic reporter mice to label a subset of hippocampal neurons and immunostained sections for three GA markers (GOLGA5, ST3GAL, and ERGIC), which label canonical GA, Golgi outposts (GO), and ER to Golgi intermediate complex, respectively. Confocal imaging was used to quantify the fluorescence intensity of each marker in cell bodies and dendrites. Additional high-resolution images were acquired to determine the relative fluorescence between dendrites and spines. We found that canonical GA marker GOLGA5 is confined to the cell body and very proximal dendrites, while both GO and ER to Golgi intermediate markers are found throughout the cell body and dendrites, with evidence for localization in distal dendrites and dendritic spines. Our data are consistent with evidence that canonical GA markers are not found in distal dendrites, and provide support for a noncanonical trafficking pathway utilizing GO to process transmembrane proteins in distal dendrites. Identifying the mechanisms regulating local translation at synapses is critical for understanding the processes underlying learning and memory and for developing effective therapies for ASD.

Title: Neuronal membrane-specific proteasomes homeostatically regulate neural circuit activity and are required for learning-induced behavioral plasticity in vivo

Authors: *H. HE[1], K. RAMACHANDRAN[2], N. MCLAIN[3], R. L. FAULKNER[3], A. AHSAN[1], R. BERA[1], S. S. MARGOLIS[4], H. T. CLINE[3];

Abstract: Recent studies in neuronal cultures found that uncapped 20S core subunits of proteasomes specifically bind to the neuronal plasma membrane and may be involved in the regulation of neuronal activity, possibly through degradation of nascent proteins. The *in vivo* function of these neuronal membrane-specific proteasomes (NMPs) is unknown. Here, we examined the expression and function of NMPs in Xenopus laevis tadpole brains. A significant proportion of 20S core subunits was detected in the membrane fractionation of brain homogenate and were found to colocalize with the neuronal membrane in electron micrographs, demonstrating the presence of NMPs in tadpole brain. To probe the proteolytic function of NMPs *in vivo*, we employed a bio-orthogonal metabolic labeling method to tag nascent proteins with azidohomoalanine (AHA) in the brain of live tadpoles, which allows specific detection and purification with subsequent biotinylation of tagged proteins. Application of bicuculline methiodide (BMI), a $GABA_AR$ antagonist, significantly increased the amount of nascent protein, consistent with activity-dependent increase in protein synthesis. Acute NMP inhibition resulted in a further increase in the total amount of nascent protein, suggesting that NMPs actively degrade nascent proteins in response to elevated neuronal activity. Further examination of specific protein candidates in purified nascent protein samples suggest that not all nascent proteins are degraded by NMPs. *In vivo* Ca^{2+} imaging in the optic tectum showed that NMP inhibition in BMI-treated tadpole brain rapidly increased spontaneous neuronal activity on top of the BMI-induce activity increase and significantly increased the synchronization among the neuronal population. Such an elevation of the network activity is predicted to reduce the signal to noise ratio of the signal processing and impair circuit function. Indeed, NMP inhibition during visual training abolished learning-induced behavioral plasticity and resulted in a deterioration of baseline visual avoidance behavior in tadpoles. Intriguingly, without the visual training, NMP inhibition did not interfere with the behavior, suggesting a specific protective role of NMPs in experience-dependent circuit plasticity. Activity-induced protein synthesis is a signature of synaptic plasticity. Timely degradation of nascent proteins may hold activity-induced synaptic changes in check, preventing them from plunging into a destabilizing positive-feedback loop. Together our data suggest that NMP-mediated degradation of nascent proteins may serve as a novel homeostatic mechanism in neurons for the regulation of circuit plasticity.

Title: Presynaptic FMRP and local protein synthesis support structural and functional plasticity of glutamatergic axon terminals

Authors: *S. C. KHAROD[1], H. R. MONDAY[1], Y. J. YOON[2], R. H. SINGER[2], P. E. CASTILLO[3]; [1]Neurosci., [2]Anat. and Structural Biol., [3]Neurosci.; Psychiatry and Behavioral Sci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The molecular mechanisms that govern long-term forms of presynaptic plasticity are largely unknown. The hippocampal mossy fiber (MF)-CA3 synapse, which expresses robust presynaptic plasticity and has notably large and complex boutons (MFBs), contains surprisingly high levels of Fragile X mental retardation protein (FMRP), an RNA-binding protein known to repress translation, but whose function at the presynapse and in long-term plasticity is unclear. FMRP interacts with polyribosomes and mRNAs to form granules, which can be trafficked in an activity-dependent manner, and dephosphorylation of FMRP triggers granule disassembly and loss of translational repression. Here, using mouse acute hippocampal slices, we found that MF-LTP and associated structural plasticity requires protein synthesis. Moreover, selective deletion of FMRP from presynaptic neurons impaired both structural and functional MF-LTP and resulted in an increase in protein synthesis in the MF tract. Taking advantage of a novel viral vector expressing an FMRP-Halotag fusion protein, we not only confirmed that FMRP granules are localized to MFBs, but also found that MF-LTP induction disassembled FMRP granules in the MF tract. Remarkably, enriched environment exposure also increased protein synthesis in the MF tract and this increase was exacerbated by presynaptic deletion of FMRP. Finally, using high-resolution microscopy, we identified endogenous ribosomes in presynaptic MFBs, suggesting that these boutons are capable of synthesizing protein locally, likely under the regulation of FMRP. Together, these results indicate that presynaptic FMRP dynamically regulates protein synthesis and plastic changes at an excitatory synapse in the mature mammalian brain, which may have important implications in memory formation.

Title: Autophagy regulates local synaptic RNA metabolism

Authors: *Y. JOO, D. R. BENAVIDES;
Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: RNA transport and local translation are crucial for neuronal signal transmission and synaptic plasticity. Dysfunction of RNA metabolism has been implicated in numerous neuronal disorders. However, the RNA metabolism for local translation in the postsynaptic density (PSD) remains to be fully elucidated. We used dissociated primary neuron culture, proteomics, pharmacology, and RNA imaging to investigate the translational mechanisms of local RNA and translational regulation in the PSD. We discovered that activity-dependent regulation of local RNA content is induced in the PSD. In addition, pharmacological inhibition of autophagy, using Bafilomycin A1, results in local synaptic RNA regulation. mRNAs encoding synaptic proteins such as NMDA receptor subunits, AMPA receptor subunits, and adhesion molecules as well as immediate early genes displayed differential regulation. Thus, autophagy may contribute to synaptic plasticity via regulation of local RNA metabolism. This study may contribute to understanding of the underlying pathophysiology of neurological disorders and pathways for novel therapeutics.

Title: Ubiquitination of Arc regulates alcohol-induced synaptic plasticity in central nucleus of amygdala and alcohol seeking

Authors: *A. SALAMIAN, P. TAHERI, E. SKONIECZNA, K. RADWANSKA;
Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: The activity-regulated protein Arc/Arg3.1 (Arc) is one of key molecules that regulate synaptic plasticity and memory processes. The role of Arc in psychiatric disorders, including alcohol use disorder (AUD), remains less understood. However, our data show that Arc mRNA and protein is upregulated in the amygdala during alcohol withdrawal, suggesting its function in alcohol-induced plasticity and

behaviours. The expression of Arc protein at synapses is tightly controlled: it rapidly increases following enhanced network activity and quickly declines due to protein ubiquitination. We found that alcohol withdrawal along with Arc mRNA upregulates mRNA of Arc E3 ubiquitin-protein ligase, RNF216. To investigate the role of Arc ubiquitination in AUD-related behaviours, we used Arc ubiquitination-deficient mutant mice (ArcKR) (Mark et al. 2018) with disrupted temporal control of Arc degradation. Arc KR and wild-type littermates (WT) underwent alcohol self-administration training in the IntelliCages: free access to 8% ethylalcohol (30 days) followed by 7-day withdrawal (7DW) and presentation of alcohol-predicting cue light (cue relapse) in the reward corner. Next, we analyzed synaptic transmission and plasticity in the central nucleus of the amygdala (CeA) following 7DW: evoked local potentials were recorded in medial part of CeA after electrical stimulation of basolateral amygdala (BLA). There was decreased synaptic strength, measured as input/output, and decreased GluN1, but increased GluN2B, NMDAR subunits levels in Arc WT following 7DW compared to water, yet, no difference in Arc KR mice. Furthermore, theta burst stimulation-induced LTP was significantly boosted in Arc WT mice following 7DW compared to water group. We did not observed, however, such plasticity in Arc KR littermates. Finally, we found less alcohol seeking by Arc KR mice during alcohol withdrawal and cue relapse compared to Arc WT littermates. Together, our data suggest that temporal control of Arc degradation plays a crucial role in alcohol-induced synaptic plasticity in CeA and alcohol seeking during withdrawal.

Abstract: Activity-driven changes in the neuronal surface glycoproteome are known to occur with synapse formation, plasticity and related diseases but their mechanistic basis and significance are unclear. *N*-glycans on surface glycoproteins of dendrites shift from immature to mature forms containing sialic acid in response to increased neuronal excitation. In exploring the basis of these *N*-glycosylation alterations, we discovered they results from the growth and proliferation of Golgi satellites scattered throughout the dendrite. Golgi satellites that formed with neuronal excitation were in close association with ER exit sites and early endosomes and contained glycosylation machinery without the Golgi structural protein, GM130. They functioned as distal glycosylation stations in dendrites, terminally modifying sugars either on newly synthesized glycoproteins passing through the secretory pathway, or on surface glycoproteins taken up from the endocytic pathway. These activities led to major changes in the dendritic surface of excited neurons, impacting binding and uptake of lectins, as well as causing functional changes in neurotransmitter receptors, such as the nicotinic acetylcholine receptor. Neural activity thus boosts the activity of the dendrite's satellite micro-secretory system by redistributing Golgi enzymes involved in glycan modifications into peripheral Golgi satellites. This remodeling of the neuronal surface has potential significance for synaptic plasticity, addiction and disease.

Title: Translation regulation in development of hyperalgesia

Authors: *N. KORNEEVA[1], R. FAN[2], A. RYAZANOV[3], T. ARNOLD[2];
[1]Emergency Medicine; 2Department of Pharmacology, Toxicology and Neurosci., Louisiana State Univ. Hlth. Sci. Ctr., Shreveport, LA; [2]Emergency Med., LSUHSC-Shreveport, Shreveport, LA; [3]Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: Despite widespread abuse of opioids, we know little about the long-term consequences of chronic use. Several studies demonstrated that chronic opioid exposure alters gene expression profiles underlying the acute and chronic neuronal plasticity. These changes in gene expression contribute to the opioid-induced analgesic effect, as well as the development of addiction, tolerance, dependence, and hyperalgesia. Eukaryotic elongation translation factor 2 kinase, eEF2K, is a non-conventional calmodulin-dependent protein kinase (CaMK III) belonging to the alpha kinase family. It is activated downstream of AMPK and PKA signaling as well as by Ca^{2+}-dependent calmodulin binding. The eEF2K phosphorylates eEF2 on Thr56, leading to inhibition of elongation step of protein synthesis and, thus, a suppression of general protein synthesis. However, translation of several specific mRNAs is upregulated by phosphorylated eEF2. Among them, mRNAs involved in the control of synaptic plasticity: CamK II ,

activity-regulated cytoskeleton associated protein Arc/Arg3.1, brain-derived neurotrophic factor BDNF, and microtubule-associated proteins. Both eEF2K and eEF2 are ubiquitous in all eukaryotes and are present in various tissues including brain. It was shown that prolong opioid administration is associated with development of hyperalgesia or increased pain sensitivity. In our experiments, we observed increased phosphorylation of eEF2 in various brain areas in rats and mice chronically treated with opioids. Moreover, it coincided with translational upregulation of BDNF, factor implicated in nociceptive response. To investigate the eEF2K role in development of hyperalgesia, WT and eEF2K KO mice were chronically treated with morphine for 12 days. WT mice demonstrated signs of hyperalgesia by 4th day of morphine treatment, while KO mice demonstrated lack of increased sensitivity to pain during 12 days. It was shown that microglia-released BDNF promotes development of morphine-induced hyperalgesia in mice. In our experiments, we observed increase in BDNF level in brain stem samples of WT but not in KO mice treated with morphine. Lower level or delayed increase in morphine-induced BDNF expression in brain may explain lack of hyperalgesia after chronic morphine administration in KO mice.

Title: Longitudinal characterization of hippocampal pathology in the intrahippocampal kainate mouse model of temporal lobe epilepsy

Authors: D. TRAVER, M. B. PAREKH, E. T. SEVILLA, W. BLANKENBERGER, H. KIM, P. HAMPEL, N. PICARD, C. NICHOLAS, *C. PRIEST;
Neurona Therapeutics, Inc, South San Francisco, CA

Abstract: Approximately one-third of people with epilepsy do not achieve adequate seizure control with current anti-seizure drugs, and treatment of drug-resistant epilepsy remains a significant unmet clinical need. Temporal lobe epilepsy (TLE) is the most common type of focal epilepsy, and is characterized by mesiotemporal seizures and hippocampal sclerosis. Hippocampal sclerosis involves damage to several cell types and layers, including dentate granule cell dispersion, inhibitory interneuron and excitatory neuron cell loss, gliosis, mossy fiber sprouting, tissue atrophy, and inflammation (Blümcke et al., 2013, Houser, 1990, Devinsky et al., 2013). Long-term longitudinal characterization of hippocampal sclerosis in animal models of TLE may aid in the development of more effective anti-seizure therapies. In this study, hippocampal histopathology and inflammation were examined for up to 12 months during the chronic epileptic phase in the intrahippocampal kainate mouse model of mesiotemporal seizures and sclerosis. Eight-10 week old immunocompromised NOG mice received kainic acid into the right dorsal hippocampus to induce status epilepticus. Brain tissue was collected 1-2, 8, and 11-13 months post-induction (MPI). Quantitative analysis of hippocampal pathology was performed. Hippocampal neuronal loss in CA1, CA3, and the hilus was scored semi-quantitatively using hematoxylin and eosin staining. Granule cell dispersion was measured using PROX1 immunofluorescence labeling. Inflammation was

assessed using quantitative immunofluorescence labeling for reactive astrocytes (GFAP), and microglia (IBA1). For all measures, the ipsilateral epileptic hippocampus was compared to the contralateral hippocampus and to the hippocampi of naïve, age-matched mice. By 8 MPI, significant dispersion of the dentate granule cell layer, neurodegeneration, and inflammation were observed in the ipsilateral epileptic hippocampus while the contralateral hippocampus was largely spared. In conclusion, the epileptic hippocampus in a mouse model of chronic TLE exhibits histopathological hallmarks of human mesiotemporal sclerosis. By conducting an extended time course in the model, we have established an important baseline progression of hippocampal damage that will facilitate the future investigation of anti-seizure therapeutic candidates.

Title: Co-administration of anti-seizure drugs with NRTX-1001 GABAergic interneuron therapy is well-tolerated and effective in mice

Authors: *E. SEVILLA, P. HAMPEL, W. B. BLANKENBERGER, H. K. KIM, D. A. TRAVER, J. LI, M. B. PAREKH, C. PRIEST, C. R. NICHOLAS;
Neurona Therapeutics, Inc., South San Francisco, CA

Abstract: The inhibitory cell therapy candidate NRTX-1001 is derived from human pluripotent stem cells and is being developed for the potential future treatment of drug-resistant focal epilepsy. The product is a clinical-grade cellular therapeutic comprised of human post-mitotic GABAergic interneurons of an MGE/pallial-type lineage. NRTX-1001 persists in the epileptic mouse hippocampus and provides stable seizure freedom in a chronic temporal lobe epilepsy (TLE) mouse model of mesiotemporal seizures and sclerosis. Here, preclinical studies were conducted to understand potential effects of anti-seizure drugs, levetiracetam and diazepam, on transplanted NRTX-1001 engraftment and disease-modifying activity.
Levetiracetam was infused chronically at 400 mg/kg/d, and control animals received vehicle injections for comparison. Stable therapeutic plasma levels of levetiracetam were confirmed. All of the mice received an intrahippocampal transplant of NRTX-1001 on day 3. At 30 days post-transplant (PT), histological analysis was conducted to assess human cell distribution, persistence, fate, and local inflammatory tissue

response. NRTX-1001-treated animals that received levetiracetam or vehicle had similar human cell persistence and hippocampal distribution, with appropriate interneuron fate and minimal host inflammatory response at 30 days PT. Mice were healthy throughout the study, and no behavioral abnormalities were detected in either group that received NRTX-1001.
In a second study, acute doses of the anti-seizure drug diazepam were administered several months PT in NRTX-1001-treated or vehicle-injected epileptic mice that model chronic TLE. To examine potential drug-cell therapy interactions, mesiotemporal seizures were measured by EEG in cell-treated and vehicle-injected cohorts. Most epileptic animals that received NRTX-1001 were seizure-free by 7 months PT, and the administration of two doses of diazepam did not impair the disease-modifying activity of the interneuron therapy.
In summary, combination treatment with the GABAergic interneuron therapy NRTX-1001 and two anti-seizure drugs, with different mechanisms of action, is well-tolerated and does not affect cell engraftment or disease-modifying activity.

Title: Preclinical development of the human inhibitory interneuron cellular therapeutic NRTX-1001 for the treatment of chronic focal epilepsy

Authors: *P. HAMPEL, M. B. PAREKH, W. B. BLANKENBERGER, E. T. SEVILLA, D. A. TRAVER, H. K. KIM, N. PICARD, A. BATES, D. CHERKOWSKY, A. ADLER, L. FUENTEALBA, S. LEE, S. KRIKS, N. SALTER, M. WATSON, M. BERSHTEYN, Y. MAURY, S. HAVLICEK, A. BULFONE, G. BANIK, C. PRIEST, C. R. NICHOLAS;
Neurona Therapeutics, Inc., South San Francisco, CA

Abstract: Objective:
Approximately 30% of people living with mesial temporal lobe epilepsy (TLE) do not achieve adequate seizure control with currently available pharmacological treatment options. A cellular therapeutic targeted to the temporal lobe could potentially restore balanced neural activity in the seizure focus, avoid the

unwanted side effects common to systemic drugs, and provide an alternative to tissue-destructive lobectomy and laser ablation surgery. NRTX-1001 is a clinical-grade cellular therapeutic comprised of post-mitotic GABAergic interneurons of an MGE/pallial-type lineage derived from human pluripotent stem cells. The product candidate is efficacious and safe across a broad dosing range in a chronic mouse model of TLE. The current study examined the reproducibility of safety and efficacy across independently manufactured lots of NRTX-1001.
Design/Methods:
NRTX-1001 was evaluated in the intra-hippocampal kainate mouse model of chronic TLE that displays key aspects of human TLE pathology, including pharmacoresistant mesiotemporal seizures and sclerosis. In the chronic epileptic stage, animals received intra-hippocampal transplantations of independent lots of NRTX-1001, or vehicle control. EEG was recorded continuously to determine focal electrographic seizure frequency, and animals were observed for potential behavioral abnormalities, hippocampal pathology, and human cell engraftment for 7-9 months post-transplant.
Results:
NRTX-1001 matured into appropriate interneuron subtypes, distributed throughout the epileptic mouse hippocampus, and stably persisted for the study duration. Overall, approximately two-thirds of mice that received cell transplants became stably seizure-free by 5 months post-transplant. Cell transplantation reproducibly led to stable seizure suppression with ~75% fewer electrographic seizures recorded than in vehicle-injected control animals. The cumulative duration of focal seizures was also reduced. Hippocampal neurodegeneration and dentate granule cell dispersion were significantly decreased in the cell-treated mice. No ectopic human tissues or teratomas were found, and no adverse behavioral effects were detected.
Conclusions:
NRTX-1001 persisted in the epileptic mouse hippocampus, was well tolerated, and resulted in stable seizure freedom. These findings support further development of NRTX-1001 for chronic focal epilepsy.

Title: Hippocampal low-frequency stimulation prevents seizure generation in a mouse model of mesial temporal lobe epilepsy

Authors: *E. PASCHEN[1,2], P. KLEIS[1,2], J. LINK[1,2], D. VIEIRA[3,4], K. HEINING[3,2,4], P. JANZ[1], U. EGERT[3,4], U. HÄUSSLER[1,5], C. HAAS[1,5];

Abstract: Mesial temporal lobe epilepsy (MTLE) is the most common form of focal, pharmacoresistant epilepsy in adults and is often associated with hippocampal sclerosis. For MTLE patients, one alternative to surgical resection of the epileptic focus is electrical deep brain stimulation in the hippocampus. Due to the low duty cycle, low-frequency stimulation (LFS) may be advantageous over high-frequency stimulation, as it requires less electric current injection, thus allowing for longer battery life. In an *in vivo* mouse model of MTLE, we showed previously that optogenetic LFS in the hippocampus (1 Hz and 0.5 Hz) interfered with the generation of spontaneous epileptiform activity. Stimulation at higher frequencies (5-20 Hz) often resulted in the induction of behavioral seizures. Here, we aimed at successful seizure control by the application of electrical LFS (eLFS) in chronically epileptic mice. We injected kainate (KA) unilaterally into the hippocampus and a channelrhodopsin2-encoding viral vector into the entorhinal cortex of C57BL/6 mice. We implanted one electrode for local field potential recordings in each hippocampus and an optic fiber parallel to a stimulation electrode in the sclerotic hippocampus. This way we could optogenetically induce behavioral seizures and assess the seizure-suppressive effects of eLFS. We applied unilateral 1 Hz pulses for one to three hours daily for three weeks. In addition, KA- and control mice were stimulated and subjected to behavioral tests to infer a potential impact of eLFS on cognitive performance. We found that (i) 1 Hz eLFS successfully interfered with both spontaneous epileptiform activity and evoked behavioral seizures originating from the KA-injected hippocampus; (ii) suppression of epileptiform activity during eLFS was effective over several weeks without desensitization; (iii) discontinuous (open-loop) stimulation was also highly effective. On the behavioral level, preliminary results suggest that eLFS does not impair hippocampus-related cognitive functions, since mice were (i) able to navigate successfully in the Barnes Maze and (ii) showed no increase in the anxiety level following eLFS. Our results indicate that hippocampal eLFS reliably suppresses the generation of spontaneous epileptiform activity and the generalization into behavioral seizures without losing effectiveness over prolonged treatment and without affecting hippocampus-related cognitive functions. Thus, eLFS at 1 Hz may constitute a promising approach for seizure control in MTLE.

Title: Toll-like receptor inhibition reduces epileptiform activity in a mouse model of temporal lobe epilepsy

Authors: *S. RAHIMI, M. DREXEL, S. SANTOS-SIERRA;
Med. Univ. of Innsbruck, Innsbruck, Austria

Abstract: Introduction: Neuroinflammation is a significant underlying cause of epileptogenesis and epilepsy and Toll-like receptors (TLR) seem to play a key role in the inflammatory process. TLR activation leads to pro-inflammatory cytokine production what may lead to neuronal hyper-excitability. Thus, inhibition of TLR function is a promising therapeutic strategy in drug-resistant epilepsy. Our group have discovered several small-molecule inhibitors of TLR2 function (e.g. INH50) that are potential candidates to reduce epileptiform activity.**Methods:** Initial in *silico/in vitro* studies led to the selection of INH50, a small-molecule that reduced the activity of TLR2 (luciferase and ELISA assays). The inhibitory effect of the compound in immune cells (human monocytes, mouse macrophages) was further confirmed via immunoblot assays against downstream proteins in the TLR2 pathway (p-JNK, p-p38, IkBα). Further, nitric oxide assays were used to test the anti-inflammatory potential of INH50 in microglia. INH50 effects were tested *in vivo* in a kainic acid-induced epilepsy mouse model. INH50 or vehicle (DMSO) were injected in the ventral hippocampus of three to four months male C57BL/6 mice. After one hour, they received intra-hippocampal injections of kainic acid and then, they were subjected to telemetric EEG recording for two weeks. Using a customized MATLAB code, epileptiform activities were measured during the status epilepticus (initial 48 hours) and ten days afterward (for 24 hours). **Results:**INH50 is an anti-inflammatory small molecule that decreased TLR2-mediated NF-kB activation in HEK293-TLR2 cells. Further, it reduced the pro-inflammatory cytokine production (IL-6, TNFα) in activated mouse macrophages and human monocytes and the nitric oxide production in microglia. The phosphorylation status of the downstream proteins JNK, p38 and the degradation of IkBα were reduced after treatment with the compound.*In vivo*, during the status epilepticus, the group of mice treated with INH50 presented a significantly lower mean of total daily number of spikes trains ($p < 0{,}0001$), total daily duration of spike trains ($p < 0{,}0001$) and total daily number of spikes (in trains, $p < 0{,}0001$) in comparison to the vehicle group. Interestingly, the same marked difference between groups persisted even after ten days ($p < 0{,}0001$ for all three measures). **Conclusion:**These results indicate that INH50 is a promising hit to develop derivatives with anti-inflammatory properties that decrease epileptiform activity.

Abstract: No targeted treatments for temporal lobe epilepsy (TLE) exist, and the majority of patients are resistant to approved drug therapies. Recurrent mossy fiber sprouting from dentate granule cells (DGCs) is an anatomical hallmark of TLE, which leads to an aberrant excitatory network between DGCs that operates via ectopic kainate receptors (KARs) composed of GluK2/GluK5 heterodimers. Our prior demonstration that GluK2 knockout mice are protected from pilocarpine-induced seizures led us to explore the tractability of an anti-Gluk2 approach to address TLE therapeutically. We have designed AAV9 vectors expressing engineered miRNA designed to knockdown the *grik2* mRNA, with the goal of reducing GluK2 subunit expression in the hippocampus and thus ameliorating the epileptic phenotype. Using this approach, we observed a reduction in GluK2 protein levels following transduction into primary neuronal cultures from both mice and rats. Furthermore, direct hippocampal delivery in pilocarpine-induced epileptic mice significantly reduced the number of epileptic seizures in these mice, and normalized the pathological hyperlocomotion phenotype associated with this model. Finally, transduction of organotypic hippocampal tissue surgically resected from TLE patients showed an almost complete suppression of recorded epileptiform discharges.
These data support the pivotal role of GluK2/GluK5 in triggering the epileptic seizures human TLE, and that a reduction in their expression may be expected to reduce the epileptic phenotype. We believe that AAV-mediated RNAi targeting the expression of GluK2/GluK5-KARs in DGCs is a viable approach to reduce seizures associated with intractable TLE and to address unmet needs in this patient population

Title: Effect of anticonvulsant drugs on nitric oxide levels of neurons in primary culture, possible proconvulsant role of neuronal nitric oxide

Authors: *L. VEGA RASGADO[1], V. ALCÁNTARA FARFÁN[2];
[1]LAB. NEUROQUÍMICA, DEPTO. BIOQUÍMICA, ESCUELA NACIONAL DE CIENCIAS BIOLÓGICAS, INSTITUTO POLITÉCNICO NACIONAL, CDMX, Mexico; [2]LAB. BIOQUÍMICA FARMACOLÓGICA, DEPTO. BIOQUÍMICA, ESCUELA NACIONAL DE CIENCIAS BIOLÓGICAS, INSTITUTO POLITÉCNICO NACIONAL, CDMX, Mexico

Abstract: Epilepsy affects about 50 million people worldwide, but 30% of the patients are refractory to the traditional treatments. Thus, the development of new antiepileptic drugs is necessary. Nitric oxide (NO) regulates neuronal excitability in physiological and pathological conditions, with protective as well as deleterious actions. NO participation in epilepsy is demonstrated, but its role in seizures generation is controversial. Some reports indicate that NO plays a role of anticonvulsant, while other show that it leads to proconvulsant effect. Clarification of the dual effects of NO might lead to the design of new antiepileptic drugs, but it is a great challenge. The ubiquity of NO in the central nervous system implies that drugs designed to modify the biological activity of NO may have distinct effects. The therapeutic challenge would be to succeed in manipulating the NO pathways selectively. NO levels are regulated by two constitutive isoforms of the nitric oxide synthase (NOS): neuronal NOS (nNOS) and endothelial NOS (eNOS). However, NO effects are conditioned not only by keeping its concentration between certain limits. Previous results in our laboratory suggest that the contradictory role of NO in seizures generation could depend on the NOS isoform involved. Even they could play an opposite role; one of them proconvulsant, but the other anticonvulsant. Here we study the effect of anticonvulsant drugs on neuronal NO levels (nNO). With that aim primary cultures of neurons were used as a study model, and the effect of different concentrations and time of treatment with amino-oxyacetic acid (AAOA), valproate (VALP), diazepam (DIAZ) and gabapentin (GBPT) on NO levels were investigated, using a spectrophotometric method based on Griess reaction ($N \geq 5$, observations each experiment=4, post-hoc analysis Newman-Keuls test). The effect of anticonvulsant drugs on nNO levels dependent on the concentration and time of treatment. AAOA (except for 10 and 25 mM and 72 hours of treatment), VALP (excluding 10 µM, all times of treatment tested), DIAZ and GBPT (exception of 10, 75 and 100 µM at 24 hours of treatment) decreased nNO levels. The influence of the time of treatment is diverse, depending on the concentration employed. Described results, together with the fact that convulsant drugs increased nNO levels, indicate that apparently it possesses convulsant properties. It seems to be mediated not only by its effect on glutamatergic system but also on GABAergic system, probably through $GABA_A$ receptors. However, this requires forward investigation considering the limitations of this kind of studies and the unexplored influence of inducible NO.

Title: Two candidate K-Cl cotransporter 2 (KCC2) enhancers prevent epileptiform activity in vitro and in vivo

Authors: *F. DONNEGER[1,2,3], A. ZANIN[1,2,3], Y. KADIRI[1,2,3], J. ZHANG[4], B. DEVAUX[5], F. CHASSOUX[5], S. LÉVI[1,2,3], J.-C. PONCER[1,2,3];

Abstract: In neurons, the cation-chloride cotransporters (CCC) KCC2 and Na-K-Cl cotransporter 1 (NKCC1) control intraneuronal chloride homeostasis and, subsequently, the efficacy and polarity of gamma-aminobutyric acid (GABA) signaling. In many neurological disorders, including epilepsy, reduced KCC2 expression or function may result in depolarizing GABA signaling that may then contribute to pathological activities and seizures. Compensating for the dysregulation of CCC function in the pathology therefore appears as a promising therapeutic strategy. Bumetanide, an antagonist of the NKCC1 transporter, failed to prevent acute neonatal seizures in a clinical trial. Here, instead, we tested the effects of two compounds identified from library screening as candidate KCC2 enhancers. However, their mode of action in cortical neurons and their therapeutic potential in epilepsy remain unknown or even controversial. We first compared the mode of action of these two compounds in rat hippocampal neurons. We showed that both of them enhance KCC2 function, as detected in electrophysiological assays. This effect was accompanied by a direct modulation of GABA signaling, involving either positive allosteric modulation of extrasynaptic GABAA receptors or enhanced synaptic GABA release. Single particle tracking experiments revealed that both compounds reduce the lateral diffusion of KCC2 in the plasma membrane. This effect was associated with enhanced KCC2 clustering with no change in total or plasmalemmal KCC2 expression. Both compounds effectively suppressed spontaneous, interictal-like discharges recorded in postoperative hippocampal tissue resected from mesial temporal lobe epilepsy patients. In addition, chronic administration of a Food and Drug Administration (FDA)-approved KCC2 enhancer reduced seizure occurrence by about 67% in a lithium-pilocarpine mouse model of temporal lobe epilepsy. Collectively, our data decipher the mode of action of two candidate KCC2 enhancers in hippocampal neurons and demonstrate for the first time their antiepileptic potential in pharmacoresistant epilepsy.

Title: Aging induces asymmetric trafficking of PDE11A4 in the ventral hippocampus

Authors: *S. BRUCKMEIER, K. PILARZYK, L. PORCHER, M. KELLY;
Univ. of Maryland Sch. of Medicin Program In Neurosci., Baltimore, MD

Abstract: In the context of both regular function and disease, the hippocampus exhibits molecular asymmetries between hemispheres. Our lab studies phosphodiesterase 11A4 (PDE11A4), a hippocampally-enriched enzyme that degrades cyclic nucleotides (cAMP and cGMP). PDE11A4 expression increases with age in the human and rodent hippocampus and increasingly accumulates in filamentous "structures" resembling axons. Here, we determine if these age-related ectopic accumulations of PDE11A4 occur asymmetrically between hemispheres. Aged C57BL/6J mice show a greater age-related increase in PDE11A4-filled structures in the right versus left ventral hippocampus, with no hemispheric asymmetry observed in the hippocampi of young mice. To determine if high PDE11A expression is sufficient to drive asymmetries in PDE11 accumulation, we quantified PDE11A4-filled structures in young BALB/cJ mice as PDE11A expression in young BALB/cJ mice is equal to that of old C57BL/6J mice. Young BALB/cJ mice showed an equal number of PDE11A4-filled structures in the right versus left ventral hippocampus. Finally, we tested possible mechanisms driving age-related asymmetries in PDE11A4 trafficking. We showed phosphorylation of serine 117 on PDE11A4 correlates with asymmetric trafficking of PDE11A4 in vCA1. We also showed isoflurane mimics age-related asymmetric trafficking of PDE11A in the vSub of young C57BL/6J mice, pointing to a possible role for altered glutamatergic signaling. Together, these data suggest that the PDE11A asymmetries observed in aged C57BL/6J mice are not simply driven by higher expression levels, but rather by other aging-specific mechanisms that are unique to each subregion of the ventral hippocampus.

Title: Motor learning deficits and SOCE-dependent gene expression changes in STIM1 Deficient mice can be reversed by reducing Septin7

Authors: *S. K. DHANYA[1,2], G. HASAN[3];
[1]Lab. of Intracellular Calcium signalling, Natl. Ctr. for biological sciences, Bangalore, India; [2]Sch. of Chem. and Biotech., SASTRA Univ., Thanjavur, India; [3]Lab. of Intracellular Calcium signalling, Natl. Ctr. For Biol. Sciences,Tata Insti, Bangalore, India

Abstract: Calcium (Ca^{2+}) plays an important role in multiple aspects of neuronal signaling and function. In addition to ligand and voltage-gated calcium channels, Ca^{2+} entry in neurons also occurs through store-operated channels (SOCs) that consist of the pore-forming Orai proteins and the Endoplasmic Reticulum (ER) calcium sensor, the Stromal Interaction Molecule (STIM). Dysregulated Ca^{2+} signaling has been associated with many neurodegenerative disorders in humans and these findings have been replicated in

mouse models. Restoring intracellular calcium homeostasis by modulating components of Store-operated Ca^{2+} entry (SOCE) could be a therapeutic strategy for the treatment of such neurodegenerative disorders. Here we tested this idea by using a Purkinje cell specific Septin 7 knock out for modulating Store-operated Ca^{2+} entry (SOCE). Septin 7 (SEPT7) is a cytoskeletal protein and is known to be a negative regulator of SOCE in both *Drosophila* and human stem-cell derived neurons (1, 2). Our study shows that either lowering or abolishing SEPT7 exclusively in *STIM1* knockout Purkinje neurons modulates the age-dependant gene expression changes brought about by loss of STIM1 (3). Importantly, reduction of SEPT7 in Purkinje neurons could significantly rescue the motor deficits observed in *STIM1* knockout mice (3). Thus, our data identify SEPT7 as an important regulator of neuronal calcium homeostasis and gene expression, thereby modulating neural circuit functions of Purkinje neurons. Our findings are relevant in the context of identifying SEPT7 as a putative therapeutic target for various neurodegenerative diseases caused by reduced intracellular calcium signaling. Title: Automated development, monitoring, and analysis of iPSC-derived 3D cerebral organoids

Authors: *O. SIRENKO, A. LIM;
Mol. Devices, San Jose, CA

Abstract: Cerebral 3D organoids are a rapidly developing technology that has great potential for understanding brain development and neuronal diseases and can be used for testing effects of compounds and genetic mutations. There has been great progress in developing reproducible methods for culturing brain organoids from induced pluripotent stem cells, that allows characterization of later events in cortical development. Further method development needs to include adoption of the model for testing effects of compounds and drug candidates, as well development methods for testing the functional neuronal activity. We describe method for automated culture and monitoring of cerebral organoids, as well as testing functional neuronal activity by recording and analyzing Ca2+ oscillations. Cerebral organoids were developed from iPSC using Lancaster & Knoblich 2014 method and Cerebral Organoid Kit (STEMCELL Technologies). The method was adopted for partial automated workflow using media

exchanges by Biomek i7 liquid handler (Beckman) and culture monitoring using the ImageXpress Confocal imaging system. We monitored size and morphology of developing brain microtissues in transmitted light over 20 weeks of development using AI-based image analysis (IN Carta) for defining the size, shape, and density of the tissues. Selected microtissues were analyzed during the different phases of development using confocal imaging by expression of Sox2, TuJ1, and GAFP markers. For detection of functional activities calcium oscillations from selected clusters of the microtissues were recorded by imaging and analyzed using MetaXpress image analysis software for kinetic peak analysis. Oscillations were observed after day 50 in culture. Those were sporadic through the volume of micro-tissue, while significantly activated by 4-aminopyridine. Cellular viabilities and organoid morphologies were analyzed using viability markers and 3D image analysis. For assay characterization, we used several neuromodulators including 4-aminopyridine, GABA, NMDA, muscimol, and others. In addition, we tested known neurotoxins rotenone and mercury. The observed changes in oscillation patterns were consistent with expected actions of respective compounds, while the levels of baseline activities and degree of drug responses varied between different micro-tissues. The method demonstrates a promise for evaluation of effects of pharmaceutical drugs, toxins, and genetic mutations, while further method development is needed for screening applications.

Title: Antagonistic roles of ras-mapk and akt signaling in integrin-k^+ channel complexes-mediated cellular apoptosis

Authors: *E. FORZISI[1], F. SESTI[1], P. RAJWADE[2];
[1]Rutgers Univ. Grad. Program In Neurosci., Piscataway, NJ; [2]Rutgers Univ., Piscataway, NJ

Abstract: Complexes formed by α5-integrins and the voltage-gated potassium (K+) channel KCNB1 (Kv2.1), known as IKCs, transduce the electrical activity at the plasma membrane into biochemical events that impinge on cytoskeletal remodeling, cell differentiation and migration. However, when cells are subject to stress of oxidative nature, IKCs turn toxic and cause inflammation and death. Here, biochemical, pharmacological and cell viability evidence demonstrates that integrins activate an apoptotic Mitogen Activated Protein Kinase/Extracellular signal-Regulated kinase (Ras-MAPK) pathway. Simultaneously, wild type (WT) KCNB1 channels sequester Protein kinase B (Akt) causing dephosphorylation of BCL2 associated agonist of cell death (BAD), a major sentinel of apoptosis progression. In contrast, IKCs formed with C73A KCNB1 variant that does not induce apoptosis (IKC-C73A), do not sequester Akt and thus are able to engage cell survival mechanisms. Taken together, these

data suggest that apoptotic and survival forces co-exist in IKCs. Integrins send death signals and KCNB1 channels simultaneously sabotage survival mechanisms. Thus, the combined action of integrins and KCNB1 channels in IKCs advances life or death.

Title: Adenosine A_{2A} receptor over-functioning as a determinant of brain aging

Authors: *R. A. CUNHA[1,2];
[1]Univ. Coimbra, Coimbra, Portugal; [2]CNC-Center for Neurosci. and Cell Biol., Univ. Coimbra, Portugal

Abstract: Background: The regular consumption of moderate doses of coffee is associated with increased longevity and healthspan (N Engl J Med 2012; 366:1891). One particular component of coffee, caffeine, has been shown to attenuate memory deficits and mood deterioration through its ability to rebalance a modulation system operated by adenosine (J Alzheimers Dis 2010; 20:S1). Adenosine is a stress signal released in an activity-dependent manner and over-activation of its A_{2A} receptors ($A_{2A}R$) is paramount to trigger neuronal damage (J Neurochem 2016; 139:1019). Since neurodegenerative diseases are prevalent on aging, we now tested if $A_{2A}R$ blockade with the selective $A_{2A}R$ antagonist SCH58261 (0.1 mg/kg/daily, ip) can revert synaptic and memory deficits in aged (20-22 months-old) rats. Results: SCH58261-treated aged rats recovered performance in memory tests to the level of young rats, in which SCH58261 had no effects. Memory-impaired aged rats also displayed lower hippocampal long-term potentiation, a form of synaptic plasticity, together with a lower density of vesicular glutamate transporter type 1 (vGluT1) and increased $A_{2A}R$ density in hippocampal synapses. All these changes were reverted by treatment with SCH58261 in aged rats. In humans, $A_{2A}R$ density in the hippocampus was also increased in aged individuals (72-85 years) compared to young adults (27-35 years) and $A_{2A}R$ density was even higher in patients with early AD, mainly in hippocampal neurons.Conclusions: These findings show that $A_{2A}R$ over-function is critically required for the development of age-associated memory deficits, likely involving synaptic dysfunction. This prompts considering increased $A_{2A}R$ density as a biomarker of poorer quality of brain ageing.

Title: Aging compromises Oligodendrocyte Precursor Cell maturation and efficient remyelination in the aging monkey brain.

Authors: *C. DIMOVASILI, A. E. FAIR, K. V. BATTERMAN, T. L. MOORE, D. L. ROSENE; Boston Univ. Sch. Med., Boston, MA

Abstract: Non-neurodegenerative normal aging in primates does not entail loss of neurons. Instead, myelin degenerates, leading to loss of white matter volume and axons. This age-related loss of white matter occurs predominantly in the anterior regions of the corpus callosum and cingulum bundle and is tightly associated with cognitive decline, likely due to cortical disconnection. In the young brain, local oligodendrocyte precursor cell (OPC) populations respond to myelin damage by proliferation and differentiation into mature oligodendrocytes which produce new myelin. However, in the aging brain, remyelination is less effective. Here we tested whether the intrinsic differentiation potency of old OPCs is a bottleneck to remyelination in the aging brain. For this, we used frozen sections of frontal white matter from 5 young (<10 years) and 6 old (>20 years) cognitively characterized rhesus monkeys. We applied immunohistochemistry and stereological counting of BCAS1 cells, stratified by morphology into early differentiating (Type 1) and mature myelinating (Type 2) oligodendroglia. We also applied *in situ* hybridization to a subset of these subjects, to quantify the expression of transcription factor Nkx2.2, combined with anti-PDGFRa immunofluorescence as a marker of OPCs. Results were analyzed relative to age and our Cognitive Impairment Index (CII). We found that Type 1 BCAS1 cells were decreased 2.3-fold in the anterior cingulum bundle of aged monkeys ($p=0.0034$), and 2.4-fold in the rostral corpus callosum (=0.03). This change did not correlate with cognitive impairment. Interestingly, Type 2 BCAS1 cells did not differ between age or cognition groups. Nkx22 expression, which is necessary for OPC to oligodendrocyte differentiation, was decreased 2-fold in the OPC populations of the aging anterior cingulum bundle ($p<0.0001$). Nkx22 decrease was also tightly associated with cognitive impairment ($p<0.0001$). These results collectively show that with aging, OPCs fail to differentiate into new mature oligodendrocytes, likely impairing remyelination in the aging brain. Interventions to stimulate OPC differentiation and promote remyelination could potentially reduce or reverse the accumulation of age-related myelin and damage associated cognitive decline.

Title: Characterization of the molecular and morphological changes underlying synapse loss in the vulnerable aging rhesus macaque brain

Authors: *E. WOO[1], D. DATTA[4], I. PERONE[1], Y. M. MOROZOV[2], L. SANSING[3], A. F. ARNSTEN[1]; [2]Dept Neurobiol, [3]Dept. of Neurol., [1]Yale Univ. Sch. Med., New Haven, CT; [4]Yale Univ., New Haven, CT

Abstract: Loss of excitatory synapses on spines highly correlates with cognitive impairment in Alzheimer's disease (AD) and is region-specific, leaving some areas of the brain largely unaffected while devastating circuits in the association cortices. However, the underlying mechanisms leading to synapse loss, including this circuit specificity, are poorly understood. We hypothesize that vulnerable excitatory spines express high levels of calcium which become dysregulated with advancing age, and that chronically elevated cytosolic calcium leads to calcium overload of mitochondria and the generation of inflammatory, "eat-me" signals (e.g. calreticulin) to nearby glia to initiate synapse phagocytosis. This hypothesis was studied in *ex vivo* studies of the aging rhesus monkey dorsolateral prefrontal cortex (dlPFC), and in *in vitro* primary cortical cultures designed to mimic the sustained calcium dysregulation that develops in the aging dlPFC. Aging rhesus macaques naturally develop region-selective synapse loss and cognitive impairment, as well as amyloid plaques and tau pathology, and thus are an advantageous model to study the molecular and cellular events associated with age-related neurodegeneration. In particular, the circuits in deep layer III (LIII) of the dlPFC that subserve working memory are especially vulnerable to spine loss with age. These circuits are normally dependent on elevated calcium signaling to support the persistent firing needed for working memory, but lose regulation of calcium-cAMP signaling with advancing age, e.g. with loss of PDE4D from dendrites and spines (Alzh&Dem 17:920-932, 2021). Aged LIII dlPFC pyramidal cells also express dysmorphic mitochondria in their dendrites, identified as "Mitochondria-on-a-string" (MOAS), which are also seen in familial AD mouse models and human AD postmortem cortices. The current study used immunoEM in young vs. aged rhesus layer III dlPFC and found that MOAS are associated with the expression of complement C1q, while there is decreased association between MOAS and PDE4D. We next asked whether calreticulin, a known "eat-me" signal, is expressed by LIII dlPFC neurons and could mediate synaptic phagocytosis. We find that calreticulin is robustly expressed in LIII dlPFC. The explicit role of chronic calcium dysregulation in causing mitochondrial dysfunction and inflammatory C1q and calreticulin signaling is currently being tested in primary neuronal cultures. Interventions that restore regulation of calcium in higher cortical circuits may protect neuronal integrity and cognitive function.

Title: Identification of an age-related plasma protein with effects on cognitive function

Authors: *J. M. ADAMS[1], S. V. REGE[1], R. HARISH[1], A. T. LIU[2], R. BRITTON[1], S. S. MINAMI[1], E. CZIRR[1], M. KERRISK CAMPBELL[1];
[1]Alkahest Inc, San Carlos, CA; [2]CODA Biotherapeutics Inc, South San Francisco, CA

Abstract: In the coming decades, it is expected that people over 65 years of age will make up 15% of the global population. With that comes the challenge of addressing age-related, neurological disorders, like Alzheimer's and dementia, thus motivating the identification of new therapeutics to alleviate and improve symptoms, such as cognitive decline. Although multiple candidates for therapeutics have been proposed and proved beneficial in pre-clinical models, few have managed to translate well into the clinic. To this effort, we identified a detrimental enzyme, leukotriene A4 hydrolase (LTA4H), found at high levels in plasma of aged and cognitively impaired humans and show that an increase in this enzyme correlates with decreased cognition in Alzheimer's patients. When we dosed mice with a recombinant form of this enzyme, we were able to induce cognitive deficits. We also show in rodents that chronic inhibition of this enzyme with a small molecule inhibitor leads to improvement in cognition-based behavioral readouts and histological changes in the water-channel protein, aquaporin-4, pointing to changes along the blood-brain barrier. These data support the finding of a novel enzyme involved in age- and disease-related cognitive decline and an inhibitor that can effectively act in different species to modulate this detrimental enzyme.

Title: The role of L-type calcium channels in age-associated memory decline

Authors: *V. RAJANI, S. GHOSH, T. N. CRITCH, A. MAZIAR, Q. YUAN;
Biomed. Sciences, Fac. of Med., Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Aging is associated with cognitive decline and memory loss in humans. In rats, age-associated impairment of spatial and olfactory learning has also been observed. We investigated the role of L-type calcium channels (LTCCs) in both the piriform cortex (PC) and the hippocampus, which may be involved in the disruption of calcium homeostasis, contributing to changes in synaptic plasticity with age. We employed spatial and olfactory behavioral tasks that involve the hippocampus and PC. In an odor-associative learning task, both intraperitoneal (i.p.) and local infusions of nimodipine into the PC (5.5mg/kg for i.p; and 1-100uM 0.5uL/side infused) prevented the ability of young Sprague-Dawley rats (6-9 months) to learn that a positive odor contained a food reward. In aged rats (>18 months), on the other hand, i.p. and local infusion of nimodipine into the CA1 layer of the hippocampus improved odor-associative learning and spontaneous location recognition compared to vehicle controls. We then examined neuronal excitability in both pyramidal neurons of the PC and in the CA1 layer of the hippocampus. In young rats (<5 months old) and aging rats (>18 months old), we used whole-cell patch clamp recording to measure intrinsic electrophysiological properties of pyramidal neurons in each region. In both regions, action potential (AP) threshold was significantly higher for aged rats, with larger fast afterhyperpolarization (AHP). Aged hippocampal neurons also displayed a reduced excitability, along with higher input resistance and a significantly larger slow AHP, suggestive of increased LTCC activity. However, AHP and excitability differences were not observed in the aged PC neurons. Indeed, immunohistochemistry reveals that the LTCC subunit Cav1.2 has significantly increased expression in CA1 soma and increased Cav1.3 in CA1 dendrites in aged rats compared to young rats. In contrast, Cav1.3 expression was lower, and Cav1.2 expression was unchanged in the soma of the aged PC neurons. Altogether our data suggests that LTCCs have increased hippocampal expression with age and play a significant role in age-related mechanisms of reduced synaptic plasticity and overall cognitive decline.

Title: Age-related decline of neuronal function involves a loss of inhibitory signaling in C. elegans

Authors: *G. WIRAK[1], J. FLORMAN[2], M. J. ALKEMA[2], C. W. CONNOR[3], C. V. GABEL[1];
[1]Physiol. and Biophysics, Boston Univ. Sch. of Med., Boston, MA; [2]Dept. of Neurobio., Univ. of

Massachusetts Med. Sch., Worcester, MA; [3]Dept. of Anesthesiology, Perioperative and Pain Med., Brigham and Women's Hosp., Boston, MA

Abstract: Neural function declines with age resulting in behavioral deficits. How this age-related decline is related to changes in neural connectivity and circuit function on the cellular level is largely unknown. The nematode worm *Caenorhabditis elegans* is well suited for the investigation of neural aging, given its fully-mapped neural connectome and tractability for functional neuronal imaging. The advent of multi-neuron functional imaging in *C. elegans* presents an opportunity to define, for the first time, the effects of aging on nervous systemwide function with cellular resolution. Moreover, this animal is a powerful model system for the genetic investigation of molecular factors influencing aging. Here we employ multi-neuronal fluorescence imaging in *C. elegans* to measure changes in neural activity and connectivity with age across the animal's nervous system. Employing transgenic pan-neuronal expression of the fluorescent calcium indicator GCaMP6s, we capture neural activity at single-cell resolution across the organism's entire head region, using light sheet microscopy. We identify substantial age-related alterations in the activity dynamics of neurons as well as changes in connectivity and functional organization of the system. As the animals age, we observe a loss of systemwide organization and a corresponding shift in individual neuron activity toward higher frequencies. We also observe a specific loss of anti-correlative (i.e. inhibitory) signaling between neurons, resulting in an overall shift in the excitatory-inhibitory (E/I) balance of the system. In support of this, we find that application of the $GABA_A$ agonist muscimol diminishes aspects of nervous system decline in aged animals. Interestingly, age-related effects are recapitulated in young animals bearing a gain-of-function mutation within the *unc-2* gene, encoding a pre-synaptic voltage-gated calcium channel. Conversely, aging effects are greatly diminished by a loss-of-function mutation in *ced-4*. *Ced-4* is a key regulator of a calcium-activated caspase pathway known to play a role in synaptic elimination across multiple species. During development, UNC-2/CaV2 activity is known to trigger the removal of inhibitory GABAergic synapses in motor neurons through a CED-4 dependent pathway. Our results suggest that a similar process is occurring as the animals age, resulting in a loss of inhibitory signaling and disruption of system dynamics. Through comprehensive multi-neuronal imaging, we measure the progressive breakdown of neural activity and system dynamics with age and begin to identify the cellular processes and changes in synaptic signaling that contribute to this decline.

Abstract: Recent advances in genetic sequencing have enabled comprehensive genetic analyses of human diseases, resulting in the identification of numerous genetic risk factors for heritable disorders including Alzheimer's disease (AD). Such analyses enable AD risk prediction well before disease onset, which is critical for early interventions. However, current analytical approaches have limited ability to accurately estimate the risk effects of genetic variants owing to epistatic effects, which have been overlooked in most previous studies, resulting in unsatisfactory disease risk prediction. Herein, we modeled AD polygenic risk using deep learning methods, which outperformed existing models (i.e., lasso model) for classifying disease risk. Moreover, by examining the associations between the outcomes from deep learning methods and AD plasma biomarkers in our in-house Chinese AD cohorts, we showed the polygenic risk captured by the model is associated with levels of plasma Aβ and p-tau181 in normal controls. Thus, our results demonstrate the utility of deep learning methods for modeling the genetic risks of human diseases, which can facilitate both disease risk classification and the study of disease mechanisms.

Title: Cyclic multiplex fluorescent immunohistochemistry and machine learning reveal distinct states of astrocytes and microglia in normal aging and Alzheimer's disease

Authors: *C. MUÑOZ-CASTRO[1,2,3,4], A. NOORI[1,5], C. MAGDAMO[1,2], J. D. MARKS[1], M. P. FROSCH[1,2,3], S. DAS[1,2,3], B. T. HYMAN[1,2,3], A. SERRANO-POZO[1,2,3];

Abstract: Background: Astrocytes and microglia react to Aβ plaques and neurofibrillary tangles in the Alzheimer's disease (AD) brain, but the consequences of such responses remain elusive partly due to the limited multiplexing capability of immunohistochemistry. We have developed a methodology of cyclic multiplex fluorescent immunohistochemistry on human postmortem brain sections followed by an analysis pipeline that enables a deep morphological quantitative characterization of these glial cells in the context of their spatial relationships with plaques and tangles. **Methods:** Single FFPE sections from the temporal association cortex (n=7 control and n=7 AD) were subjected to 8 cycles of multiplex fluorescent immunohistochemistry, including 7 astroglial, 6 microglial, 1 neuronal, Aβ, and p-tau markers. Our analysis pipeline consisted of: (1) image alignment across cycles; (2) background subtraction; (3) manual annotation of 5,172 ALDH1L1+ astrocytic and 6,226 IBA1+ microglial profiles; (4) local thresholding and segmentation of profiles; (5) machine learning models on marker intensity data; and (6) deep learning on image features. **Results:** Spectral clustering identified three phenotypes of astrocytes and microglia, which we termed "homeostatic," "intermediate," and "reactive." Reactive and, to a lesser extent, intermediate astrocytes and microglia were closely associated with AD pathology (≤50 μm). Compared to homeostatic, reactive astrocytes contain substantially higher GFAP and YKL-40, modestly elevated vimentin and TSPO as well as EAAT1, and reduced GS. Intermediate astrocytes are defined by markedly increased EAAT2, moderately increased GS, and intermediate GFAP and YKL-40 levels. Relative to homeostatic, reactive microglia show increased expression of all markers (CD68, ferritin, MHC2, TMEM119, TSPO), whereas intermediate microglia exhibit increased ferritin and TMEM119 as well as intermediate CD68 levels. Machine learning models accurately discriminated between control and AD subjects at the single-cell level, either applied on high-plex signal intensity data (gradient boosting machine) or directly on image features (convolutional neural networks). **Conclusions:** Cyclic multiplex fluorescent immunohistochemistry combined with machine learning models allow the deep phenotyping of glia at single-cell resolution in postmortem brain specimens to identify distinct states in health and

disease. Besides the homeostatic and reactive, we identified a novel “intermediate” state of astrocytes and microglia in AD, which may represent a resilience mechanism or, alternatively, a transitional state between homeostatic and reactive.

Title: EEG based tool for detection of cognitive impairment - results from a large ecological trial on seniors

Authors: *J. DREO[1,2], J. JUG[2,3], B. ALJAŽ[3], D. SAKIć[2], I. AKSENTIJEVIć[4,2];
[1]Med. Faculty, Univ. of Ljubljana, Ljubljana, Slovenia; [2]BrainTrip Limited, Naxxar, Malta; [3]Fac. for Computer and Information Sci., Ljubljana, Slovenia; [4]Fac. of Social Sci., Ljubljana, Slovenia

Abstract: Dementia is fast becoming one of the leading causes of impairment in old age with major dementia advocacy groups increasingly advocating for populational screening programs. Early detection coupled with early intervention (pharmacological, social, rehabilitation), even in the absence of a disease-modifying cure, is the only way for patients to maintain quality of life and independence. However, the tools currently used to diagnose dementias in clinical practice (brain imaging, CSF biomarkers, psychometric testing, and clinical observation) are simply not adequate for large-scale, cost-effective, and practical populational screening. We have tested a new approach of screening for cognitive impairment based on fully automatic analysis of EEG signals obtained with a mobile 24-channel EEG amplifier (mBrainTrain), sponge-based EEG caps (Greentek), and custom software (BDI) for EEG recording and analysis of cognitive function (BrainTrip). The BDI software a) guides minimally-trained users through the EEG recording, b) provides online EEG data quality assessment, c) performs fully automated qEEG analysis of the recorded data and returns immediate feedback on potential cognitive impairments in the tested subject. The BDI software first analyzes EEG data by automatically labeling and correcting for common artifacts. It then calculates spectral EEG features known to be associated with poor cognitive performance and combines them into a prediction model based on density clustering and a neural net classifier. We conducted a large-scale ecological evaluation of the accuracy, specificity, and sensitivity of this EEG-based tool for cognitive assessment by performing 840 EEG recordings on 220 seniors recruited from senior care homes in Slovenia between May and October 2021. Each senior participated in 4 separate recording sessions with 1-3 weeks between sessions. In each session an 8-min long rest EEG recording (eyes open and closed) was done with the BrainTrip system. Additionally, during each session participants’ cognitive abilities were tests with one of four cognitive tests (MoCA, ADAS-Cog11, WAIS, Eurotest+Phototest). Preliminary results of BDI performance (compared to a gold standard based on a

factor-analysis of all psychometric tests on 320 recordings obtained up to July 2021) for mild cognitive impairment/dementia are: Sensitivity 74.6% / 89.3%, Specificity 93.5% / 97.0%, Accuracy 86.2% / 94.3%. Based on this performance we conclude that EEG-based assessment of cognitive function is a promising option of screening for MCI and dementia.

Title: Clinical utility of blood-based, microglial derived exosomes as biomarkers for Alzheimer’s disease

Authors: *C. N. WINSTON[1], R. A. RISSMAN[2];
[1]Neurosciences, UC San Diego, LA Jolla, CA; [2]Neurosci, UCSD Sch. of Med., La Jolla, CA

Abstract: Background: Recent studies suggest neuronal and astrocyte-derived exosomes may serve as the source of biomarkers for many neurodegenerative diseases, include AD. However very few studies have characterized the biomarker potential of microglial derived exosomes. **Method:** Plasma exosomes were extracted and precipitated from AD, mTBI patients and age matched controls. Extracted exosomes were enriched against a microglial source (TMEM119) using magnetic immunocapture and fluorescence-activated cell sorting (FACS) sorting. MDEs were characterized by size (Nanosight) and shape (TEM). Exosome marker profiling was done by western blot. MDE cargo proteins will be quantified using ELISA. **Result:** Blood-based MDEs demonstrate similar size distributions and shape to previously reported exosome preparations. Western Blot demonstrated that MDEs were positive for exosome marker Flotilin-1; microglial markers CD68 and IBA1 and negative for astrocyte marker, GLAST. Further characterization of MDE protein cargo levels, which include AD-related (Aβ and p-tau) and inflammatory markers, will be analyzed, and presented. **Conclusion:** MDEs can be successfully isolated from human blood. MDEs may also serve as useful blood-based biomarkers for AD diagnosis, akin to other CNS-derived exosomes. Further characterization is required to determine the biomarker potential of MDEs for mTBI and AD.

Title: Longitudinal measurement of neuronal network activity in multiple brain regions in APP/PS1 mice

Authors: *F. C. VAN HEUSDEN[1], A. VAN NIFTERICK[2], A. A. GOUW[2], A. B. SMIT[1], R. E. VAN KESTEREN[1];

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder, with a long preclinical and prodromal phase. To enable the study of disease mechanisms, AD has been modeled in transgenic animal lines and over the years our knowledge on the molecular and cellular processes underlying the early stages of AD pathogenesis has expanded. However, translating these findings to the clinic has proven difficult in terms of finding good biomarkers or treatment for AD. In mouse studies, neuronal hyperactivity and interneuron dysfunction have been observed. Whereas at an early disease stage hippocampal parvalbumin (PV) interneurons seem to be hyperactive in APP/PS1 mice, a commonly used mouse model for AD-associated amyloidosis, they appear to be impaired at a later disease stage. As the balance between excitation and inhibition is crucial to the generation of oscillatory activity in the brain, and since network activity provides an opportunity for mouse-to-human translation, we here investigate longitudinal changes in network activity in APP/PS1 mice. Local field potential (LFP) recordings were performed in three different brain areas - prefrontal cortex, hippocampus and parietal cortex - in male mice from 3 months of age (moa) until 10 moa. LFP activity within brain regions and synchronization between brain regions were analyzed. We observe a shift in LFP power from the lower to the higher frequencies in APP/PS1 mice compared with wildtype controls, as well as alterations in connectivity between brain regions. Using MEG and EEG data from PSEN1 mutation carriers, patients with mild cognitive impairment (MCI) and AD patients we aim to further elucidate whether and how mouse LFP data translate to human patients, and whether mouse LFP recordings hold potential for the identification of novel biomarkers for AD.

Title: Vascular risk biomarkers are linked to frontal memory-related neuromarkers

Authors: J. J. LATHAM[1], T. L. SUDDUTH[2], B. WANG[3], J. M. BARBER[1], M. R. KELLY[1], K. SNYDER[1], B. J. MARTIN[1], G. A. JICHA[1], D. M. WILCOCK[1], *Y. JIANG[1];

Abstract: Vascular Risk Biomarkers are Linked to Frontal Memory-related Neuromarkers
Jeremy Latham, Tiffany L. Sudduth, Baoxi Wang, JM Barber, MR Kelly, KE Synder, BJ Martin, GA Jicha, Donna Wilcock, & Y Jiang
We reported longitudinal evidence that left frontal memory-related signals predict risk of amnestic Mild Cognitive Impairment (MCI) about 5 years before clinical diagnosis (Jiang et al., 2021) in healthy cognitively intact older adults. MCI is a prodrome of dementia. There is limited understanding of MCI due to mixed Alzheimer's disease (AD) and vascular pathologies. Identifying cause-specific MCI risk pre-symptomatically increases the ability to slow cognitive decline. The relationship between subtypes of MCI induced by vascular dementia was not clear. Here we test the hypothesis that increased vascular risk alters brain signals during a cognitive task in older adults.
20 cognitively intact healthy older adults (median age 68, 9 females) from the University of Kentucky Alzheimer's Disease (AD) Research Center participated in the study. Each volunteer was assessed with the Montreal Cognitive Assessment (MoCA) and vascular/AD plasma markers were collected. Brain activity and memory performance were recorded during the 15-min Bluegrass working memory test using a 14-channel, wireless electroencephalography (EEG) headset (eMOtiv; Borhani et al., 2021). Pearson correlations were used to assess associations between frontal EEG sites and plasma markers for Vascular risk factors.
Increased frontal F7 or F3 "difference brainwaves" (Diffs: Nontarget > target) were associated with reduced ability to hold the memory target. We found that frontal F3 Diffs are negatively correlated with MoCA scores (R= -0.457) while diastolic and systolic blood pressure were positively correlated with F7 Diffs (R=0.431 and R=0.463). Left frontal signals were also significantly correlated with multiple serum biomarkers. The most significant biomarker was serum A1C (a known risk factor for developing vascular MCI-like states), which was positively correlated with mean Diffs at F3/F7 sites, F3, and F7 (R=0.645, 0.528, and 0.313).
We report that a variety of plasma biomarkers for vascular risks, specifically changes in hemoglobin and blood pressure, were associated with decreased working memory-related neural functions. Our findings directly link increased vascular risk factors with reduced neural functions of holding items in working memory in pre-symptomatic older adults.

Title: Heart failure decouples the precuneus from other brain regions - A link to Alzheimer's disease?

Authors: *M. L. SCHROETER[1], F. THIEL[1], F. BEUTNER[2], A. TEREN[2], A. VILLRINGER[1], K. MUELLER[1];
[1]Neurol., MPI Human Cogn Brain Sci., Leipzig, Germany; [2]Leipzig Heart Ctr., Leipzig, Germany

Abstract: Aging increases the risk to develop neurodegenerative diseases, most importantly Alzheimer's disease. Understanding mechanisms and strategies to prevent disease and modify its course are of uttermost importance. A proteome-wide association study identified N-terminal prohormone of brain natriuretic peptide (NT-proBNP), a biomarker for heart failure (HF), to be associated with development of dementia over five years (Walker et al.; Nature Aging 2021;1:473-489). Recently, we had investigated consequences of HF associated with coronary artery disease (CAD) for brain structure in eighty patients of the Leipzig Heart Center in Germany (Mueller et al.; Circulation Research 2020;126(6):750-764). Gray matter density (GMD) as measured with structural magnetic resonance imaging (MRI) was diminished in patients with HF due to CAD across the brain, i.e. in frontomedian, parietal, posterior cingulate cortex, and precuneus, when compared with controls. This finding was replicated and focused onto the posterior cingulate cortex and precuneus in patients with CAD with HF compared with those without HF. The impact of HF on brain structure was further supported by biomarkers for HF. Cardiac ejection fraction correlated positively with GMD across the whole frontal and parietal medial cortex, whereas NT-proBNP was negatively associated with GMD in the medial and posterior cingulate cortex, hippocampus, and precuneus. Remarkably, these brain regions have been identified meta-analytically as core hubs involved in Alzheimer's disease, and its risk state mild cognitive impairment (Schroeter et al.; NeuroImage 2009;47(4):1196-1206). Here, we investigated the impact of HF on brain connectivity with functional resting-state MRI in the same cohort. HF was associated with decreased connectivity (network centrality) in the precuneus if patients with and without HF were compared - the same brain region identified as predicting conversion from mild cognitive impairment to Alzheimer's dementia. Regional centrality was correlated with HF-related biomarkers ejection fraction and NT-proBNP. In sum, HF due to CAD decouples the precuneus as the decisive connectivity hub from other brain regions, which might indicate higher vulnerability for the development of cognitive dysfunction such as in Alzheimer's disease.

Title: A spreadsheet structure for an EEG/neurofeedback-based re-classification of Alzheimer-disease trajectories with a novel philosophical approach

Authors: *J. F. GOMEZ-MOLINA[1], U. M. RICOY[2], Á. L. GÓMEZ-MOLINA[1];
[1]Intl. Group of Neuroscience, IGN:N(S,E,P), Medellin, Colombia; [2]Dept. of Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Studies (classification, monitoring, intervention) of Alzheimer's Disease (AD) should, ideally, be based on evidence, tools and concepts accessible and replicable to the patient and marginalized communities (Gomez-Molina March for Science 2017, "Unbiased Science constructed for all and for the common good", 2017, Medellín, Metro Station/Stadium). Abnormalities of activation states in EEG-rhythms and their "interrelatedness"/connectivity are present in AD (Babilony, GBC-group 2021; Gomez-Molina et. al 1999, 2003). They show, in simple terms, "sleep-like slowing". See details in Gomez-Molina SfN-J-abstract. RESULTS. I.Classification arrays of AD progression based on chrono-biological issues (24 h, 7 days, 360 days, 3-11 years?) and "real-time" responses to treatments (drugs, nutrition, neuromodulation, neurofeedback, behavioral/cognitive therapies, sleep-pattern therapies). II.Algorithms: "If h[(alpha+ k*beta/gamma)/g(delta+theta)] have increased, then try to repeat what you did recently (7 days); 0<k<1, g(.) corrects for normal aging, h[.]: spectral band corrections for alpha-peak/theta-minima periodicity"."Calculate pijr, the probability of having the result r given lifestyle/treatment i and environmental condition j"."Given patient's preferences (weights) for i, r, calculate expected total risks, costs, benefits on a week-by-week basis and projected to the future". With their physician, patients propose treatments and AD-trajectory. CONCLUSIONS: I. Participation in the design of their own AD-trajectories may give sense of autonomy, freedom and dignity to patients. Contribute to mind exploration, science and other patients gives them existential meaning. II. Additional use of portable low-cost accelerometers can be useful. III. Multiple membership fuzzy-functions allows jumps across AD-classifications. IV. MRI/MEG, if available, can correct for skull and gray matter distance/co-alignment of pyramidal cells (see YouTube keywords: neurolectric minds Gomez-Molina). Conception/initiative/develop/writing/analysis: JFGM. Comment/Anal.: ALGM

Title: Environmental enrichment promotes cognitive recovery after a pediatric traumatic brain injury in rats

Authors: *J. ZAMUDIO FLORES, A. SALINAS GARCÍA, J. MEJIA OLIVA, N. LAJUD;
Ctr. de Investigación Biomédica de Michoacán, Inst. Mexicano del Seguro Social, Morelia, Mexico

Abstract: Pediatric traumatic brain injury (TBI) is a global public health concern that represent one of the main causes of death and disability in children and adolescents. Studies have reported that TBI-related disabilities in early life are worse than those that occur after a TBI in adult life. Environmental enrichment (EE) is a rodent model of rehabilitation which has been shown to efficiently simulate the recovery observed in clinical practice. EE confers motor and histological benefits and restores cognitive performance after adult TBI. Therefore, we consider that EE can be a useful tool to promote functional recovery after pediatric TBI. To prove this, male Sprague-Dawley rats undergoing controlled cortical impact surgery at PND 21 were used (depth: 2.5 mm, velocity: 4 m/s; n=20). They were later divided into groups with standard (STD) or EE conditions and allowed to recover for 14 days. We evaluated cognitive performance in the Morris water maze (MWM) test from post-injury day 14 to 19. The results indicated that TBI+STD significantly impaired cognitive performance in the training phase of the MWM when compared to Sham+STD; however, no differences were observed between TBI+EE and Sham groups. There was no effect of EE or injury on the probe trial performed at P19. In conclusion our data indicate that EE improves cognitive outcome after pediatric TBI.

Abstract: Inflammation is a key event after traumatic brain injury (TBI). Chronic inflammation is triggered and sustained by brain tissue-derived molecules (B-Ag) recognized as self-antigens by T and B

cell receptors. This work explored the possibility of avoiding the negative consequences of chronic inflammation by the induction of tolerance to B-Ag through anterior chamber associated immune deviation (ACAID) prior to TBI. To do this, 46 female rats (postnatal day 75-80) were randomly allocated to two experimental groups and injected in the anterior chamber of the eye with vehicle (PBS) or B-Ag. Both groups were then divided into two subgroups (SHAM and TBI). The sham groups were only craniotomized (SHAM-PBS n=12; SHAM-B-Ag n=12), while the TBI groups were also injured by a controlled cortical impact 7 days after anterior chamber injection (TBI-PBS n=11; TBI-B-Ag n=11). Motor recovery was evaluated 5 days post-injury with the beam-balance test. Cognitive performance was evaluated in the Morris water maze during post-injury days 14-18 (5 days of training to find the escape platform and then a memory test without platform). Induction of immune tolerance was evaluated at the end of the behavioral trials by delayed hypersensitivity tests. The results showed an effect of injury ($F_{(1, 42)}$=31.32, p<0.001) and the day of training on the latency to find the platform ($F_{(4,168)}$=42.94, p<0.001). However, there was no effect of immune tolerance to B-Ag on the time to find the platform during training (p>0.05), or during the memory test (p>0.05) or an effect of the interaction between factors (p>0.05). Delayed hypersensitivity tests confirmed the induction of immune tolerance to B-Ag ($F_{(1,42)}$=16.07, p<0.001). Together, the results show that immune tolerance to B-Ag does not improve cognitive defects produced by TBI. More studies should evaluate the inflammatory profile induced by B-Ag and its effect on lesion size and on the number of preserved cells

Title: Effects of positive allosteric modulation of α7 nicotinic acetylcholine receptors on sustained attention and cholinergic neurotransmission after experimental traumatic brain injury

Authors: *T. RANELLONE[1], E. H. MOSCHONAS[1], N. RACE[1], P. RENNERFELDT[1], R. REDDY[1], B. WEHRMEYER[1], S. BALAJI[1], J. P. CHENG[1], S. W. CARLSON[2], C. E. DIXON[2], A. E. KLINE[1], C. O. BONDI[1];
[1]Physical Med. & Rehabil., [2]Neurosurg., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Introduction: Traumatic brain injury (TBI) is a leading cause of cognitive disability. Impaired attention and memory are due, in part, to cholinergic dysregulation, which suggests that pharmacological strategies that amplify activation of acetylcholine (ACh) receptors may ameliorate behavioral deficits. Hypothesis: NS-1738, a novel type-I positive allosteric modulator at the α7 nicotinic ACh receptors (α7

nAChRs) will normalize cholinergic neurotransmission and restore sustained attention after TBI. Methods: Rats were trained on the abbreviated 3-choice serial reaction time task (3-CSRT) using a 2-s cue presentation. Anesthetized adult male rats received either a cortical impact of moderate severity or sham injury and then randomly assigned to NS-1738 (3 mg/kg) or vehicle (1.0 mL/kg). Treatments began 24 h after surgery and were given once daily for either 7 or 28 days. Assessment of sustained attention, which consisted of percent accuracy, percent omissions (i.e., distractibility), and premature responses (i.e., impulsivity) was performed on days 14-24. On post-injury day 30, markers of cholinergic neurotransmission were examined in the medial prefrontal cortex, a region previously implicated in mediating sustained attention via Western blot. The data were analyzed by two-way ANOVAs with repeated measures, followed by Newman-Keuls post hoc tests when appropriate. Results: Deficits on sustained attention, demonstrated by decreased percent accuracy and increased percent omissions, in the 3-CSRT were observed after TBI relative to the pooled sham group. Subacute NS-1738 did not improve accuracy or omissions when compared to the vehicle TBI group ($p>0.05$), however chronic NS-1738 significantly restored sustained performance and reduced distractibility ($p<0.05$). The lack of differences in the subacute group may have resulted from a drug wash-out period. Western-blot analysis reveals a general injury effect toward the reduction of cholinergic modulation after TBI. Conclusions: The data suggest that subacute augmentation of cholinergic modulation via NS-1738 after TBI was not effective in restoring higher-order attention long-term, while chronic, steady-state treatment was effective at restoring sustained attention. We are now evaluating the possibility that chronic NS-1738 may further improve cognitive function when co-administered with enriched environment. Significance: To date, there are no FDA approved pharmacotherapies for the amelioration of TBI-induced cognitive deficits. Hence, examining the efficacy of NS-1738 after experimental TBI is imperative to improve translatability of pharmacological interventions.

Title: Lipoxygenase inhibitors for the treatment of traumatic brain injury

Authors: *J. ROGERS[1], X. LIU[1], L. JONG[1], Y. LIU[2], Y. WANG[2], M. BAUDRY[2];
[1]Biosci., SRI Intl., Menlo Park, CA; [2]Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Multiple reports suggest that neuroinflammation plays a significant role in traumatic brain injury (TBI), a condition that can turn a minor head injury into life-long cognitive, behavioral, and motor deficits. Nonetheless, no consensus treatment for the neuroinflammatory sequelae of TBI has been recognized. Cyclooxygenase (COX) and lipoxygenase (LOX) pathways provide an important non-steroidal alternative for controlling innate inflammatory responses. Because COX inhibitors (e.g., ibuprofen, naproxen) are associated with gastrointestinal and cardiovascular adverse reactions, we have developed lipoxygenase (LOX) inhibitors that simultaneously inhibit 5-, 12-, and 15-LOX at low nM levels. In cell cultures (THP-1 differentiated macrophages) and mouse animal models, these compounds showed little to no toxicity, high CNS penetration when given orally or by intraperitoneal (ip) injection, and inhibition of a broad range of pro-inflammatory cytokines, chemokines, and growth factors. To evaluate the effect of LOX inhibition on TBI, wild-type C57/Bl6 mice were subjected to controlled cortical impact (CCI) followed by daily ip injection of vehicle or a proprietary LOX inhibitor, SRI 31291 (40 mg/kg), for seven days. Compared to vehicle-treated controls, mice treated with SRI 31291 exhibited enhanced recovery of weight, reduced spread of brain damage, enhanced recovery of long-term potentiation in CA1 of hippocampal slices, and reduced cognitive impairment (novel object recognition, fear conditioning context and tone tests) 30 days after CCI. SRI LOX inhibitors do not act by chelating iron, the mechanism of action for the only FDA- approved LOX inhibitor, Zileuton, and may thereby avoid its adverse reactions. Collectively, our findings suggest that further evaluation of LOX inhibitors in general, and our LOX inhibitors in particular, may be warranted as potential treatments for TBI.

Institute, City of Hope, Duarte, CA; [4]Dept. of Computat. and

Quantitative Medicine, Div. of Mathematical Oncology, Beckman Res. Institute, City of Hope, Duarte, PA

Abstract: The self-renewal capacity of neural stem cells (NSCs) and the inherent ability to migrate to sites of injury and proliferate holds high therapeutic potential in attenuating functional impairments after traumatic brain injury (TBI). To explore the possibility of NSC-based therapy after TBI, isoflurane-anesthetized adult male rats received a controlled cortical impact (CCI) of moderate severity (2.8 mm deformation at 4 m/s) or sham injury (i.e., no cortical impact). Beginning 1-week post-injury, the rats were immunosuppressed and 1×10^6 human NSCs (LM-NS008.GFP.fLuc) or vehicle (VEH) (2% human serum albumen) were administered intranasally (IN) on post-operative days 7, 9, 11, 13, 15, and 17. To evaluate the spatial distributions of the LM-NSC008 cells, half of the rats were euthanized on day 25, one day after completion of the cognitive task, and the other half were euthanized on day 46. 1 mm thick brain sections were optically cleared (CLARITY), and volumes were imaged by confocal microscopy. In addition, LM-NSC008 cell migration to the TBI site by immunohistochemistry for human-specific Nestin was observed at day 39. Acquisition of spatial learning was assessed in a well-established Morris water maze task on six successive days beginning on post-injury day 18. IN administration of LM-NSC008 cells after TBI (TBI + NSC) significantly facilitated spatial learning relative to TBI + VEH rats ($p < 0.05$) and had no effect on sham + NSC rats. Overall, these data indicate that IN-administered LM-NSC008 cells migrate to sites of TBI damage and that their presence correlates with cognitive improvement. Future studies will expand on these preliminary findings by evaluating other LM-NSC008 cell dosing paradigms and evaluating mechanisms by which LM-NSC008 cells contribute to cognitive recovery.

Title: Simultaneous targeting of ER stress and oxidative stress by a tri-combo drug therapy confers neuroprotection following traumatic brain injury in mice

Authors: *C. KOZHIKKADAN DAVIS[1], S. BATHULA[1], R. VEMUGANTI[1,2];
[1]Univ. of Wisconsin Madison, Madison, WI; [2]William S. Middleton Veterans Admin. Hosp., Madison, WI

Abstract: TBI pathophysiology is multifactorial. Therefore, a drug combination therapy that targets multiple events in the pathogenesis of TBI may confer better outcomes. TBI leads to oxidative as well as ER stress, and they play a crucial role in its pathophysiology; moreover, they potentiate each other. In this study, we tested if a combination of drugs that prevent oxidative and ER stress promotes better outcomes after TBI. Male and female C57BL/6 mice aged 12 to 13 weeks were subjected to moderate (1mm impact

depth) controlled cortical impact-induced TBI. The treatment group received a combination of apocynin (10 mg/kg; NADPH oxidase inhibitor), tert-butylhydroquinone (tBHQ) (25 mg/Kg; Nrf2 activator), and salubrinal (3 mg/kg; eIF2α phosphatase inhibitor) at 5 min, 24h, and 48h after TBI compared to DMSO in the vehicle group. Rotarod and beam walk tests were carried out on days 2, 4, 7, 30, 60, and 100 after TBI. Morris water maze experiment was performed on weeks 4 and 10 following injury. Subsequently, 14 weeks after TBI, animals were euthanized, and lesion volume was measured. In a different cohort of animals, qualitative measurement of activated microglia and oxidative DNA damage, and expression levels of some of the proinflammatory genes were carried out at 72h after TBI. The tri-combo treatment significantly improved motor function, spatial memory, and reduced lesion volume compared to the sex-matched vehicle group. Further, compared to vehicle treatment, the number of activated microglia, cells with oxidative DNA damage, and expression levels of pro-inflammatory genes (TNFα, MIP-1α, IL-1β, and CD206) were seen reduced by the tri-combo treatment in the ipsilateral cerebral cortex of injured animals. In conclusion, post-TBI treatment with a drug combination of apocynin, tBHQ, and salubrinal that target ER stress and oxidative stress conferred neuroprotection in mice by suppressing inflammation.

Title: Evaluation of music medicine to ameliorate traumatic brain injury-induced neurobehavioral and cognitive deficits

Authors: V. J. VOZZELLA[1], I. N. COOPER[1], E. H. MOSCHONAS[1], J. P. CHENG[1], J. M. JARVIS[1], E. L. FINK[2], C. O. BONDI[1], *A. E. KLINE[1];
[1]Physical Med. & Rehabil., [2]Pediatric Critical Care Med., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Introduction: Traumatic brain injury (TBI) is a leading cause of death and disability for children and adults worldwide. In the USA there are approximately 2.8 million TBI-related emergency department visits each year. The majority of TBI survivors have long-lasting disturbances in motor, cognitive, and emotional health (e.g., anxiety) that negatively impact their long-term academic, occupational, and social functioning. Despite the individual, medical, and societal burden of TBI, interventions to remediate the TBI sequelae and promote recovery are lacking and/or have not successfully translated from the bench to the hospital, thus strongly supporting the need to test and implement novel, safe, effective, nonpharmacological strategies. Music holds untapped potential for improving cognition and neurobehavior after TBI as evidenced by clinical studies in adults with brain injury where music-based interventions were associated with improved physical, cognitive, and emotional

functioning. Basic science data in non-TBI rats also show that music enhances cognition. The aim of this study was to increase our understanding of how music affects the brain when used as a therapy to confer cognitive and neurobehavioral recovery after TBI. Hypothesis: Classical music provided to adult rats after TBI will ameliorate TBI-induced deficits in cognition and neurobehavior. Methods: Adult male rats received a TBI of moderate severity, or sham injury, and 24 h later were randomized to classical or no music (i.e., ambient room noise), which consisted of exposure for 3 h/day from 7:00 pm to 10:00 pm (rat awake period) for 32 days (last day of behavior). Motor (beam), cognitive (spatial learning and executive function), anxiety-like behavior (open field and shock probe defensive burying), histology (lesion volume), and Iba1 were evaluated. The behavioral data were analyzed by two-way ANOVAs with repeated measures over testing days, followed by the Newman-Keuls post-hoc test, which corrects for multiple comparisons. Results: The data showed that classical music improved motor, cognitive, and anxiety-like behavior, reduced lesion volume, and increased Iba1+ staining vs. no-music. Conclusions and Significance: These findings support the role of music as a beneficial therapy for TBI that can be implemented by the 8000 certified music therapists in the USA.

Title: Positivity in the spinal cord: Learning promotes adaptive responding in the face of uncontrollable stimulation

Authors: *K. E. HUDSON[1,2], M. M. TARBET[1], J. W. GRAU[1];
[1]Texas A&M Univ., College Station, TX; [2]Texas A&M Col. of Med., Bryan, TX

Abstract: Prior studies have shown that neurons within the spinal cord can support instrumental learning (Grau et al., 1998, Behav. Neurosci., 112, 1366). In a typical experiment, rats undergo a thoracic (T2) transection and are subsequently tested for 30 min by applying electrical stimulation (shock) to one hind leg. Animals given shock whenever the leg is extended (controllable stimulation) quickly learn -often within the first 6 min- to maintain the stimulated leg in a flexed position that minimizes net shock exposure over the remaining 24 min of testing. Yoked rats, that are given shock whenever the master rat is shocked (uncontrollable shock), do not learn, suggesting that controllability is essential for learning to occur. Exp. 1 examined whether trained rats would continue to maintain the learned response after 6 min of training in the absence of response-contingent stimulation. Rats underwent a spinal transection and were trained for either 6 min or 30 min with controllable shock the next day. After training, maintenance of the learned response was assessed for 30 min. Animals were then challenged with 6 min of uncontrollable shock. Just 6 min of training was sufficient to induce a lasting increase in flexion duration.

Pre-trained animals continued to maintain a flexion response when stimulated with uncontrollable shock. Interestingly, the few animals that did not maintain a lasting flexion response re-acquired this behavior during uncontrollable shock. Recognizing that exposure to uncontrollable shock should drive a learned helplessness effect rather than learning, animals in Exp. 2 were pre-trained in the same manner and then tested with controllable/uncontrollable shock applied to the opposite leg. Minus pre-training, only controllable shock brought about an increase in flexion duration during testing. In contrast, animals pre-trained for 30 min with controllable shock exhibited a learning-like increase in flexion duration when challenged with uncontrollable shock to the contralateral leg. This suggests that initial stimulation can prime (bias) the spinal cord to interpret stimulation as adaptive and may have significant therapeutic implications in spinal cord injury.

Title: Targeted modulation of spino-reticulo-cerebellar circuit to determine effects on recovery of skilled forelimb function after spinal cord injury

Authors: *T. J. CAMPION, III[1], R. D. SMIT[3], R. STINGEL[4], J. CHEN[5], G. M. SMITH[2];
[2]Dept of Neurosci., [1]Temple Univ., Philadelphia, PA; [3]Shriners Hosp. Pediatric Res. Ctr., Temple Univesity Sch. of Med., Philadelphia, PA; [4]Purdue Univ., West Lafayette, IN; [5]Temple Univ. Sch. of Med., Shriners Hosp. Pediatric Res. Ctr., Philadelphia, PA

Abstract: Reestablishing functional connections in the central nervous system (CNS) after spinal cord injury (SCI) continues to be a primary goal for scientists and physicians. One way this is being probed is by modulating existing CNS circuits that were spared from injury, with the goal of inducing axonal sprouting and synaptic plasticity to compensate for lost motor pathways. The corticospinal tract (CST) provides a major source of supraspinal motor input into the spinal cord, controlling goal-directed forelimb function and skilled reaching behavior. In the rat, selective lesioning of the dorsal column at the C5 spinal cord effectively severs this descending CST input and leads to a corresponding decrease in skilled forelimb function. However, rats recover almost complete forelimb function after 4 - 6 weeks of rehabilitative training. Our group recently showed that this spontaneous recovery is largely facilitated through a group of C3-C4 propriospinal interneurons (PNs). Interestingly, these C3-C4 PNs bifurcate and divergently project, with one branch descending towards C6-T1 motor pools and the other branch ascending to the lateral reticular nucleus (LRN) in the medulla. The LRN receives both sensory and motor input from different CNS structures and relays this information predominantly to the cerebellar cortex. This spino-reticulo-cerebellar circuit is hypothesized to mediate an internal motor copy of the original supraspinal motor command that is processed through the cerebellum to make real-time error corrections

in limb trajectory during skilled motor tasks. Using chemogenetic tools that allow us to both silence (hM4Di) or excite (hM3Dq) specific neuronal populations, we modulated this circuit following C5 dorsal column lesion (DCL) to study its effects on behavioral recovery. Furthermore, as the connections that make up this circuit are not well defined, we used a combination of anterograde and retrograde tracers, including those that act transsynaptically such as AAV1, to further characterize the various afferents and efferents involved in this pathway. We are presently examining the neurotransmitter specificity of these post-synaptic neurons, using RNA scope. This study characterizes some of the reticular connections emanating from the spinal cord neurons and attempts to define the functional attributes of these connections.

Title: Novel candidates in exercise-induced plasticity: exercise training reduces aggrecan mRNA expression and fine tunes perineuronal nets in the male rat hippocampus.

Authors: *N. E. DOODY[1], E. C. AKAM[2], G. N. ASKEW[1], J. C. F. KWOK[1,3], R. M. ICHIYAMA[1]; [1]Univ. of Leeds, Leeds, United Kingdom; [2]Loughborough Univ., Loughborough, United Kingdom; [3]The Czech Acad. of Sci., Prague, Czech Republic

Abstract: Studies exploring the effects of exercise in the healthy central nervous system (CNS) mainly focus on the increase in neurotrophic factors that facilitate plasticity. However, much less is known regarding the modulation of molecules that restrict neural plasticity with exercise training. This project investigated the expression of inhibitory molecules, which are known to restrict neural plasticity, following exercise training, and whether such modulation enhanced structural plasticity. Male Wistar rats (~200g) underwent six weeks of either moderate intensity continuous training (MICT) or high intensity interval training (HIIT) on a motorised treadmill and were compared to a sedentary control group. RT-qPCR was used to measure the gene expression of 26 genes involved in the RhoA/ROCK pathway. Exercise reduced the mRNA expression of inhibitory molecules within the hippocampus; specifically, aggrecan ($F(2,17)=16.902$, $p=0.002$; MICT: -0.61 Log2 fold-change compared to controls $p<0.05$, HIIT: -1.21 Log2 fold-change $p<0.05$), and Nogo-Receptor-2 ($F(2,17)=8.383$, $p=0.014$; HIIT: -1.38 Log2 fold-change $p<0.05$) (n=4). Aggrecan is a component of perineuronal nets (PNNs): lattice-like structures that enwrap subsets of neurons, restrict plasticity, and are implicated in learning and memory. We used immunohistochemistry to label PNNs with anti-aggrecan and Wisteria floribunda agglutinin (WFA) to visualise aggrecan core protein and CS-GAG chains, respectively. Exercise training did not alter total PNN counts significantly in the hippocampus. Although, MICT increased the proportion of aggrecan positive/WFA negative PNNs in the CA1 (Control: 2.43%, MICT: 11.36%, HIIT: 2.82%, $\chi^2 = 11.16$ $p<0.05$), CA2 (Control: 9.36%, MICT: 36.51%, HIIT: 34.73%, $\chi^2 = 23.72$ $p<0.0001$) and CA3

hippocampal regions (Control: 0.48%, MICT: 6.33%, HIIT: 1.54%, $\chi^2 = 7.19$ $p<0.05$) (n=3). All analyses were completed blinded to experimental groupings. This project so far has provided a novel insight into how exercise training can be implemented to modulate the expression of inhibitory molecules and alter PNN composition within the CNS. Digestion of CS-GAG chains is known to re-open a window of plasticity in the CNS. It is possible that a shift towards a higher number of PNNs that do not express CS-GAG chains following exercise may facilitate improvements in learning and memory.

Title: Hcn channel activation and intrinsic excitability of motor neurons are affected by spinal cord injury

Authors: *B. BENEDETTI[1,2,3], L. BIELER[1,2,3], C. KREUTZER[1,2,3], D. JAKUBECOVA[1,2,3], A. BENEDETTI[1,2,3], S. COUILLARD-DESPRES[1,2,3];
[1]Inst. of Exptl. Neuroregeneration, Paracelsus Med. Univ., Salzburg, Austria; [2]Spinal Cord Injury and Tissue Regeneration Ctr. Salzburg (SCI-TReCS), Salzburg, Austria; [3]Austrian Cluster for Tissue Regeneration, Vienna, Austria

Abstract: Spinal cord injury (SCI) affects the neocortex directly, and SCI-derived alteration in cortical excitability causes deranged activity and output of lower cortical layers. Controlling cortical pathophysiology after SCI may help to promote recovery. However, the cortical dysfunction ensuing SCI is poorly resolved at cellular and molecular level. Focusing on the primary motor cortex layer V (M1LV), we hypothesized that principal neurons, axotomized upon SCI, would become hyperexcitable and we questioned the role of hyperpolarization cyclic nucleotide gated channels (HCN channels) in such context. To model SCI, adult female rats underwent transection of the corticospinal tract at vertebral level C4. One week after injury, acute pharmacological manipulation of HCN channels *ex vivo* allowed to analyse the mechanisms of derangement affecting M1LV. To this end, patch clamp experiments were carried out on acute brain slices, targeting axotomized M1LV neurons (N = 21) that were identified by retrograde tracer applied at the time and point of injury. Our results revealed that HCN channels, which control the resting membrane potential and intrinsic excitability of healthy M1LV neurons, lost their relevance after SCI when the resting membrane potential of injured neurons exceeded the voltage-range of channel activation. Thus, loss of regulation by HCN channel was provoked by chronic depolarization. In conclusion, some M1LV neurons are chronically depolarized and hyperexcitable after SCI. In this regard, targeting HCN channel pharmacologically would have mixed effects because the non-homogenous dysfunction of HCN

channels in axotomized M1LV neurons combines with other root-causes of depolarization and hyperexcitability.

Title: Mice with vestigial PNN present altered spinal circuits leading to motor impairment

Authors: *J. SÁNCHEZ VENTURA[1], C. CANAL[1], J. HIDALGO[1], K. FOUAD[2], A. TORRES ESPIN[3], E. UDINA[1];
[1]Inst. of Neurosci., Univ. Autònoma de Barcelona, Bellaterra, Spain; [2]Neurosci. and Mental Hlth. Institute, Dept. of Physical Therapy, Fac. of Rehabil. Medicine, Univ. of Alberta, Edmonton, AB, Canada; [3]Dept. of Neurolog. Surgery, Brain and Spinal Cord Injury Ctr., Univ. of California Sant Francisco, Sant Francisco, CA

Abstract: Perineuronal nets (PNN) are a specialized extracellular matrix rich in chondroitin sulfate proteoglycans (CSPGs) that wraps neurons in the central nervous system, with a key role in stabilizing synaptic contacts and inhibiting plasticity. However, PNN activity-dependent modulation allows to rearrange their structure depending on neural activity and consequently promote or inhibit plasticity. Hence, PNN play a crucial role maintaining the right balance between plasticity and stability in the adult nervous system. A lot of insight has been gathered in the brain and thus, other functions like neuroprotection, ionic buffering, and synaptic refinement have been attributed to cortical PNN. However, in the spinal cord, their functional role is still unclear. While cortical PNN reduction is linked to several neurological pathologies, spinal PNN removal by the enzyme Chondroitinase ABC (ChABC) promotes regeneration after a spinal cord injury (SCI). Considering this apparent contradiction and the reduced information on PNN after SCI, the main goal of our study is to elucidate the role of PNN on motor function and plasticity in intact and spinal cord injured animals. Hence, we have used transgenic mice with vestigial PNN due to the lack of the link protein 1 (LP1), which is implicated in the assembly of PNNs. First, we histologically corroborate the absence of LP1 around lumbar motoneurons, which consequently generates a vestigial PNN with an altered proportion of their components. Then, these transgenic mice were subjected to different behavioral and electrophysiological tests and finally were histologically evaluated. In addition to reduced body weight, the functional test revealed that LP1-KO mice present hypoactivity, altered motor coordination and hyperreflexia in the spinal circuits compared to WT mice. This hyperreflexia could be attributed to an increase in excitatory synapses around lumbar motoneurons and the dorsal horn in LP1-KO mice. Altogether, the lack of LP1 generates a non-functional

PNN that disrupts synapses and alters spinal circuits, thereby producing motor impairments. These data highlight the importance of PNN as well as the relevance of a more precise modulation of these nets after injury. Further steps would be focused on studying the role of PNN in the plasticity of the injured corticospinal tract determining whether the sprouting of spared axons in LP1-KO mice differs from WT mice.

Title: Sensorimotor paired stimulation targeted to spinal cord is more effective than cortex in rats with and without spinal cord injury

Authors: *A. PAL[1], A. S. ASAN[1], J. B. CARMEL[1,2];
[1]Orthopedic Surgery, [2]Neurol., Columbia Univ., New York, NY

Abstract: To strengthen sensory and motor system interactions, pairs of stimuli have targeted their integration, but the best site of convergence is not known. The most common human protocol, paired associative stimulation, targets the cortex. We have developed a protocol, spinal cord associative plasticity, that pairs motor cortex stimulation (MCS) with spinal cord stimulation (SCS). Here we compared convergence in MC with convergence in the SC by altering the timing of stimulation. We hypothesized that spinal convergence would have the largest effect on convergence. All experiments were done in awake, freely moving adult rats. For paired stimulation, we implanted three sets of electrodes: epidural screw electrodes over each MC, EMG electrodes in each biceps muscle, and spinal epidural electrodes over the dorsal C5-C6 SC. We stimulated the MC and recorded from the SC and vice versa. To compare the effectiveness of convergence in the SC and MC, we stimulated them using 110% or 90% of their MEP thresholds. We further tested this hypothesis in two rats with a moderate C4 contusion injury. Subthreshold SCS augmented suprathreshold MC MEPs at multiple time points with a strong peak when both stimuli converge in the SC (155% ± 27%, $p < 0.0001$ compared with MCS only). There were also smaller increases in MEPs when both stimuli converge in the MC (17% ± 6%, $p = 0.019$, compared with MCS only). When compared directly, the spinal convergence was significantly stronger than the cortical convergence ($p = 0.003$). When tested for subthreshold stimulation of both MC and SC, these subthreshold stimuli did produce an MEP, when timed to converge in the SC only. Finally, in SCI rats, we observed a similar augmentation in MEP as observed in uninjured rats with peak effect when both stimuli converge in the SC (134% ± 20 %, $p = 0.0001$) with no effect at cortical convergence. Thus, the

circuits spared by SCI are sufficient to enable this strong effect of convergence. Together, these results support the hypothesis that timing paired stimulation to converge in the SC was optimal.

Title: Functional electrical stimulation therapy facilitates corticospinal excitability of the soleus muscle

Authors: *K. FOK[1,2], N. KANEKO[1,2,3,4], S. TAJALI[2], K. MASANI[1,2];
[1]Inst. of Biomed. Engin., Univ. of Toronto, Toronto, ON, Canada; [2]Motion & Adaptation Sci. Lab., KITE - Toronto Rehabil. Inst., Toronto, ON, Canada; [3]Japan Society for the Promotion of Sci., Tokyo, Japan; [4]Dept. of Life Sci., Grad. Sch. of Arts and Sci., Tokyo, Japan

Abstract: Partial disruption of corticospinal tract by injury such as incomplete spinal cord injury (iSCI) could result in impairments in the leg muscles resulting in frequent falls. Recently, paired corticospinal-motoneuronal stimulation (PCMS), has been used to increase the corticospinal excitability and improve motor function in upper extremities. As individuals with iSCI have imperfect transmission in the spinal cord, PCMS could facilitate the transmission and lead to positive changes in corresponding motor functions, like increasing the bandwidth of an internet connection between a computer and servers. Similarly, repetitive application of functional electrical stimulation on upper extremities with voluntary efforts, known as functional electrical stimulation therapy (FEST), has been shown to increase the corticospinal excitability resulting in improved motor functions. Although its mechanism of action remains poorly understood, it is hypothesized that it is a similar mechanism to PCMS. Further, FEST has yet to be utilized on the plantarflexor muscles which are critical to maintaining upright posture. Here, we investigated the effect of FEST on the corticospinal and spinal reflex excitability of the soleus muscle. We utilized two stimulation frequencies, 40Hz in condition 1 (three participants) and 100Hz in condition 2 (four participants). The participants were instructed to exert plantarflexion torque at 20% maximum voluntary effort with FEST on soleus muscle 200 times (~33mins). Motor evoked potentials (MEPs) and H-reflex recruitment curves were recorded prior to, immediately after and 40 minutes after the intervention as a measure of corticospinal and spinal reflex excitability, respectively. MEPs significantly increased immediately after (Condition 1: 24.4±9.78%, $p = 0.005$; Condition 2: 38.3±26.8%, $p = 0.030$) and stayed increased up to 40 minutes (Condition 1: 41.6±19.7%, $p = 0.009$; Condition 2: 56.2±16.5%, $p = 0.002$) after FEST. Spinal reflex excitability appeared unchanged in both conditions as no changes were observed for the peak H-reflex amplitude immediately after (Condition 1: -0.03±15.8%, $p = 0.960$; Condition 2: (-4.36±11.3%, $p = 0.573$) or 40 minutes (Condition 1: 6.07±12.2%, $p = 0.393$; Condition 2: (-2.94±8.98%, $p = 0.628$) after FEST. We also demonstrated that FEST with different frequencies (40 Hz and 100Hz) had similar effects on the corticospinal excitability, as determined by similarly sized MEPs immediately after ($p = 0.308$) and 40 minutes after ($p = 0.239$) FEST. Therefore, we conclude that FEST

has the potential to reduce the degree of impairment after iSCI, by enabling more rehabilitation opportunities for these individuals.

Title: Short-term and long-term effects of weak electrical stimulation of sensorimotor cortex on soleus H-reflex in rats.

Authors: *Y. CHEN[1], X. Y. CHEN[1], Y. WANG[1], L. CHEN[1], X. Y. PU[1], T. FAKE[1], A. VATO[1,2], J. S. CARP[1,3], J. R. WOLPAW[1,3,2];

Abstract: Operant conditioning of the H-reflex (HR), the electrical analog of the spinal stretch reflex, is associated with plasticity in brain and spinal cord (for review: Curr Op Behav Sci 20:138-144, 2018). HR conditioning requires the corticospinal tract and sensorimotor cortex (SMC) (J Neurophysiol 78: 1730-1734, 1997; 87:645-652, 2002; 96: 119-127, 2006). Weak electrical cortical stimulation of SMC (ECS) also changes HR size (J Neurophysiol 98: 878-887, 2007). We are further exploring the short- and long-term effects of ECS on spinal physiology, anatomy, and genomics.
The Stratton IACUC approved this study. Under anesthesia, Sprague-Dawley rats are implanted with EMG electrodes in right and left soleus (SOL) muscles, volley recording electrodes over dorsal surface of spinal cord at T12, nerve stimulating cuffs on both posterior tibial nerves, and epidural stimulating electrodes over left SMC. After control H-reflex data are collected, Experimental rats receive weak SMC ECS (25 <30 μA 40-ms pulses for 1s every 10s) for 30 d. ECS amplitude is continually adjusted to maintain a stable small descending volley. ECS causes no visible distress and produces no visible responses in the rats. Rats are perfused either 4 days after ECS ends (short-term) or up to 109 days after (long-term). Control rats receive comparable surgery but no ECS, and are simply perfused 30-60 days later. HR data are collected 24/7 throughout. Just prior to perfusion, SOL motoneurons (MNs) are retrogradely labeled with cholera toxin subunit B (CTB). The lumbar spinal cord is sectioned for anatomical, histochemical, and genomic analyses.

Data from six rats studied to date show bilateral increases in SOL HR just after ECS ends. HR averaged 194.7(±42.6SE)% of pre-ECS baseline on the right ($p=0.02$) and 182.6(±18.8)% ($p<0.01$) on the left. These HR increases were associated with decreased $GABA_{B1}$ receptor immunoreactivity (IR) in both right (93±2.0% of control, $p<0.01$) and left (93±2.1%, $p=0.01$) SOL MNs. In two rats studied to date 15 weeks after ECS ended, HR size remained elevated. Further immunohistochemical and initial genomic data analyses are underway.

If confirmed in additional rats, these early results confirm and extend previous data on the spinal effects of ECS and the likely role of $GABA_{B1}$ receptor decrease in HR increase. Ongoing analyses and more data should provide further insight into the neurotransmitter and genomic mechanisms of these short and long-term spinal effects of weak SMC ECS. The results offer new understanding of cortical impact on spinal function and suggest novel therapeutic approaches for improving sensorimotor function impaired by CNS injury or disease.

Title: Electrocortical stimulation (ECS) of rat sensorimotor cortex (SMC) may regulate glutamate ionotropic AMPA receptors and their associated mRNA in spinal cord motoneurons

Authors: *B. J. HERRON[1,2], Y. WANG[2], X. Y. CHEN[2], Y. CHEN[2], A. VATO[2,1], J. S. CARP[2,1], J. R. WOLPAW[2,1];
[1]Univ. At Albany, Sch. of Publ. Hlth., Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Stratton VA Med. Ctr., Albany, NY

Abstract: Several weeks of weak electrocortical stimulation (ECS) of rat sensorimotor cortex (SMC) increases soleus H-reflex (SOL HR) size. This increase persists for at least 3 months after ECS ends. It correlates with a transient increase in GAD67 terminals on SOL motoneurons (MNs) and an equally persistent decrease in GABA receptors in these MNs [J Neurophysiol 98: 878-887, 2007; 108: 2668-2678, 2012]. We are now exploring the impact of ECS on spinal cord excitatory neurotransmission by comparing ECS rats to Control (unstimulated) rats in: (1) expression of SOL MN glutamate receptor 2 and 3 ($GluR_{2/3}$-IF); and (2) expression of SOL MN *Gria2*, the mRNA for glutamate receptor 2. Rats are implanted with SOL EMG electrodes and a posterior tibial nerve stimulation cuff in both legs, and ECS electrodes over left hindlimb SMC. ECS (1-s 25-Hz train of 0.1-ms biphasic <30-uA pulses every 10 s) is

delivered 24 hr/d X 30 days, with no visible effect on behavior. The Stratton IACUC approved this study. SOL HRs are recorded throughout. Right and left SOL MN are retrograde-labeled with cholera toxin subunit B (CTB) either on Day 1 after ECS ends (ECS_{early} rats) or on Day 105 (ECS_{late} rats). All rats are perfused 3 days after CTB injection; L4-L5 spinal cord are removed and sections are processed for $GluR_{2/3}$-IF or single molecule *in situ* hybridization targeting *Gria2*, and are photographed. $GluR_{2/3}$-IF and *Gria2* expression in SOL MNs are quantified in a double-blind manner. Results for ECS rats are expressed in % of average values from Control rats. Intergroup differences are compared by ANOVA.To date, we have analyzed results from 5 Control, 3 ECS_{early}, and 2 ECS_{late} rats. In ECS_{early} rats $GluR_{2/3}$-IF was not significantly changed in right & left SOL MNs of (94±4%(right), 95±3%(left); nor was *Gria2* mRNA expression (96±5%(right), 87±6%(left)) (all $p>0.05$ vs control). In contrast, in ECS_{late} rats, $GluR_{2/3}$-IF was significantly decreased (80±4%(right), 87±6%(left) ($p<0.001$, $p=0.041$)); and so was *Gria2* mRNA expression (66±6%(right) and 69±6%(left) ($p<0.0001$ for each)). These initial results suggest that ECS does not alter MN spinal excitatory function (measured by $GluR_{2/3}$ receptor density & *Gria2* gene transcription) immediately following stimulation, but it does significantly decrease it several months later. Confirmation of these initial results and recent genome-wide expression studies will provide new insight into the long-term impact of SMC stimulation on spinal cord function.

Title: Electrocortical stimulation (ECS) of sensorimotor cortex (SMC) in rats decreases expression of G-protein-coupled inwardly rectifying potassium channel 2 (GIRK2) in spinal cord motoneurons

Authors: *Y. WANG[1], B. HERRON[2,3], Y. CHEN[1], X. Y. CHEN[1], T. FAKE[1], J. CARP[1], A. VATO[1,3], J. R. WOLPAW[1,3];
[1]VA, Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [2]Wadsworth Center, NYSDOH, Albany, NY; [3]State Univ. of New York, Albany, NY

Abstract: Electrocortical stimulation (ECS) of sensorimotor cortex (SMC) in rats for several weeks increases soleus (SOL) H-reflex (HR). HR increase correlates with $GABA_B$ receptor decrease and GAD67 terminal increase on soleus motoneurons (SOL MN), showing that ECS affects spinal cord GABAergic function (Chen et al. 2007; Wang et al. 2012; 2021). G-protein-coupled inwardly rectifying

potassium channel 2 (GIRK2) is a key effector of $GABA_B$-mediated synaptic input (Trends Neurosci 37: 20-29, 2014; Mol Genet Metab 105:64-72, 2012). We are exploring the impact of ECS on GIRK2 expression in SOL MNs. The Stratton IACUC approved this study. Rats are implanted with SOL EMG electrodes and a posterior tibial nerve stimulation cuff in both legs, and ECS electrodes over left hindlimb SMC. ECS (1-s 25-Hz train of 0.1-ms biphasic <30-uA pulses every 10 s) is delivered 24 hr/d X 30 days, with no visible effect on behavior. SOL HRs are recorded throughout. Right and left SOL MN are retrograde-labeled with cholera toxin subunit B (CTB) either on Day 1 after ECS ends (ECS_{early} rats) or on Day 105 (ECS_{late} rats). All rats are perfused 3 days after CTB injection; L4-L5 lumbar cord is sectioned and assayed for $GABA_{B1}$ or GIRK2 immunofluorescence (IF) or hybridized with GIRK2 *in situ* probes. In a double-blind manner, $GABA_{B1}$-IF and GIRK2-IF in SOL MNs on right and left sides are measured, and SOL MN GIRK2 mRNA is quantified by single molecule *in situ* hybridization. Results from ECS rats are expressed in % of average values from Control (CNTRL) rats. Intergroup differences are compared by ANOVA. Consistent with previous data, ECS increased SOL HR (232±78(SD)% of initial size (p<0.05, n=6; paired t-test); $GABA_{B1}$-IF in SOL MNs decreased to 89.6±4% (right) and 92.4±1.3 %(Left) of Control (each vs CNTRL: p<0.001). SOL MN GIRK2-IF in ECS rats decreased to 82±3% (right) and 86±3% (left) (each vs CNTRL: p<0.001). GIRK2 mRNA number/MN decreased to 73±5% (right) and 85±4% (left) (p=0.0001 and p=0.023 vs CNTRL). These initial results show that ECS-induced SOL MN $GABA_{B1}$ reduction is associated with GIRK2 channel and gene transcription decreases; they are consistent with GIRK2 functional properties and suggest that GIRK2 has a key role in ECS effects on spinal motor function. Combined with the evidence that ECS decreases MN $GABA_B$ receptors without affecting *Gabbr1* mRNA (Wang et al 2021), these results suggest that the $GABA_B$ receptor depletion underlies the GIRK2 expression decrease.

Title: Reliability and face validity of the modified Function In Sitting Test (mFIST) in Veterans with spinal cord injury

Authors: *M. N. HATCH[1,2], V. CHAVEZ[1], J. JUDY[2], B. M. SMITH[3];
[1]Physical Med. & Rehabil. Dept., UCI Sch. of Med., Orange, CA; [2]SCI/D Ctr., Long Beach VAMC, Long Beach, CA; [3]Ctr. for Innovation for Complex Chronic Healthcare, Edward Hines Jr. VAMC, Chicago, IL

Abstract: Objectives: Seated balance is essential for individuals who perform their daily activities from a wheelchair. Current outcomes available to test seated balance abilities in individuals with SCI are unidimensional or cost and time prohibitive for the clinical setting. We investigated reliability and face

validity of a new seated measure developed by our team, the modified Function In Sitting Test (mFIST), for use in a SCI clinical rehabilitation setting.
Design/Methods: The mFIST was administered on 46 Veterans with SCI (C4-L2; AIS grades A-D) twice within 1 week by the same evaluator while being video-recorded for spectator scoring. Intra-rater reliability (test re-test) was determined from in-person scoring; inter-rater reliability was determined by comparing spectator to in-person. To test the effect of video rating, reliability between video raters, and self-reliability (rescoring ones' own via video at least 2 months after in-person) were performed. Reliability was determined using intra-class correlations (ICC). Face validity was performed on 20 SCI consumers who completed reliability procedures. Likert-based and open-ended questions were used to assess item difficulty, clarity of instructions, and appropriateness.
Results: Our cohort was predominantly Caucasian (n=34, 72%), male (n=43, 91%), mean age of 62(SD $\pm$ 13), with equal distributions of motor incomplete (n=26, 54%) and complete injuries (n=21, 44%). Test re-test reliability was strong (ICC = 0.87, CI: 0.78 – 0.93): inter-rater reliability was slightly lower (ICC = 0.80, CI: 0.66 – 0.90)). Reliability between video raters was very high (ICC = 0.90, CI: 0.80 – 0.95) and self-reliability was almost identical to inter-rater reliability (ICC = 0.80, CI: 0.35 – 0.94). All ICC displayed p's < 0.001. A total of 95% thought the mFIST properly tested their balance ability, thought the directions were clear, and took the appropriate time. Overall, 45% indicated that the mFIST made them aware of balance issues, 35% thought it would be useful in clinic, 10% believed it confirmed their ability, and 10% didn't think it was useful. The largest variability in self-reported difficulty were retrieving items from the floor or behind them, and leaning. All interviewees agreed that balance was an important part of their daily life.
Conclusions: High levels of acceptability and initial reliability confirm use of the mFIST on individuals with SCI in clinical rehabilitation setting. Use of 2 individuals (one guarding, one scoring) is recommended for the highest reliability. Reproducibility in an Australian SCI cohort is ongoing and will help confirm these results.

Title: Transspinal stimulation actions on reflex excitability and locomotor muscle activity during walking in individuals with and without SCI

Authors: A. ISLAM[1], **T. S. PULVERENTI**[2], *M. ZAAYA[1], M. KNIKOU[3];
[2]Dept. of Physical Therapy, [1]CUNY Col. of Staten Island, Staten Island, NY; [3]The Grad. Ctr., City Univ. of New York, Staten Island, NY

Abstract: Proprioceptive feedback and spinal reflexes refine locomotor muscle activity during stepping and contribute to recovery after spinal cord injury (SCI). Activity-based rehabilitation, like locomotor training, is thus widely used to improve stepping for individuals with SCI. Recent studies have also supported the potential benefits of non-invasive spinal (termed here transspinal) stimulation in enhancing locomotor rehabilitation. However, stepping-related feedback and spinal reflexes share similar neuronal pathways to those activated by transspinal stimulation. Consequently, transspinal stimulation may interact with stepping-induced feedback and reflexes. In this study we investigated the neuromodulatory effects of transspinal stimulation on the modulation of soleus H-reflex excitability and electromyographic (EMG) muscle activity during stepping in humans with and without SCI. Thirteen able-bodied adults and 5 individuals with SCI participated in the study. Locomotor muscle EMG activity was recorded bilaterally from steps without, during, and after single pulse or pulse train transspinal stimulation delivered during stepping randomly at different phases of the step cycle. The modulation pattern of the soleus H-reflex was recorded in both subject groups under control conditions and following single pulse transspinal stimulation at an individualized positive and negative conditioning-test interval. The locomotor muscle EMG activity was decreased in both subject groups during transspinal stimulation, while intralimb and interlimb coordination was altered only in SCI subjects. Immediately after transspinal stimulation, the phase-dependent EMG modulation pattern remained unaffected in able-bodied subjects. The conditioned soleus H-reflex was depressed throughout the step cycle in both subject groups. The soleus H-reflex modulation pattern was nearly completely absent in individuals with SCI. Transspinal stimulation modulated depolarization of motoneurons over multiple segments, limb coordination, and soleus H-reflex excitability during stepping. The soleus H-reflex depression may be the result of complex spinal inhibitory interneuronal circuits activated by transspinal stimulation and collision between orthodromic and antidromic volleys in the peripheral mixed nerves. The soleus H-reflex depression by transspinal stimulation may suggest an interaction between proprioceptive reflexes that could have negative consequences for functional recovery after SCI, and should be examined in future studies. Conversely transspinal stimulation may be applied to normalize spinal reflex excitability after SCI.

Title: Auditory localization in the chicken - neurophysiology and behavior

Authors: G. MALDARELLI, U. FIRZLAFF, L. KETTLER, J. M. ONDRACEK, *H. LUKSCH;
Tech. Univ. of Munich, Freising, Germany

Abstract: The ability to locate a sound source is crucial for the survival of birds. During the last decades, research in avian auditory neuroscience has mainly focused on the barn owl, which has unique peripheral specializations and hypertrophied brain structures which enable outstanding localization performances. However, in generalist birds without these specializations, the behavioral capabilities and the neuronal processing for orientation responses are only insufficiently characterized. We used the chicken as an animal model in order to 1) characterize auditory processing in specific structures of the avian midbrain and 2) measure the accuracy of sound source localization in behaving chickens.
First, we conducted *in vivo* extracellular recordings of single units in the deep layers of the OT (a presumably multimodal midbrain area involved in the avian auditory pathway) and in the *formatio reticularis pars externa* (FRLx) - a brain structure described as a relay between the inferior colliculus (IC) and the OT - of anaesthetised chickens, while presenting binaurally broadband (BB) noise filtered by the head-related transfer function (HRTF). We found two main types of auditory spatial receptive fields (aSRFs): the round and annular aSRFs. The round aSRFs responded to lateral positions of the auditory space and were mainly present in the OT, while the annular aSRFs had a ring-like shape, responded to areas around the interaural axis, and were mainly present in the FRLx. Altogether these results suggest that, in the midbrain of generalist birds, the auditory space is represented by aSRFs arranged in a concentric manner around the interaural and visual axis.
In the second experiment, chickens were trained to discriminate the location of BB noises presented from different directions with free field loudspeakers. This study allowed us to measure the sound localization accuracy by calculating a minimum audible angle of 20°.This result, compared with data from other bird species, provides evidence that the sound localization accuracy in generalist birds is affected by both the head size and the lack of auditory specializations.
The electrophysiological and behavioral data suggest that generalists like the chicken, who are not relying on sound localization for prey capture or intraspecific communication, adapted their auditory system to align with the visual axis. We also hypothesize that the auditory localization does not rely on a snapshot of the auditory stimulus as it is perceived by the animal, but rather on searching movements where the head is successively brought into a position that aligns the visual axis with the sound source.

Title: Location-specific facilitation in marmoset auditory cortex

Authors: *C. CHEN, X. WANG;
Johns Hopkins Med. Institutions, Baltimore, MD

Abstract: It has been well established that responses of neurons in auditory cortex are influenced by stimulus context. Contextual modulations can occur in spectral, temporal or spatial domain. However, comparing to spectral and temporal contextual effects, much less is known on spatial contextual effects in auditory cortex. In this study, we explored how spatial contextual modulations evolve over time by stimulating neurons in awake marmoset auditory cortex with sequences of sounds either randomly from various spatial locations (equal probability mode) or repeatedly from a single location (high probability mode). To our surprise, instead of inducing adaptation as expected from well documented stimulus-specific adaptation (SSA) literature, repetitive stimulation in the high probability mode from spatial locations away from the center of a neuron's spatial receptive field evoked lasting facilitation observed by both extracellular and intracellular recordings from single neurons in auditory cortex. Nearly half of the sampled neuronal population exhibited this spatial facilitation, irrespective of stimuli type and visibility of the test speaker. Facilitation with longer duration occurred when the repetitive stimulation was delivered from speakers with firing rates ranked lower than the best speaker's firing rate under the equal probability mode. The extent of the facilitation decreased with decreasing presentation probability of the test speaker. Interestingly, the induced facilitation did not change spatial tuning selectivity, tuning preference and spontaneous firing rate of the tested neurons. Taken together, our findings revealed a location-specific facilitation (LSF) instead of SSA to repetitively presented sound stimuli which has not been observed in auditory cortex. This form of spatial contextual modulation may play an important role in supporting such functions as auditory streaming and segregation.

Abstract: Motivation: Hearing-impaired listeners experience difficulty in attending to a specific talker in the presence of interfering talkers. Cognitively-controlled hearing aids address this problem by decoding the attended talker from neural signals using auditory attention decoding (AAD) algorithms, separating the speech mixture into clean streams and selectively amplifying the attended speech stream. In most

AAD algorithms, a representation (envelope or spectrogram) of the attended speech is reconstructed from neural signals. The decoded attended talker is considered as one whose speech representation yields the highest correlation with the reconstructed speech representation. As talkers in a cocktail party environment are often spatially separated, a supporting approach for an AAD algorithm could be decoding the location where attention is directed, i.e., the location of the attended talker. Recent deep learning-based multi-channel speech separation algorithms preserve location information (interaural cues) in the separated binaural speech streams. The attended location decoded from neural signals can then be compared with the locations of talkers (estimated from their binaural speech streams) to improve the attended talker decoding accuracy. In this study, we attempt to decode the location of attended talker in a spatially separated multi-talker setting using neural signals recorded from intracranially implanted electrodes. Approach: We recorded from seven epilepsy patients using depth electrodes (sEEG) as they listened to spatial multi-talker speech stimuli via headphones. Head-related transfer functions (HRTFs) were used to ensure two parallel speech streams (one male, one female) arrived at the subject from two locations at different azimuthal angles: -45 degrees (front-left) and +45 degrees (front-right). The locations of the male and the female speech streams switched randomly between trials. The subjects were asked to attend to a particular gender throughout a block. Results: We find electrodes whose steady-state mean response levels (MRLs) are modulated by attention to a talker location. Such electrodes have significantly higher steady-state MRLs when attending to a talker on the contralateral side than the ipsilateral side. Attended location can be decoded significantly above chance levels on a window-by-window basis, with a window duration as small as 500 milliseconds. Decoding accuracies improve with an increase in window durations. Significance: The ability to reliably decode attended location suggests a potential for improving the performance of existing AAD algorithms by incorporating spatial information.

Title: Spatial Hearing Deficits in a Guinea Pig Model of Noise-Induced Cochlear Synaptopathy

Authors: *M. A. BENSON[1], J. PEACOCK[1], N. T. GREENE[2], D. J. TOLLIN[1];
[1]Dept. of Physiol. and Biophysics, [2]Dept. of Otolaryngology, Univ. of Colorado Denver Anschutz Med. Cam, Aurora, CO

Abstract: Hearing loss is typically characterized by permanently raised auditory thresholds due to cochlear dysfunction. However, recent animal studies have shown that brief and moderate noise exposure can cause a temporary threshold shift that recovers within a couple of weeks, but a permanent loss of ribbon synapses between inner hair cells and auditory nerve fibers. Such noise-induced cochlear

synaptopathy has therefore been called ‘hidden hearing loss’ because while there is a degeneration of ribbon synapses (up to 50%), the resulting hearing dysfunction is hidden from typical clinical assays. Here we used Guinea pigs to study the mechanisms leading to hearing deficits resulting from synaptopathy caused by a 2-hour 106 dB SPL 4-8 kHz octave band noise. We measured auditory brainstem responses (ABRs), distortion product otoacoustic emissions (DPOAEs), tested spatial hearing behaviorally through the prepulse inhibition (PPI) of the acoustic startle reflex, and performed immunohistochemistry. ABR and DPOAE recordings were made prior to noise exposure, 24 hours post-exposure, and 1, 2, 4, and 8 weeks following exposure. Brainstem circuits subserving spatial hearing were assessed physiologically via the binaural interaction component (BIC) of the ABR and also behaviorally through PPI (pre-noise and 8 weeks post-noise). PPI was used to measure hearing-in-noise ability, or spatial release from masking, by having the animal detect a target sound (broadband chirp) at varying SPLs from one spatial location in the presence of background noise presented from other spatial locations. This test relates theoretically to our daily hearing requirements, as we focus on someone while trying to ignore the background noise around us, like in a classroom or cocktail party.
Results show that the noise exposure induces no persistent hearing threshold shift, as measured by the DPOAEs and ABR thresholds, but results in a depleted BIC amplitude relative to control animals. Spatial hearing deficits were seen in the PPI measures. Cochlear synaptopathy was objectively confirmed by visualizing the loss of ribbon synapses in the cochlea. Labeling for the presynaptic ribbon (Ctbp2) and post synaptic ribbon (GluA2) allowed us to visualize any permanent changes to synapses in the cochlea induced by the noise exposure.
The results demonstrate that cochlear synaptopathy can cause deficits in brainstem circuits known to be critical for sound localization and that this can lead to deficits in hearing abilities that require integration of inputs from both ears.

Title: Neural dynamics of spatial auditory attention in multi-talker speech perception

Authors: *P. PATEL[1], S. BICKEL[2], J. L. HERRERO[3], A. D. MEHTA[4], N. MESGARANI[1];
[1]Columbia Univ., New York, NY; [2]Neurosurg. / Neurol., Hofstra Northwell Sch. of Med., Manhasset, NY; [3]Neurosurg., The Feinstein Inst. For Med. Res., Manhasset, NY; [4]Neurosurg., Hofstra North Shore LIJ Sch. of Med., Great Neck, NY

Abstract: The ability to track and attend to a moving talker is important for communication in naturalistic multi-talker speech perception. The previous studies have used EEG to show that a switch in target’s location suppresses the ERP components from the target’s stream and disrupts alpha band lateralization. Other studies have used fMRI to show transient activation of parietal cortex following spatial shift in auditory attention. Due to limitations in the resolution of non-invasive methods and the use of

unnaturalistic stimulus, some questions remain unanswered. What are the cortical signatures of spatial attention switch throughout the auditory cortex as well as in the proposed dorsal and ventral attentional networks? How does the neural dynamics enable a change in spatial attention for successful tracking of a moving target's speech? We recorded intracranially from neurosurgical patients while they performed a naturalistic spatial attention task of following a target talker in multi-talker scene where the target randomly switches their location in each trial among the two possible azimuthal locations (45 and -45). Thus, we mimic a naturalistic everyday scenario where listeners need to track and attend to a moving talker in a simulated multi-talker scene. We report a neural signature of increased high-gamma envelope activity localized in time during the trial onsets for spatial auditory attention switch throughout the primary and secondary auditory cortex. The neural responses in dorsal and ventral attention network areas show distinct dynamics. We show higher high-gamma activity when the spatial direction of attention switches compared to when the spatial attention is sustained. This contrastive response which appears at the onset of attention switch is present for both dorsal and ventral attention networks but the dorsal network shows transient response to the stimulus that goes down to baseline after 1s and the ventral network shows longer sustained response to the stimulus. Furthermore, a switch in target's location momentarily disrupts the encoding of the target speech features until the attention switch is completed, highlighting the temporal dynamics of spatial attention switch and its consequence in encoding the target speech. These findings provide insights into temporal dynamics of spatial auditory attention control in the auditory cortical population and sheds light on the role of the dorsal and ventral attention networks in tracking and maintaining listener's focus on a moving talker in multi-talker acoustic scenes.

Abstract: Spatial hearing relies on the accurate detection and extraction of binaural cues performed in the auditory brainstem. In this process, the neural activity from the two auditory nerves initially propagates

through separate monaural nuclei and subsequently converges onto the superior olivary complex, where the interaural time difference (ITD) is processed in the medial superior olive (MSO), and the interaural level difference (ILD) is analyzed in the lateral superior olive (LSO). Even after propagating across several neurons, fiber bundles, and synaptic stations along this pathway, the temporal precision of the neural activity remains preserved enough such that binaural cues can still be precisely extracted by the binaural neurons in the MSO and LSO. The involved neural circuit shows multiple mechanisms designed to preserve the timing of neural activity, some of which are not completely understood. Here, we present a computational model of the auditory brainstem using spiking neuronal networks. In the model, the LSO and MSO circuits are modeled and stimulated with complex sounds presented under multiple binaural conditions. The resulting neuronal activity was further analyzed on a single cell and population level with a decoding model to estimate the precision of spatial hearing and the transformation of the binaural spatial information. Based on these in silico experiments, the simulated neural responses and ITD/ILD tuning curves are comparable to experimental findings. Correspondingly, the model exhibits acute sensitivities to ITD and ILD cues that match the behavioral performance. Moreover, the model was also used to demonstrate the influence of axon myelination and hyperexcitability on the sound localization process. These results suggest that the proposed model is capable to encode binaural cues in a biologically plausible manner. Furthermore, the model can be used to explore the functioning of the auditory brainstem under various conditions, such as developmental stages or pathological alterations.

Title: Comparison of click vs. chirp stimuli in evoking the binaural interaction component (BIC) of the auditory brainstem response (ABR)

Authors: *Z. L. OWRUTSKY, J. PEACOCK, D. J. TOLLIN;
Physiol. and Biophysics, Univ. of Colorado, Aurora, CO

Abstract: Comparison of click vs. chirp stimuli in evoking the binaural interaction component (BIC) of the auditory brainstem response (ABR)
Zoe Owrutsky, John Peacock, Daniel J. Tollin*Department of Physiology and Biophysics, University of Colorado School of Medicine, Aurora, CO 80045*
Chirp stimuli are specifically designed to enhance temporal synchrony in the responses of the auditory nerve and brainstem by accounting and compensating for the frequency- and level-dependent delays accrued by the traveling wave in the cochlea. Chirps have been shown to produce larger amplitude responses in specific waves/peaks of the auditory brainstem response (ABR). Here we test the hypothesis

that chirp stimuli can increase the amplitude of the binaural interaction component (BIC) of the ABR. The BIC of the ABR is a potential biomarker for binaural hearing. However, clinical use of the BIC has been limited because it is unreliably measured using click stimuli in humans. Here we generate and compare different chirp stimuli methods to maximize the BIC.
ABR peak latencies were measured in response to tone bursts over a range of stimulus frequencies and intensity levels in seven chinchillas. Stimuli consisted of 5-ms tone bursts (1, 2, 4, 8, 16, 24 kHz) presented via sealed and calibrated insert earphones from ~10 dB below to 50 dB above ABR detection threshold. Latencies of ABR waves I-IV and the BIC DN1 wave (the largest amplitude peak in the BIC) were plotted against frequency and then fit to a power function: Tau=k*f^(-d), where tau is latency in seconds, f is frequency, and k and d are constants. The values of k and d were then used to construct a series of sound level-specific chirps for three above-threshold stimulus intensity levels based on 1) monaural ABR wave I and 2) BIC DN1.
Monaural ABR peak latencies decreased systematically with increasing sound frequency as expected from the corresponding latencies due to cochlear delay. Consistent with other studies, our results show that monaural ABR peak amplitudes were enhanced by chirps which compensate for that latency relative to those measured with clicks. Surprisingly though, BIC DN1 peak latencies did not show a similar frequency-dependent latency shift. Rather BIC DN1 latencies appeared to be relatively constant despite increases in stimulus frequency.
Traditional chirp stimuli designed to optimize monaural ABR peak amplitudes by accounting for frequency-dependent cochlear delays appear ill-suited for eliciting optimal BIC peak amplitudes. Traditional broadband clicks or other non-traditional chirp stimuli may be preferable for eliciting an optimal BIC.

Title: Brain-derived neurotrophic factor is required for the structural and physiological refinement of MNTB neurons along the tonotopic axis

Authors: *M. WOLLET[1], E. KIM[1], E. A. GOULD[1], J. KIM[2];
[1]Univ. of Texas Hlth. Sci. Center, San Antonio, San Antonio, TX; [2]Physiol., Univ. of Texas Hlth. Sci. Ctr. San Antonio Sch. of Nursing, San Antonio, TX

Abstract: In the mammalian brain, central auditory nuclei are arranged topographically according to acoustic frequency responsiveness, called *tonotopy*. The medial nucleus of the trapezoid body (MNTB) is

one of auditory brainstem nuclei responsible for sound localization. During postnatal development, the axon initial segment (AIS), a key axonal domain responsible for action potential initiation, of MNTB neurons undergoes structural refinement depending on neuron location along the tonotopic axis within the MNTB. However, the molecular mechanisms underlying the structural differentiation of the AIS along the tonotopic axis in the auditory brainstem have not been explored. In this study, we investigate BDNF as a potential mediator responsible for structural development and refinement of the MNTB in activity-dependent manner. We hypothesized that BDNF, a key factor for activity-dependent plasticity, is necessary for structural refinement of MNTB neurons after hearing onset. Using *BDNF* heterozygous (*BDNF*$^{+/-}$) mice, we examined impact of global BDNF reduction on structural and functional development of MNTB neurons by assessing AIS structural properties and intrinsic properties. *BDNF*$^{+/-}$ mice had no differentiation of AIS length or location along the tonotopic axis unlike WT mice. BDNF reduction inhibits the establishment of the structural differentiation of the AIS along the tonotopic axis in the MNTB and impacts their AP firing properties. These data suggest BDNF is essential for structural and physiological development of MNTB neurons after hearing onset. Sound deprivation and enhancement have been shown to dynamically modify length and location of the AIS in MNTB neurons. However, in *BDNF*$^{+/-}$ mice, sound enhancement (16kHz, 3 hrs, 7 days) did not impact structural dynamics of the AIS nor neuronal excitability tonotopically in the MNTB, indicating that structural plasticity of MNTB neurons in response to increased sound input requires BDNF signaling. Taken together, structural development and functional refinement of auditory neurons within the auditory brainstem requires physiological levels of BDNF in order to establish proper tonotopic organization that allows for precise binaural sound processing.

Title: Adaptation to unilateral conductive hearing loss and its generalization to different acoustical conditions in the adult ferret

Authors: *A. I. SANCHEZ JIMENEZ, K. WILLARD, V. M. BAJO-LORENZANA, A. J. KING, F. R. NODAL;
Physiology, Anat. and Genet., Univ. of Oxford, Oxford, United Kingdom

Abstract: Accurate sound localization relies on the ability of the brain to extract spatial information embedded in the auditory signal. To that effect, the brain integrates information provided independently by each ear (monaural spectral cues) or correlated between them (binaural cues). Unilateral conductive hearing loss (UCHL) produces an asymmetric input, which compromises the binaural computations

required for sound localization, whilst leaving intact the monaural spectral cues available at the normally functioning ear. Previous studies have shown that training in a sound localization task enables individuals with UCHL to partially recover their spatial accuracy and that the auditory cortex plays an essential role in such adaptation.
It remains unclear to what extent this adaptive process generalizes beyond the training stimuli to other sounds. Seven ferrets were trained to localize broadband noise bursts in a silent background. All animals showed a severe reduction in localization accuracy when one ear was plugged, which then recovered with training. Over the course of adaptation, the operant approach-to-target response accuracy reached 70-90% from an initial 20% and the response precision improved with a decrease in the error size from 47.9 ± 14.3 to 11.1 ± 10.7 degrees. Similarly, the accuracy of head orienting responses, which were initially biased toward the side of the non-occluded ear, recovered in two of the animals, suggesting the likely involvement of adaptation of neural responses at subcortical levels.
We also measured localization accuracy before and after adaptation using noise bursts of different bandwidth or amplitude modulated noise (AM) against a background of either constant or AM noise presented from an overhead loudspeaker. A positive correlation was observed between the degree of adaptation achieved and the generalization to other stimulus types. Animals that achieved an almost complete recovery of response accuracy with the broadband training stimulus showed a similar degree of improvement with the other stimuli. Thus, while localization accuracy varied with stimulus type depending on the cues available and the masking effects of the background noise, the relative performance of the animals for different sounds was unaffected by UCHL. However, those animals that adapted less with broadband noise also performed less well in the other sound conditions. Overall, these results suggest that the recovery in spatial hearing can generalize to other sounds and that adaptation and generalization may occur simultaneously.

Title: Auditory brainstem specific binaural hearing ability in Fragile X Syndrome mice

Authors: A. CHAWLA, S. ALAM, I. RAY, *E. MCCULLAGH;
Oklahoma State Univ., Stillwater, OK

Abstract: Binaural hearing is critical for parsing sound streams into individual spatial locations and is the basis for more complex listening situations. Binaural hearing begins in the auditory brainstem, where the brain computes interaural intensity and timing differences (IID and ITD respectively), which are both crucial aspects of binaural hearing ability. One of the dominant sensory issues described in patients with

Fragile X Syndrome (FXS) is hypersensitivity to sound. FXS is the most common monogenic form of autism. We, and others, have shown that there are indeed anatomical, physiological, and behavioral changes to the auditory brainstem in *Fmr1* knockout (KO) mice. In this study, we explored whether *Fmr1* KO mice have impaired binaural hearing as measured by the binaural interaction component (BIC) of the auditory brainstem response (ABR). The ABR is a non-invasive electrophysiological measure recording a pattern of waveforms that is directly related to the different brain areas that encode sound processing in the auditory brainstem. The BIC, especially as it varies with ITDs, is a direct measure of physiological auditory brainstem mediated binaural hearing. We examined latency and amplitude of ABR waves, BIC amplitude and latency across ITDs, and hearing thresholds between 1 kHz - 64 kHz in male and female C57BL/6J wildtype, *Fmr1* KO and heterozygote female mice. Our preliminary data shows that while the overall ABR waveforms do not show changes to ABR latencies, there is a decreased latency for the BIC, in *Fmr1* KO mice compared to controls. Further studies will show when during development brainstem specific phenotypes arise in this *Fmr1* KO strain to help better target treatment timepoints and efficacy specific to auditory phenotypes. The BIC and ABR is a measurement that can be directly translated to humans and is likely a good candidate for testing mechanistically how the auditory brainstem is changed in FXS and autism.

Title: Grating orientation information tolerant to stimulus contrast revealed by directional analyses of BOLD fMRI activity patterns of human primary visual cortex

Authors: *F. M. RAMIREZ, C. REVSINE, E. P. MERRIAM;
Lab. of Brain and Cognition, NIMH, BETHESDA, MD

Abstract: Multivariate pattern analyses are widely used in neuroimaging studies. However, it is unclear what these analyses reveal about neural coding. Such approaches often obfuscate the link between neural measurements and the stimulus, limiting their utility. Linear classification, a highly-popular approach, exploits the Euclidean distance among pattern vectors. Our recent theoretical work suggests that information regarding tuning properties is best captured by angular distances, not Euclidean distances. Specifically this is the case because the former distances, but not the latter, are explicitly sensitive to the relative direction of pattern-vectors in a high-dimensional space. The goal of this experiment was to relate specific aspects of multivariate measurements to parametrically defined dimensions of visual stimuli. We used primary visual cortex as a model system to test the following predictions: (i) Euclidean distances conflate information regarding response amplitude and selectivity, (ii) angular distances best reflect information about selectivity. In particular, if these predictions are correct, one might expect that angular,

but not Euclidean distances, might reveal information about grating orientation that is tolerant to changes in stimulus contrast. fMRI BOLD activity was measured from 5 participants (7T, 32-channel coil, 1.2x1.2x1.2 mm resolution). Stimuli consisted of Cartesian sinusoidal gratings multiplied by flower-shaped apertures. The orientation of the "petals" was controlled by the phase of the radial frequency (RF) used to generate the aperture. In a fully crossed experimental design, the compound stimulus varied along three dimensions: grating orientation, contrast, and RF-phase, resulting in a total of 96 unique conditions. We found that the Euclidean metric was sensitive to stimulus contrast and relatively insensitive to grating orientation and aperture phase. In contrast, Angular distances proved sensitive to grating orientation and aperture phase. Crucially, angular distances were also found to be significantly more robust to changes in stimulus contrast than the Euclidean distance. We propose a biologically-inspired computational model to provide a theoretic account of these observations. Our results have fundamental implications for the interpretation of MVPA, and serve to inform the development of data analysis strategies more readily interpretable in terms of the underlying neurophysiology.

Title: A norm-based neural model for the recognition of dynamic facial expressions across species

Authors: *M. STETTLER[1], N. TAUBERT[2], R. SIEBERT[3], S. SPADACENTA[4], P. DICKE[5], P. THIER[6], M. A. GIESE[7];
[2]Cognitive Neurol., [1]Eberhard Karls Univ., Tübingen, Germany; [3]Cognitive Neurol., Hertie Inst. for Clin. Brain Res., Tuebingen, Germany; [4]Hertie Inst. For Clin. Brain Sci. / CIN, Tuebingen, Germany

Abstract: Dynamic facial expression recognition is an essential skill of primate communication. While the neural mechanisms of the recognition of static facial expressions have been extensively investigated, it remains largely unclear how dynamic facial expressions are neurally encoded. We studied physiologically plausible neural encoding mechanisms exploiting highly-controlled and realistic stimulus sets generated by computer graphics. The stimulus set showed dynamic human and monkey expressions, and it allowed to study how the perception of facial dynamics interacts with changes of head shape. In psychophysical experiments, we found that the perceptual encoding of facial dynamics was largely

independent of facial shape (human vs. monkey). This raises the question how such independence can be explained in terms of neural mechanisms. Testing standard deep neural network models, we did not find a good generalization of expression recognition between different head shapes. We then developed a model based on *norm-referenced encoding*. This model assumes that snapshots of the facial movies are represented by neurons that encode the vector differences between the neutral face (norm pattern) and the actual frame in a high-dimensional face space. The output of these face neurons were then processed by temporal differentiator neurons, resulting in selective responses to dynamic faces.The model was tested with movies of human and monkey avatars that showed human and monkey expressions, and morphs between them. The proposed neural model recognizes reliably the tested dynamic facial expressions of humans and monkeys and correlates with behavioral finding, that dynamic facial expressions perception is largely independent of the basic face shape. Specifically, the model reproduces that dynamic expressions can be recognized on the face of the other species, even if the model was trained only with dynamic expressions of the head model of the other species. In addition, the neuron responses in the model show a highly gradual, almost linear dependence on the expressivity of the stimuli and good generalization to morphed expressions. Some of these characteristics match initial observations in dynamic face-selective neurons in the Superior Temporal Sulcus (STS) of macaque monkeys.

Title: Temporal Mechanisms of Binocular Rivalry and Perception in the Human Brain

Authors: *V. RANGARAJAN[1,2], D. KING-STEPHENS[3], K. D. LAXER[4], P. WEBER[4], J. J. LIN[5], K. AUGUSTE[6,7], E. F. CHANG[6], R. T. KNIGHT[1];
[1]Psychology, Univ. of California, Berkeley, Berkeley, CA; [2]Sch. of Engin. and Applied Sci., Univ. of Pennsylvania, Philadelphia, PA; [3]Dept. of Neurol., Yale Sch. of Med., New Haven, CT; [4]California Pacific Med. Ctr., San Francisco, CA; [5]Dept. of Neurol., Univ. of California, Irvine, Irvine, CA; [6]Neurosurg., Univ. of Califonia, San Francisco, San Francisco, CA; [7]Benioff Children's Hosp., Oakland and San Francisco, CA

Abstract: Binocular rivalry (BR) is a striking form of perception where different images are presented concurrently to each eye and conscious perception alternates between the images. This provides a unique opportunity to disentangle conscious perception from sensory processing since perception alternates, while the sensory input remains static. We leveraged intracranial recordings in patients with refractory epilepsy to study how F-P regions support rapid shifts in conscious perception. Subjects (n=9) were

implanted with intracranial electrodes and participated in 2 experiments: Exp 1 was a category localizer in which subjects saw faces, houses, words, bodies, and scrambled images while performing an odd-ball paradigm; Exp 2 was a face/house BR paradigm in which the (red/blue) stimuli were presented independently, but simultaneously to each eye. Subjects reported when a perceptual switch occurred during 2 conditions: *rivalry*, in which perceptual switches were endogenous or self-driven, and *replay*, in which switches were replayed based on previous behavior. Behaviorally, subjects reported perceptual alternations between stimuli every 2-6 seconds with subjects reporting an average of 49.5 percepts (± 19.7 std). During *rivalry*, we found that high-frequency broadband activity (HFB: 70-150 Hz) was active during 3 main temporal response windows: (i) at the onset of stimulus presentation, and (ii) time-locked or (iii) immediately after the perceptual switch. First, we found that the initial perception of a BR stimulus is largely driven by the visual cortices, with earlier activation than associative areas. Notably, HFB activity in these regions predicted subsequent behavioral reports of the subject's perception. In contrast, later changes in perception during switching in BR are initiated by associative cortices revealing HFB activity onsetting before later sensory reactivation after a change in perception. Peak timings for occipital electrodes (avg peak=278 ms) were significantly later than frontal (avg Δ = 228 ms, *ks*-test=0.72, $p=9.1x10^{-8}$), parietal (avg Δ =225 ms, *ks*-test=0.72, $p=1.91x10^{-9}$), and temporal (avg Δ = 125 ms, *ks*-test=0.43, $p=3.55x10^{-4}$) electrodes. These patterns were not mirrored during *replay*, indicating that BR does not merely reflect perceptual decision making. Together, these findings support a bi-directional relationship between sensory and F-P associative areas providing insights into the neural substrates of conscious perception.

Title: Cortical magnification in human primary visual cortex correlates with contrast sensitivity

Authors: *M. HIMMELBERG, M. CARRASCO, J. WINAWER;
New York Univ., New York, NY

Abstract: The size and organization of primary visual cortex (V1) varies within and between individuals. The overall size of V1 varies up to threefold in neurotypical observers. Within an individual, the cortical magnification (mm^2 of cortex per deg^2 of visual field) varies with eccentricity and polar angle. This variation in cortical anatomy has important consequences for visual perception. Averaged across observers, contrast sensitivity and cortical magnification co-vary with eccentricity, as shown by Virsu and Romano (1979), who hypothesised that contrast sensitivity is limited by the number of activated V1 neurons. Here, we extend this logic to contrast sensitivity asymmetries as a function of polar angle -

contrast sensitivity is higher along the horizontal than vertical meridian, resulting in a horizontal-vertical asymmetry - and across individuals.
In 22 observers, we employed an orientation discrimination task to measure contrast sensitivity (Gabor patches; 4 cycles per deg, 4.5º of eccentricity, 3º diameter) at the four cardinal meridians, and used fMRI to measure their V1 maps. We then calculated the surface area of four wedge-regions-of-interest (ROIs) in each observer's V1 that matched the angular location of the contrast sensitivity measurements. Each wedge-ROI represented a wedge in the visual field that was centered along one of the four cardinal meridians and spanned ±15° of polar angle and 1-8° of eccentricity.
We used Spearman's correlations to assess the relation between contrast sensitivity and V1 surface area measurements across observers at multiple scales. First, contrast sensitivity was positively correlated with the overall size of V1 (n=22, r_ρ=0.4); observers with higher contrast sensitivity tended to have a larger V1. Second, contrast sensitivity measurements were positively correlated with the surface area of the wedge-ROIs centered at the corresponding meridians (n=22 observers x 4 locations, r_ρ=0.6); this indicated that the link between contrast sensitivity and surface area holds at a finer scale. Third, we computed the horizontal-vertical asymmetry for contrast sensitivity and for V1 surface area (i.e., the difference between horizontal and vertical measurements divided by their sum). The two measures were correlated (n=22, r_ρ=0.6); a stronger horizontal-vertical asymmetry in the distribution of V1 surface area corresponded to a stronger horizontal-vertical asymmetry in contrast sensitivity.
These data confirm that contrast sensitivity is linked to V1 surface area, and we extend this link to explain both individual variation and polar angle asymmetries in visual performance.

Title: Evidence for a ventral visual stream in the human pulvinar

Authors: *D. R. GUEST[1], E. J. ALLEN[1], Y. WU[1], T. NASELARIS[2], M. J. ARCARO[3], K. N. KAY[1]; [1]Univ. of Minnesota, Minneapolis, MN; [2]Neurosciences, Med. Univ. of South Carolina, Charleston, SC; [3]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The pulvinar is a major thalamic nucleus that is highly interconnected with visual cortex and supports a range of visual functions such as visual attention. Work in non-human primates has shown that inferior and lateral portions of the pulvinar connect predominantly to early visual cortex, have clear retinotopic organization, and are sensitive to low-level visual features such as contrast. However, less is understood about the role the pulvinar may play in processing high-level visual stimuli such as scenes, faces, and objects. To address this gap, we investigated subcortical activity in the Natural Scenes Dataset (NSD). In NSD, 8 human participants completed a visual fMRI experiment during which they were exposed to 9,000-10,000 unique natural scenes. Whole-brain fMRI data were collected at ultra-high field strength (7T) with 1.8-mm spatial resolution, ensuring high-quality measurements from subcortical regions. We fit population receptive field (pRF) models to individual voxels, systematically evaluating different stimulus features (contrast, saliency, faces, bodies, foreground, background, words) that might be encoded in voxel responses. This analysis confirmed that the LGN and inferior-lateral pulvinar respond selectively to contrast located in the contralateral visual hemifield and are retinotopically organized. Notably, the analysis also revealed a portion of the pulvinar, located medial and posterior to the contrast-selective portion, that responds selectively to bodies and faces located in the contralateral visual hemifield. To further explore these findings, we performed a thalamocortical correlation analysis in which stimulus-evoked responses in the thalamus are correlated with stimulus-evoked responses in cortex, where stimulus representations are better understood. This analysis revealed that pulvino-cortical correlations are largely restricted to the visual cortex. The contrast-selective portion of pulvinar correlates most with early visual cortex while the body- and face-selective portion of pulvinar correlates most with face- and body-selective cortical regions (e.g., FFA, FBA). More generally, we find a gradient of pulvino-cortical correlations in which the progression from anterior-lateral to posterior-medial in the pulvinar recapitulates the posterior-to-anterior organization of visual cortex. While emphasis is often placed on the pulvinar's role in visual attention, our results indicate that the pulvinar also plays a role in high-level vision and illustrate that principles of cortical organization (e.g. functional clustering and hierarchical organization) hold for the thalamus as well.

Title: A spatiotemporal pRF model of sensory suppression in human visual cortex

Authors: *E. R. KUPERS[1], I. KIM[1], K. GRILL-SPECTOR[1,2];
[1]Psychology, [2]Wu Tsai Neurosciences Inst., Stanford Univ., Stanford, CA

Abstract: When multiple visual stimuli are presented simultaneously in the receptive field the neurophysiological response is surprisingly lower compared to when the identical stimuli are presented sequentially. The prevailing hypothesis suggests this suppression is due to competition effects within the receptive field (Kastner et al. 1998, 2001; Kim et al.; 2021; Reynolds, Chelazzi & Desimone, 1999). Alternatively, this suppression may be due to nonlinear, compressive summation within the receptive field—nonlinearities may be spatial (compressive spatial summation, CSS, Kay et al. 2013), temporal (compressive temporal summation, CTS, Zhou et al. 2017; Stigliani et al. 2019), or both. Here, we built a new spatiotemporal population receptive field (pRF) model and tested CSS and CTS models using fMRI. We collected data from two experiments: (i) retinotopic mapping with cartoon stimuli (Finzi et al. 2021) to define visual areas in ventral, dorsal, and lateral streams, as well as to estimate spatial pRF parameters for each voxel, and (ii) simultaneous vs sequential presented stimuli. Each trial contained 4 colorful squares (2x2°) presented in the upper right quadrant (3-9° eccentricity). In sequential trials, each square appeared for 250 ms and the 4 squares appeared in random order. In simultaneous trials, the identical 4 squares appeared at once for 250 ms followed by 750 ms blank. Each sequential and simultaneous block had 8 trials with random stimuli followed by 8 s blank. Results replicate prior findings of lower BOLD responses for simultaneous vs sequential blocks in individual voxels as early as V2 in all 3 observers. We then tested which model best predicts these suppressive effects: (i) linear temporal + spatial summation, (ii) compressive spatial + linear temporal summation (CSS), (iii) linear spatial + compressive temporal summation (CTS, 2-channel temporal model by Stigliani et al. 2019). Both nonlinear models predict lower responses for simultaneous than sequential blocks in single voxels, but the linear model predicts the same level of response across sequential and simultaneous blocks. Across the visual hierarchy, the CTS model explains most variance in the data (27±5.2%, up to ~60% in ventral and lateral areas), and significantly more than both the CSS (23±4.3%, up to ~50%) or linear model (24±4.6%, up to ~54%). These results indicate that a linear pRF model cannot explain the observed sensory suppression and the underlying mechanism involves nonlinear summation. Our new spatiotemporal pRF model offers a quantitative approach to study dynamic visual stimuli and provides insight into neural computations of sensory suppression in the human visual pathways.

Sebastian, Spain; [3]Biomed. Engin., Sungkyunkwan Univ., Suwon, Kyunggi-Do, Korea, Republic of; [4]Wu Tsai Neurosciences Inst., Stanford, CA

Abstract: Computational modeling to predict neural responses to stimuli varying in basic visual dimensions of space and time is crucial for understanding how we perceive dynamic visual scenes. However, standard population receptive field (pRF) models only characterize neural responses to the spatial aspects of the stimulus (Dumoulin & Wandell, 2008; Kay et al., 2013). Currently, no pRF model explains responses across both space and time in the human visual system. Here, we built and tested a stimulus-referred spatiotemporal pRF model using simulated and experimental fMRI data. The spatiotemporal model derives fMRI time series from spatial 2D gaussians and nonlinear temporal neural impulse functions in millisecond resolution (Stigliani et al., 2019; Zhou et al., 2019). First, we developed simulation software to ensure computational reproducibility and validity of our spatiotemporal model. The software (i) generates synthetic fMRI time series from a stimulus and spatiotemporal pRFs, (ii) solves spatiotemporal pRF parameters, and (iii) tests the solution to the ground truth parameters used to synthesize the fMRI time series. The ground truth parameters were accurately recovered from the synthetic fMRI time series. Second, we tested how well the spatiotemporal pRF model predicts experimental fMRI data (n=10). The visual stimuli consisted of bar apertures systematically traversing across the visual field (12° radius, 4 directions, 9 discrete steps) with varying temporal dynamics (33 ms to 5 s duration, 33 ms to 200 ms interstimulus intervals). We found that the spatiotemporal pRF model had higher cross-validated accuracy than the standard pRF in all the tested visual areas (V1, hV4, and TO1). Interestingly, the spatiotemporal model showed substantially higher accuracy for brief, transient visual stimuli compared to the standard pRF model. Overall, the spatiotemporal pRF model quantitatively predicts each voxel's responses to a wide range of visual stimuli that vary in spatial location, size, timing, and duration ranging from milliseconds to seconds. These results suggest that incorporating stimulus components of space and time in pRF models is important for modeling a wide range of spatiotemporal stimulus evoked responses in the human visual cortex.

Title: Neural tuning modulation modeling in R: A software package for inferring the form of neuromodulation from fMRI tuning functions

Authors: *P. SADIL, R. A. COWELL, D. E. HUBER;
Psychological and Brain Sci., Univ. of Massachusetts, Amherst, MA

Abstract: Many neuroscience theories assume that changes in human cognition are underpinned by changes in neural tuning. However, neural tuning cannot be measured directly in humans with non-invasive measurements; standard voxels from fMRI aggregate the signal of hundreds of thousands of neurons. We present a statistical framework called Neural Tuning Modulation Modeling, which allows researchers to use fMRI to infer how changes in cognitive states -- e.g., viewing a stimulus with versus without attention -- modulate neural tuning functions. The framework comprises two tools: one tool uses hierarchical Bayesian modeling and cross-validated model comparison, and the other is a nonparametric check using regression slopes. These methods exploit the fact that voxels in an fMRI dataset, like single neurons, exhibit tuning functions (e.g., the activation of a voxel in visual cortex may vary systematically with orientation), and these voxel tuning functions can be modulated across the same conditions that modulate neural tuning functions. Distinct changes in voxel-level activation are predicted by different modulations at the neural level, allowing adjudication between different forms of modulation in neural tuning with non-invasive fMRI. The framework has been validated using fMRI data collected from participants viewing oriented gratings at high- and low-contrast, which is known from electrophysiology to cause multiplicative scaling of orientation tuned neurons. Beyond orientation, this approach could be applied to determine the form of modulation in any fMRI experiment, provided that the experiment tests multiple points along a stimulus dimension to which neurons are tuned (e.g., direction of motion, pitch, stimulus location, etc.). We showcase a new R software package that aims to make it easy to apply the framework.

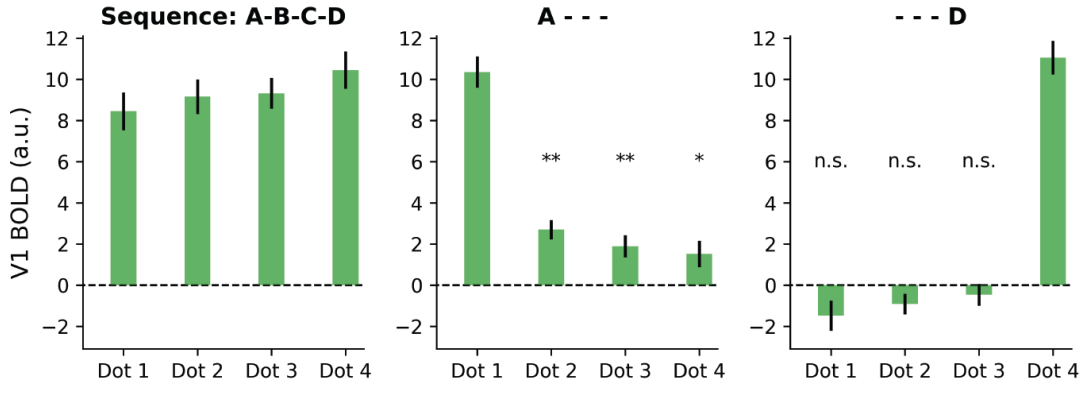
Title: V1 as a predictive map: successor-like representation of upcoming events in human visual cortex

Authors: *M. EKMAN, S. KUSCH, F. DE LANGE;
Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands



Abstract: Predictions of upcoming visual events may constitute an important mechanism to guide flexible behavior and have been observed in animal (Ji & Wilson 2007; Xu et al. 2012) and human visual cortex (Ekman et al. 2017). These predictions are based on an experience-dependent representation ('model') of our environment. However, it remains unknown what the inherent features and limitations of the model underlying our predictions are. Recently, it has been proposed that representations take the form of a map-like structure, the so-called successor representation (SR). The SR hypothesis makes two testable predictions, namely that population activity represents future states, and that these future states are discounted, such that events in the close future are more prominently represented compared to events in the distant future (Stachenfeld et al. 2017; Dayan 1993). Here we used human fMRI to probe whether

visual activity adheres to these properties of the SR. Participants were exposed to a spatio-temporal sequence consisting of four items (A-B-C-D). We found that after repeated exposure to the sequence, merely presenting the starting point of the sequence (i.e., A - - -) resulted in forward replay of the full sequence in V1, reflecting the anticipation of upcoming stimulus events. During forward replay, V1 BOLD activity decreased as a function of distance in successor space, independent of spatial distance. Further, forward replay was also observed when only intermediate sequence points were shown (i.e., - B - -, and - - C -), indicating that the relational structure of the sequence is represented in V1. Importantly, forward replay was only observed at the successor- but not at the predecessor states of the sequence. Additionally, representations of future sequence states were also observed in the anterior Hippocampus and correlated with V1 representations on behaviorally correct trials, but not on incorrect trials, suggesting an important functional relationship between V1 and Hippocampus for forming a 'predictive map-like' representation of the environment.

Title: Receptive field mapping of face neurons during naturalistic viewing

Authors: W. S. ONG[1], K. N. KAY[2], M. S. LIVINGSTONE[3], *M. ARCARO[1];
[1]Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA; [2]Radiology, Univ. of Minnesota Twin Cities, Minneapolis, MN; [3]Harvard Med. Sch., Boston, MA

Abstract: Inferotemporal cortex (IT) contains neurons that respond selectively to complex shapes and visual categories. These neurons are thought to be critical for our ability to recognize objects in our environment. Though traditionally underemphasized, prior work has demonstrated that object representations in IT can exhibit a high degree of spatial specificity (Op de Beeck & Vogels 2000; Issa & DiCarlo 2012). However, it has remained challenging to assess spatially specific responses under naturalistic viewing conditions. Here, we recorded multi-unit spiking activity from multielectrode arrays implanted in fMRI-defined macaque posterior (PL), middle (ML), and anterior (AL) lateral face patches during viewing of naturalistic scenes and used model-based receptive field mapping methods to estimate the location and size of neuronal receptive fields (RF). We found that RF parameters derived from modeling the location of faces in naturalistic scenes were comparable to RFs derived from conventional mapping approaches using isolated faces on a uniform background. Interestingly, the sizes of RFs tended to be smaller for faces in naturalistic scenes. RF sizes reflected the hierarchical organization of IT. RF sizes were smallest in PL (0.5-2 degrees), larger in ML (2-6 degrees) and largest in AL (5-12 degrees). Model fits (variance explained) for faces in scenes were good for both ML and AL where face selectivity is strong, but poorer for PL likely reflecting the weaker selectivity for faces. Position and size measurements were reproducible across sessions for the same stimuli. Finally, we found that correctly identifying the visual features that drive neurons was critical for accurately measuring RFs. For example, the receptive fields of PL and ML neurons for one monkey were offset along the y-axis when modeling upright and inverted faces, reflecting specific selectivity for the eyes within a presented face. These results suggest that previously reported variation in neuronal firing to different faces (or viewpoints) may in part reflect simple shifts in the retinal position of specific facial features for which a neuron is selective (e.g., eyes). More broadly, these results illustrate that space and visual feature coding are intertwined throughout the ventral visual hierarchy and indicate a prominent role for spatial coding in object processing during natural visual experience.

Title: Spatial Tuning of Alpha Oscillations in Human Visual Cortex

Authors: *K. YUASA[1], I. I. A. GROEN[1,2], G. PIANTONI[3], S. MONTENEGRO[4], A. FLINKER[4], S. DEVORE[4], O. DEVINSKY[4], W. DOYLE[4], N. F. RAMSEY[3], N. PETRIDOU[3], J. WINAWER[1]; [1]Dept. of Psychology, New York Univ., New York, NY; [2]Video & Image Sense Lab., Inst. for Informatics, Univ. of Amsterdam, Amsterdam, Netherlands; [3]Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [4]New York Univ. Sch. of Med., New York, NY

Abstract: The alpha oscillation (8-13 Hz) is a pronounced neuronal signal measured from the human occipital lobe. Alpha oscillations are thought to reflect cognitive functions including attention and alertness, and to be synchronized across a large cortical extent. However, there is some evidence that suppression of alpha oscillations in visual cortex can be spatially specific. Here, we used intracranial electrodes (ECoG) to measure alpha oscillations in visual cortex of 9 human subjects. Subjects viewed contrast patterns masked by an aperture at different visual field locations. We used a model to separate the alpha oscillation from broadband signals that overlap the alpha range. This was essential because power in the alpha band reflects both signals, and the two tend to oppose one another. A simple measure of alpha power that does not remove the broadband signal would incorrectly quantify the alpha rhythm.

We find that for a given electrode, alpha oscillations were suppressed only when stimuli appeared in specific regions of the visual field. We fit a 2D Gaussian population receptive field (pRF) model to the time series of the alpha response and compared the solutions to pRF models fit to broadband responses measured from the same electrodes at higher frequencies (70-180 Hz). The pRF centers were similar for the two measures, but the sizes differed, with alpha pRFs several times larger. The results demonstrate that alpha suppression in human visual cortex is spatially tuned and is in agreement with the underlying retinotopic map.

To complement analyses of the alpha amplitude, we examined the coherence of the alpha oscillation between electrodes on a high-density ECoG grid (1 mm diameter, 3 mm center-to-center spacing). When the stimulus was in an electrode's pRF, coherence with neighboring electrodes decreased, compared to a blank screen. Overall, we found a modest correlation such that when the alpha oscillatory amplitude decreased, coherence with neighboring electrodes also tended to decrease. We extrapolate that when coherence with neighboring electrodes decreases, coherence within the neural population under the electrode decreases. This would imply that neural coherence contributes to the changes in amplitude we observe during the mapping experiment.

Our findings support the possibility that the alpha suppression reflects part of the computations in generating neural responses to visual stimulation. We speculate that suppression of alpha oscillations to stimuli within or near the receptive field of a patch of cortex increases the responsivity of that cortical location, consistent with psychophysically measured benefits of attentional cueing.

Title: Visual receptive fields in the posterior parietal cortex of the common marmoset

Authors: *K. JOHNSTON[1], S. EVERLING[2], J. SELVANAYAGAM[3];
[1]Univ. of Western Ontario, London, ON, Canada; [2]Physiol., Univ. Western Ontario, London, ON, Canada; [3]Western Univ., London, ON, Canada

Abstract: The common marmoset (*Callithrix jacchus*), is an emerging model in visual neuroscience. This species possesses comparable oculomotor behaviour and visual and frontoparietal areas homologous to the rhesus macaque, which has historically been the standard model for electrophysiological investigations of oculomotor and cognitive control. The locations and sizes of visual receptive fields (RFs) reflect a fundamental aspect of the organization of cortical visual and oculomotor areas. In the marmoset, RF properties have been investigated in primary and tertiary visual areas, and frontal cortex in anesthetized preparations, but knowledge of the properties of RFs areas in the awake, behaving marmoset, and in posterior parietal cortex (PPC), encompassing areas LIP, MIP, and VIP, remain limited. Here we investigated RF properties of PPC neurons in the awake marmoset by recording with high density Neuropixels laminar probes in a receptive field mapping paradigm. In this paradigm, black dots (radius 0.3 deg) were briefly flashed (SOA: 100-200ms) on a grey background at one of 24 locations (5x5 grid in +/-10 deg). To determine whether units exhibited visual responses and spatial tuning, we conducted a two-way mixed ANOVA (Epoch x Location) comparing activity 50-100ms post-stimulus onset to a 50ms prestimulus period for each location. Of 3727 total units recorded, 698 showed a significant interaction of Epoch and Location. To investigate the receptive field properties of these units, we fit their responses to a 2D elliptical gaussian to estimate RF center and extent. 23.5% of all RFs were located in the contralateral hemifield and 4.3% in the ipsilateral hemifield, with the remaining RFs extending bilaterally. 64.8% of all RFs were located in the upper visual field. RF eccentricities ranged from 1 to 19 deg (median=3.35 deg). RF widths ranged from 3 - 20 deg (median=7.25). In 25 of 30 penetrations, we observed similar RFs across units. Altogether, we observed large bilateral RFs and smaller contralateral RFs similar to those observed in macaque PPC. In addition, RF widths resembled those found in macaque PPC at comparable eccentricities. These data suggest that RF properties and organization are similar in macaque and marmoset PPC, and provide further support for the marmoset model in investigations of the neural circuitry of the primate PPC and it's role in visual and cognitive processes.

Title: Cortical microcircuitry underlying target discrimination in the posterior parietal cortex of the common marmoset

Authors: *J. SELVANAYAGAM, K. D. JOHNSTON, S. EVERLING;
Physiol. and Pharmacol., Western Univ., London, ON, Canada

Abstract: The concept of a "canonical circuit", derived from investigations in primary sensory cortex, suggests a basic local, laminar cortical structure shared by all areas of neocortex. Investigations in rhesus macaques have revealed functional classes of cells in the frontoparietal network that play an important role in oculomotor control and visual attention. However, due to the difficulty in accessing key nodes of this network that are embedded within sulci (e.g., FEF and LIP) in the macaque, knowledge of the laminar microcircuitry of these areas and its function in cognitive tasks remains limited. To address this gap, we exploited the relatively lissencephalic cortex and homologous frontoparietal networks of the common marmoset (Callithrix jacchus). We carried out ultra high-density laminar recordings from one node of the frontoparietal network, the posterior parietal cortex (PPC), in two adult marmosets, targeting regions identified using fMRI as having strong BOLD responses in a saccade task. Recordings were conducted with high density laminar neuropixel probes (384 electrodes spanning 3.84mm), as the animals completed a visual target selection task, in which the animal was required to make a saccade to a target stimulus in the presence or absence of a distractor presented in the opposite hemifield. The animals correctly made a saccade to the target in the absence of a distractor faster (median RT: 158.5ms) and more accurately (mean accuracy: 82.5%) than in the presence of a distractor (median RT: 164.1ms; mean accuracy: 68.8%). We recorded from 3913 units, of which 945 units showed significant visual or saccade related activity. Of these units, 262 units discriminated between target and distractor stimuli prior to making a correct response; 66.7% of these units showed increased activity for the target stimulus. For these units, we computed the latency at which each unit's discharge activity selected for its preferred stimulus. The earliest discrimination time varied as a function of depth, occurring at approximately 60ms for units in more superficial locations (500 μm from the surface of the brain) followed by 80ms in deeper units (1500 and 2500 μm). Altogether we found that marmoset PPC neurons discriminated between target and distractor stimuli and that the latency to discriminate between target and distractor stimuli was shortest in superficial units followed by longer latencies in deeper units. These data provide novel insight into the laminar organization of visual responses in primate PPC.

Title: Interocular suppression in primary visual cortex in strabismus: Impact of sequential rather than simultaneous stimulation

Authors: J. R. ECONOMIDES, M. D. DILBECK, D. L. ADAMS, J. C. HORTON;
Ophthalmology, UCSF, San Francisco, CA

Abstract: Diplopia, or double vision, results from strabismus because misalignment of the visual axes causes images to fall upon non-corresponding locations in the two retinas. In children who develop strabismus early in life, this noxious sensation is prevented by suppression of the image originating from one of the eyes. Our goal is to elucidate the neural mechanism of diplopia suppression. In a recent study directed at this question, we recorded neurons in primary visual cortex of two Rhesus macaques raised with exotropia (an outwards ocular deviation) induced by surgical weakening of the medial rectus muscles. Remarkably, simultaneous display of stimuli to each eye in the alert, behaving monkeys did not induce suppression in V1 neurons. Puzzled by this negative result, and guided by previous evidence suggesting that the timing of stimulus presentation may have a critical impact on receptive field interactions, in this present study we modified our protocol to display stimuli in a staggered sequence, rather than simultaneously. Additional recordings were made in the same two macaques, following two paradigms. In Trial Type 1, as the monkeys performed a simple fixation task, the receptive field in one eye was stimulated for 5 seconds with a drifting sinusoidal grating while the other eye was occluded. The occluder then was removed and the neuron was stimulated for another 5 seconds. The effect of uncovering the eye, which potentially exposed the animal to diplopia, was quantified by the peripheral retinal interaction index (PRII). In Trial Type 2, the receptive field in the fixating eye was stimulated with a drifting grating during binocular viewing. After 5 seconds a second grating appeared in the receptive field of the non-fixating eye. The impact of adding the second grating, which had the potential to generate visual confusion, was quantified by the receptive field interaction index (RFII). For 82 cells recorded from calcarine cortex in the two monkeys, the mean PRII was 0.48 ± 0.05 (0.50 = no suppression) and the mean RFII was 0.46 ± 0.08 (0.50 = no suppression). These values suggest a mild net suppression in V1, but the modest decline in spike rate registered during the second epoch of visual stimulation might have been due to neuronal adaptation, rather than interocular suppression. In a few instances neurons showed unequivocal suppression, but overall, these recordings did not support the contention that staggered sequential stimulus presentation is more effective than simultaneous stimulus presentation at evoking interocular suppression in primary visual cortical neurons.

Title: Adaptation to retinal blur occurs in monocular channels

Authors: *C. J. NG[1], M. S. BANKS[2], R. BLAKE[3], D. TADIN[4], G. YOON[1];
[1]Sch. of Optometry, Univ. of Houston, Houston, TX; [2]Optometry, Univ. of California Berkeley, Berkeley, CA; [3]Psychology, Vanderbilt Univ., Nashville, TN; [4]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Adaptation is a canonical function that shapes behavior from experience. In vision, retinal images are the primary source of information for visual perception but subject to blur from the eyes' imperfect optics. Would long-term experience with the native blur patterns contribute to vision? We asked this question in relation to stereovision, because it was counterintuitive that stereo-performance did not always improve with optical correction. Two out of seven of our human participants - those with the very best optics - performed worse instead. The mean stereoacuity, or the smallest discriminable depth given in terms of disparity in arcsecs, was 18.61arcsec through their own eyes but 33.34arcsec with the improved optics when tested with three-dimensional wave stimuli cycling at 1cpd. Likewise, stereoacuity with narrower waves of 2cpd was 28.22 and 53.82arcsec respectively, and 46.30 vs 85.50arcsec with the narrowest waves at 3cpd. This suggested that familiarity to one's own blur patterns is important. In a separate experiment, evidence that the visual system had adapted to maximize stereovision came from manipulating the native blur using adaptive optics. We replaced our participants' optics with someone else's so that everyone would have the same blur patterns. Stereoacuity was also poorer in everyone compared to the person from whom the optics came (1cpd: 53.64arcsec [mean replacement] vs 8.46arcsec; 2cpd: 101.5 vs 12.91 arcsec; 3cpd: 182.34 vs 16.76arcsec). Next, we asked about its neural locus. Did adaptation occur before or after binocular combination? To answer, we swapped the optics of the two eyes in six human participants and compared the results to the native stereoacuity where the left and right eyes each received their habitual blur. Swapping caused unfamiliarity in the monocular channels, but the binocular channels still received the same average blur as well as the same difference of the two eyes. We observed that stereoacuity was worse with the swap, indicating that adaptation had occurred in monocular channels towards the blur patterns of the individual eyes (1cpd: 28.4arcsec with the native optics vs 43.4arcsec swapped; 2cpd: 53.6 vs 123.0arcsec; 3cpd: 144.5 vs 221.9arcsec). The detriment grew with interocular difference (1cpd: $r=0.91$, $p=0.01$; 2cpd: $r=0.97$, $p=<0.01$; 3cpd: $r=0.91$, $p<0.01$) as expected because swapping would matter only if the blur patterns in the two eyes were different. These results indicate a component of adaptation that happens before binocular combination; that is, in monocular channels and towards the blur patterns of individual eyes.

Title: Connectivity gradients as a tool for examining use-dependent plasticity in the human visual system

Authors: L. L. FLEMING[1], R. A. CHUA[2], M. DEFENDERFER[3], P. DEMIRAYAK[4], ***K. VISSCHER**[5]; [1]Neurobio., Univ. of Alabama At Birmingham Sch. of Med., Birmingham, AL; [2]UAB, Univ. of Alabama, Birmingham, Birmingham, AL; [3]Grad. Biomed. Sci., [4]Univ. of Alabama At Birmingham, Birmingham, AL; [5]Univ. of Alabama, Birmingham, Birmingham, AL

Abstract: Experience-dependent plasticity in the human visual system involves complex modifications that balance maintaining a stable visual representation with the capability to change the system. Describing these multi-factorial changes in connectivity and comparing them across participants has been historically challenging. We applied the tools of connectivity gradients to this issue, an approach that allows for individual differences in the specific plastic changes, but can quantify changes in the long-range, large-scale connection patterns of individual portions of the visual cortex.

A voxel can be characterized based on its specific patterns of input and output connections to the rest of the brain, and assigned an identifier known as a connectivity fingerprint. Using voxel-wise connectivity fingerprints, we can produce valid topographic representations of functional connectivity. The Congrads method (Haak et al., 2018) is a data-driven technique for connectopic mapping within a predefined region of interest. This method involves fitting the results with a spatial statistical model that summarizes the map in terms of a limited number of trend surface model coefficients, making it possible to disentangle multiple overlapping dimensions of organization that may be present in a given a brain region (such as representations of polar angle and eccentricity in visual cortex, for example).

While the broad principle of topographic mapping of functional connectivity has been well established, quantitative study of changes in this topographical organization with experience is comparatively limited. We apply the method to data in healthy controls as well as from participants with central vision loss due to macular degeneration. These patients have well-documented patterns of vision use (well characterized retinal loss and increased use, including a “preferred retinal locus”). Using connectivity gradients in this population has the benefits of examining specific hypothesized regions of interest, but removes the requirement for examining individual connections. The method has promise as a nuanced way to examine the multidimensional changes in functional connectivity profiles that may occur as a function of differential use of vision.

Title: Both high-frequency repetitive transcranial magnetic stimulation and visual training enhanced plasticity-induced neurochemical changes in early visual areas but with different neurochemical mechanisms

Authors: *S.-H. LIN[1], Y. LIEN[1], K. SHIBATA[2], Y. SASAKI[3], T. WATANABE[3], C.-P. LIN[1], L.-H. CHANG[1];
[1]Inst. of Neurosci., Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan; [2]RIKEN Ctr. for Brain Sci., Wako, Japan; [3]Dept. of Cognitive, Linguistics, & Psychological Sci., Brown Univ., Providence, RI

Abstract: It has been found that repetitive transcranial magnetic stimulation (rTMS) and visual training increase visual plasticity. This finding led some researchers to assume that rTMS and visual learning are subserved by the same or highly similar visual mechanisms. Here, we tested whether this assumption is true, by measuring the E/I ratio in early visual areas after the rTMS application in one group (n=18) and visual training in the other group (n=12). The E/I ratio refers to the concentration of glutamate as an excitatory neurotransmitter divided by the concentration of GABA as an inhibitory neurotransmitter by multiple magnetic resonance spectroscopy (MRS) and is regarded as an index of the degree of plasticity (Bang et al., 2018; Shibata et al., 2017; Tamaki et al., 2020). Although the E/I ratios changed both after the HF rTMS application and visual training reflecting visual plasticity enhancements, the time courses and major metabolites were significantly different in the two conditions. The peak E/I ratio was observed 3.5 hours after the HF rTMS with a significant decrease in GABA, whereas the peak E/I ratio occurred 30 minutes after visual training with increased glutamate. Our findings suggest that although both rTMS and visual learning increase the plasticity in early visual areas, the consequent neurochemical changes are fundamentally different. Previous conclusions in some studies examining the effect of rTMS may need to be reconsidered.

Title: Stability and plasticity of steady-state visual evoked potential contrast-response functions

Authors: *R. T. ASH[1], K. NIX[2], M. LEE[2], Y. CHEN[2], K. BUTTS PAULY[3], N. R. WILLIAMS[1], A. M. NORCIA[2];
[1]Dept. of Psychiatry, [2]Dept. of Psychology, [3]Dept. of Radiology, Stanford Univ., Stanford, CA

Abstract: A repeated measure of neural activity that is stable over time when unperturbed is needed to be able to meaningfully measure neuroplastic changes, e.g. following a plasticity induction protocol. We assessed the repeated-measure across-day stability of the steady-state visual-evoked potential (ssVEP), an exceptionally high signal-to-noise electrophysiological readout of neural activity in human visual cortex, in preparation for studies of visual cortical neuroplasticity. We re-analyzed data from Dmochowski et al *Neuroimage* 2015, in which ssVEP contrast-sweep responses (90 trials, 22 subjects) were measured daily for 4 days using a 128-channel EGI hydrocel EEG system and custom xDIVA software (*Fig. a*). High signal-to-noise (SNR > 1) responses were acquired from 20/22 subjects (*Fig. b*). The across-day coefficient of variation (CV= SD/ Mean) of the response was 0.22±0.13 (mean±SD) and did not significantly vary with contrast (*Fig. c*). Contrast-sweep ssVEP responses were fit well by the Naka-Rushton equation (*Fig. d*, r^2 = 0.24±0.18) Naka-Rushton parameters were also mostly stable with across-day CV<0.3 *(Fig. e*). We calculated the sample size needed to detect changes in response amplitude or contrast-response function parameters with a power of 0.8 given the measured across-day variability (*Fig. f*). Our ssVEP protocol could detect a 10% change with 40 subjects, a 20% change with 12 subjects, and a 40% change with 6 subjects. Restricting the analysis to the 1/3 most reliable subjects (*Fig. f* red line, n=8, CV=0.11±0.04) the contrast-sweep ssVEP was powered to detect a 5% change with 40 subjects, a 10% change with 12 subjects, and a 20% change with 5 subjects. Future work will partition the sources of response variability including brain state, learning/plasticity effects, physiological noise, and measurement. We are currently developing methods to induce plasticity in ssVEP contrast-response functions using repetitive transcranial magnetic stimulation, repetitive sensory stimulation, and transcranial focused ultrasound.

Title: Sleep-independent generalization of visual texture discrimination skills

Authors: N. D. LUTZ, M. KARN, C. VO, ***K. RAUSS**;
Univ. of Tübingen, Tübingen, Germany

Abstract: Sleep-dependent consolidation of visual experience has been shown to improve texture discrimination skills. This improvement is thought to be specific for the trained location in the visual field. In the current study, we tested if previously acquired texture discrimination skills can be generalized to different locations and if such generalization benefits from sleep.
We trained healthy young participants on a visual texture discrimination task in one quadrant of the visual

field before a night of sleep or daytime wakefulness. After the retention interval, participants were tested the following morning (Sleep group) or in the evening of the same day (Wake group) in both the trained as well as an untrained quadrant. Importantly, participants were explicitly informed about this testing procedure before training.
Visual texture discrimination performance was better after retention compared to training, as suggested by reduced threshold stimulus onset asynchronies. However, performance was not different between trained and untrained visual quadrants. There was also no difference between Sleep and Wake groups.
Our results suggest that, unlike previously assumed, visual texture discrimination skills trained in a specific location can generalize to other parts of the visual field. This effect appears to be independent of sleep. Additional experiments are needed to assess whether explicit prior knowledge about the generalization test may explain these findings.

Title: Functional reorganization of the cortical connectivity following localized ischemic stroke in the mouse visual cortex.

Authors: *S. TISSIER[1], C. ALBERT[1], V. CHOUINARD[1], B. OLIVEIRA FERREIRA DE SOUZA[1], J.-F. BOUCHARD[2], C. F. CASANOVA[3], M. P. VANNI[1];
[1]Univ. de Montréal, Montreal, QC, Canada; [2]Univ. of Montreal, Montreal, QC, Canada; [3]Univ. Montreal, Montreal, QC, Canada

Abstract: Goal : In cortical damage caused, for example, by a stroke, some of the lost cortical function can be recovered through cellular and molecular mechanisms that induce cortical plasticity. These reorganizations involve changes in the connectivity between regions as well as in the functional properties of the spared cortical areas. Thanks to the significant development of calcium imaging in recent years, the connections and functional properties of different regions of the cortex can be measured longitudinally in mice with great precision. Several studies have shown the involvement of endocannabinoid receptors, such as CB2, on plasticity and neuronal growth. The objective of this study was to first document the impact of restricted lesions on the cortical functional organization of the cortex and the demonstrate the role of endocannabinoid receptors on the observed reorganization. Methods In this study, n = 22 male and female mice (2 to 4 mo, n=10 cnr2+/+ and n=12 cnr2-/- lacking functional CB2 receptors) were injected (IV) with a virus allowing the expression of a calcium indicator throughout the entire cortex (AAV.PHPeB.Syn.GCaMP6s). Following implantation of a chronic optical chamber, calcium imaging of the dorsal cortex was assessed weekly with and without visual stimuli. After 3 weeks of baseline, a

photothrombotic stroke was induced in the primary visual cortex (V1) by photothrombotic in 12 mice (n=5 cnr2+/+ and n=6 cnr2-/-). Rose bengal was injected (IP) and a green laser was focused to achieve thrombosis in the visual cortex. The limits of cortical damage were established using Speckle imaging to spatially measure blood flow. These limits were later confirmed with histology using SYTOX Orange labelling. After induction of stroke, changes in resting state functional connectivity (using correlation between selected seeds) and visual evoked response were measured every week for 8 weeks post-stroke. Results Histological and speckle contrast imaging showed that our photothrombotic model of visual stroke induced a defined lesion of 1 mm3 associated with long-term functional deficits in the cortical circuitry. Visually evoked responses in visual cortex stimulation were impaired after a stroke and partially recovered after five weeks. The absence of CB2 receptors disrupted the functional reorganization following these lesions in the visual cortex. Conclusion: Calcium imaging proved to be a successful approach to characterize the mechanisms involved in cortical plasticity following damage to the visual cortex. In future, the impact of the environment in which an animal thrives will be explored using this experimental approach.

Title: Using the visual cliff assay to detect and study recovery from amblyopia in mice

Authors: *H. DE JESÚS-CORTÉS[1], D. A. BOWEN[2,1], A. MORELLO-MEGIAS[1], S. I. TORRES-BIGIO[1], P. A. ALICEA-ROMÁN[1], A. M. ALEJANDRO-SOTO[1], F. REILLY-ANDÚJAR[1], M. F. BEAR[1];
[1]Picower Inst. for Learning and Memory, Brain and Cognitive Sci., MIT, Cambridge, MA;
[2]Ophthalmology, Boston Children's Hosp., Boston, MA

Abstract: Amblyopia is a neurodevelopmental disorder of the visual system caused by uncorrected refractive error, cataract, strabismus, or ptosis during infancy and early childhood. The current standard of care is to strengthen the weak eye by depriving, or patching, the fellow eye. While this treatment can improve acuity in the amblyopic eye, these gains often come at the expense of acuity in the fellow eye, are not associated with improvements in binocularity, and are typically only achieved if treatment is initiated in early childhood (within the critical period). In our lab we use a mouse model of amblyopia induced by monocular deprivation (MD) to study the pathophysiology of this disorder and test novel therapeutics. The visual cliff assay (VCA) has been used in multiple animal models, including humans, to

assess stereopsis and depth perception, two key features of binocular vision that are disrupted in amblyopia. However, to date, no study has used the VCA to assess the effects of MD and characterize the recovery from amblyopia in mice. The VCA is advantageous in that we can compare functional and behavioral deficits within animals to determine the severity of amblyopia and track subsequent recovery, and it does not require operant conditioning. We first characterized and validated multiple aspects of the VCA including contribution of binocular vision, and the test-retest reliability. We demonstrate that after long-term MD (3 weeks), mice exhibit reduced preference for the safe side and more crosses to the cliff side and take less time to cross into the cliff side compared to their "sham" (no MD) littermate controls. When mice perform the VCA with their fellow eye closed, they spend less time in the safe side, have more crosses between sides, and take less time to cross into the cliff side compared to animals with their amblyopic eye closed. We conclude that the VCA is sensitive to detect amblyopia and therefore can be leveraged to study the efficacy of various treatments targeted at curing amblyopia in mice.

Title: Sleep and binocular experience promote optimal recovery of visual deficits in a mouse model of amblyopia

Authors: *J. D. MARTINEZ, M. J. DONNELLY, D. S. POPKE, D. TORRES, L. G. WILSON, W. P. BRANCALEONE, S. SHESKEY, B. C. CLAWSON, S. JIANG, S. J. ATON;
Univ. of Michigan, Ann Arbor, MI

Abstract: Amblyopia is a visual disorder that arises from imbalances in visual input to the primary visual cortex (V1) during childhood and leads to long-lasting visual disruption. Altered visual experience via monocular deprivation (MD) profoundly changes ocular dominance (OD) in V1, and is a well-studied experimental model for understanding amblyopia. Traditional amblyopia treatment includes patching the dominant eye, a monocular visual experience. However, the relative impact of monocular vs. a binocular experience on recovery of V1 function is not well understood, nor is the contribution of sleep timing relative to experience. We compared how binocular recovery (BR) or reverse occlusion (RO) of identical duration and visual content affects post-MD recovery of visual function in regular spiking neurons and fast-spiking (FS) interneurons within binocular mouse V1 (bV1). We find that BR is quantitatively superior to RO with respect to normalization of bV1 neurons' OD, and parvalbumin-expressing FS interneurons visual responsiveness. Sleep deprivation in the hours following BR visual experience disrupt

both the renormalization of OD and firing rate response changes in bV1. Thus a combination of BR experience and subsequent sleep together promote optimal recovery of binocular vision in a mouse model of amblyopia.

Abstract: Monocular deprivation early in development causes amblyopia, a severe visual impairment. Prognosis is poor if therapy is initiated after an early critical period. However, clinical observations have shown that recovery from amblyopia can occur later in life when the non-deprived (fellow) eye is removed. The traditional interpretation of this finding is that vision is improved by relieving interocular suppression in primary visual cortex. However, an alternative explanation is that elimination of activity in the fellow eye establishes conditions in visual cortex that enable the weak connections from the amblyopic eye to gain strength. Here we show in cats and mice that temporary inactivation of the fellow eye is sufficient to promote a full and enduring recovery from amblyopia at ages when conventional treatments fail. Thus, connections serving the amblyopic eye are capable of substantial plasticity beyond the critical period, and this potential is unleashed by reversibly silencing the fellow eye.

Title: Effect of stimulus location on visually-evoked potentials (VEPs) in hearing and deaf subjects

Authors: *T. MITZELFELT, X. BAO, P. BARNES, S. G. LOMBER;
Dept. of Physiol., McGill Univ., Montreal, QC, Canada

Abstract: Cross-modal plasticity is a phenomenon in which areas of the brain are repurposed and reorganized to compensate for sensory deficits. Significant activation of auditory areas in response to visual stimuli was observed in fMRI of deaf, but not hearing, children suggesting the use of auditory cortex in processing visual input. Deaf cats, compared with hearing cats, have superior visual localization in the peripheral field and reversible deactivation of posterior auditory cortex selectively eliminated this superior visual localization ability. Given the evidence in support of auditory-visual cross-modal plasticity provided by these studies, we sought to determine changes in the peripheral visual field following deafness by examining visual evoked potentials (VEPs), a commonly used non-invasive ophthalmological technique. VEPs were recorded from lightly anesthetized adult (>6M) cats (.04mg/kg dexmedetomidine, IM): 6 hearing and 5 deaf cats (deafness induced in the first postnatal month by systemic administration of ototoxic drugs). A screen was placed 16.5 cm from the right eye, with the left eye obstructed by a black contact lens. A circular checkerboard (12° visual angle) was inverted every 0.5 s , at one of 7 different azimuth angles between 0° and 90° . At least 200 inverts were presented at each angle in total. From the averaged VEP waveforms, peak-to-peak amplitude was quantified for each angle in each subject. A threshold azimuth angle was determined for each subject by selecting the most peripheral angle in which a clear VEP signal was observable. In both groups, peak-to-peak amplitudes decreased as visual stimuli were present more peripherally. However, a larger decrease was observed for deaf cats when the checkerboard was present at the most central locations compared to hearing cats, while a smaller decrease was observed at the most peripheral locations (75° & 90°). No statistical significance was revealed for peak-to-peak amplitudes between the two groups. The threshold azimuth angles (the most peripheral angle with VEPs present) for deaf subjects were larger compared to hearing subjects (Mann-Whitney U test, p = .052). The increase in visually-evoked cortical activity shown by VEPs in deaf subjects may result from the structural change of sensory cortices and underlie their advantage in visual localization. Similar cortical plasticity in humans may to have a profound influence in the development of language. With further research (in both animal models and human), VEPs can potentially serve as an auxiliary tool in the rehabilitation after cochlear implants, given its objective, non-invasive nature. Study was funded by CIHR and NSERC.

Abstract: Objective
Brain-computer interface (BCI) for completely locked-in state (CLIS) patients, who cannot move any body part including eyes, are especially challenging. In this study, we designed a deep convolutional neural network (CNN) model to automatically localize and learn task-dependent features from intracortical recordings of a CLIS patient to facilitate a YES/NO binary communication. Advanced decoders are necessary to overcome decreased performance of the original linear classifier due to high variability and decreased signal-to-noise ratio.
Method
The patient, diagnosed with amyotrophic lateral sclerosis and in CLIS, was implanted with two 64-channel microelectrode arrays in motor cortex. The patient learned to modulate multi-unit activity to control a YES/NO BCI paradigm based on a pre-trained linear classifier model with auditory feedback. We used spike-band power (SBP) features computed at 20 Hz from the 128 electrodes. We designed a CNN model by stacking 1-D temporal convolutional layers applied along the time axis with a pooling layer after each group of convolutional layers to increase the receptive field, followed by a global max pooling, fully connected layer and output layer. For training the CNN, we used the data recorded during calibration sessions of the paradigm, originally used to train the linear classifier model. The test data for CNN came from signals recorded during a cued online BCI session, where the patient received a feedback based on the daily-trained linear classifier model.
Result
The proposed model achieved 74% single-trial accuracy from 3440 testing trials (65% online accuracy with linear classifier, chance level threshold=51.4% at α=0.05). Interestingly, we observed distinct phase and amplitude responses from convolutional filters (see Figure). A clear difference can be also seen between the two conditions.
Conclusion
In this single-case study, a CNN with temporal filters met the dual purpose of achieving a higher performance compared to the previous classifier and capturing discriminative dynamics from multi-channel signals.

Abstract: Patients with amyotrophic lateral sclerosis (ALS) lose all muscle-based routes of communication as motor neuron degeneration progresses, and ultimately, they are left without any means of communication. Despite many attempts using non-invasive and intracranial brain-computer interfaces (BCI), enabling communication for people in completely locked-in state (CLIS) remains a challenge. With consent of the participant, family, and approval from legal and health authorities for this study, two 64 microelectrode arrays were implanted in the supplementary and primary motor cortex of a CLIS patient with ALS. The last successful communication session with non-invasive eye movement recordings was recorded one month prior to implantation.
We implemented a neurofeedback task in which the participant learned to modulate multi-unit activity (MUA) by manipulating feedback tone frequency with MUA changes. In a training task, the participant was asked to match the feedback frequency to one of two target tones in repeated trials. Later, high and low frequencies were assigned to 'yes' and 'no' responses in a speller task. The speller paradigm comprised two stages: first, groups of letters were presented in turn and either skipped or selected. When a letter group was selected, each letter of that group was presented in turn until one was chosen.
The participant could form words and phrases, often spelling hundreds of characters at a time, albeit slowly (~1 character / min on average). Ability to spell was variable: days of prolific speller use were followed by days on which the patient had little voluntary control of the speller. Ability to spell also decreased over time, and communication later on consisted mostly of short sequences of yes/no questions. This may be caused by the gradual deterioration of the electrodes leading to loss of MUA that was observed.
To our knowledge, this is the first case of a person in CLIS being implanted with intracranial electrodes

and regaining the ability to communicate. The implant led to meaningful and substantial communication about the participant's needs and wishes.

Schematic representation of signal processing, neurofeedback paradigm, and speller control

Title: Independent Home Use of a Microarray Brain Computer-Interface in a Completely Locked In-Patient

Authors: *A. TONIN[1,2], D. IBAÑEZ-SORIA[1], J. RAMOS DA CRUZ[1], K. LEE[1], A. ESPINOSA[1], N. F. RAMSEY[3,1], J. B. ZIMMERMANN[1];

Abstract: The translational aspect of brain computer interfaces (BCIs) - i.e. whether they can be reliably operated by patients and/or caretakers in home environments - is a major challenge of the field. Here, we describe the case of a BCI home use system that allows caretakers of a patient with Complete Locked in Syndrome (CLIS) to independently run BCI sessions without the supervision of investigators. The end-user is in his mid 30's and was diagnosed with amyotrophic lateral sclerosis (ALS). In 2019, the patient - already in CLIS - was implanted with two 64 microelectrode arrays (Blackrock Microsystems LLC) in the motor cortex. The patient learned to modulate his neural activity to control binary BCI paradigms. For home use, we developed a three-step procedure that enables caretakers to initialize BCI sessions allowing the patient to communicate using a speller or a yes/no response paradigm. This procedure comprises Calibration, Validation, and Communication. Calibration and Validation steps are used daily to automatically build a classifier; Validation is also used to train the end-user without the risk of delivering wrong communication. Caretakers were advised to proceed to communication only if Validation accuracy was at least 80% (chance level 75%). Weekly, supervised sessions were performed to evaluate the status quo. In addition, data were analyzed offline to evaluate whether parameters needed to be adjusted. After 5 months of home use, data from those sessions were used to train a grand classifier, reducing the home use procedure to Validation and Communication. When Validation performance did not meet the threshold, caretakers were advised to not start Communication. Finally, the classifier is regularly retrained offline when new sessions are available. Eight months into the home use deployment, analysis of the validation performance, number of characters spelled per session, and yes/no response results, show that the performance achieved in the home use is comparable to those achieved in supervised sessions. Recently, the patient's ability to control the BCI has deteriorated, affecting the reliability of the current paradigm in both home use as well as supervised sessions. For the first time a home use BCI system for ALS patients in CLIS has been successfully deployed. Results show that microarray implant is feasible for home use BCI: the system has been frequently used by the caretakers and it shows performance comparable to supervised sessions. Moreover, the involvement of the family led to a general positive psychological

effect. However, therefore investigators still need to be in the loop framework, at least sporadically, to ensure reliability of the system.

Title: Intracortical Eyes-Closed Steady-State Visual Evoked Potentials and Auditory Oddball Evoked Potentials in a Completely Locked-In Patient

Authors: *J. RAMOS DA CRUZ[1], K. LEE[1], A. TONIN[1,2], A. ESPINOSA[1], D. IBANEZ SORIA[1], N. F. RAMSEY[3,1], J. B. ZIMMERMANN[1];

Abstract: Patients with amyotrophic lateral sclerosis (ALS) can progress into complete locked-in syndrome (CLIS) where muscle-based communication is not possible. We have previously shown that motor-imagery-based communication is possible in a CLIS patient implanted with microelectrode arrays. The patient uses neurofeedback modulation of multi-unit activity (MUA) to control several brain-computer interface (BCI) applications. At over two years post-implantation, only few channels record MUA, and control of activity on remaining channels appears to be difficult and unreliable. Here, we report recent attempts to identify alternative BCI channels to improve the communication with the patient. The patient is in mid 30's and was diagnosed with ALS eventually leading to CLIS. In 2019, he was implanted with two 64 microelectrode arrays (Blackrock Microsystems LLC) in the left motor cortex. As alternative communication channels, we explored two BCI paradigms: steady-state visual evoked potentials (SSVEP) and auditory oddball. In the SSVEP paradigm, light emitting diodes flickering at different frequencies were used to present visual stimuli to the patient with his eyes closed. He was instructed to attend to one of the two light sources oppositely placed at 45 degrees from the visual field center. For the auditory oddball paradigm, sequences of repetitive sounds infrequently interrupted by a deviant stimulus were presented to the participant. He was asked to count the number of attended deviant stimuli. Besides the two microelectrode arrays, data were also recorded with frontal, parietal, and temporal electroencephalogram (EEG) electrodes with a Brain Products V-Amp amplifier for comparison. Intracortical data acquisition was performed using NeuroKey software. Offline analysis confirmed that both eyes-closed SSVEP and neuronal responses to oddball auditory stimuli can be detected by not only off-occipital EEG electrodes but also the microelectrode arrays, when using the pedestal as reference. In the SSVEP paradigm, we identified increased spectral power of the attended frequencies and corresponding harmonics. In the oddball paradigm, the frequent and deviant stimuli elicited neuronal responses, with standard peak-amplitude latencies, but evoked amplitudes differed based on the stimulus category. In sum, eyes-closed SSVEP and auditory oddball evoked potentials can be recorded from

microelectrode arrays implanted in the motor cortex of a CLIS patient. Preliminary results suggest that the patient can modulate the signals with selective attention, thus opening avenues for alternative BCI communication channels.

Abstract: Neuroscientists often need to build their own software to meet specific research requirements. Besides integration issues, it can be difficult to quickly adapt to new research conditions and developing software as a medical device for use in clinical trials can be a long, sometimes challenging, processs. Our software platform, NeuroKey (NKy), grew out of research needs. It allows neuroscientists to focus on research and spend less time on software development. NKy facilitates the translation from research tool to clinical application by providing means for scientist to design intelligent and adaptive user interfaces.NKy combines, processes and decodes electrophysiological data in real-time. It uses JUCE, an open-source C++ cross-platform library for audio processing that ensures accurate timing and low latency. Developed as a medical-grade platform, NKy is optimized for the analysis of large data streams from high channel count implantable devices and has been validated for up to 256 channels at 30000 samples/sec. NKy is also integrated with additional systems such as near-infrared spectroscopy or electroencephalographs. The software is modular allowing complex algorithms to be divided into smaller steps. Its basic units, called processors, are independent modules with specific functionalities that interface with external data sources, analyse, and decode electrophysiological data. Users can select and interconnect processors within NKy graphical user interface (GUI) to create processing pipelines. These processors include filters, spike detectors, band power estimators or machine learning-based classifiers among others. The GUI also provides the means to present information to the end-user and integrates a fully configurable keyboard widget for brain computer interface applications.NKy software development kit (SDK) written in Python allows full pipeline control and secure real-time access to all processing stages. While NKy performs the heavy real-time signal processing, the Python high-level programming language allows efficient cross-platform prototyping and development of a wide variety of neuroscience

applications.NKy BCI application is medical device software of safety class A as per IEC 62304. It is currently in home-use as part of a single case study to enable communication for a user with amyotrophic lateral sclerosis who is in completely locked-in state. NKy is also being used to explore novel closed-loop stimulation paradigms to improve recovery from spinal cord injuries. The use of NKy for stroke rehabilitation and epileptic seizure monitoring is at present at feasibility stage.

Title: Spikedeeptector in conjunction with background activity rejector (bar) as a feature extraction technique for online invasive brain-computer interface (bci) applications

Authors: *M. SAIF-UR-REHMAN[1], O. ALI[3], J. HILGENHÖNER[1], C. KLAES[4], I. IOSSIFIDIS[2]; [1]Computer Sci. Dept., Ruhr West Univ. of Applied Sci., Mülheim An der Ruhr, Germany; [2]Computer Sci., Ruhr West Univ. of Applied Sci., Muelheim An Der Ruhr, Germany; [3]Dept. of Neurosurg., Knappschaftskrankenhaus Bochum, Germany, Bochum, Germany; [4]Neurosurg., Knappschaftskrankenhaus Bochum, Bochum, Germany

Abstract: Recently developed invasive brain-computer interface (BCI) systems showed promising results to transform the lives of severely disabled persons by successfully translating the neural activity into corresponding intended actions. The translation of neuronal activity is a two-step process: feature vectors extraction and classification or regression. Non-stationary behavior of neural signals, minor perturbation of implanted microelectrode arrays, neural activities of neurons too far away from the electrodes tip, exposure of neural signals to several surrounding noise sources and external artifacts are the main obstacles for reliable feature extraction techniques that are suitable for online BCI applications. Ideally, during recording sessions, online BCI decoding applications require feature vector extraction techniques that do not require parameter tuning, and low computational cost to reduce the latency in the decoding loop. Conventionally, raw signals are first band-pass filtered and then thresholding is applied to extract the events that represent spike activity (SA). These extracted SA events are mostly used as the features for online decoding. Majority of extracted events do not necessarily represent the neural activity, but the external artifacts. Henceforth, the extracted feature vectors are contaminated with noise. Similarly, most of the implanted microelectrodes do not record any neural data but noise. Including such electrodes for feature vectors construction adversely affects the performance of online BCI decoding. Here, we

introduced a feature extraction technique that automatically detects the channels recording neural data. Then the events representing SA on the extracted channels are selected for feature vectors construction. SpikeDeeptector and background activity rejector (BAR) are stacked together to extract channels and meaningful events. SpikeDeeptector and BAR, both are deep learning-based algorithms. Here, we used pretrained model of SpikeDeeptector and BAR algorithm. In this study, we used the data recorded from a tetraplegic patient implanted with two Utah arrays on posterior parietal cortex (PPC). The patient imagined three different hand shapes. The intended shape is successfully decoded by proposed feature extraction algorithm in combination with support vector machine (SVM) as the classification algorithm. The results of proposed algorithm are compared with the most used band pass filtering in combination with thresholding process. In the preliminary results, the proposed algorithm showed significant improvements over its counterpart.

(SIN), Freiburg, Germany; [3]Ctr. for Exptl. Models and Transgenic Service (CEMT), [4]Dept. of Neurosurg., Med. Center, Univ. of Freiburg, Germany, Freiburg, Germany

Abstract: Active neural implants and bi-directional brain-computer interfaces (BCIs) are increasingly used in basic and translational neuroscientific research as well as in investigational therapeutical and medical applications. As the requirements for potential applications grow in complexity, fully implantable neural interfaces and BCI devices must provide long-term implantation compatibility, a larger range of technical flexibility, and medical safety to the user and to patients. The CorTec Brain Interchange system meets these crucial requirements: flexible electrode type and recording configuration choice, open- and closed-loop stimulation functionality, biocompatible materials, and inherent safety features.
The Brain Interchange system was chronically implanted for > 6 months in female, adult sheep. The system was equipped with two 12-contact (1.3 mm diameter) micro-electrocorticographic electrode arrays (CorTec GmbH) implanted bilaterally on the prefrontal cortex and with two 4-contact deep brain stimulation (DBS) leads (Cartesia, Boston Scientific, USA) implanted bilaterally in the medial forebrain bundle area. Neural data was obtained during resting state recordings and in experiments with application

of direct cortical electrical surface stimulation and DBS, respectively, in awake behaving animals. Different stimulation paradigms were performed: single-pulse stimulation and burst stimulation with frequencies of 200 Hz (µECoG) and 130 Hz (DBS). All conducted implantations and experiments were approved by the Animal Ethics committee of the Regierungspraesidium Freiburg and followed the EU-directive 2010/63/EU.
First, we will present neurobiological data obtained from resting state recordings over the time course of the chronic implantation period to verify the long-term recording functionality of the devices. Second, we demonstrate the flexibility of the stimulation functionality and report the presence of brain responses to single-pulse stimulation, so-called cortico-cortical evoked potentials (CCEPs). In addition, we examine brain activity changes elicited by µECoG-based burst stimulation.
The presented data underpin the flexibility and robustness of the recording and stimulation functionality of the fully implantable neural interfacing system Brain Interchange from both a technical and neurobiological perspective. The outcomes from these preclinical studies in large mammals demonstrate that the system meets the desired requirements for neuroscientific and potential medical applications as a basis for the next step towards investigational device exemption studies in human patients.

VANSTEENSEL, N. F. RAMSEY*Neurol. and Neurosurg., UMC Brain Center,University Med. Ctr. Utrecht, Utrecht, Netherlands*
Abstract: A prerequisite for implanting a minimally invasive brain-computer interface (BCI) is a detailed, non-invasive localization of the target location. Functional MRI is a natural choice for this step. We have previously demonstrated a close spatial correlation between the fMRI response and electrocorticography (ECoG) activity associated with hand movements in able-bodied people with epilepsy. Here, we investigated whether a similar relation exists in people with locked-in syndrome (LIS). We used data obtained within the Utrecht NeuroProsthesis (UNP) study from three individuals with LIS who were implanted with a chronic ECoG-based BCI to test feasibility of independent home use. Placement of electrode strips through burrholes in the skull was guided by pre-surgical fMRI (3 tesla). Strips were implanted over the motor cortex and electrode positions were confirmed post-surgically with a CT scan. Leads were tunneled to an amplifier (Activa ® PC+s; Medtronic plc; investigational device) that was implanted under the left clavicle. Based on CT images, electrode coordinates were aligned to the fMRI activity allowing direct fMRI-ECoG comparison. Per contact point, we compared the magnitude of task-related low and high frequency band (LFB and HFB, respectively) ECoG modulation with task-related BOLD activity. In two out of three participants, we found strong correlations between fMRI and HFB ECoG activity (participants UNP1 & UNP4 respectively: $r = 0.61$ & 0.80; $p = 0.02$ & 0.03). For UNP5, a non-significant trend was observed ($r = 0.41$; $p = 0.09$). Moreover, using fMRI, we could retrospectively confirm the optimal electrode pair for BCI control in UNP1 and UNP4. In UNP5, the optimal control pair as assessed by normal feature selection was the second best as predicted by fMRI. For this participant, the correlation may not have reached significance because only a limited number of ECoG datasets was available (4 datasets, compared to 13 and 12 for UNP1 and UNP4 respectively). We conclude that pre-surgical fMRI shows a close spatial correlation with the activity measured with ECoG-electrodes, suggesting that target locations for ECoG electrode implantation can be predicted using fMRI. We therefore recommend using pre-surgical fMRI to localize target regions in similar, minimally invasive BCI systems.

Title: The effect of visual and proprioceptive feedback on brain-computer interface control of a robotic arm

Authors: *M. F. LIU[1], R. A. GAUNT[2], J. L. COLLINGER[1], A. P. BATISTA[3], D. J. WEBER[3];
[2]Physical Med. and Rehabil., [3]Bioengineering, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Vision and proprioception play important roles in regulating motor output during reaching, and brain computer interfaces (BCIs) offer a unique opportunity to study the effects of sensory feedback on motor cortex (M1) neurons. During a clinical BCI trial, we implanted two 96-channel microelectrode arrays into M1 of a person who was completely paralyzed below the neck but retained intact somatosensation. Neural firing rates were transformed into a 2-dimensional velocity control signal for a robotic arm using an optimal linear estimator. We examined how visual and proprioceptive feedback were incorporated into BCI control by having the participant move this arm left and right over a centerline as many times as possible in one minute. During this task, the participant was provided with either visual or proprioceptive feedback, both, or neither. Proprioceptive feedback was provided by moving the participant's arm to match the movement of the robotic arm. Task performance with vision or proprioception alone was better than when neither were provided. However, providing proprioceptive feedback impaired performance relative to visual feedback alone, unless the decoder was trained with both modalities. In contrast, Flesher et al. (2021) showed that tactile feedback improved BCI performance although the decoder was not trained with tactile input. These results raise the question of how different sensory feedback modalities influence M1 activity and ultimately BCI performance. We examined the kinematics of the robotic arm across different feedback conditions and found that both positional variance and average speed were highest when proprioceptive feedback alone was provided. This suggests that the participant's control strategy changes to account for lower precision in proprioceptive sensation. We then examined population-level responses by identifying the dimensions of neural activity that best captured variance for different combinations of visual and proprioceptive feedback. We computed the principal angle between the neural activity during performance and the decoder, and found that the overlap between neural activity and the decode axis was largest when sensory feedback during the task matched the modalities present during decoder training. Overall performance also improved as the overlap between the decoder and the neural activity during the task increased. Combined, these results suggest that proprioceptive feedback may have a uniquely large impact on M1 activity relative to other sensory modalities, and that training a decoder with proprioceptive feedback allows the decoder to take advantage of proprioception-driven variability in M1.

Title: Gray matter volume correlates of electrocortical measures of conflict monitoring in high trait anxiety

Authors: J. FOLEY, H. GABOURY, H. M. GILBERTSON, L. FANG, *J. CARLSON;
Northern Michigan Univ., Marquette, MI

Abstract: Conflict monitoring is believed to play an important role in determining the circumstances in which top-down cognitive control processes are required for adaptive behavioral responding. The N2 is a negative event-related potential (ERP) peaking at 200-300 ms post-stimulus onset and maximal at frontocentral scalp electrodes. The N2 is thought to originate from the anterior cingulate cortex and/or supplementary motor area and reflect conflict monitoring-related cognitive control processes. Individuals with high levels of anxiety demonstrate increased N2 amplitudes during conflict processing, suggesting a relationship between hyperactive conflict monitoring and anxious symptomatology. Individual differences in the amplitude of the N2 have been linked to variability in gray matter volume in individuals with schizophrenia, autism spectrum disorder, multiple sclerosis, as well as other neurological and psychological disorders. Yet, the extent to which differences in regional gray matter volume relate to variability in N2 amplitudes in high trait anxious individuals remains untested. To address this knowledge gap, this study was conducted with a sample of 71 high trait anxious right-handed adults (female = 47) between 18 to 38 years of age. Participants completed a flanker task while EEG data was recorded. The task required participants to identify the center stimulus in a series of incongruent (e.g., < < > < <) and congruent arrows (e.g., < < < < <). EEG data were preprocessed using EEGLAB. Whole brain T1-weighted MRI scans were used to acquire estimates of gray matter volume. A voxel based morphometry (VBM) regression analysis was performed in SPM12 to assess the association between (delta) N2 amplitudes (Incongruent - Congruent) and regional gray matter volume. Incongruent N2 amplitudes were more negative than congruent N2 amplitudes, $t(70), = -7.60$, $p < .001$. Using a whole-brain cluster-level family-wise error (FWE) correction, we found that N2 amplitudes were correlated with gray matter volume in the bilateral inferior frontal gyri (xyz: -57, 32, 6; k = 1592 & xyz: 50, 41, -6; k = 641), anterior cingulate cortex (xyz: -3, 56, 5; k = 2134), supplementary/premotor motor area, (xyz: 35, -2, 57, k = 929), right superior temporal gyrus (xyz: 72, -32, -2; k = 754), and other frontal regions (all p_{FWE} values < .05). Larger gray matter volume in these regions was associated with greater N2 amplitudes. No regions showed the opposite association. Such findings provide a better understanding of the link between functional and structural measures of conflict processing in individuals with anxiety.

Title: Prefrontal cortex based intrinsic functional connectivity is related to electrocortical measures of conflict monitoring

Authors: S. LYONS, H. GILBERTSON, C. GIRARD, J. M. CARLSON, *L. FANG;
Northern Michigan Univ., Marquette, MI

Abstract: Conflict monitoring is a facet of executive functioning which prioritizes task-relevant information and inhibits distractions to ensure accurate responding. Conflict is often induced using tasks such as the flanker task where participants report the central symbol regardless of the congruent (e.g., < < < < <) or incongruent (e.g., < < > < <) symbols flanking it. Elevated anxiety is associated with heightened conflict monitoring, which is often indexed by the N2, a negative event-related potential appearing ~200-350ms at frontocentral scalp locations after stimulus presentation. It is thought that this increase in conflict monitoring reflects greater cortical recruitment to compensate for impaired inhibitory control. Moreover, previous neuroimaging research has identified that, under conflict, individuals with anxiety experience elevated activity in regions such as the anterior cingulate cortex (ACC) and regions of the prefrontal cortex (PFC). At present, despite knowing the N2 emerges from the ACC, little is known about how intrinsic connectivity associates with this electrocortical response of conflict monitoring in anxiety. The purpose of this study was to assess the association between the ACC as well as regions of the dorsolateral PFC (DLPFC) seeded functional connectivity and N2 amplitude in high trait-anxious individuals. Participants included 60 right-handed adults scoring 40 or above on the State-Trait Anxiety Inventory-Trait Scale. They were asked to complete one 10-minute resting-state fMRI session and one EEG session in which N2 data was collected during an arrow flanker task. Seed-to-voxel analysis showed that, at an uncorrected $p < .001$ level, delta N2 amplitudes (difference scores between incongruent and congruent trials) were negatively correlated with the rsFC between the ACC and superior frontal gyrus (SFG), the rsFC between the left DLPFC and parahippocampal gyrus, as well as the rsFC between the left DLPFC and parietal operculum cortex. Moreover, ROI-to-ROI analysis revealed that delta N2 was correlated with the rsFC between right SFG and left superior temporal gyrus (STG) after FDR correction at the $p < .05$ level. Adding to current literature, our study provides the first evidence that enhanced N2 amplitudes in highly anxious individuals are associated with the functional coupling between regions involved in conflict detection (e.g., ACC) and attention allocation (e.g., SFG). In addition, our findings also reveal that regions involved in cognitive control/proactive inhibition and action cancellation, are associated with elevated conflict monitoring in anxiety.

Title: Threat Bias and Resting State Functional Connectivity of the Periaqueductal Grey and Lateral Hypothalamus in Anxiety Disorders

Authors: *K. ROBERTS[1], S. HU[1], C.-S. R. LI[2];
[1]Psychology, SUNY Oswego, Oswego, NY; [2]Dept Psychiatry, Yale Univ., New Haven, CT

Abstract: The periaqueductal gray (PAG) and lateral hypothalamus(LH) are involved in processing pain and fear. This study evaluated the resting state functional connectivity (rsFC) of the PAG and LH in patients with anxiety disorders (PAD, n=30) and healthy controls (HC, n=70). Functional magnetic resonance imaging (fMRI) and behavioral data were obtained from the Nathan Kline Institute - Rockland Sample. Participants completed a 5-minute resting fMRI scan and a dot-probe task outside the scanner. The dot-probe task consisted of two faces (threatening or neutral) appearing on a screen, one of which would be replaced by a dot that required a button press. Threat bias was computed as the difference in reaction time (RT) between trials with the dot replacing the neutral vs. threatening faces (i.e., RT in neutral - RT in threat). Thus, a positive threat bias reflected a faster response to threatening vs. neutral faces, indicative of higher anxiety. Evaluated at a corrected threshold, the whole-brain rsFC of the PAG or LH showed no differences between PAD and HC. Regression analysis showed negative correlations of threat bias with left PAG-putamen and with right LH-inferior frontal gyrus rsFC in PAD but not in HC. In addition, a positive correlation between the right LH-posterior dorsal anterior cingulate cortex rsFC and threat bias was found in PAD but not HC. These connectivity metrics may serve as important neural markers of anxiety disorders.

Title: Accelerated exercise-induced stress resilience in females is not dependent on running distance

Authors: *M. K. TANNER[1], A. A. HOHORST[3], N. JAMIL[1], E. C. LOETZ[2], B. N. GREENWOOD[2]; [2]Psychology, [1]Univ. of Colorado Denver, Denver, CO; [3]Univ. of Colorado - Denver, Denver, CO

Abstract: Stress-related psychiatric disorders are the most common mental health disorders in the world and affect women at nearly twice the rate of men. Participation in regular physical activity is an inexpensive and readily available tool for preventing the effects of stress in both sexes. However, little research has been done to characterize exercise-induced stress resilience in females. Understanding exercise-induced stress resilience in females is critical since females are more susceptible to stress-related disorders than males. Rodents provide a useful model for studying stress resilience produced by exercise. Following exposure to inescapable stress, rats display anxiety-like behaviors, such as exaggerated fear in response to mild stimuli. In both male and female rats, 6 weeks of voluntary wheel running prior to inescapable stress exposure prevents the behavioral effects of stress. Interestingly, 3 weeks of wheel running is sufficient to produce stress resilience in females, but not males. Although female rats run greater nightly distances compared to males, it is currently unclear if running distance has a role in the rapid acquisition of stress resilience in females. The goal of the current study was to determine if 3 weeks of voluntary wheel running produces stress resilience in female rats that run similar distances as males.

Adult, female Sprague Dawley rats were randomly assigned to sedentary, unlimited running, or limited running conditions. Rats in the unlimited running group had 24 h access to voluntary running wheels, while rats in the limited running group had access to voluntary running wheels for 3 h after the start of the active cycle. Females in the unlimited running group ran up to 1.5x more than what is typically seen in males, while females in the limited group ran less than males. After 3 weeks of sedentary or running conditions, half of the rats were exposed to inescapable stress. The following day, freezing behavior was assessed immediately following 2 foot shocks. Sedentary rats exposed to inescapable stress, compared to non-stressed rats, had exaggerated freezing in response to the 2 foot shocks; indicative of exaggerated fear learning. Three weeks of both unlimited and limited running prevented stress-induced exaggerated fear, and the degree of stress protection afforded by 3 weeks of wheel running was similar between unlimited and limited females. These results suggest that running distance does not drive the rapid acquisition of exercise-induced stress resilience in females. Further research is needed to identify the mechanisms underlying the accelerated stress resilience produced by exercise in females.

Title: Estrous cycle modulation of conditioned fear extinction and relapse

Authors: *A. A. HOHORST[1], M. K. TANNER[1], T. J. HUBERT[1], B. N. GREENWOOD[2], E. C. LOETZ[2];
[2]Psychology, [1]Univ. of Colorado Denver, Denver, CO

Abstract: Impaired inhibition of learned fear is a feature of stress-related psychiatric disorders such as depression, generalized anxiety disorder and post-traumatic stress disorder (PTSD). Extinction-based exposure therapy is the behavioral therapy of choice for stress-related psychiatric disorders, however, it has limited long term efficacy due to the vulnerability of fear memories to later relapse. Additionally, women are up to 60% more likely to experience an anxiety disorder and up to twice as likely to experience PTSD compared to men. Although women are at a higher risk than men to develop these common stress-related psychiatric disorders, sex differences are not fully considered in the field of neuroscience. Prior research has shown that females can have enhanced fear extinction compared to males, and that the strength of fear extinction in females varies depending on phase of the estrous cycle during which fear extinction takes place. However, whether the phase of the estrous cycle during which fear extinction is learned impacts later fear relapse after extinction has not been well characterized. The goal of this experiment was to determine whether sex and phase of the estrous cycle during extinction training modulates later fear relapse. Long-Evans rats were exposed to auditory fear conditioning in

Context A, followed 24 h later by fear extinction in Context B. The next day, rats were re-exposed to the conditioned stimulus in either the same context used for extinction (Context B) to test fear extinction memory, or a different, novel context (Context C) to assess fear renewal. Spontaneous recovery of fear was assessed a week later in Context B. Female cycle progression was monitored daily. Results indicate that males and females learned auditory fear conditioning and fear extinction similarly. Levels of fear extinction retention and fear relapse were similar between males and females exposed to fear extinction during metestrus/diestrus. However, females exposed to fear extinction training during pro-estrus or estrus, had improved retention of fear extinction, as well as reduced fear renewal and spontaneous recovery compared to both males and females exposed to fear extinction training in other estrous phases. These data suggest that phase of the estrous cycle during fear extinction learning modulates fear relapse; whereby learning fear extinction during proestrus/estrus is protective against later relapse. These results could have important clinical implications for the use of exposure therapy in women.

Title: Glyphosate exposure induces novelty-induced anxiety in rats

Authors: *A. FIGUEROA-PÉREZ, M. RIVERA-LÓPEZ, M. CÁCERES-CHACÓN, O. MARTÍNEZ-GUZMÁN, D. SIERRA-MERCADO;
Anat. and Neurobio., Univ. of Puerto Rico Sch. of Med., San Juan, PR

Abstract: Glyphosate is the most common active ingredient in herbicides used in landscaping and agriculture. Glyphosate is thought to be safe for humans and animals because it acts because it acts by inhibiting a metabolic route almost exclusive to plants. However, recent studies in rodents have shown that glyphosate is capable of increasing the expression of anxiety-like behaviors in classical paradigms such as the open field test and elevated plus maze. However, the effect that glyphosate may have on novelty-induced anxiety or neophobia, has not been explored. Therefore, we aimed to evaluate the effect of prolonged oral consumption of glyphosate-contaminated drinking water on novelty-induced anxiety. To achieve this, we weighed rats weekly as well as measured their water intake to prepare a solution that

would allow us provide the rat with a target dose of 2.0mg/kg of GBH daily (chronic references dose approved by the E.P.A.) in their drinking water. Control rats were treated in the same manner but received filtered drinking water. Of note, there were no differences in neither the amounts of food or water consumption, nor body weight between the groups ($p>0.05$). After 4 weeks of exposure, we assessed for novelty-induced anxiety using a modified open field test in which an object was placed in the center of the arena. Here, glyphosate decreased the amount of time spent interacting with the object (Glyphosate: 8.71, control: 35.02, $p=0.0202$) as well as the number of interactions with the object (Glyphosate: 3.00; control: 9.42; $p=0.0255$). Next, animals were placed in an operant chamber and presented with 5 auditory tones (30 s, 4 kHz, 77 dB; 3 min intertrial interval), and the amount of time spent freezing to the tone was measured. Glyphosate significantly increased the percent time spent freezing to the tones (Glyphosate: 14.05, control: 4.95; $p=0.0201$). In conclusion, glyphosate increases novelty-induced anxiety to different types of stimuli and in different contexts. Future directions include evaluating brain regions involved in anxiety-like behaviors for changes in neuronal activity.

Title: Potential of geraniol to reduce anxiety-like symptoms and abnormal EEG wave pattern

Authors: *Z. BATOOL[1], R. NISAR[2], S. HAIDER[3];
[1]Panjwani Ctr. for Mol. Med. and Drug Research, Univ. of Karachi, Karachi, Pakistan; [2]HEJ Reseacrh Inst. of Chemistry, Intl. Ctr. for Chem. and Biol. Sciences, Univ. of Karachi, Karachi, Pakistan; [3]Univ. of Karachi, Pakistan, Karachi University, Pakistan

Abstract: Research objectives To determine the changes in electroencephalogram (EEG) wave pattern of rats upon induction of anxiety-like symptoms by a single acute stressor and its possible attenuation by geraniol treatment in rats. **Rationale** Among neuropsychiatric disorders, anxiety is wide spread globally and causes 2.3% of worldwide disability. Anxiety at a glance is body's natural response to an actual or perceived threat. But the problem complicates when this response prolongs further unnecessarily. Diagnosis of anxiety is usually based on interviews and sessions with physician. However, a unique method of evaluating anxiety is through the analysis of EEG of the affected person. Therefore, our study aims to determine rat EEG fluctuations due to anxiety in rats. Moreover, this study was also designed to analyze the potential of geraniol against anxiety disorders. Geraniol is one of the monoterpenoids which has been reported to have antioxidant and anti-inflammatory effects. Furthermore, there is some evidence that geraniol has brain calming, and anti-epileptic potential. **Material and methods** Thirty male albino Wistar rats weighing between 220-250g were divided into 5 groups (n=6) comprising of control, disease

model, low dose treatment, high dose treatment and positive control (diazepam) groups. Test rats were subjected to an electric shock (1.0 mA for 1s) followed by respective drug administration after 15 min. Low dose and high dose treatment groups were treated with geraniol at the dose of 10 mg/kg and 30 mg/kg respectively, whereas diazepam was administered at the dose of 3.5 mg/kg. Half hour after dosing, anxiety was evaluated using behavioral paradigm of elevated plus maze (EPM). EEG was monitored 15 min after performing EPM. All the experimental procedures were approved by the Institutional Animal care and use committee (IACUC). **Results** The results from EPM showed significantly increased anxiety-like symptoms in disease group while reduced anxiety-like behavior was observed in treatment groups. EEG band changes were evaluated by EEG recorder system which comprised of data acquisition system from the Science Beam Company, Iran. The EEG recording demonstrated the elevated power of low beta, high beta and gamma waves in disease group, whereas, geraniol and diazepam treatment resulted in normalization of beta and gamma power in rats subjected to electric shock. These results are in parallel with the results of EPM test. Thus, it can be concluded that geraniol exhibits a potential to reduce symptoms of anxiety and normalize the associated impaired EEG wave pattern. **Funding** International Center for Chemical and Biological Sciences, University of Karachi.

Title: Central nervous system expression of dystrophins and antisense therapy in a mouse model of Duchenne muscular dystrophy.

Authors: *T. E. GILEADI[1], M. SIDDLE[1], C. FERGUS[2], D. CHAMBERS[1], V. P. KELLY[2], J. E. MORGAN[1], R. PHADKE[1], F. MONTANARO[1], F. MUNTONI[1];
[1]The Dubowitz Neuromuscular Ctr., Univ. Col. London, London, United Kingdom; [2]Sch. of Biochem. and Immunol., Trinity Col. Dublin, Dublin, Ireland

Abstract: Duchenne muscular dystrophy (DMD) is a severe neuromuscular disease caused by mutations in the dystrophin gene, resulting in muscle degeneration and a shortened life expectancy. DMD patients also have a higher prevalence of intellectual disability, anxiety, attention deficit hyperactivity disorder, and autism spectrum disorder than the general population. The presence of at least seven alternative promoters, two polyA addition sites and alternative splicing results in several dystrophin isoforms with different expression patterns and putative roles. Mutations affecting only the full-length isoforms (Dp427) have been linked to emotional behavioural problems including anxiety, depression, and hyperactivity in DMD patients. Mdx mice carry a mutation affecting only the Dp427 isoforms and display an enhanced fear response, and increased anxiety- and depressive-like behaviours. Dystrophin expression in muscle can be restored using an exon-skipping phosphorodiamidate morpholino oligomer (PMO) treatment. In

order to improve neurobehavioural phenotypes in this pre-clinical model, we aim to map the expression of Dp427 isoforms in the mouse brain in detail and develop PMO treatment strategies aimed at restoring dystrophin expression in the brain. Dp427 transcripts have been detected across the brains of male wildtype mice including in the cerebellum, hippocampus, and cortex. The 5' regions of Dp427 transcripts have been sequenced to identify the unique sequences of each isoform. Dp427 protein has been detected in the cerebellar Purkinje and molecular layers and the hippocampal pyramidal cell layer by immunohistochemistry, and has been quantified using a capillary western immunoassay. Male mice were given a single dose of a fluorescently-tagged PMO either by a intracereberoventricular (ICV) injection or an intracisternal magna (ICM) injection, and the biodistribution of the PMO in the brain was determined 48 hours later. The commonly used ICV injection into the lateral ventricle resulted in superior biodistribution of the PMO, however ICM injections are minimally invasive and require little post-surgery recovery. These results indicate that repeated or chronic ICM injections will be required to efficiently restore dystrophin in key brain regions. Several antisense oligonucleotide therapies have now been approved for treatment of DMD in muscle only. These pre-clinical studies will allow us to explore the possibility of improving life quality by also addressing neurobehavioural comorbidities in DMD patients.

Title: Inhibition of fatty acid binding protein-5 in the prefrontal cortex reduces fear and anxiety responses by distinct endocannabinoid receptor-mediated mechanisms

Authors: *T. C. UZUNESER[1], H. J. SZKUDLAREK[1], M. J. JONES[1], M. G. NASHED[1], M. KACZOCHA[2,3,4], I. OJIMA[4,5], S. R. LAVIOLETTE[1,6];

Abstract: Current pharmacological treatments for anxiety disorders are associated with significant deleterious side-effects, including dependence, withdrawal and cognitive impairments. Recently, the endocannabinoid (eCB) system has drawn attention as a promising target for novel anxiolytic pharmacotherapies. Previous evidence has revealed that genetic and/or pharmacological manipulations altering eCB signaling change fear and anxiety responses of rodents. Anandamide (AEA), the more extensively investigated eCB ligand, is synthesized on demand, activate numerous eCB receptors, and is metabolized by fatty acid amide hydroxylase (FAAH). However, water-insoluble lipids such as AEA require chaperone proteins for their intracellular transportation to FAAH, a process which requires fatty acid binding proteins (FABP). We are investigating the effects of a novel FABP-5 inhibitor, SBFI-103, on fear and anxiety-related behaviors using adult male Sprague Dawley rats. Acute SBFI-103, when administered locally into the prelimbic region of the medial prefrontal cortex of rats (mPFC), led to an anxiolytic response as well as reduced contextual fear expression in a dose dependent manner. Surprisingly, both effects were reversed when a cannabinoid-2 (CB2) receptor antagonist, AM630, was co-infused with SBFI-103. Co-infusion of the cannabinoid-1 (CB1) receptor antagonist Rimonabant with SBFI-103 reversed the contextual fear response, yet showed no reversal effect on anxiety. Co-administration of G-protein coupled receptor 55 antagonist CID16020046 partially reversed the SBFI-103-induced changes whereas co-administration of peroxisome proliferator-activated receptor gamma antagonist T0070907 showed no effect. Furthermore, in vivo neuronal recordings revealed that intra-mPFC SBFI-103 infusion reduced activity of putative pyramidal neurons in the basolateral amygdala as well as elevated activity of pyramidal neurons in the CA1 region of the ventral hippocampus and significantly reduced alpha, beta and gamma oscillation patterns, both of which were dependent on CB2 transmission. These results indicate that intra-mPFC FABP-5 inhibition, which should elevate AEA availability in the synaptic cleft, alters neuronal activity in key regions of anxiety-related neural circuitry, resulting in an anxiolytic behavioral phenotype. Our findings identify a promising role for FABP5 inhibition as a novel anxiolytic pharmacotherapy. Furthermore, we identify a novel, CB2-dependent FABP5 signaling pathway in the PFC capable of strongly modulating anxiety-related behaviours and neuronal transmission patterns.

Title: Novel virtual reality intervention reduces e-cigarette dependence and cravings in undergraduate students

Authors: *S. SKLENARIK[1], J. KELLY[1], K. THOMPSON[2], S. BOUCHARD[3], S. KRISHNAN-SARIN[4], R. S. ASTUR[1];
[1]Psychological Sci., [2]Digital Media & Design, Univ. of Connecticut, Storrs, CT; [3]Univ. du Québec en Outaouais, Gatineau, QC, Canada; [4]Psychiatry, Yale Univ., New Haven, CT

Abstract: The use of electronic cigarettes (e-cigarettes), or "vaping," is highly prevalent and increasing dramatically among young adults (Schulenberg et al., 2020). Concerningly, there is limited data supporting clinical approaches to reduce vaping among this population (Berg et al., 2020). Previously, we demonstrated that immersing smokers in a virtual reality (VR) environment in which they are instructed to search for and crush virtual cigarettes significantly improved smoking cessation and decreased nicotine dependence (Girard et al., 2009). The goal of the current study is to investigate the efficacy of a similar intervention in reducing e-cigarette dependence among college undergraduates.This intervention consists of 4 lab sessions over a 2-week period as well as an online follow-up 1 week later. Each lab session involves a 20-minute VR session, during which participants use an immersive head-mounted display and controllers to navigate a virtual environment filled with either 100 floating vapes (experimental condition) or 100 floating tennis balls (control condition). Participants in the experimental condition are instructed to search for, throw, and destroy 60 vapes using a virtual hand that mirrors the participant's actual hand movements. In the control condition, e-cigarettes are replaced with virtual tennis balls that bounce upon being thrown. Throughout the intervention, participants are asked to complete validated assessments to quantify vaping dependence, including the Penn State Electronic Cigarette Dependence Index (PSECDI; Foulds et al., 2015) the Electronic Cigarette Dependence Scale (EDS; Morean et al., 2019), and the Fagerstrom Test for Nicotine Dependence (adapted for vaping; FTND; Fagerstrom & Schneider, 1989). Additionally, participants completed the Questionnaire of Vaping Craving (QVC; Dowd et al., 2018).To date, 8 participants that met PSECDI criteria for medium to high e-cigarette dependence and self-reported wanting to reduce their e-cigarette use have completed the intervention; all participants were assigned to the experimental condition. From session 1 to session 4, participants demonstrated significant ($p < 0.05$) reductions in vaping dependence and cravings. Specifically, we observed a 35% reduction in PSECDI scores, a 43% reduction in EDS scores, a 57% reduction in FTND scores, and a 31% reduction in QVC scores from baseline. Data collection is ongoing, and results from the control condition will be crucial to elucidating the efficacy of this intervention. Overall, this promising pilot data suggests that the destruction of addictive stimuli in a virtual environment may be helpful in decreasing vaping dependence.

Title: Testing the effects of liraglutide on nicotine-mediated behaviors in rats

Authors: *K. RAGNINI[1], R. HERMAN[1], R. MERKEL[1], S. ZEB[1], H. D. SCHMIDT[2];
[1]Dept Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [2]Dept Psychiatry, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: While consumption of traditional tobacco products is declining, the recent increase in use of electronic nicotine delivery systems such as nicotine vaping devices present a new challenge to addressing nicotine use disorder. Long-term cessation of nicotine use is often difficult to achieve due to withdrawal-induced adverse effects including weight gain. Glucagon-like peptide 1 receptors (GLP-1Rs) are expressed throughout the brain including in neural circuits that regulate nicotine taking and food intake. Liraglutide is a GLP-1R agonist that is FDA-approved for treating weight gain in humans. Our pilot preclinical findings indicate that systemic liraglutide attenuates nicotine reinstatement. Here, we investigated the effects of repeated liraglutide administration on nicotine taking and seeking as well as nicotine withdrawal-induced weight gain. Male and female rats were allowed to self-administer nicotine (0.03 mg/kg/infusion) intermittently for 20 days on a fixed-ratio 1 (FR-1) schedule of reinforcement. Rats received daily systemic liraglutide (0.025mg/ml/kg) or vehicle treatments 60 minutes prior to the operant sessions. Liraglutide decreased nicotine self-administration and reinstatement in female rats. In contrast, this dose of liraglutide did not appear to be efficacious in nicotine-experienced male rats. To assess body weight changes during abstinence, nicotine-experienced rats and yoked saline controls were housed in hanging wire cages during the self-administration, abstinence, and reinstatement phases of the experiment. During abstinence, rats received either repeated daily liraglutide (0.025mg/ml/kg, i.p.) or vehicle. Body weight, ad libitum high fat chow intake, and water intake were recorded. Our preliminary data indicates that liraglutide attenuated nicotine withdrawal-induced body weight gain as compared to vehicle-treated nicotine-experienced animals and yoked nicotine-naive controls. We hypothesize that liraglutide reduces withdrawal-induced hyperphagia for nicotine-experienced animals. These experiments will include both male and female rats to identify potential sex differences. Together, these studies will determine if GLP-1Rs represent a potential pharmacological target for reducing nicotine relapse and attenuating weight gain during nicotine abstinence.

Title: Chronic administration of synthetic contraceptive hormones alters ethanol and nicotine intake in a co-use model in freely cycling female rats

Authors: *E. E. MAHER[1], E. BONDY[1], S. KHATRI[1], J. WEAFER[2], C. D. GIPSON[1];
[1]Family and Community Med., [2]Psychology, Univ. of Kentucky, Lexington, KY

Abstract: Tobacco and alcohol use disorders (TUD and AUD, respectively) are tremendous health liabilities, and co-use of these substances is highly prevalent in the United States. Women are particularly at risk, as AUD is increasing in women at alarming rates (an 84% increase in cases from 2002-2013) and long-term smoking cessation is more difficult to achieve in women than men. Further, ovarian hormones can affect frequency of binge drinking, as well as cigarette craving, with increases in 17β-estradiol (E2) and progesterone being associated with addiction risk and resilience, respectively. Given the role of ovarian hormones in addiction, it is also important to consider how exogenous synthetic hormones, commonly found in hormonal contraceptives, may influence motivation for alcohol and nicotine. Hormonal contraceptives contain synthetic forms of estrogen (e.g., ethinyl estradiol, or EE) and/or progesterone (e.g., levonorgestrel, or LEVO). However, despite widespread contraceptive use and the influence of hormones on addiction vulnerability, little is known regarding the influence of contraceptives on nicotine and alcohol co-use.The aim of the current study is to determine the influence of EE and LEVO on nicotine and ethanol (EtOH) intake in rats. We hypothesized that female rats given LEVO will show lower rates of nicotine and EtOH intake, whereas rats given EE+LEVO will show higher rates of intake of both drugs. Prior to nicotine self-administration (SA), rats underwent a drinking in the dark (DID) paradigm when rats were given a 4-hr session in which the water bottle was replaced with a sipper tube containing 10% EtOH or vehicle (water) three hours into the dark (active) cycle. To determine intake for the day, bottles were weighed before and after DID sessions. Following DID, rats receive a subcutaneous (s.c.) injection of either LEVO, EE+LEVO, or vehicle (sesame oil) and began nicotine SA (0.06 mg/kg/infusion) on an FR1 schedule. Results show that rats that receive EE+LEVO have a higher intake of nicotine as compared to rats that received LEVO alone or vehicle. Interestingly, there was no difference in nicotine intake with hormone treatment in animals that drank EtOH prior to nicotine SA. We also show that, contrary to our hypothesis, animals that received LEVO alone consume more EtOH then either the EE+LEVO or vehicle treated animals. Overall, we found that EE+LEVO decreased EtOH intake when EtOH was co-used with nicotine, whereas this hormone combination increases nicotine consumption when rats are not concurrently drinking. Thus, these results can inform women's care by determining safer hormonal contraceptive use when women concurrently drink and smoke.

Title: Preclinical evaluation of FSNY-1 for tobacco use disorder

Authors: R. D. HILL, R. A. SHETTY, C. TAYLOR, *M. J. FORSTER;
Pharmacol. and Neurosci., Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Previous reports from this laboratory suggested that both the experimental compound FSNY-1 and the standard, varenicline, fully blocked the stimulant effects of nicotine in mice. However, nicotine-effective doses of varenicline also had locomotor depressant effects by themselves. In the current studies, FSNY-1 and varenicline were compared for their ability to diminish the reinforcing effects of nicotine, detected as an extinction-like effect in a nicotine self-administration (SA) assay. Rats previously trained to a criterion of nicotine self-administration (0.03 mg/kg/inf; FR-1) showed gradual reduction in number of responses after 3 daily sessions of extinction. After reinstatement of nicotine responding, separate groups of rats were treated with different doses of FSNY-1 or varenicline on each of three days prior to a nicotine SA session. Extinction like-effects on frequency of nicotine infusions were evident following both FSNY-1 (ongoing studies, 2.5 to 10 mg/kg) and varenicline (0.3 to 3 mg/kg). These studies provide additional evidence for clinical application of FSNY-1 in tobacco use disorder. These results also support the validity of multiple session self-administration testing for identification of drugs useful in tobacco use disorder.

Title: Nicotine exposure in mice modeled to schizophrenia: testing the self-medication theory

Authors: *Y. ABREU-VILLACA[1], A. DUTRA-TAVARES[2], L. A. COUTO[1], A. BANDEIRA-MARTINS[1], J. O. SILVA[1], T. P. SOUZA[1], A. C. MANHAES[1];
[1]Ciencias Fisiologicas, [2]Ciências Fisiológicas, Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: The self-medication theory proposes that patients with SCHZ smoke to alleviate symptoms of the disease and side effects of treatment. Accordingly, the acceptance of this theory implies that patients are more prone to become smokers after the appearance of SCHZ symptoms. Despite that, in experimental animals, few studies simulate self-medication by modeling SCHZ before nicotine/tobacco exposure. Here, C57Bl/6 mice (60-75 days, n=9-13 per group and sex) initially modeled to SCHZ and subsequently exposed to nicotine were submitted to a protocol of locomotor sensitization and to a pre-pulse inhibition (PPI) test. Hyperlocomotion is associated with the positive symptomology of SCHZ, while deficits in PPI assess sensorimotor gating, which is impaired in SCHZ patients. Initially, mice were either assigned to a CT (s.c. saline injections) or a PCP (phencyclidine 2.5mg/kg, s.c.) group and tested in an open field arena for four consecutive days (S1-S4). Phencyclidine, a NMDA receptor antagonist, was used to model SCHZ. After that, half of CT and half of PCP mice further received daily nicotine injections (0.5mg/kg, s.c.), so that 4 groups (CT, NIC, PCP and PCP-NIC) were tested for additional 4 days (S5-S8). The day after, mice received their respective treatment and were tested in the PPI apparatus. The startle responses for pairs of a prepulse (pP: 70, 75 or 80dB) followed by a pulse (P: 120dB) were registered and the %PPI calculated. The phencyclidine dose was 10mg/kg. Phencyclidine had a major impact on locomotor activity from the first day of exposure onwards. PCP mice exhibited a progressive increase in locomotion, characteristic of behavioral sensitization (S1<S8). From S5 to S8, the analysis of the four experimental groups confirmed the effect of phencyclidine (PCP and PCP-NIC groups were hyperactive when compared to CT and NIC groups), and demonstrated that PCP and PCP-NIC mice were not different from each other. These data show that nicotine did not interfere with phencyclidine-evoked sensitization. In the PPI test, the analysis of the startle responses that followed pP70+P and pP75+P acoustic stimuli indicated that phencyclidine reduced %PPI in exposed mice when compared to non-exposed ones. Nicotine failed to interfere with these results. The analysis of the pP80+P pair indicated similar results in females. Distinctively, in males, the deficient response of PCP mice was worsened when phencyclidine was combined with nicotine. In mice modeled to SCHZ, subsequent exposure to nicotine did not interfere with locomotor sensitization but worsened the pre-pulse inhibition deficit in a sex-dependent manner. These results do not corroborate the self-medication theory.

Title: Relapse-like behavior and nAChR sensitization following intermittent access nicotine self-administration

Authors: *M. A. TAPIA, X.-T. JIN, B. R. TUCKER, L. N. THOMAS, N. B. WALKER, S. E. ALBERTSON, S. R. JONES, R. M. DRENAN;
Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract: Tobacco smoking is the leading cause of preventable death worldwide. Rodent self-administration (SA) models have provided insights into tobacco addiction. Many of the previous SA models have used fixed-ratio (FR) schedules of reinforcement. These schedules may not capture the subtleties of human tobacco use, including intermittent smoke breaks during working hours and socialization. *Objective*: The present study aims to examine SA behavior during intermittent access (IntA) to nicotine to determine (1) how nicotine intake on an IntA schedule compares to continued access on a FR schedule and (2) whether nicotine IntA impacts cue-induced relapse behavior and alters nicotinic acetylcholine receptors (nAChRs) in the interpeduncular nucleus (IPN) during forced abstinence. *Methods*: Male Sprague Dawley rats were first allowed to self-administer saline or nicotine (0.03 mg/kg) for 10 2-hour acquisition sessions (known as ACQ) on a FR 1 schedule of reinforcement. Following ACQ, rats switched to 7 days of 4-hour IntA nicotine self-administration. Each IntA session consisted of 12 alternating Drug-Available and No-Drug Available periods lasting 5 and 15 min respectively. After completing ACQ and IntA sessions, we investigated nAChR using patch-clamp electrophysiology and non-reinforced operant responding for cue-induced nicotine seeking on Days 1 and 7 of forced abstinence. *Results*: Findings indicate that while rats had only half as much time available to administer nicotine during IntA, overall responding and nicotine intake was maintained and even enhanced relative to ACQ. Moreover, IntA enhanced cue-induced nicotine seeking and elevated IPN nAChR neuronal activity after 7 drug-free days. *Conclusion*: These data indicate that rats will readily self-administer nicotine on an IntA schedule and is sufficient to potentiate nicotine craving and neuronal activity in the IPN. Given the number of individuals who take intermittent smoke breaks during the day, our preclinical IntA model of nicotine SA is a useful paradigm for investigating nicotine intake and neurobiological changes associated with nicotine addiction.

Title: Nicotine-choice behavior and acetylcholine receptors in zebrafish

Authors: *H. SCHNEIDER[1], K. CHINYANYA[1], A. BUTTON[1], S. KRAUSE[1], A. PEARSON[1], D. HARRIS[1], E. KENNEDY[1], Z. CAPPEL[1], S. STEVENS[1], A. SHEMET PITCHER[1], D. ROSENE[1], S. GOLDE[1], J. ROSA[1], H. MARTON[1], K. GARDNER[1], H. AFZAL[2];

Abstract: Nicotine-use behavior is one of the main causes of preventable diseases such as cancer, cardiovascular diseases, diabetes, and chronic obstructive pulmonary disease. Helping people quit nicotine products is a main goal of our projects. Developing a zebrafish model for nicotine use behavior could provide a tool for studying the underlying genetic, environmental and neuronal elements of nicotine use behavior. Most recently, we established behavioral nicotine-choice assays for larval zebrafish using a plus-maze and a gradient-maze. EthovisionXT (Noldus) was used for the analysis of swimming paths. The assays identified nicotine-seeking, nicotine-avoiding or nicotine-neutral larval zebrafish (6-8 dpf) based on the cumulative duration larval zebrafish spent in and the frequency at which larval zebrafish enter the compartments of the test-mazes. In a random wildtype line about 20% of tested zebrafish show nicotine-seeking behavior, 25 to 30% show nicotine avoidance behavior and 50 to 55% show nicotine-neutral behavior in the gradient maze. The nicotine-choice behavior is concentration dependent and changes with nicotine-preincubation. As a first step towards the neurogenomics of nicotine-seeking and avoidance behavior in zebrafish, we investigated single nucleotide polymorphisms (SNPs) in zebrafish acetylcholine receptor genes (chrna3, chrna5, chrnb4) that have been linked in human homologs to heavy smoking. Some of these SNPs are conserved and weakly linked to nicotine-seeking behavior in larval zebrafish. In addition, we discovered sequence variations in introns of zebrafish chrna3 and chrna5 genes that include a microsatellite region and a deletion that could have a regulatory function.
In summary, our results indicate that variations of nicotine-seeking behavior in larval zebrafish could be associated with variants in acetylcholine receptor genes. Future studies will explore acetylcholine receptor variants in nicotine-seeker and avoider lines and aim for a better understanding of the neurogenomics of nicotine-seeking and avoidance behavior and responses to pharmacotherapeutics used in smoking cessation treatment.

Title: A pilot study of whole-brain reactivity to flavored e-cigarettes among women smokers: The association with depressive symptoms

Authors: *A. C. KRISTICH[1], C. R. BORDNER[2], A. L. HOBKIRK[1], K. R. HOUSER[1], B. HOGLEN[1], J. FOULDS[2], D. MUKHERJEE[3];
[1]Psychiatry and Behavioral Hlth., [2]Publ. Hlth. Sci., Penn State Col. of Med., Hershey, PA; [3]Psychiatry, Penn State Hershey Med. Ctr., Hershey, PA

Abstract: A pilot study of whole-brain reactivity to flavored e-cigarettes among women smokers: The association with depressive symptoms Ava Kristich, Candace R. Bordner, Kenny R. Houser, Brianna Hoglen, Jonathan Foulds, Dahlia Mukherjee, Andrea L. Hobkirk**Background:** Clinical depression is a risk factor for nicotine dependence (Breslau et al., 2004). Electronic cigarettes (e-cigarettes) contain nicotine, a nicotinic acetylcholine receptor agonist that can improve depressive behaviors by desensitizing and increasing acetylcholine receptors (Gandelman et al., 2018). E-cigarettes with sweet flavors are popular among adults who are new users or established cigarette smokers (Schneller et al., 2018). Appealing sweet flavors in e-cigarettes have the potential to increase the risk for addiction by stimulating corticostriatal reward pathways (Small et al., 2012, Tang et al., 2012). The aim of the analysis was to assess if brain reward reactivity to sweet-flavored and unflavored e-cigarettes varied with the level of self-reported depressive symptoms among women smokers. The findings have implications for the risk of e-cigarette addiction and use of e-cigarettes as a smoking harm-reduction method for depressed smokers.**Methods:** Nine adult female daily smokers inhaled aerosolized strawberry-vanilla flavored and unflavored e-liquid with low concentrations of nicotine during two functional magnetic resonance imaging (fMRI) scans. Participants completed the Center for Epidemiological Studies Depression Scale (CES-D) to determine levels of depressive symptoms. The CES-D scores were correlated with whole-brain blood-oxygen level-dependent (BOLD) signals during each fMRI scan using voxel-wise general linear models in the FMRIB Software Library (FSL). Brain regions with significant clusters of BOLD signal were identified using the Harvard-Oxford Cortical and Subcortical atlases. **Results**: There were five significant brain clusters showing a positive correlation between CES-D scores and BOLD signal during the flavored aerosol, located in the ventromedial prefrontal cortex, cuneus, bilateral precentral and postcentral gyrus, and the cingulate gyrus. There was only one region in the cuneus with a significant positive correlation between CES-D scores and BOLD signal during inhalation of the unflavored aerosol. No brain regions showed a negative correlation. **Conclusions**: We observed that higher depressive symptoms associated with more cortical brain reactivity during flavored e-cigarette use. The results highlight potential mechanisms in which flavored e-cigarettes may increase addiction potential or alter depressive symptoms for women smokers.

Title: Regulation of nicotine intake by the gut hormone cholecystokinin: evidence for brain-body interactions in addiction

Authors: *K. M. BRAUNSCHEIDEL, L. WILLS, Y. R. HACHICHA, S. P. B. CALIGIURI, P. J. KENNY;
Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Nicotine addiction in the form of habitual tobacco use is the leading cause of premature death in the United States. In addition to the direct effects of nicotine on hedonic neurocircuitry, recent evidence implicates aversion neurocircuitry and peripheral structures in nicotine habit formation. For instance, circulating levels of the satiety-signaling gut-hormone cholecystokinin (CCK) is disrupted in smokers following meal consumption. The effects of CCK receptor (CCKR) activity on nicotine intake is undetermined. Here, we address this gap in knowledge and describe a potential neural mechanism for peripheral control over nicotine intake. We first confirmed that nicotine increases postprandial, but not fasting plasma CCK concentration in mice. We then found that the peripherally-restricted CCKR agonist, CCK-8 (10 $\mu*kg^{-1}$), decreased volitional nicotine intake, especially at anxiogenic nicotine doses. CCK-8 did not affect nicotine-craving or food rewards earned in an operant-based task or interfere with nicotine ($0.5mg*kg^{-1}$, SC) conditioned place preference. CCK-8 did, however, increase anxiety-like behaviors during preference testing. Taken together, these data suggest CCKR activation is involved in regulating aversive, not hedonic, properties of nicotine. We hypothesize that the presence of CCK receptors in gut-innervating vagal sensory neurons of the nodose ganglia (NG) potentiates aversive nicotine signals from the periphery similar to CCK's regulation of appetite. In support of this idea, we found that an equimolar dose of the peripherally-restricted nicotine analogue, methlynicotinium caused an enhanced place aversion relative to nicotine ($1.5mg*kg^{-1}$, SC). Next, using Targeted Recombination in Active Population (TRAP) mice, we identified nicotine-responsive populations in the NG as well as its primary target, the nucleus of the solitary tract. A final cohort of mice were injected subcutaneously with saline, nicotine, or methlynicotinium. After 90 minutes, NG were processed for single-nuclei RNA sequencing to determine overlapping changes to the transcriptome between central and peripheral nicotinic receptor activation. Future studies will aim to describe how these neuronal NG subpopulations regulate nicotine intake. The existence of "bottom-up" regulation of nicotine intake by circulating hormones and the NG may prove useful for the development of novel addiction therapies for two reasons: first, direct electrical stimulation of the vagus nerve has already been validated as a treatment for other neurological disorders; and second hormone levels & vagal activity can be altered by non-invasive means. Funding: R37DA020686.

Title: Dynamic activity of interpeduncular nucleus GABAergic neurons controls expression of nicotine withdrawal.

Authors: *P. KLENOWSKI, R. ZHAO-SHEA, T. G. FREELS, S. MOLAS, A. R. TAPPER; Deparment of Neurobiology, Brudnick Neuropsychiatric Res. Inst., Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: A critical brain area implicated in nicotine dependence is the interpeduncular nucleus (IPN) located in the ventral midbrain and consisting primarily of GABAergic neurons. Previous studies indicate that IPN GABAergic neurons contribute to expression of somatic symptoms of nicotine withdrawal, however, whether IPN neurons are dynamically regulated during withdrawal in-vivo and how this may contribute to *both* somatic and affective withdrawal behavior is unknown. To bridge this gap in knowledge, we expressed GCaMP in IPN GABAergic neurons and used in-vivo fiber photometry to record changes in fluorescence, as a proxy for neuronal activity, in male mice during nicotine withdrawal. Mecamylamine-precipitated withdrawal significantly increased activity of IPN GABAergic neurons in nicotine-dependent, but not nicotine-naïve mice. Analysis of GCaMP signals time-locked with somatic symptoms including grooming and scratching revealed reduced IPN GABAergic activity during these behaviors, specifically in mice undergoing withdrawal. In the elevated plus maze, used to measure anxiety-like behavior, an affective withdrawal symptom, IPN GABAergic neuron activity was increased during open-arm versus closed-arm exploration in nicotine withdrawn, but not non-withdrawn mice. Optogenetic silencing IPN GABAergic neurons during withdrawal significantly reduced withdrawal-induced increases in somatic behavior and increased open-arm exploration. Together, our data indicate that IPN GABAergic neurons are dynamically regulated during nicotine withdrawal, leading to increased anxiety-like symptoms and somatic behavior, which inherently decrease IPN GABAergic neuron activity as a de-arousal mechanism. These results provide a neuronal basis underlying the role of the IPN in the expression of somatic and affective behaviors of nicotine withdrawal.

Title: Adolescent nicotine hystory does not worsen schizophrenia-like symptoms evoked ky a phencyclidine-induced mice model

Authors: *A. DUTRA-TAVARES, *K. SEMEÃO, *J. MAIA, *L. COUTO, *A. MANHAES, *Y. ABREU-VILLAÇA;
Univ. Do Estado Do Rio De Janeiro, Rio De Janeiro, Brazil

Abstract: The first symptoms of schizophrenia (SCHZ) are usually observed during adolescence, a developmental period during which first exposure to psychoactive drugs also occurs. These epidemiological findings point to adolescence as critical for nicotine addiction and SCHZ comorbidity. However it is not clear whether exposure to nicotine during this period has a detrimental impact on the development of SCHZ symptoms since there is a lack of studies that investigate the interactions between these conditions during this period of development. To elucidate the impact of a short course of nicotine exposure across the spectrum of SCHZ-like symptoms, we used a phencyclidine-induced adolescent mice model of SCHZ (2.5mg/Kg, s.c., daily, postnatal day (PN) 38-PN52; 10mg/Kg on PN53), combined with an established model of nicotine minipump infusions (24mg/Kg/day, PN37-44) (PCP-NIC). Additional groups include CT (saline minipumps with injections), PCP (saline minipumps with PCP injections) and NIC (nicotine minipumps with saline injections). Behavioral assessment began 4 days after the end of nicotine exposure (PN48) using the following tests: open field to assess the hyperlocomotion phenotype; novel object recognition, a declarative memory task; three-chamber sociability, to verify social interaction and prepulse inhibition, a measure of sensorimotor gating. In open field, a progressive increase in locomotion was observed (rANOVA: Day × Phencyclidine × Nicotine - $F_{2,204} = 2.9$, $p = 0.056$). This increase was identified in PCP group from day 1 to day 2 ($p = 0.039$) and from day 1 to day 3 ($p = 0.015$). Nicotine history reduced the magnitude of phencyclidine-evoked hyperlocomotion and impeded the development of locomotor sensitization. Phencyclidine-treated male mice (PCP and PCP-NIC) (uANOVA: Phencyclidine - $F_{1,53} = 6.0$, $p = 0.017$) presented a smaller preference for the new object when compared to non-treated ones (CT and NIC). Phencyclidine treatment (Phencyclidine x Nicotine - $F_{1,90} = 6.1$, $p = 0.015$) increased the latency for the first entry into the social side (PCP > CT, $p = 0.003$; PCP > NIC, $p = 0.002$, FPLSD), while nicotine history mitigated this effect (PCP > PCP-NIC, $p = 0.001$, FPLSD). Deficient PPI response was revealed in phencyclidine-treated mice (PCP and PCP-NIC) when compared to non-treated ones (CT and NIC) to the higher Pp level (80 dB) (uANOVA: Phencyclidine - $F_{1,102} = 8.2$, $p = 0.005$). In conclusion, our results show for the first time that nicotine history, restricted to a short period during adolescence, does not worsen SCHZ-like symptoms evoked by a phencyclidine-induced mice model.

Title: Connectome of the basal forebrain cholinergic system in rat

Authors: *L. ZABORSZKY[1], P. GOMBKOTO[2], *C. CHAVEZ[1], P. VARSANYI[3];
[2]Neurosci., [1]Rutgers The State Univ. of New Jersey, Newark, NJ; [3]CMBN, Rutgers Univ. Newark, Newark, NJ

Abstract: Cholinergic neurons of the basal forebrain (BF) project to the entire cortex. Although this system was described initially as part of the diffuse cortical projection system, recent studies suggest that cholinergic projection to the cortex is not diffuse, but organized into segregated or overlapping pools of projection neurons. The extent of overlap between BF populations depends on the degree of connectivity between cortical targets of these projection populations (Zaborszky et al., 2015). The cortical target-specific groups of cholinergic neurons receive specific combination inputs (Gielow and Zaborszky, 2017). In order to analyze connectional data from different animals, we developed a pipeline for spatial registration of vectorial and image data. In more than 70 rat brains, that received pairwise conventional retrograde (FB and FG) or virus tracer injections in cortex, cholinergic neurons in the BF were mapped with the Neurolucida^{R} system. After mapping fluorescently labeled cells from 200 µm series, sections were restained with Nissl and images of sections were aligned to the existing maps. We implemented a Postgres schema to store vectorial cell data, delineations and images. This solution provided with a complete set of functions for analyzing cell densities, determining spatial relationships, and manipulating delineations. We implemented all the scripts for data visualization around the QGIS framework. This framework provides with very fast and smooth visualization of high-resolution images as well as vectorial data. We created a reference brain from a full series of 50 micron sections of a single brain, in which all cholinergic cells were mapped irrespective of their targets and then sections were stained for Nissl. These sections were imaged with 3 micron/pixel resolution and aligned in 3D. The software (Java, ImageJ) is able to slice this high resolution 3D stack of images in any plane to match sections from the experimental brains. The spatial registration of experimental sections to the reference brain is carried out using mixed rigid body, affine and B-Spline based elastic transformations. For each reference cell within its environment, we will be able to assess the probability of projection to each cytoarchitectonically defined cortical target ("context vector"). By assigning this context vector to each reference cell, we will use unsupervised methods such as K-means and hierarchical clustering to classify BF cells according to their projection probability to cortical areas. This connectome model, that captures the organizational principles of the basalo-cortical network, will facilitate the understanding the function of this network.

Title: Network Configurations Underlying External Versus Internal Attention

Authors: *P. LI[1], Y. WANG[2], N. B. TURK-BROWNE[3,4], B. HUTCHINSON[1];
[1]Psychology, Univ. of Oregon, Eugene, OR; [2]Amazon, East Palo Alto, CA; [3]Psychology, [4]Wu Tsai Inst., Yale Univ., New Haven, CT

Abstract: Attention is critical for nearly every cognitive operation, with a fundamental distinction between attending to sensory (external) versus self-generated (internal) information. This distinction has manifested in a debate about the relationship between selective visuospatial attention and episodic remembering, and whether these processes share a common neural substrate. Exploring the neural bases of visuospatial attention and episodic remembering is difficult because they rely on coordinated activity distributed across the entire human brain. However, recent studies have shown that whole-brain functional connectivity can reliably capture attentional states, raising the possibility that similar techniques might reveal differences in large-scale brain networks across external and internal attention. In the current study, participants (N = 24) performed tasks that required attending to information that was either sensory (external) or mnemonic (internal), with the experimental conditions otherwise matched in terms of visual content and task difficulty. We then leveraged a data-driven technique known as full correlation matrix analysis (FCMA) to examine (i) whether whole-brain connectivity patterns differ systematically across external and internal attention and (ii) which connectivity patterns across brain regions characterize such differences. For the first goal, FCMA showed that patterns of background connectivity could be used to reliably decode external versus internal attention (77% accuracy). For the second goal, this approach revealed 16 regions of interest falling within the default mode network (DMN), task positive network (TPN) and retrosplenial cortex (RSC) whose connectivity configurations characterized the two attentional states. Specifically, connectivity within TPN and within DMN was significantly greater during external and internal attention, respectively, while RSC regions coupled flexibly with TPN/DMN depending on the task. Complementary representational similarity analyses suggested that RSC further differentiated external from internal attention based on its task-evoked pattern of activity. Together, these results suggest that the network configuration of DMN, TPN, and RSC indicate how attention is being directed outwards or inwards.

Title: High-amplitude co-fluctuations drive connectivity of intrinsic neural oscillations and underlie auditory attentional control

Authors: *M. ALAVASH[1], M. WÖSTMANN[2], J. OBLESER[2];
[1]Univ. of Lübeck, Lübeck, Germany; [2]Univ. of Luebeck, Luebeck, Germany

Abstract: Recent advances in network neuroscience suggest that human resting state functional connectivity is driven by bursts of high-amplitude co-fluctuations of hemodynamic responses measured using fMRI (Faskowitz et al., 2020). We here build on these new insights and ask (1) whether connectivity of intrinsic neural oscillations manifests high-amplitude co-fluctuations as such, and (2) whether and how these connectivity events unfold during the deployment of auditory selective attention? We reanalyzed two recently published EEG data sets of resting state (N = 154; Alavash, Tune, Obleser, 2021) and an auditory attention task (N = 33; Wöstmann, Alavash, Obleser, 2019), respectively. During the task, an auditory spatial cue was presented to the participants asking them to attend to one of two concurrent tone streams and judge the pitch difference (increase/decrease) in the target stream. We source-localized EEG, and following leakage correction, measured time-resolved power-envelope correlations across the entire cortex within alpha and beta frequency ranges. Specifically, per time point (50-ms resolution) we calculated the product of power-envelopes across all node pairs. Next, to capture co-fluctuations around the mean, timeseries of products were z-scored. Finally, per time point we calculated the standard deviation of z-scored products across the entire cortex. Accordingly, we obtained a timeseries of standard deviations per individual during rest or the auditory task. Connectivity events were defined as time points during which the standard deviation exceeded its 95th percentile. In line with recent fMRI work, alpha and beta connectivity derived from high-amplitude co-fluctuations showed higher similarity with static connectivity as compared to low-amplitude co-fluctuations (paired permutation test; alpha: $t = 9.1$, $p < 0.01$; beta: $t = 6.8$, $p < 0.01$). Similar results were found during the auditory task (alpha: $t = 15.6$, $p < 0.01$; beta: $t= 20.8$, $p < 0.01$). In addition, cortical maps of the alpha and beta connectivity events overlapped with posterior and frontoparietal connections, respectively. Importantly, during the auditory attention task, beta connectivity events occurred often during processing of the spatial cue, while alpha connectivity events occurred during processing of the tone streams. Our results suggest that high-amplitude power-envelope co-fluctuations drive connectivity of alpha and beta oscillations. Critically, these connectivity events appear to underlie ongoing deployment of auditory selective attention in a functionally distinct manner, that is, anticipation of stimuli versus selective processing of them.

Title: A brain-based universal measure of attention

Authors: *K. YOO[1], M. D. ROSENBERG[3], Y. KWON[1], Q. LIN[1], E. W. AVERY[1], D. SCHEINOST[1], R. T. CONSTABLE[2], M. M. CHUN[1];
[2]Dept. Diagnos. Radiology, [1]Yale Univ., New Haven, CT; [3]Univ. of Chicago, Chicago, IL

Abstract: Attention has a ubiquitous role in perception and cognition [1]. Attentiveness explains behavioral performance fluctuations both within and across individuals [2], and attention deficits are common in mental illness and symptomatic of brain damage [3]. Despite this central importance, there is no singular way to measure a person's overall attentional functioning across tasks. The fact that there are so many different attention tasks suggests that attention is not a unitary construct but rather multifaceted [1]. Therefore, it is important to understand what is common and what is unique among the different attention tasks and to predict them with minimal testing.
To develop a universal measure that integrates a common component of attention, we analyzed original data from 92 participants performing three different attention-demanding tasks - gradual-onset continuous performance task (gradCPT) [4], multiple object tracking (MOT), and visual short-term memory (VSTM) - during fMRI. We first constructed a suite of whole-brain network models that significantly predict a profile of multiple attentional components (sustained attention, divided attention and tracking, and working memory capacity) from task- or rest-based connectomes of novel individuals. We leveraged the network models to probe brain systems that support common and separable factors of attention functions across individuals. Multiple brain regions across the salience, subcortical, and frontoparietal networks drove accurate predictions, supporting a general attention factor across tasks, which is distinguishable from task-specific ones.
Furthermore, connectome-to-connectome transformation modeling [5], a novel approach for generating an individual's task-related connectomes from their resting-state connectome alone, substantially improved the predictive power of resting-state fMRI for attention function.
Finally, we built a new universal attention measure by combining the connectome transformation and general attention factor models. The universal attention model showed superior generalization to various attention measures across four independent datasets (total $N = 495$), including two local datasets [6, 7] and two open databases (ADHD-200 consortium [8] and Human Connectome Project [9]), suggesting the broad utility of our model for both research and clinical applications in diverse settings.

Title: Tracking the dynamics of neural synchrony with time-resolved inter-subject correlation

Authors: *T. CHAMBERLAIN[1], A. L. CORRIVEAU[3], H. SONG[1], M. D. ROSENBERG[2];
[2]Dept. of Psychology, [1]Univ. of Chicago, Chicago, IL; [3]Natl. Inst. of Hlth. Office of Intramural, Washington, IL

Abstract: Recent work has demonstrated the utility of decomposing functional connectivity into its time-resolved parts to study the contribution of moment-to-moment activity fluctuations (Esfahlani et al., 2020). Here, we extend this work to ask if the same method of "temporally unravelling" Pearson correlation can be used to calculate a TR-by-TR estimate of intersubject correlation (ISC). Compared to traditional dynamic ISC approaches, this method would be less computationally intensive, eliminate the need for extra parameters such as window size, and provide a more fine-grained estimate of changes in ISC over time.

We analyzed data from 575 6-21-year-olds from the Healthy Brain Network dataset. Functional MRI data were collected as participants watched a 3-min and a 10-min film clip (Clip 1, Clip 2). To track moment-to-moment changes in neural synchrony across participants, we computed a novel form of dynamic ISC, time-resolved ISC (trISC). Specifically, we performed element-wise multiplication of each z-scored time series in a given node with that of the group average, resulting in a trISC time course for each participant, node, and movie clip.

Validating trISC as a measure of changes in stimulus-driven brain activity, we observed significantly higher trISC for participants watching the same movie than different movies in 98% of nodes in the 268-node atlas. Of the nodes where this difference was greatest, there were significantly more nodes in high-level visual regions than expected by chance.

We next asked whether participants showed greater trISC doing more engaging movie moments as demonstrated in recent work relating sliding-window dynamic ISC to narrative engagement (Song et al., 2020). Because we did not have an in-scanner measure of participants' attention to the movies, we collected engagement ratings in an independent online sample (n = 20). To validate these ratings, we used eye-tracking data collected as a subset of participants in the HBN sample watched Clip 1 and 3 min of Clip 2 during EEG. Changes in gaze standard deviation were negatively correlated with the independent engagement ratings for both clips, indicating greater gaze synchrony during more engaging movie moments. Finally, we found that trISC scaled with engagement across individuals, such that participants showed greater neural synchrony during more engaging moments in 12 nodes for Clip 1 and 32 nodes for Clip 2. In contrast, replicating past work, lower neural synchrony during engaging moments was only observed in 3 and 1 nodes, respectively. Ultimately this study offers proof of concept for a novel form of dynamic ISC which allows time-resolved tracking of neural synchrony across individuals.

Title: Neural Mechanisms of Attentional Control Modulates Task Performance in Deep Neural Networks

Authors: *S. DAS[1], G. R. MANGUN[1], M. DING[2];
[1]Ctr. for Mind and Brain, Univ. of California Davis, Davis, CA; [2]Univ. Florida, Gainesville, FL

Abstract: Feature-based attention modulates neural activity in the sensory cortex to enhance the processing of task-relevant stimuli and suppress task-irrelevant stimuli. The feature similarity gain model of attention proposes that feature-based attention modulates neural activity according to the neuron's tuning property. We tested the idea in a deep neural network (DNN) model of the ventral visual pathway. Transfer learning was applied to fine-tune VGG16 pretrained separately on two different datasets (ImageNet and VGGFace) to enable the DNN to classify images from 4 object categories: (1) male and female faces in the face categories, and (2) natural and manmade scenes in the scene categories. The images used in the test set though belonging to these 4 categories, were neither part of nor belonged to any category in the pretraining datasets. The task for the network was to detect the presence of a certain object category. Performance of 91% was achieved. When tested on compound or merged images (images from two different categories were superimposed), however, the network's performance fell to chance level. Attention mechanisms were then introduced to enhance performance. Tuning curves were estimated for artificial neurons. Both multiplicative and additive modulations were applied according to the neuron's response preference. Attention increased network performance by 15% ± 10% across specific categories. The network responded to attention only when the category belonged to its repertoire, i.e., the network pretrained on ImageNet only responded to the scene categories. Similarly, the task performance of the network pretrained on VGGFace only improved when tested on the face categories. Thus, by using images and labels which are not a part of the database on which the model is pretrained, we explore how attention is generalizable to modulate the performance of a deep neural network based on its pretraining or prior expertise. These results demonstrate that DNNs (1) provide a fruitful testing bed for attention mechanisms and (2) the attention mechanisms are heavily dependent upon the pretraining of the network model, (3) may yield predictions that can be further tested in experimental studies.

Title: Frontoparietal Control of Willed Attention

Authors: *Q. YANG[1], S. MEYYAPPAN[1], J. J. BENGSON[2], G. R. MANGUN[3], M. DING[1];
[1]Univ. of Florida, Gainesville, FL; [2]Sonama State Univ., Rohnert Park, CA; [3]Univ. of California Davis, Davis, CA

Abstract: Cueing paradigms are commonly used to study the neural mechanisms of visual spatial attention control. In these paradigms, each trial starts with an external cue, which instructs the subject to pay covert attention to a spatial location in order to process an impending stimulus. Neuroimaging studies have consistently shown that the dorsal attention network (DAN) is activated following the cue. Recent work has introduced a new form of cueing which asks the subject to spontaneously decide which spatial location to attend (willed attention). We examined the neural substrate of willed attention control by analyzing fMRI data recorded at two institutions (UF and UC Davis) using the same willed attention paradigm. In addition to instructional cues, a choice cue was included, which prompted the subject to choose the side of the visual field to attend. Applying the general linear model we found that both instructional cues and choice cues activated the DAN. Choice cues additionally activated frontoparietal regions including the dorsal anterior cingulate cortex (dACC), anterior insula (AI), dorsal lateral prefrontal cortex (DLPFC) and inferior parietal lobule (IPL). An MVPA analysis showed that for neural activity evoked by choice cues, decoding accuracy in these frontoparietal regions was significantly above chance level, whereas for instructional cues, decoding accuracy was at chance level. These results, consistent across the two datasets, suggest that willed visual spatial attention is controlled by three major brain networks: the salience network (dACC and AI), the central executive network (DLPFC and IPL), and the DAN.

Title: Interacting rhythms enhance sensitivity of target detection in a fronto-parietal computational model of visual attention

Authors: A. AUSSEL[1], I. C. FIEBELKORN[3], S. KASTNER[3], *N. KOPELL[2], B. R. PITTMAN-POLLETTA[1];
[1]Mathematics & Statistics, [2]Boston Univ., Boston, MA; [3]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Even during sustained attention, the enhanced processing of attended stimuli waxes and wanes rhythmically. Humans and non-human primates performing a sustained visual attention task exhibit periods of enhanced and relatively diminished visual processing and target detection. These periods of enhanced and diminished visual processing alternate in both time (at 4 or 8 Hz, depending on the prior appearance of a statistically informative cue) and space (between cued and uncued locations). These alternating attentional states occur alongside alternating dynamical states, in which a spatial attention network including lateral intraparietal cortex (LIP), the frontal eye field (FEF), and the mediodorsal pulvinar exhibits different patterns of rhythmic activity and functional connectivity at α;, β;, and γ; frequencies - rhythms associated with visual processing, working memory, and motor suppression. To assess whether and how these multiple interacting rhythms contribute to periodicity in attention, we constructed a biophysically-detailed computational model of this attention network consisting of multiple functional modules. Our model reproduced the rhythmic dynamics and behavioral consequences of observed attentional states, and suggested a novel dynamical mechanism for the switch from a 4 to 8 Hz rhythm in hit rates after cue appearance. *In silico* manipulations demonstrated that the frequencies and mechanisms of experimentally observed rhythms optimize sensitivity in visual target detection while maintaining functional flexibility. The model illuminates how multiple functional modules, each exhibiting oscillatory dynamics arising from distinct mechanisms, both compete and collaborate to allocate attentional resources in a variety of conditions.

Title: Assessing the efficacy of the brain's networks of attention: Evolution of the Attention Network Tests, a database of their findings and a more engaging version

Authors: *R. M. KLEIN[1], S. ARORA[1], R. ALMEIDA[2], C. R. MCCORMICK[1], N. D. MCDONALD[1]; [1]Dalhousie Univ., Halifax, NS, Canada; [2]Univ. Federal Fluminense, Rio de Janeiro, Brazil

Abstract: Developments in attention research have produced a number of methodologies for assessment. One such tool, the Attention Network Test (ANT), measures the efficacy of three networks of attention (alerting, orienting and executive control) as described ~30 years ago by Posner & Petersen. The ANT (developed 20 years ago) and its many variants will be featured in this presentation. We have developed an open-access website repository called the ANT Database (http://attentionnetwork.ca/) which allows users to retrieve the findings from the roughly 900 studies that, to date, have used any version of the ANT to answer any question. We will exemplify the use of this resource by describing how it has been used to generate a number of quantitative meta-analyses on such topics as development, ADHD, cross-cultural differences, bilingual differences, depression, anxiety, autism spectrum disorder, and how it provided the basis for a review of lifestyle influences on attention. We will discuss the particular benefits of some of the different ANT variants, with an emphasis on the AttentionTrip (first described at the 2013 meeting of the SFN), a game-like task that increases engagement and is now accessible to participants on a portable iPad. Since its development we have validated its use with younger adults, adults with autism, and child participants. More recent experiments have aimed at exploring its applicability with older adults, and how to generate more robust executive network scores that are similar to the original ANT. For situations that might encourage, and for participants who might experience, boredom, the demonstrated engagement advantage of AttentionTrip might make it the ANT of choice.

Title: The neural coordination of attention and decisions

Authors: *F. J. DOMÍNGUEZ-ZAMORA[1], J. J. GENG[2], J. P. GOTTLIEB[3,1];
[1]Mortimer B. Zuckerman Mind Brain Behavior Inst., Columbia Univ., New York, NY; [2]Psychology, Univ. of California Davis, Davis, CA; [3]Neurosci., Columbia Univ. Med. Ctr., New York, NY

Abstract: To make adaptive decisions in natural environments, we must not only commit to an action but must also determine which information to gather to best guide those actions. Because the amount of information available in natural environments far exceeds our processing capacity, we must select which information to rely on for guiding our actions. However, most studies of selective attention have highly constrained situations where participants are instructed where to attend. This approach is not suitable for probing natural attentional control, and an open question is how the brain determines attentional priority of task-relevant information. Our hypothesis is that priority is defined by the information gains that a sensory discrimination is expected to bring. Our approach rests on the premise that attention should optimally conform to Bayesian rules of inference under uncertainty. According to Bayesian logic, to update posterior beliefs, prior beliefs and new information are combined in proportion of their reliability. Thus, the priority of a stimulus should increase with its predictive validity (%V) and prior uncertainty. We used a novel task that combines probabilistic inference with an attention manipulation. Participants inferred a hidden state (a jar containing upright and inverted letters), after seeing two letters -that could differ in their %V- sequentially drawn from the jar. To manipulate attention, we flashed the 2nd letter in the periphery, and we measured perceptual sensitivity. Consistent with a Bayesian strategy, participants prioritize second letters with high %V over low %V, and this bias is enhanced by prior uncertainty. Uncertainty and predictive validity also influenced the decision weight in the final jar decision. The influences of %V and uncertainty on attention can be dissociated from other factors, including reward expectation, pupil size and the decision weight in the final jar decision. We will use this task in combination with fMRI to determine how %V and uncertainty are integrated within the executive network. We expect that the frontal eye field and intraparietal sulcus -areas computing attentional priority- will encode attentional biases based on %V, and this bias will be modulated by areas encoding decision uncertainty. Overall, our results suggest that expected information gains modulate top-down attentional control, and provide empirical evidence about the coordination of attention and decisions.

Title: 18-months stability of neural auditory-attentional filters and listening behaviour in a large longitudinal sample

Authors: *S. TUNE[1,2], M. ALAVASH[1,2], J. OBLESER[1,2];
[1]Univ. of Lübeck, Lübeck, Germany; [2]Ctr. for Brain, Behavior, and Metabolism, Univ. of Lübeck, Lübeck, Germany

Abstract: Successful listening is thought to depend on forms of neural filter strategies that separate relevant from irrelevant information. In a recent EEG study (Tune et al., in press), using a challenging spatial-attention listening task, we probed how two prominent auditory filtering strategies relate to listening success; namely the lateralization of auditory alpha power versus the alignment of slow auditory cortical responses to speech input ('speech tracking'). In a large longitudinal cohort of healthy aging adults, at T1 (N = 155, 38-80 yrs, median = 61 yrs), stronger speech tracking (estimated as reconstruction accuracy of speech envelopes) at the state-(within-participant)-level and at the trait-(between-participants)-level predicted better behavioral performance while alpha lateralization did not. These findings provide compelling evidence for speech tracking as a neural marker of individual, trial-specific listening success.
Yet, the reliability of both trait-level auditory filter strength and the link of auditory filter state to single-trial listening behavior is currently unknown. Here, we address these questions in a subsample who underwent measurements again after ~1.5 years (T2; N = 100, median = 63 yrs, 42-82 yrs).
First, we asked whether trait-level strength of speech tracking or alpha lateralization at T1 would be predictive of its respective strengths at T2 while accounting for potentially modulating influences of age or hearing acuity. Unexpectedly, the individual average strength of each neural filter was largely uncorrelated from T1 to T2, that is, neither one poses a reliable neural trait measure (tracking: $\beta = .12$, SE = .10, p =.23; alpha: $\beta = .13$, SE = .10, p =.20).
Next, we scrutinized the previously observed beneficial effect of stronger state-level speech tracking on trial-wise behavior within the T2 sample. Here, lending credibility to the functional relevance of speech tracking as neural measure of attentional state, we replicated the effect of speech tracking state on accuracy in both its size and direction (OR = 1.09, SE = .03, p =.013). The stability of this singe-trial brain-behavior relationship provides important support for the role of speech tracking as individualized neural marker of listening success.
In sum, our results underscore the functional importance of state-level neural variability for behavior while calling into question the robustness of trait-level characterization of neural-attentional filters.

Abstract: Computational models and animal studies suggest that ongoing hippocampal theta rhythm coordinates high frequency activity (HFA) to support memory encoding and retrieval. Here, we show evidence of similar theta phase coding regime in humans during offline periods immediately following episodic encoding. We analyzed hippocampal activity from intracranial electroencephalography (iEEG) recordings from epilepsy patients who encoded unique picture sequences depicting life-like episodes followed by a 2sec offline period. Memory for these episodes were tested immediately after the encoding task and after 24hrs. We found that hippocampal patterns of HFA (30-12Hz) elicited during picture encoding were reinstated at the offset period and the degree of HFA reinstatement predicted memory recollection for the episode in the delayed test (i.e., at 24hrs). We also found that hippocampal HFA coupled specific theta (6-9Hz) phase states during picture encoding and at the offset period. Critically, episodic offset hippocampal HFA coupled to opposed theta phase states as a function of whether episodes would be later recollected or forgotten in the delayed memory test. Our findings provide important evidence of the hippocampal mechanisms that support memory formation during offset periods immediately following episodic encoding.

Title: Partially overlapping spatial environments trigger reinstatement in the human hippocampus and schema-like representations in the prefrontal cortex

Authors: *L. ZHENG[1], Z. GAO[2], A. MCAVAN[1], E. ISHAM[1], A. D. EKSTROM[1];

Abstract: When asked to think about a city that we have visited, we typically retrieve not only places directly related to finding our goal within that city but also retrieve other locations within this city incidentally, a phenomenon termed "holistic" retrieval. Yet, the neural mechanisms underlying such holistic retrieval in spatial memory remains unsolved, particularly for multiple spatial environments that share common elements. Here, we asked 27 human participants to learn three partially overlapping virtual reality environments and retrieve the details of each environment while undergoing high-resolution functional magnetic resonance imaging (fMRI). The novel functional sequences we employed permitted imaging of the hippocampal subfields but also coverage of the whole brain, including the prefrontal cortex, allowing us to test hypotheses about both hippocampal and cortical contributions to spatial memory. Using multivariate pattern analysis, we found that the unique landmarks of an environment were reinstated "incidentally" in the hippocampus, even when they were not presented in the retrieval probe. This finding therefore provides empirical evidence for "holistic retrieval" of spatial memory. In addition, for stores that were shared between cities, we found evidence for pattern separation (representational orthogonalization) in hippocampal subfield CA23/DG and "repulsion" in CA1: differentiation beyond orthogonalization. This finding therefore suggests a possible neural mechanism for how common elements across different environments might be accessed. Furthermore, we found evidence for representation of the common spatial layout across the three environments in medial prefrontal cortex, suggestive of "schema" like representations that may contribute to learning of the spatial structure across the three environments. Finally, we also found evidence for unique environmental codes within hippocampal subfields, consistent with our past work identifying specific neural codes for spatial environments within the hippocampus. Taken together, our findings therefore provide a novel framework for how unique and common elements of multiple spatial environments are accessed computationally within the human brain and implicate specific roles for hippocampus and prefrontal cortex in such processes.

Abstract: While experience is continuous, memories are organized as discrete episodes ("events"). Cognitive boundaries are thought to segment experience and structure memory, but how this process is implemented remains unclear. To address this question, we investigated the neuronal mechanisms underlying the identification of cognitive boundaries in humans under semi-realistic continuous experience (i.e., video clips). We recorded single neuron activity (in total 985 neurons) from 20 drug-resistant epilepsy patients while subjects encoded and retrieved their memory of video clips embedded with different cognitive boundaries (soft boundaries: episodic transitions between related events; hard boundaries: episodic transitions between unrelated events from different movies). Behaviorally, both soft and hard boundaries enhanced recognition of video clip content that followed a boundary, whereas hard boundaries impaired memory of the temporal order between events. Single neurons in the medial temporal lobe signaled the presence of boundaries (either only hard boundaries n = 36, or both soft and hard boundaries, n = 42) with increased firing rates. The firing rate and spike phase (i.e., spike timing relative to the theta phase of local field potentials) of these boundary-responsive neurons during encoding predicted subjects' memory strength as assessed by scene recognition and temporal order discrimination accuracy, respectively. Moreover, boundary-induced neural state changes during encoding correlated with improved scene recognition memory and were anti-correlated with temporal order memory, suggesting a plausible neural mechanism for shaping episodic memories. Lastly, successful recognition correlated with the reinstatement of the neural state presented shortly after a boundary during retrieval. These findings reveal a neuronal substrate for detecting cognitive boundaries that transform experience into mnemonic episodes and structure mental time travel during retrieval.

Title: The relationship between MTL functional brain activity at encoding and subsequent memory depends on post-encoding sleep quality during a daytime nap

Authors: *R. BOTTARY[1,2], P. THAKRAL[1], M. RITCHEY[1], E. KENSINGER[1];
[1]Psychology and Neurosci., Boston Col., Chestnut Hill, MA; [2]Div. of Sleep Med., Harvard Med. Sch., Boston, MA

Abstract: Introduction: Brain state changes following emotional memory encoding can serve as "mnemonic filters", increasing the contingency of memory outcomes on encoding-related functional brain activity in medial temporal lobe (MTL) structures (Ritchey et al., 2017). Memory traces are replayed in the MTL during non-rapid eye movement (NREM) sleep, in turn strengthening communication between MTL and cortical structures during memory retrieval. However, it is unknown whether NREM sleep moderates the association between MTL activity during encoding and emotional memory retrieval success. The present study aimed to address this question.
Methods: 37 healthy, young adults successfully completed two fMRI scans separated by a nap opportunity. Pre-nap, participants viewed negative, neutral and positive images paired with sound clips and verbal labels. Participants' memory for these multisensory stimuli was tested post-nap. Encoding parameter estimates (stimulus > fixation) from two MTL structures (amygdala and hippocampus) were entered into a Memory (subsequently remembered, subsequently forgotten) x Valence (negative, neutral, positive) x Hemisphere (left, right) ANOVAS. Separate ANCOVAs covaried total sleep time (TST) and NREM sleep percentage (NREM%).
Results: No significant Memory main effect or interactions between Memory, Valence and Hemisphere were observed in the hippocampus or amygdala (all Fs < .60). In the hippocampus, Memory (remembered > forgotten) was significantly modulated by TST ($F[1,34] = 4.92$, $p = .033$) and NREM% ($F[1,34] = 6.01$, $p = .02$). We further observed a trending Valence x Memory x NREM% interaction ($F[2,68] = 2.82$, $p = .085$). In the amygdala, we observed a significant Memory x Hemisphere x TST interaction ($F[1,34] = 12.35$, $p = .001$), driven by greater right hemispheric activity for subsequently remembered items. We further observed marginal Memory x NREM% ($F[1,34] = 3.43$, $p = .073$) and Valence x Memory x Hemisphere x NREM% ($F[2,68] = 2.70$, $p = .077$) interactions, driven by subsequent memory activity for negative stimuli and the right hemisphere.
Conclusions: Our findings suggest that the relation between MTL activity during memory encoding and post-nap memory depends upon the quality of sleep in the nap. Sleep effects appear strongest for negative memory retrieval.

Title: Effects of Age on Item and Source Subsequent Memory Effects Identified with fMRI

Authors: *E. S. LIU[1], J. D. KOEN[2], J. T. MATTSON[3], M. D. RUGG[1];

Abstract: Effects of Age on Item and Source Subsequent Memory Effects identified with fMRI
E. Song Liu, Joshua D. Koen, Julia T. Mattson, Michael D. Rugg
Age-related decline in episodic memory performance is attributed in part to ineffective encoding. In the present study, we examined the effects of age on the neural correlates of the encoding of item and source memories using an experimental procedure that minimized the potentially confounding effects of memory strength. We combined the data from two independent but closely similar experiments (total Ns = 45 younger and 52 older adults). The participants underwent fMRI while performing a study task requiring one of two judgments ('bigger or smaller than a shoebox' or 'found indoors or outdoors') on a series of images of common objects. On a subsequent surprise memory test administered outside of the scanner participants were required make an 'old/new' recognition judgment on each test object and, for any object judged old, to then judge the task it was associated with at study. Of importance, both judgments were made on a 5-point confidence scale, and only highly confident judgments were used to define, for the purposes of the fMRI analyses, correct source (CS; source plus item correct) and correct item (CI; source incorrect, item correct) judgments. A third class of events – item misses (IM) – was also included in the analyses. A 2 (experiment) x 2 (age group) x 3 (subsequent memory judgment) ANOVA on the fMRI data acquired at study was conducted to identify ROIs that were then subjected to further analysis. We identified 8 clusters where BOLD activity was greater for remembered than less well remembered or forgotten study items, and 7 clusters that demonstrated the reverse pattern. In general, age differences were subtle: subsequent memory effects (SMEs) tended to show a 'strongly' graded pattern (CS > CI > IM) in young, and 'weakly' graded pattern (CS > IM) in older adults. Notably, in bilateral hippocampus, subsequent memory effects (SMEs) did not differ according to age and were uniquely associated with successful source rather than item memory (CS > CI = IM). Moreover, the magnitude of hippocampal SMEs robustly predicted source memory performance in the older ($r = 0.422$, $p = 0.002$) adults. No such relationship was evident, however, in the young group ($r = 0.050$, $p = 0.743$). These findings suggest that, after controlling for item memory strength, age differences in SMEs are subtle, when they are evident at all, and do not extend to the hippocampus. Additionally, variation in hippocampal activity appears to play a more important role in mediating source memory performance in older than in young adults.

Title: Latent infantile memories influence new learning experiences in adulthood

Authors: *B. BESSIÈRES[1], L. SILENZI[1,2], C. M. ALBERINI[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Wake Forest Univ., Winston-Salem, NC

Abstract: Early life experiences are known to shape the development of the brain, resulting in lifelong consequences on adult cognitive functions and behavior. Paradoxically, the memories formed in infancy appear to be rapidly forgotten and the mechanistic bases by which they can influence adult learning remain to be identified. Using rodent models, we previously demonstrated that the apparently forgotten infantile memories are not actually lost. In fact, at later ages, and up to adulthood, they can be reinstated by certain reminders, implying that infant memories are stored long term in latent forms. Here we show that infant episodic learning influences adult behavior by forming stable memory traces or schemas, i.e., frameworks of acquired knowledge that affects the processing of new information. Mice exposed to contextual fear conditioning (CFC) in infancy can reinstate the memory in adulthood if they are presented with a low intensity footshock in the same context in which they received the CFC training; a protocol (known as saving) that by itself is unable to elicit any detectable memory. We also found that only infantile, but not adult CFC, facilitates a new CFC learning received in a distinct context in adulthood, indicating that during a developmental critical period, learning builds long lasting memory representations that later affect the processing of new information. By using state-of-the-art genetic tools to map and silence the cell networks activated by learning in infancy, we also found that the reactivation of the cell ensembles active during infantile learning is necessary for the return of memories in adulthood, as well as for facilitating a similar novel adult learning. These results led us to conclude that infantile learning builds long-lasting memory schemas that influence new learning experiences in adulthood.

Title: A selective disengagement of CA3 for the retrieval of very remote memories: a fundamental principle of memory consolidation

Authors: *E. ATUCHA[1], C. FUERST[1], M. SAUVAGE[1,2];
[1]Leibniz Inst. For Neurobio., Magdeburg, Germany; [2]Otto von Guericke Univ., Magdeburg, Germany

Abstract: The CA3 hippocampal subfield has been suggested to contribute to memory retrieval by supporting pattern completion, the completion of full memory representations based on detailed features

of these representations. However, detailed features degrade as memory ages raising the possibility that pattern completion/CA3 might not contribute to a decisive manner to the retrieval of very remote memories (20, 40 years-old memories in humans comparable to 6 month and 1 year-old memories in mice based on life expectancy). We have recently established that, unlike CA1 that is engaged in fear memory retrieval independently of the age of the memory (up to 1 year-old memories in mice), CA3's contribution is limited to the recall of recent and early remote memories (i.e. up 1 months old memories). In addition, we showed that parahippocampal areas (MEC, LEC, PER, POR) were optimally recruited upon the retrieval of the most remote memories as reported for the prefrontal cortex, also tightly connected to the hippocampus, in studies focusing on early remote memory retrieval (Lux et al, Elife, 2016; Atucha et al, Bioarchiv 2021). Here, we tested if the disengagement of CA3 overtime is a fundamental principle of memory consolidation by investigating if CA3 is also disengaged for the retrieval of memories devoid of fearful content. Very little is known about early remote and very remote memory retrieval of neutral events due to the difficulty of retaining neutral memories over delays greater than 1 month in rodents. Hence, we first optimized an object-in-place paradigm to allow for memory traces to persist up to 6 months after memory encoding and imaged activity during memory retrieval in CA1 and CA3, parahipppocampal areas and prefrontal cortex (ACC, IL, PL) with high resolution by detecting the RNA of the immediate early gene Arc. As observed with fear memories, we found that the contribution of CA3 was limited to the retrieval of recent (1 day, 1 week) and early remote (1 month) memories while CA1 was engaged independently of the age of the memory and received a maximal support from parahippocampal areas for the most remote memories (6 months-old). In addition, this latter activation matched that observed in the ACC, suggesting a comparable kinetic of recruitment of cortical areas connected to the hippocampus that play a role in memory. Altogether, our results bring further support to a new concept of memory consolidation according to which distinct MTL subnetworks support memory retrieval as memories age and underline the necessity for further investigations aiming at dissociating the qualitative contribution of the parahippocampal areas and ACC to memory retrieval overtime.

Title: Optogenetic stimulation of the basolateral amygdala after spatial Barnes maze training modulates recent versus remote memory in rats

Authors: *B. GLICKMAN[1,2], R. T. LALUMIERE[1,2,3];
[1]Interdisciplinary Grad. Program in Neurosci., [2]Iowa Neurosci. Inst., [3]Dept. of Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: How recent versus remote memories are consolidated and recalled is an extensively debated topic within the field of learning and memory, but it is well known that the basolateral amygdala (BLA) modulates many types of memories consolidated across multiple memory systems. Systems consolidation asserts that, over time, memories undergo neural reorganization becoming less dependent on the hippocampus and more dependent on neocortical networks, such as the mPFC. Recent work indicates that contextual fear memory traces for recent and remote retrieval are laid down at the time of training but in separate brain regions that are then responsible for the recall of those memories depending on the length of time since the original learning. This raises the possibility that the BLA modulates the consolidation of each trace in a dissociable manner. Although some prior work has examined roles for the BLA in recent vs. remote memory consolidation, such work used footshock-based training paradigms, which are confounded by the BLA being a potential storage site for these memories. Thus, it is not known how the BLA modulates a single non footshock-based memory expressed at different timepoints following learning. To address this question, male and female Sprague-Dawley rats received bilateral intra-BLA microinjections of an AAV with a CaMKIIα promoter to express the opsin ChR2(E123A), a depolarizing cation channel, and implantation of optical fibers aimed at the BLA. Rats then underwent 4 consecutive training trials on a spatial version of the Barnes maze, in which they had to use extramaze cues to find the escape port. Immediately following training, rats received 15 minutes of bursts of 40 Hz (473 nm, 5 ms pulse width, given for 2 seconds every 10 seconds) optical stimulation of BLA cell bodies. Retention tests occurred 2- and 30-days after training. Following testing, rats were euthanized, and histology was performed to verify virus and optical fiber placement. Initial results found no effect of such stimulation on retention at the 2-day (recent) timepoint. However, the results indicate decreased latency to locate the escape port and increased duration spent in the target quadrant of the maze at the 30-day (remote) timepoint, suggesting enhanced retention at the remote timepoint compared to control animals. Ongoing experiments are examining whether inhibiting the BLA immediately after training affects recent and remote retention. Nonetheless, these initial results suggest that the BLA is capable of dissociably modulating the consolidation of memories later expressed at recent vs. remote timepoints.

Title: Individual differences in Glutamate/Glutamine (Glx), but not GABA, predict behavioral performance in older and younger adults

Authors: *M. SIMMONITE[1,2], T. A. POLK[1];
[1]Dept of Psychology, Univ. of Michigan, Ann Arbor, Ann Arbor, MI; [2]Dept of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Healthy aging is associated with changes in the neurochemical profile of the brain. Previous studies have demonstrated age-related reductions in both gamma-aminobutyric acid (GABA; the primary inhibitory neurotransmitter of the human brain), and glutamate (the most abundant metabolite and primary excitatory neurotransmitter). However, regional differences in metabolite changes and their impact on behavioral performance are not yet fully understood. In 58 young adults (aged 18 to 29 years) and 79 older adults (aged 65+), we used 3 Tesla Magnetic Resonance Spectroscopy (MRS) to quantify GABA and Glx (a composite measure of glutamate and glutamine) concentrations in three visual cortex voxels, two auditory cortex voxels, and two sensorimotor cortex voxels. Out of the scanner, participants completed an extensive behavioral battery, on which factor analysis was performed to extract summary measures quantifying performance in visual, auditory, tactile, and motor domains. We used these scores to investigate relationships between regional GABA and Glx concentrations and behavioral performance. Young adults demonstrated significantly higher GABA and Glx concentrations in multiple brain regions than older adults. In both young and older adults, both GABA and Glx concentrations correlated more strongly across hemispheres (e.g., left and right auditory cortex) than across different regions within hemisphere (e.g., left auditory and motor cortex). Finally, across the full participant sample and in each age group separately, regional Glx concentrations explained significant variability in associated factors underlying behavioral performance. Visual Glx concentrations best predicted higher-level visual performance, auditory Glx concentrations best predicted higher-level auditory performance, and sensorimotor Glx best predicted fine motor performance. This pattern was not observed for GABA concentrations. These findings demonstrate age-related alterations in multiple neurotransmitter systems across multiple brain regions and link regional Glx concentrations with associated behavioral performance.

Title: Data-driven MRI analysis reveals fitness-related functional change in Default Mode Network following exercise intervention, which is associated with cognitive performance

Authors: *K. MCDONALD[1], T. MORRIS[1], S. ANTERAPER[2], M. VOSS[3], S. WHITFIELD-GABRIELI[1], K. ERICKSON[4], E. MCAULEY[5], A. KRAMER[1];
[1]Northeastern Univ., Boston, MA; [2]Carle Illinois Advanced Imaging Ctr., Champaign, IL; [3]Univ. of Iowa, Iowa City, IA; [4]Univ. of Pittsburgh, Pittsburgh, PA; [5]Univ. of Illinois, Champaign, IL

Abstract: As the U.S. population grows older, more effective and predictive methods are needed to maintain and improve cognitive and brain health in later life. Previous research has indicated that cardiorespiratory fitness is structurally and functionally neuroprotective in healthy older adults, and may

delay the onset of neurodegenerative diseases such as Alzheimer's and vascular dementias. However, many questions remain with regard to the role of fitness on cognitive and brain health. Data were collected in the "Fit and Active Seniors Trial" from 2015-2018. One purpose of this study was to investigate whether baseline fitness was associated with change in functional brain connectivity during a six-month exercise intervention and to determine whether the magnitude of change in connectivity was related to post-intervention cognitive performance. Low active older adults (n=139) enrolled in and completed a 6-month exercise intervention and underwent neuropsychological testing, functional neuroimaging, and cardiorespiratory fitness testing before and after the intervention. Participants (60-80 years, 71.9% female) were randomized into one of four groups: Dance (n=40), Walk (n=28), Walk + nutritional supplement (n=31), or active control (i.e., stretch and tone; n=40). A data-driven multi-voxel pattern analysis was performed on resting-state functional MRI scans to determine whole-brain patterns of connectivity. The correlation between pre-intervention fitness in all groups ($\bar{x}$ = 19.72, $\sigma = \pm 4.55$) and connectivity change was significant in the precentral gyrus (voxel threshold $p < 0.001$, cluster threshold $p<0.05$, corrected for family-wise error), which was associated with the Somatosensory Network. Using the precentral gyrus as a seed, post-hoc analyses revealed that the connectivity pattern was derived from increased correlations in the Dorsal Attention Network and increased anti-correlations in the Default Mode Network (DMN). Increased anti-correlations between the precentral gyrus seed and the DMN were associated with improved post-intervention performance on fluid reasoning (p=0.02) and perceptual speed (p=0.03) tasks. The findings suggest that in a sample of low-active older adults, those with higher fitness at baseline were more likely to experience increased functional connectivity as a result of participating in less sedentary activity for six months, and the characterizations of the connectivity change was associated with components of cognition. These findings emphasize the need for older adults to maintain a physically active lifestyle that enhances cognitive and brain health.

Title: Segregation of functional brain networks confer network resilience and mediate relationships between network resilience and cognition

Authors: *W. STANFORD[1], P. J. MUCHA[2], E. DAYAN[1];
[1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Dartmouth, Hanover, NH

Abstract: Functional brain networks must balance between segregation and integration to maintain the adaptive cognitive processing required for normal cognitive function. Associative functional brain networks, in particular, tend to be highly segregated from other brain networks, reflecting their

specialized roles in cognition. However, segregation of associative brain networks declines in late aging, which is typically viewed as a compensatory mechanism, and is associated with disruptions in cognitive abilities. In many complex systems, segregation of function between subcomponents within systems can enhance resilience of system function against perturbations, but it is currently unknown whether segregation similarly facilitates resilience within functional brain networks. Here we use a subset of the Human Connectome Project - Aging dataset (n=324, ages 60-90) to investigate the relationships between network resilience, functional segregation and cognition in aging individuals. We first reproduced earlier results, finding that the degree of whole brain segregation, quantified with the previously established segregation index, was correlated with cognitive performance in elderly subjects. Next, we simulated targeted attacks on functional brain networks, as a proxy for their resilience, and show that segregation in many functional networks underlies resilience against such attacks. Finally, we found that segregation in associative brain networks mediates an association between network resilience and cognition. Together these findings indicate segregation as a general network mechanism brain networks use to facilitate cognitive abilities, confer network resilience, and mediate relationships between network resilience and cognition.

Abstract: Cognitive training shows promise in reducing dementia risk and mitigating cognitive decline in older adults, yet the functional neural correlates have not been explored. Resting state networks (RSN) are anatomically distinct brain areas that function together over time. The connectivity of the frontoparietal control network (FPCN), cingulo-opercular network (CON), dorsal attention network (DAN), and default mode network (DMN) are involved in inter-network modulation, executive functioning, attention, and

cognitive status in aging. Previous research suggests these RSNs may be associated with cognitive training. By identifying underlying brain networks associated with cognitive interventions, researchers could improve efficacy of cognitive training. This study examined RSN changes associated with 3 months of cognitive training in a sample of healthy older adults.58 healthy older adults (M age = 71.2, SD = 4.7) were recruited as part of a larger clinical trial through the University of Florida and the University of Arizona. Participants were randomized into a cognitive training (CT; n=30) or education control (ET; n=28) group. CT group underwent 40 hours of cognitive training on 4 attention/speed of processing and 4 working memory tasks over a span of 12-weeks. The ET group watched 40-minute educational videos. Participants in CT and ET groups received either sham or active transcranial direct current stimulation, although this was not a variable of interest. Participants underwent resting-state functional magnetic resonance imaging at pre- and post-training time points. Functional images were processed and average connectivity of FPCN, CON, DMN, and DAN were extracted through use of the CONN Toolbox v18b via SPM 12. Group by time interactions were assessed through mixed repeated measures ANCOVA controlling for tDCS group, mood, age, sex, education, and scanner.There were no statistically significant group by time interactions for FPCN, CON, DMN, or DAN. However, FPCN group by time interaction had a small-medium effect size [$F(1,50) = 2.77$, $p=.102$, partial $\eta^2=.053$] and pairwise comparisons revealed increased FPCN connectivity in the CT group after training ($p=.027$).Our results suggest that 3 months of cognitive training may result in higher connectivity of the FPCN in a sample of healthy older adults, although power analysis suggests a larger sample size is needed. This implies the FPCN, which has a role in modulating between network connectivity, may be a neural target to strengthen cognitive training response. Future research should assess functional brain changes after cognitive training in a larger group and at more time points.

Title: Age-related neural dedifferentiation for scenes and faces: evidence from ERPs

Authors: *R. E. PICHOT, D. HENRECKSON, M. FOLEY, J. D. KOEN;
Univ. of Notre Dame, South Bend, IN

Abstract: There is a growing body of work showing that age-related neural dedifferentiation - reductions in the selectivity and precision of neural representations - contributes to cognitive aging. This research has

primarily used fMRI to examine age-related reductions in neural selectivity for different categories of visual stimuli. Unlike fMRI, the temporal resolution of EEG permits examination of whether neural dedifferentiation results from an age-related reduction in 'maximal' levels of neural selectivity, a delay in the time the maximal neural selectivity, or both. The present research examined age-related neural dedifferentiation by examining scene-sensitive (P200) and face-sensitive (N170) ERP components. A total of 44 young and 44 older adults viewed images of scenes, objects, and faces in the context of a 1-back task. The scene-selective P200 and face-selective N170 components were measured from first presentation scene and face trials, respectively, contrasted with objects. Relative to young adults, the P200 in older adults was reduced in peak amplitude and delayed in peak latency. A similar pattern was observed for the N170 but only over right hemisphere electrodes. We also tested a prediction from a computational model proposing that age-related neural dedifferentiation results from age increases in "neural noise" (i.e., the aperiodic signal). However, our findings did not clearly support the prediction of this model. There was no clear relationship between the aperiodic signal and the P200 and N170 components. These findings provide novel evidence that neural dedifferentiation results from both reductions in the amplitude of and delays in the selectivity of neural activity, and motivate future research to identify the mechanism giving rise to this phenomenon.

Title: Frontoparietal brain activation during dual-task walking is associated with cardiovascular and motor coordinative fitness

Authors: *R. STOJAN[1], M. MACK[1], O. L. BOCK[2], C. VOELCKER-REHAGE[1];
[1]Univ. of Muenster, Muenster, Germany; [2]Univ. of Cologne, Koeln, Germany

Abstract: Walking while performing an additional task is an integral part of our daily life. With increasing age, this dual-tasking (DT) performance typically declines. Cardiovascular and motor coordinative fitness have been shown to be positively associated with DT performance. Whether brain activation patterns while DT differ with respect to the physical fitness level, however, has not been investigated so far. Here, we applied fNIRS to investigate the neural correlates during DT walking in healthy older adults and its association with cardiovascular and motor coordinative fitness. Data of 41 older adults were analyzed (age: 68.79 ± 3.79, 22 females). Participants completed a baseline task (standing) and three tasks (treadmill walking at 1 m/s, Stroop task, Serial 3's task) under single and DT conditions (Walking + Stroop, Walking + Serial 3's). Task order was mixed with 5 trials per task, 30 s per

trial. Behavioral outcome measures were gait (step time variability) and cognitive performance (Balance Integration Score [BIS_{cog}]). Brain activity was measured using fNIRS over prefrontal and parietal regions. Neurophysiological outcome measures were oxygenated (OxyHb) and deoxygenated hemoglobin (DeoxyHb). Cardiovascular fitness ($VO2_{peak}$) was assessed by use of a graded exercise test (Spiroergometry) and motor coordinative fitness by use of three different motor tests to assess manual dexterity, balance and movement speed (composite score). Four linear models were applied to investigate the effects of Task (DT Stroop, DT Serial 3's), Region (DLPFC, VLPFC, IPL, SPL (for OxyHb, DeoxyHb only)), and Cardiovascular or Motor Coordinative Fitness on OxyHb, DeoxyHb, Step Time Variability (gait), and BIS_{cog} (cognition). First results indicate that both Cardiovascular Fitness ($p < .001$, $\eta^2 = .05$) and Motor Coordinative Fitness ($p = .016$, $\eta^2 = .02$) were positively associated with overall OxyHb and negatively with overall DeoxyHb ($p < .001$, $\eta^2 = .04$ and $p < .001$, $\eta^2 = .01$) during DT. These effects were neither task nor region-specific (no interactions). Partly in line with that, both Cardiovascular Fitness and Motor Coordinative Fitness were positively related to BIS_{cog} ($p = .031$, $\eta^2 = .01$ and $p = .006$, $\eta^2 = .02$), but not Step Time Variability ($p = .788$, $\eta^2 < .01$ and $p = .090$, $\eta^2 < .01$). We could confirm that a higher physical fitness was accompanied by higher brain activation and higher cognitive performance during DT. Results indicate improved brain health and DT performance in physically fit participants.

Title: Neural evidence for age-related deficits in the representation of state spaces

Authors: *A. RUEL[1], F. BOLENZ[2], S.-C. LI[3], A. G. FISCHER[4], B. EPPINGER[1];
[1]Concordia Univ., Montreal, QC, Canada; [2]Max planck institute for human development, Berlin, Germany; [3]Lifespan Developmental Neurosci., Fac. of Psychology, TU Dresden, Dresden, Germany; [4]Dept. for natural Sci., Otto-von-Guericke Univ. Magdeburg, Magdeburg, Germany

Abstract: Current theories of decision-making distinguish between model-free (MF) decision strategies which rely on action/outcome associations and model-based (MB) decision strategies, which rely on a complete representation of the task structure (Daw et al., 2011). These decision strategies are located on the extremes of an efficiency/flexibility trade-off (Bolenz et al., 2019; Eppinger et al., 2021). The MF strategy requires little cognitive effort but is inflexible if the environment changes. The MB strategy requires much more cognitive effort but is highly flexible as it relies on a model of the task structure that can be used to adapt to changes in the environment.While younger adults flexibly engage in a

combination of MF and MB decision-making, older adults have been shown to rely on MF decision-making which has been attributed to deficit in the representation of the decision-making environment, necessary to engage in the MB strategy (Eppinger et al., 2013; Eppinger et al., 2017). To understand the neural mechanisms that underly this age-related shift, we used a combination of computational modeling and EEG to examine older adults' performance and neural activity under high compared to low demands on the representation of the task structure. We had younger and older adults complete a modified two-stage Markov decision task under two transition probability conditions. In the 80%–20% condition, due to the large difference between the common and rare transitions, the internal structure of the task should be simpler to represent, and thus the upcoming state should be easier to predict than in the 60%–40% condition. We used computational modeling, and single-trial EEG analyses to establish neural markers of age-related changes in MB decision-making across both conditions. In line with our behavioral results, we found neural evidence (P300 component) that younger, but not older adults had a better task representation in the 80%-20% condition. Further, single trial analyses revealed that participants' neural activity (P300) covaried with the degree to which they updated their cognitive map of the state space of the task (state value prediction errors). Consistent with the diminished state space hypothesis of human aging, our findings suggest that deficits in goal-directed, MB behavior in older adults result from impairments in the representation of state spaces of cognitive tasks.Based on previous work in younger adults (Momennejad et al., 2017) we are currently investigating whether older adults may also engage in intermediate strategies. In a follow-up study, we test this possibility and examine the neural mechanism supporting successor representation using EEG.

Title: The functional neural correlates of the Useful Field of View (UFOV) task in older adults

Authors: *J. N. KRAFT[1], A. ALBIZU[1], A. O'SHEA[2], H. K. HAUSMAN[2], C. HARDCASTLE[2], N. D. EVANGELISTA[2], E. M. BOUTZOUKAS[2], E. VAN ETTEN[6], P. K. BHARADWAJ[6], H. SONG[6], S. G. Abstract: Declines in processing speed occur in aging, and are critical markers of cognition. Studies suggest that Useful Field of View (UFOV) training may ameliorate cognitive decline, with interventions demonstrating up to a 29% reduction of Alzheimer's disease risk. Despite its efficacy, little is known about the neural correlates of this paradigm. The current study investigated the functional neural correlates of the UFOV task by assessing blood oxygen level dependent (BOLD) activation patterns in older adults.

233 healthy older adults completed the UFOV task while undergoing task-based functional MRI. During the *stimulus* portion of this task, the participant must identify a target in the center of the screen and the location of a peripheral target. During the *probe* portion, the participant performs a forced choice response, deciding if the object in the center and the location of the peripheral target are identical to the *stimulus* screen. First level contrasts modeled hemodynamic response within participants. Group level analyses assessed the unique BOLD response associated with the *stimulus* and *probe* components of the task and shared patterns of activation Age, education, sex and scanner were included as covariates in all second-level models. Significant clusters were corrected at a false discovery rate (FDR) of $p<0.05$. The above models were rerun with task performance included to assess the differential impact of accuracy on BOLD activation.

Widespread whole brain activation was evidenced in the *stimulus>probe* contrast [$t(228)=16.00$; 95,175 voxels]. Conversely, the *probe>stimulus* contrast was associated with unique activation patterns within the inferior temporal gyrus, middle frontal gyrus, and parahippocampal gyrus [$t(228)=7.30$; 6,634 voxels]. In the *stimulus+probe>rest* conjunction analysis, we observe activation patterns within the precentral gyrus, occipital pole, insula, and middle frontal gyrus [$t(460)=13.92$; 32,724 voxels]. Evaluating the impact of accuracy, we observe similar whole brain activation patterns in the *stimulus>probe with accuracy* contrast [$t(227)=6.21$; 38,981 voxels]. Interestingly, no significant clusters survive FDR corrections in the *probe>stimulus with accuracy* contrast. Analyzing the *stimulus+probe> rest with accuracy* contrast, we see activation patterns more focally centered in the frontal and parietal lobes [$t(459)=6.28$, 11,862]. To date, this is the largest study assessing BOLD activation during UFOV task completion. Understanding the neural underpinnings of the UFOV could provide insight into potential avenues for intervention optimization, further increasing the efficacy of UFOV interventions.

Title: Preclinical Alzheimer Disease Pathology Partially Mediates the Relationship Between Cortical Thickness and Cognitive Control

Authors: *N. S. MCKAY[1], A. DINCER[1], V. MEHROTRA[2], A. J. ASCHENBRENNER[1], D. BALOTA[1], R. C. HORNBECK[1], J. C. MORRIS[1], T. L. S. BENZINGER[1], B. A. GORDON[1];
[1]Washington Univ. Sch. of Med., St Louis, MO; [2]Case Western Sch. of Med., Cleveland, OH

Abstract: Previous research has shown that with age and disease, the integrity of grey matter structures decline. One such measure of grey matter integrity is cortical thickness, where lower values represent thinning of the cortical surface. Given that cognitive performance tends to decline with age, we were interested in investigating whether performance on attention-based tasks was related to cortical thickness measured using magnetic resonance imaging (MRI) in an unimpaired older adult cohort. Further, although often unmeasured in studies of cognitive aging, many older adults will present with Alzheimer Disease (AD) pathologies such as beta-amyloid (Aβ) deposition, despite being asymptomatic. Therefore, we were also interested in quantifying how much of the behavior-structure relationship seen in older adult cohorts is driven by preclinical AD. 511 cognitively unimpaired (CDR™=0) older adults (Age: *M*=68.2, *SE*=0.38) enrolled in studies at the Knight Alzheimer Disease Research Center, were included in these analyses. All participants completed an MRI and several cognitive measures (Stroop, Simon, and CVOE); a subset of individuals (*n*=396) also underwent Aβ-positron emission tomography (PET). A spatial cortical map highlighting regions where cortical thickness and cognition were related was created and this map was entered into subsequent analyses as our MRI variable. We used an established attentional control composite as our behavioral measure of interest. Linear models were conducted to elucidate the relationship between cortical thickness and cognition, and a mediation analysis was performed to examine whether Aβ deposition impacted this relationship. Using vertex-wise general linear models, we found that reduced cortical thickness in temporal, medial- and lateral-parietal, and dorsolateral prefrontal cortex, predicted worse performance on an attention task composite. Interestingly, mediation analysis showed that levels of Aβ partially account for the observed relationship between cortical thickness and attentional control. These results demonstrate that behavioral variability seen in older adult populations reflects corresponding changes in brain anatomy, specifically cortical thickness. Furthermore, our results support the hypothesis that preclinical AD, as measured by Aβ deposition, is partially driving what would otherwise be considered general aging in a cognitively normal older adult population.

Title: Next generation lineage tracing of brain development by single-cell and spatial transcriptomics

Authors: *M. RATZ, L. VON BERLIN, J. FRISÉN;
Karolinska Inst., Stockholm, Sweden

Abstract: The mammalian brain contains a large number of cells that develop from a thin sheet of neuroepithelial progenitor cells. High throughput single cell technologies have been used to define the molecular diversity of hundreds of cell types in the nervous system. However, the lineage relationships between mature brain cells and progenitor cells are not well understood, because transcriptomic studies do not allow insights into lineage relationships and classical fate-mapping techniques are not scalable. Here we show *in vivo* barcoding of early progenitor cells that enables simultaneous profiling of cell phenotypes and lineages in the mouse brain using single cell and spatial transcriptomics. We reconstructed more than 2,000 clones to uncover the existence of fate-restricted progenitor cells in the mouse hippocampal neuroepithelium and show that microglia and perivascular macrophages are derived from primitive myeloid precursors that massively expand to generate widely dispersed progeny. By coupling spatial transcriptomics with lineage tracing, we obtained clonal and regional maps that revealed the differential expression of molecular signals sensed by clonally related cells to adapt to their microenvironment. Finally, we uncovered shared single cell gene expression programs of clonally related cells that might be associated with distinct response behaviors of brain cells originating from the same progenitor cell.

[3]CHDI Management/CHDI Fndn., New York, NY

Abstract: Selectively targeting mutant (m)*HTT* mRNA remains an important therapeutic objective for HD. Phenotypic screening efforts focusing on m*HTT* mRNA as target require a robust and high-throughput method to identify novel small molecule inhibitors, but an existing allele-selective assay read-out is lacking. Here we aim to validate a cellular assay developed for screening modulators of endogenous m*HTT* mRNA in an allele-specific manner. This tool encompasses a hESC line that harbors one barcoded *HTT* allele (either wt or m*HTT*) and employs ViewRNA technology to quantify both barcoded and non-barcoded *HTT* mRNA expression levels. An HD hESC line (22/56 CAG repeats) was engineered using CRISPR/Cas9 gene editing of the CAG repeat with introduction of silent mutations throughout one of the *HTT* exon 12 alleles to generate a mono-allelic barcode. After homology directed substitution of one allele, clones were isolated and characterized for on-target integration, mono-allelic linkage and HTT protein expression. We show that these *HTT*-barcoded hESCs could demonstrate an applicable pharmacological response with an allele-specific quantification method, and further that these cells retain disease-relevant differentiation potential. We demonstrated non allele-selective *HTT* mRNA lowering in *HTT*-barcoded hESCs treated with Branaplam, a compound targeting an RNA splicing mechanism, using ViewRNA quantification. By characterization of neuronal fate marker expression using branched DNA and immunocytochemistry methods, we have confirmed that wt *HTT* barcoded hESCs retain the capacity for successful differentiation towards a disease-relevant neuronal phenotype. *HTT*-barcoded striatal-like neurons were then investigated to confirm that the multiplexed ViewRNA assay method remained applicable after differentiation, and assessed for differentiation dependent sub-cellular *HTT* transcript localization. These *HTT*-barcoded striatal neurons can be similarly interrogated by ViewRNA assay and represent a tool allowing high throughput investigation of allele-specific *HTT* mRNA pharmacological modulation potential in a disease relevant cell type.

Title: Single-nucleus RNA-sequencing reveals cell-type-specific RNA isoform diversity in the human brain

Authors: *C. LIU[1,2], C. PALMER[2,1], W. J. ROMANOW[1], J. CHUN[1];
[1]Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA; [2]UCSD, La Jolla, CA

Abstract: Single-cell sequencing technologies have expanded our ability to investigate transcriptomes at a cellular level. Single-nucleus RNA-sequencing (snRNA-seq) can identify cell-type-specific alterations in gene expression, however, this approach does not provide information about how RNA isoform expression may vary among different cell types or physiological conditions. Long-read transcriptomic solutions, such as Pacific Biosciences' Iso-seq approach, produce reads up to 10kb in length which can resolve full-length isoforms. Utilizing long-read (Pacific Biosciences) as well as short-read (Illumina) sequencing technologies, we conducted snRNA-seq on 29 human Down Syndrome (DS) and non-DS control prefrontal cortex samples. Combining these approaches allowed us to identify cell types and attribute isoforms identified in long reads to individual cells. We detected vast RNA isoform diversity within specific cell types and numerous novel sequences that varied across cell types. Isoforms containing novel features such as intra-exonic junctions (IEJs) - previously associated with somatic gene recombination - novel exons, and partial intronic retention were identified. These results underscore the presence of diverse and varied RNA isoforms contributing to cellular functions in the human brain.

Title: Qcr: a snakemake pipeline for quality control assessment of single cell or nucleus rna sequencing data

Authors: *S. SOMASUNDARAM, N. JORSTAD, K. SMITH, J. GOLDY, J. GUZMAN, T. PHAM, A. TORKELSON, N. GUILFORD, A. YANNY, E. LEIN, R. D. HODGE, T. BAKKEN, J. A. MILLER;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Over the past decade single cell and nucleus RNA sequencing (sc/sn RNA-seq) technologies have been instrumental for identifying and characterizing gene expression profiles of cell types in multiple organ systems in many species. Application of snRNA-seq in human brain has provided new insights into cell type function, connectivity and susceptibility to disease. Droplet-based methods such as 10x Chromium 3' v3 sequencing can capture tens of thousands of data points per experiment. While the majority of these represent individual nuclei, some include two or more nuclei, are missing nuclei

entirely, or contain damaged or otherwise low-quality nuclei. Therefore snRNA-seq data needs to be filtered to infer the true nuclei prior to clustering to identify distinct and accurate cell type populations without losing biologically relevant cell types. Previous studies have used either manual selection or one of several published computational algorithms that employ different strategies to identify low quality nuclei. However, manual selection is only feasible with a small number of donors and few flexible and intuitive pipelines exist got large batch processing.
Here we present Quality Control on snRNA-seq (QCR), which is a Snakemake pipeline for robust and reproducible quality assessment and filtering of sc/sn RNA-seq data. QCR incorporates several steps for flagging and a thorough filtering of low-quality cells. This comprehensive pipeline takes a Seurat object of a single sample or integrated samples as input, performs a series of steps for flagging and filtering nuclei as potential low quality data points for exclusion, and outputs these results along with a report containing UMAPS, bar plots and scatter plots for visual and quantitative verification of results. Quality metrics are calculated both for nuclei and for "metacells" (small group of cells from Louvain clustering in Seurat) to mark poor quality cells. Furthermore, each step of QCR is implemented as a separate module, making the pipeline adaptable to different experimental protocols.
We have run QCR on a publicly accessible set of nuclei collected from the neocortex of 78 human donors during neurosurgical resections for tumors and intractable epilepsy and show that it excludes predominantly low-quality data points while retaining predominantly high-quality nuclei.

Abstract: Defining and characterizing cell types in the brain is a critical problem in modern neuroscience. The BRAIN Initiative Cell Census Network (BICCN) has generated and reported on a multimodal atlas of cell types in mammalian primary motor cortex consisting of large-scale, integrated datasets describing single-cell transcriptomes, chromatin accessibility, DNA methylomes, spatially resolved single-cell transcriptomes, morphology, electrophysiological properties, neuronal connectivity and novel transgenic mouse lines and viral tools. Using the single cell transcriptomic data as a framework, a taxonomy of cell types with a hierarchical organization that is conserved across mouse, marmoset, and human has been defined. The Cell Type Explorer is an interactive web-based tool that allows users to browse data comprising the BICCN primary motor cortex atlas at each level of the taxonomy. This tool contains individual Cell Type Cards that cover transcriptomically-defined cell types in the primary motor cortex, as well as biologically driven, lower-resolution groupings of these types ("subclasses" and "classes") that are highly consistent across modalities and match historically defined types. Each Cell Type Card provides text summaries and data visualizations across multiple modalities and describes key characteristics of a given cell class, subclass, or type, including specific marker gene combinations. Cell Type Cards and their underlying taxonomies are associated via a data-driven ontology, allowing for text-based search and comparison of cell type properties across the motor cortex. Each Card also provides links to archives containing both raw and processed data files, relevant manuscripts, and other resources for analysis and visualization from the Allen Institute and collaborating BICCN laboratories. The Cell Type Explorer represents a rich new resource for the neuroscience community that can serve as a complement to studying cell types from manuscripts and traditional data viewers.

Title: Widening the 3D view: processing and presentation pipeline of brain volume imaging data

Authors: E. HUSÉN[1], *J. MULDER[1], D. TABAR[2], M. UHLÉN[1], T. HÖKFELT[1], C. ADORI[1]; [1]Neurosci., Karolinska Inst., Solna, Sweden; [2]Atomontage, Wilmington, DE

Abstract: OBJECTIVE AND RATIONALE Traditional immunohistology and immunofluorescence-based analysis of brain tissue is performed on thin sections. Volume immunostaining- and clearing methods (e.g. iDISCO, Scale, CLARITY), in combination with three-dimensional (3D) image acquisition

by light sheet microscopy, generate a more comprehensive tissue overview. This becomes vital in case of complex tissues, such as the brain. The main challenges in the field of volume imaging are related to quality of staining and lipid clearing, image acquisition, 3D data-processing, analysis, visualization, and data sharing. In the recent years, the number of neuroscience publications using volume imaging approaches has increased. In most of these publications, 3D data are provided as movie files to highlight and illustrate biological concepts or findings. For educational purposes, we earlier generated volume imaging of various human tissues, which are publicly accessible as videos on the webpage of the Human Protein Atlas; for instance, imaging of human Alzheimer's disease-affected brain tissue (https://youtu.be/RqKRSU3fJKY), or human locus coeruleus (https://www.youtube.com/watch?v=GK_FUs6KiIw) and substantia nigra tissues (https://youtu.be/8J150NZa14k). We used this project to establish an optimised workflow for future volume imaging projects. The video format however limits the size of the shared data and does not allow interactive presentation. METHODS AND RESULTS We have worked with tissue samples of the human brainstem nucleus locus coeruleus and optimized iDISCO volume immunostaining protocol and image acquisition strategy for human brain tissue. Furthermore, we developed image processing and cell segmentation workflows using ImageJ. In collaboration with Atomontage, we explored possibilities to share our 3D data using a novel volumetric 3D content-sharing platform. This 3D platform maintains data in its pure voxel form, preserving the integrity of data. The platform is cloud based, allowing more flexible data processing, and generating an efficient sharing of volume data in real time. We explored and visualized various aspects of the locus coeruleus connectivity in the Atomontage platform, such as the complex circuitry and spatial relation of tyrosine hydroxylase expressing neurons. CONCLUSION Voxelized data that is rendered in the cloud allows in-depth analysis, provides a more interactive way for users to investigate 3D data, as well as presents an alternative for sharing movie files. Using voxel rendering will not deform the datasets, and image quantification routines can be built within the cloud environment.

Title: Antigenicity is preserved in mice brains fixed with three different solutions used in human gross anatomy laboratories

Authors: *E.-M. FRIGON[1], M. DADAR[2], D. BOIRE[3], J. MARANZANO[4];
[1]Univ. Du Quebec A Trois-Rivieres, Trois-Rivieres, QC, Canada; [2]Laval Univ., Quebec, QC, Canada;

[3]Univ. du Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada; [4]Univ. du Quebec a Trois-Rivieres, Trois-Rivières, QC, Canada

Abstract: Brain banks are the main source of brain tissue available to researchers. However, a much larger number of specimens could be obtained from gross anatomy labs at a lower cost. These specimens are fixed with different types of embalming solutions appropriate for dissections, but we ignore if they also preserve brain tissue antigenicity. Since the fixation periods of human bodies are long (2-7 months), we applied different fixative solutions on mice brains. The goal was to assess and compare the tissue quality and antigenicity of the main cell populations in mice brains fixed by perfusion with three solutions used for human body preservation. We used six C57BL/6J mice (3 males, 3 females) perfused with: 4% paraformaldehyde (PAF, N=2), saturated salt solution (SSS, N=2) and alcohol solution (AS, N=2). The brains were extracted, cryoprotected, frozen and cut into 40µm sections for histological analysis. The macroscopic and microscopic quality of the tissue were compared. The antigenicity was assessed by immunohistochemistry of five antigens: myelin proteolipid protein (PLP), myelin basic protein (MBP), neuronal nuclei (NeuN), glial fibrillary acidic protein (GFAP) (astrocytes) and ionized calcium binding adaptor molecule1 (Iba1) (microglia). Antigenicity was qualitatively compared and NeuN was quantitatively assessed using an automatic algorithm based on a multi-level filtering approach. The tissue fixed with SSS and AS showed a poorer macroscopic quality than the PAF fixed tissue according to three variables: texture, ease of manipulation and ease of mounting. The SSS and AS slices had a viscous texture, were difficult to manipulate (fragile and adherent) and difficult to mount (not completely displayed on the slide without tears). Microscopically, we assessed quality using two variables: presence of blood vessels and cutting/manipulation artifacts. Both were present in SSS and AS and absent in PAF fixed tissue, reflecting a better quality of the latter. However, all five antigens were present and correctly observable in every specimen, regardless of the fixative solution. Quantitative comparison of NeuN across the three types of fixed tissues showed similar counts (normalized to surface area): 446 (PAF), 434 (SSS) and 478 (AS) in layers 2-3 of the secondary motor cortex. Although these solutions are designed to preserve specimens for dissections, they preserved tissue antigenicity for several brain cell populations and do not alter the number of neurons. Fixation with the PAF-based solution produced sections that were easier to manipulate, with less artefacts. Histological analysis may be applied on human brains from gross anatomy labs and brain banks.

Title: Revising the Nissl stain: reducing hazards and expanding access

Authors: *K. R. URSTADT;
Cognitive Sci., Occidental Col., Los Angeles, CA

Abstract: The Nissl stain is a widely-used standard for delineating the neuroanatomical boundaries and locations of brain regions under brightfield microscopy. However, the accessibility of this classic stain to younger audiences or classrooms with lower budgets has been hindered A) by its potential hazards, B) subsequent expenses required to protect trainees from those hazards, and/or C) expenses from procuring such reagents from a scientific supplier versus local drug stores. In particular, flammable, toxic, irritant, and/or carcinogenic chemicals are typically used in this staining process in regular lab settings. Here, lower hazard and less costly alternative reagents are proposed to replace some or all of those hazardous components. The primary goals were to replace 1) Xylene or chloroform as a defatting/delipidation agent, 2) Acidified 100% ethanol as a differentiating agent, and 3) Permount or DPX as a coverslipping medium. For defatting and differentiation purposes, the following reagents were assessed: 100% ethanol, 91% isopropanol, 0.2% and 10% Triton X-100, 2% dish soap (~0.2-0.6% SDS), and acidic (pH 5.5) water. For coverslipping, polyvinyl alcohol, Karo (corn syrup), medium chain triglyceride oil, and mineral oil were assessed. Stains with these lower hazard reagents were compared against slices from the same brains that underwent traditional Nissl staining, and quantification was performed with colorimetric and overall intensity measurements in ImageJ. Results suggest that A) ethanol, isopropanol, 0.2% Triton, and 10% Triton are effective defatting agents, B) ethanol, isopropanol, 0.2% Triton, and potentially 10% Triton are effective differentiating agents, and C) mineral oil is the most effective non-hazardous coverslipping medium tested. By revealing alternative reagents for performing the Nissl stain, this classic neuroanatomical tool will be more accessible to a wider audience of students and trainees.

Title: Diversifying the Nissl stain's utility as a fluorescent counterstain

Authors: *H. C. PONCE[1], K. R. URSTADT[2], P. A. VIEIRA[3];
[1]Psychology, California State University, Long Beach, Torrance, CA; [2]Dept. of Cognitive Sci., Occidental Col., Los Angeles, CA; [3]Psychology, CSU Dominguez Hills, Carson, CA

Abstract: The Nissl stain is a standard histological method used to identify neural structures and locations within the brain. A lesser-known fact is that this stain can also be used as a red fluorescent counterstain when diluted substantially. However, this method is not always accessible to young scientists or classrooms with tighter budgets due to 1) potential hazards, 2) expenses to provide sufficient protection from said hazards, and/or 3) costs from procuring said reagents from scientific suppliers versus convenience stores. Additionally, the use of certain nonpolar/nonaqueous chemicals in regular Nissl staining makes this stain less compatible with other fluorescent reporters commonly used in neuroscience. Thus, it was imperative to find safer and more fluorophore-compatible alternatives to xylene and chloroform (defatting agents), acidified ethanol (differentiating agent), and Permount and DPX (coverslipping media). Thus, the following reagents were assessed for defatting and differentiation

efficacy: 100% ethanol, 91% isopropanol, 2% dish soap (~0.2-0.6% SDS), 0.2% and 10% Triton X-100, and acidic (pH 5.5) water. For coverslipping, mineral oil was assessed. After applying protocols substituting these reagents and using cresyl violet to stain rat brain sections, those sections were compared against a color-inverted version of Nissl stains from the rat brain atlas. Subjective rankings were performed, assessing similarity of staining intensity, Nissl body contrast from background, and gray vs white matter differentiation. Results suggest that ethanol, isopropanol, and potentially 0.2% Triton and 10% Triton are effective defatting agents, while ethanol, isopropanol, 0.2% Triton, 10% Triton, and acidic water are effective differentiating agents. Interestingly, acidic water may be a gentler differentiating agent compared to others. Although it is non-drying, mineral oil is a comparable coverslipping medium to DPX or Permount. These results show that various lower-hazard reagents can be used to perform Nissl staining, and are likely more compatible with fluorophores commonly used in neuroscience, thus enabling a wider audience of students, trainees, and researchers to use this classic stain.

Title: Performance of an automated multi-level filtering approach to count immunolabeled neurons in the mouse brain

Authors: *M. DADAR[1], E.-M. FRIGON[2], D. BOIRE[3], J. MARANZANO[4];
[1]Laval Univ., Quebec, QC, Canada; [2]Anatomie, Univ. Du Quebec A Trois-Rivieres, Trois-Rivieres, QC, Canada; [3]Anatomie, UQTR, Trois-Rivieres, QC, Canada; [4]Univ. du Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: Histopathology is the Gold Standard assessment to determine the biological substrate of changes taking place in an organ. Quantification of neurons performed either fully manually or assisted by microscopic softwares is a time-consuming task. Our goal was to develop a MATLAB open-source software to quantify neurons in a consistent fashion, comparable to counts performed by an expert rater. The brain of a C57BL/6J mouse perfused with 4% paraformaldehyde was extracted, cryoprotected, frozen and cut into 40µm sections. Neurons were immunolabeled with a NeuN antibody. The sections were photographed (20x magnification) using a DSU Spinning Disk confocal microscope (Olympus BX51W1) coupled to Neurolucida software (MBF Bioscience). The secondary motor cortex (layers 2-3) was chosen as the region of interest (ROI) in left (L) and right (R) hemispheres for this analysis. The automated method counts cells through the following steps: 1-Conversion to grayscale; 2-Multi-level morphological top and bottom hat filtering (disk-shaped structuring element with radius values of 100, 50, 20, and 10 voxels, respectively); 3-Conversion of the filtered image to a binary image using a histogram based

threshold; 4-Separating connected components; 5-Removing components smaller than a minimum acceptable cell size threshold (180 voxels); 6- Splitting components larger than a maximum acceptable cell size threshold (1800 voxels) by repeatedly removing edges from the binary mask and morphologically opening the image; 7-Labeling each separate component as a cell. An expert rater counted the neurons in the ROIs using Neurolucida software (jp2 format) and Display software (minc format). The expert counted 433 (L) and 381 (R) cells on Neurolucida and 446 (L) and 387 (R) cells on Display (within overlapping areas), with 402 and 360 cells co-localizing in the two counts: i.e. 90-93% agreement across softwares. In a second read using Display, the expert counted 489 (L) cells, with 459 cells co-localizing with the first read: i.e. 93% agreement. The automated method counted 504 (L) and 541 (R) cells, compared with expert counts (using Display) of 485 (L) and 461 (R). 430 (L) and 403 (R) cells were detected by both: i.e. 89% and 87% agreement. Our results show that the variability across softwares is similar to intra-rater variability. The automated neuronal counts generated by our new algorithm had an excellent agreement with expert rater counts (similar to intra-rater agreement) and can be used to analyze entire brain surfaces for multiple specimens, a task that would be too time consuming to perform manually.

Title: Morphofunctional mapping of the anterior part of the human thalamus

Authors: *A. SALMA[1,2], C. DÁVID[1,3], L. ACSÁDY[1];
[1]Lab. of Thalamus Res., Inst. of Exptl. Med., Budapest, Hungary; [2]János Szentágothai Doctoral Sch. of Neurosciences, [3]Dept. of Anatomy, Histology and Embryology, Semmelweis Univ., Budapest, Hungary

Abstract: The connectivity between the anterior part of the human thalamus (ATh) and the frontal cortex is crucial for complex cognitive processes. The ATh is also a major target for deep brain neurosurgery in various neurological disorders such as epilepsy, Parkinson's disease or essential tremor. Functionally relevant nuclear segmentation is essential for understanding both healthy and pathological processes of the brain, however, a comprehensive division of the human ATh, based on morphological and biological properties, is still lacking. Our aim in this study was to create a reliable nuclear segmentation of the ATh based on thalamic cell types and afferents using functional neurochemical markers.
We used series of coronal thalamic sections from postmortem brains and performed immunocytochemistry for vesicular glutamate transporter types 1 and 2 (vGluT 1, 2), parvalbumin, calretinin and calbindin. The combination of the selected markers clearly outlined the major nuclear divisions of the human ATh. We also performed quantitative analysis of the density distribution of $vGluT2^{+}$ subcortical afferents to validate our nuclear segmentation. Albeit, the exact position, proportion

and afferentation of particular nuclei differed from the accepted schemes. We found major deviations in the relative position of the two major motor thalamic nuclei receiving cerebellar and basal ganglia afferents and excitatory afferents in the human rostral mediodorsal nucleus was also unexpected. We found that inter-individual variation in nuclear positions is more prevalent than in rodent models. The quantitative analysis of the subcortical afferents showed characteristic intra- and inter-nuclear differences that became the basis for our segmentation.
Our process of using a combination of several neurochemical markers yields a relevant and functionally informative nuclear segmentation which provides a novel understanding of the functions of the thalamic nuclei. Our results indicate nucleus-specific, complex combinations of afferent systems which display both evolutionary conserved and highly derived human features. Further findings, in particular the understanding of inter-individual variation, will provide a uniquely useful perspective for neurosurgical procedures.

Title: Deep phenotype profiling of iPSC-derived neurons with CODEX® multiplexed-imaging

Authors: A. TORRES[1], L. HEINRICH[1], F. ZAFAR[1], M. CHEN[1], J. SINGH[2], C. HEMPEL[2], N. NIKULINA[2], O. BRAUBACH[2], *B. SCHUELE[1];
[1]Stanford Univ. Sch. of Med., Stanford, CA; [2]Akoya Biosci., Menlo Park, CA

Abstract: Human-induced pluripotent stem cell (hiPSC) models have been hailed as a breakthrough for understanding disease and developing new therapeutics. The major advantage of iPSC-derived neurons is, that they carry the genetic background of the donor, and such models could be more predictive for clinical translation. However, these cell models are time-consuming and expensive. It is therefore essential to develop highly multiplexed assays to maximize the readout from these models. Here, we employed a new ultra-high multiplexed immunofluorescence imaging technology CO-Detection by indEXing (CODEX) based on based on the principle of cyclic detection of oligo-conjugated antibodies. We differentiated human iPSCs into mixed neuronal cultures on glass coverslips. We tested and optimized over 30 human antibodies to phenotype these neuronal cultures for neuronal subtypes of cortical, dopaminergic, and medium-spiny neurons, glia including microglia, astrocytes, and oligodendrocytes, and pre- and postsynaptic markers. We show that CODEX can be applied to iPSC culture conditions and developed protocols for the neurons to sustain multiple wash-stain cycles. CODEX is a powerful technique to complement single-cell technologies for in-depth phenotype analysis.

Title: Brain-wide cellular resolution snapshots of neuronal activity with Npas4 and cFos

Authors: *D. G. WHEELER[1,2], C. LO[1], A. MURRY[1], N. GUANZON[1], A. A. KEISER[3,4], M. PETERS[3], M. A. WOOD[4,3], R. AZEVEDO[1,3,4], S. GANDHI[1,3,4];
[1]Translucence Biosystems, Irvine, CA; [2]Activity Signaling, San Diego, CA; [3]Ctr. for the Neurobio. of Learning and Memory, [4]Dept. of Neurobio. and Behavior, UC Irvine, Irvine, CA

Abstract: Recent advances in optical clearing and light sheet imaging have opened an exciting new avenue for brain-wide, cellular resolution immunostaining at the forefront of a dimensional shift from 2D to 3D histology. Providing access to the intricate anatomy of the whole intact brain, new tissue clearing methods can provide neuroscientists with unbiased and complete pictures of brain anatomy and function. With our optimized iDISCO-based clearing methods and our Mesoscale Imaging System for the ZEISS Lightsheet Z.1 microscope, we can image entire mouse brains in ~25 min. Further, our machine learning-enabled 3TK software identifies individual cells throughout the brain and aligns them to the Allen Reference Atlas to produce a regionalized read-out of cellular patterns across 100's of brain areas. We have applied this technology to generate cellular resolution maps of neuronal activity by measuring the immediate-early gene (IEG) products Npas4 and cFos. Expression of cFos is driven by Ca^{2+}-signaling downstream of neuronal activity and is commonly used to mark active neurons. However, cFos expression is also driven by cAMP elevations and signaling pathways engaged by neurotrophins or other paracrine factors. In contrast, Npas4 expression is neuron-specific and tightly tuned to Ca^{2+}-dependent signaling pathways. Using our Npas4 recombinant rabbit monoclonal antibody and a commercial cFos antibody, we developed whole-brain co-staining procedures and performed experiments on mice kept in the dark and exposed to light for various periods of time. After 24 hours in the dark, we found a large number of cFos(+) neurons, yet these same neurons did not express Npas4, suggesting that factors other than neuronal activity *per se* drove cFos expression at baseline. After light exposure, the lower baseline expression of Npas4 supported a much larger fold-change increase in expression than with cFos, where the elevated baseline of cFos(+) cells masked the precise identification of the stimulus-related 'trace'. The fidelity of the Npas4 response allowed our statistical anatomics tools to identify a large number of brain regions, some expected and some not, that had elevated neuronal activity after light exposure. Similarly, in Contextual Fear Conditioning experiments, home cage mice expressed much less Npas4 than cFos,

allowing for more precise monitoring of changes in neuronal activity after context exposure and shock. Our pipeline for brain-wide monitoring of cFos and Npas4 expression allows for high-fidelity monitoring of neuronal activity with Npas4 and also allows for mapping responses to GPCRs or trophic factors by measuring cFos(+)/Npas4(-) neurons.

Title: Sex difference in colorectum innervated mechanosensitive afferents distribution characterized by GCaMP recording in DRGs (SPARC)

Authors: *T. GUO, J. LIU, L. CHEN, Z. BIAN, G. ZHENG, B. FENG;
Univ. of Connecticut, Storrs, CT

Abstract: *Background*: Significant sex difference is present in the clinical symptoms of visceral pain associated with irritable bowel syndrome (IBS): female patients report more intense pain sensation. The gastrointestinal (GI) motility properties also differ in sex with male showing shorter transient time and faster gastric empty. Consistent with the clinic observations, female rats showed a more sensitive and cycle-dependent visceral motor response to colorectal distension. However, very little is known regarding the potential sex differences in the GI neurophysiology. In this study, we implement a high-throughput optical recording approach to detect sensory afferents innervating distal colon and rectum (colorectum) in mice of both sexes. We further assessed the changes of sensory innervation in hypersensitized mice induced by zymosan treatment. *Methods*: Mice carrying GCaMP6f gene were crossbred with VGLUT2-Cre mice. Colorectum with pelvic nerve, lumbar splanchnic nerve, and T12 to S1 dorsal root ganglia (DRGs) from the offspring were dissected out in continuity. DRG neurons in response to colorectal distension and/or shear flow were functionally categorized into 4 classes: muscular-mucosal, mucosal, high- and low-threshold muscular afferents. To induce visceral hypersensitivity, zymosan (30mg/mL, 0.2 mL) was transanally administrated for 3 consecutive days. *Results*: More than 2400 colorectal afferents were recorded from saline- and zymosan-treated mice of both sexes. Within the male group, colorectum has higher proportion of thoracolumbar (TL) innervation (T12, T13, L1, L2) than lumbosacral (LS) innervation (L5, L6, S1). In male mice, zymosan treatment resulted in significant increase in the

proportion of TL innervation and the number of mucosal neurons per mouse in all four TL DRGs. In contrast, female mice showed comparable innervation properties between saline- and zymosan-treated groups. *Conclusion*: Our results have revealed a sex difference in sensory innervation of the colorectum and zymosan induced a significant increase in mucosal populations in the TL pathway in male mice. This current study draws further research on the potential innervation differences between sexes, which could play critical roles in the sex difference in visceral pain and other GI-related symptoms.

Title: Precise Spatial Multiplexing for Neuronal Cell Profiling in Mouse Brain Fresh Frozen Tissue with ChipCytometry

Authors: A. J. NORTHCUTT, A. PANDITA, C. WINKELER, M. TYLER, T. CAMPBELL, *K. GAMBER, E. WEINSTEIN;

Abstract: Understanding the spatial distribution of key neuronal cell populations is critical in advancing our understanding of disease to inform the development of novel therapeutics. Here we present the analysis of fresh frozen (FF) tissue samples from mouse brain using a novel precise spatial multiplexing technology called ChipCytometry, which combines iterative rounds of targeted fluorescent staining with high dynamic range imaging to facilitate quantitative phenotyping with single-cell resolution. Standard FCS files are generated from multichannel OME-TIFF images, enabling identification of cellular phenotypes via flow cytometry-like hierarchical gating. In this study, a 13-plex assay was used to identify and quantify relevant cellular phenotypes and subtypes for neurobiology and neuro-oncology applications. The results show precise expression levels for each marker in the assay in each individual cell in the sample, while maintaining spatial information about each cell. Spatial analysis of the samples reveals neuronal cell heterogeneity including clusters of microglia and cholinergic neurons in a region rich with glutamatergic neuronal cells, demonstrating the utility of the ChipCytometry platform for the in-depth cellular profiling of mouse FF tissue samples.

Title: A comparison of tissue clearing techniques for high-resolution imaging of the cortical vasculature

Authors: *M. MATOSSIAN, A. BORTEL, D. THOMMANA, V. M. MOCANU, A. SHMUEL; McGill, Montreal, QC, Canada

Abstract: Introduction To gain a clear understanding of the mechanisms underlying Blood Oxygenation Level-Dependent functional magnetic resonance imaging in the brain, we need to quantify the structural organization and density of blood vessels. The goal of our current project is to compare and optimize methods of in-vivo labeling of the vasculature and tissue clearing for obtaining high-resolution images of vessels in the neocortex. We compare the aqueous solution-based tissue clearing method 'Clear, Unobstructed Brain/body Imaging Cocktails" (CUBIC) to the organic solvent-based clearing method 'three-dimensional imaging of solvent-cleared organs' (3DISCO) and its variant, iDISCO+. Methods We cut 3 mm thick coronal slabs of the mouse brain. We intracardially inject wheat germ agglutinin Alexa Fluor before perfusion. Next, we incubate our samples into a series of solutions to achieve transparency. Finally, we image our samples using the Opera Phenix microscope, a spinning disk confocal that allows screening multiple samples in one imaging session with the use of multi-well plates. Results Organic solvents clear the brain significantly faster than CUBIC-related solutions. Using the two DISCO methods, it takes 3 ± 1 days to have optically transparent mouse brain slabs. With CUBIC, it takes 32 ± 10 days. CUBIC introduces variations in clearing duration as a function of tissue thickness and animal age. Clearing a 3 mm thick slab takes 8 ± 3 more days relative to a 2 mm thick slab for a mouse of a same age. The clearing duration increases with increasing age of the mouse. Based on our Opera Phenix images, we can obtain homogenous vasculature labelling throughout the cortex. Finally, we noticed, qualitatively, that iDISCO+ provides greater signal to noise ratio compared to the two other methods.

Title: A red fluorescent protein-based calcium indicator to study rapid calcium dynamics in the endoplasmic reticulum

Authors: *K. BERGLUND[1], X. DENG[2], M. A. STERN[1], X.-Q. YAO[2], B. DONG[2], D. OUEDRAOGO[2], M. A. GHANE[2], Y. ZHUO[2], C. MCBEAN[2], Z. Z. WEI[1], S. GOZEM[2], S. P. YU[1], L. WEI[1], N. FANG[2], A. M. MABB[2], G. GADDA[2], D. HAMELBERG[2], R. E. GROSS[1], J. J. YANG[2];

Abstract: Calcium indicator proteins are versatile and indispensable tools for cell type-specific and subcellular imaging in the biomedical field, especially in neuroscience. Here we report a novel calcium indicator, R-CatchER, engineered from a red fluorescent protein that targets the endoplasmic reticulum (ER). Unlike conventional calcium indicator proteins, R-CatchER does not utilize the EF-hand motif as a calcium sensing mechanism. Instead, a single calcium binding site was engineered within the scaffold of RFP near the chromophore through point mutations and molecular dynamics simulation. *In vitro* characterization of the recombinant protein confirmed one-to-one binding stoichiometry and showed that the new indicator had affinity and kinetics suitable to study rapid calcium dynamics in the ER. When transiently expressed in primary cortical neurons in culture, R-CatchER showed proper targeting in neuronal ER. We quantified ER calcium responses to electrical stimulation as well as activation of metabotropic glutamate receptors in different compartments of neurons. R-CatchER was sensitive to reveal an ER calcium transient to a single electrical stimulus and its red-shifted spectrum allowed for simultaneous monitoring of cytosolic calcium through commonly used calcium-dependent green/yellow fluorescent proteins, such as jGCaMP7s and XCaMP-Y. We further developed a recombinant adeno-associated viral vector to express R-CatchER and XCaMP-Y in the same neurons *in vivo*. Two-photon imaging in the mouse motor cortex revealed fluctuations of ER calcium in awake animals during locomotion. Thus, R-CatchER provides unique opportunities to study ER calcium dynamics quantitatively in neurons while leaving green/yellow spectra for different imaging purposes.

Title: An updated suite of viral vectors for in-vivo calcium imaging using local and retro-orbital injections

Authors: *S. GRØDEM, I. NYMOEN, G. H. VATNE, V. BJÖRNSDOTTIR, K. LENSJØ, M. FYHN;
Univ. of Oslo, Oslo, Norway

Abstract: Calcium imaging using genetically encoded Ca2+ indicators (GECIs) is a widely adopted method to measure neural activity in modern neuroscience. Here, we explore the use of systemically administered viral vectors for brain-wide expression of GECIs, and adapt novel GECIs to optimize signal-to-noise. We show that systemic injections of PHP.eB AAVs to express GECIs is a highly promising technique for imaging neural activity and circumvent the need for transgenic GECI expressing mouse lines. We also establish the use of novel soma-targeted GECIs that outperform current Ca2+ indicators using both systemic and local virus injections.

Title: Electroporation as a noninvasive method for loading neurons with calcium indicators in the gastropod mollusk Berghia stephanieae

Authors: J. W. BROWN, E. S. HILL, W. N. FROST;
Ctr. for Brain Function and Repair, Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: With central nervous systems comprising on the order of 10,000 large, often identifiable neurons, gastropod mollusks represent attractive systems for large-scale activity imaging, in which the

correlations between brain and behavior can be readily interrogated and manipulated at the level of individual neurons and complete neural circuits. Although absorbance voltage-sensitive dyes (VSDs) have proven profitable in imaging simultaneous activity in dozens to hundreds of gastropod neurons over extended periods of time and can be loaded through simple bath application, these indicators are not ideal for smaller-diameter neurons due to their low signal-to-noise ratios. Other activity indicators, including certain fluorescent VSDs and AM ester calcium dyes, generate more intense signals in smaller neurons but may require surgical intervention for loading, including the de-sheathing of ganglia or pressure injection of dye into the neuropil. Here, we present two variations of a noninvasive dye-loading protocol, involving electroporation of the charged calcium indicator Cal-520 potassium (Cal-520-K; AATBioquest) directly through the tissue sheath overlying the isolated CNS of the aeolid nudibranch *Berghia stephanieae*, the subject of an NIH BRAIN Initiative project. In one iteration of our method, *Berghia* neurons are individually electroporated by placing a 1-µm-tipped electrode loaded with 5-55 mM Cal-520-K against the overlying ganglionic sheath and generating a high-frequency pulse train (50 Hz/7 s trains with 5 ms/-25 V pulses) using a pulse stimulator. We have furthermore had preliminary success bulk-loading Cal-520-K into over a dozen neurons simultaneously: after briefly proteasing the brain, it is placed into a customized chamber between two Ag/AgCl electrodes, immersed in a 5 mM solution of Cal-520-K, and electroporated (1-2 Hz, 5-7 s trains with 50-100 ms/15-30 V biphasic pulses). Following a recovery period of 45-90 minutes, preparations loaded via both methods are imaged using widefield fluorescence microscopy. This approach has been used to record spontaneous action potential activity from neuronal somata as small as 10 µm in diameter. Additional experiments involving simultaneous calcium imaging and sharp-electrode intracellular recordings of neurons in the abdominal ganglion of *Aplysia californica* individually electroporated with Cal-520-K have moreover demonstrated a one-to-one correspondence between calcium transients and action potentials in tonically firing neurons driven at rates up to ~9 Hz. Higher firing rates result in fusion of the calcium signal into a smooth parabola useful for detecting bursts of activity.

Abstract: In many brain areas, neural populations act as a coordinated network whose state is tied to behavior on a moment-by-moment basis and millisecond timescale. Two-photon (2p) calcium imaging is a powerful tool to probe network-scale computation, as it can measure the activity of individual neurons, sample from multiple layers simultaneously, and sample from identified cell types. However, estimating network states and dynamics from 2p measurements has proven challenging. Here we present the Recurrent Autoencoder for Discovering Imaged Calcium Latents (RADICaL), a deep learning method to precisely infer network dynamics from 2p measurements. RADICaL builds on AutoLFADS - a state-of-the-art method for modeling neural dynamics from spiking activity - for application to deconvolved calcium signals, whose statistics and temporal dynamics are quite distinct from electrophysiologically-recorded spikes. In particular, we developed a novel network training strategy, selective backpropagation through time (SBTT), which allows recovery of network dynamics with substantially higher temporal precision than previously possible. SBTT enables training neural networks at sub-frame temporal resolution by accurately accounting for the differences in the sampling times of individual neurons caused by 2p laser scanning. In synthetic tests, RADICaL inferred network states with higher fidelity than current state-of-the-art methods, particularly for high-frequency components (e.g., a 2-5x increase in accuracy for 15 Hz signals with 33 Hz frame rate). When applied to 2p recordings from motor and somatosensory cortical areas in mice performing a water grab task, RADICaL de-noised individual neurons' responses on single trials and produced estimates of neural population states that closely corresponded to single-trial variations in reach kinematics. The de-noised representations led to substantially higher performance in decoding the mice's paw position and velocity on a moment-by-moment basis (~1.5-2x improvement). Taken together, these results demonstrate that RADICaL infers network states from 2p imaging data with unprecedented accuracy and temporal resolution, which is valuable for understanding how population activity is linked to ongoing behavior on a moment-by-moment basis.

Title: Identify the sampling rate contribution to the Ca^{2+} temporal dynamics detected by fiber photometry

Authors: Y. JIANG, S. GHIASVAND, B. ZHANG, *X. YU;
Massachusetts Gen. Hosp., Charlestown, MA

Abstract: In contrast to the conventional optical imaging methods, fiber photometry enables the detection of Ca^{2+} transients in a similar temporal scale of local field potential (LFP) spikes, providing a powerful surrogate of in vivo electrophysiological recordings with simultaneous functional MRI. A critical issue has been raised when comparing the slow calcium responses acquired at the sub-second sampling rate by optical imaging methods with the fast Ca^{2+} transients with fiber photometry over 1kHz. **Methods:** we recorded the fiber photometry-based Ca^{2+} transients at different sampling rates with simultaneous LFP. **Results: Fig. 1A** shows representative calcium traces at 39 and 5k Hz and simultaneous LFP spikes upon stimulation. The averaged calcium transients demonstrated comparable amplitudes in trials with different sampling rates but with increased variation at the lower sampling rate (**Fig. 1B)**. Importantly, the contrast-to-noise ratio (CNR) showed the lowest values in the trial with a 39 Hz sampling rate (**Fig 1D**), of which a monophasic slow response was represented across the 3 stimulation-on period (**Fig 1C**). **Conclusion**: This work offers a thorough analysis of sampling rate contribution to different temporal dynamics of Ca^{2+} transients detected by fiber photometry. The monophasic slow Ca^{2+} response acquired at 39Hz raises a critical issue when interpreting the slow dynamics of recorded Ca^{2+} events from individual neurons or neuronal ensembles detected by conventional optical imaging methods with a 20-40 frame rate.

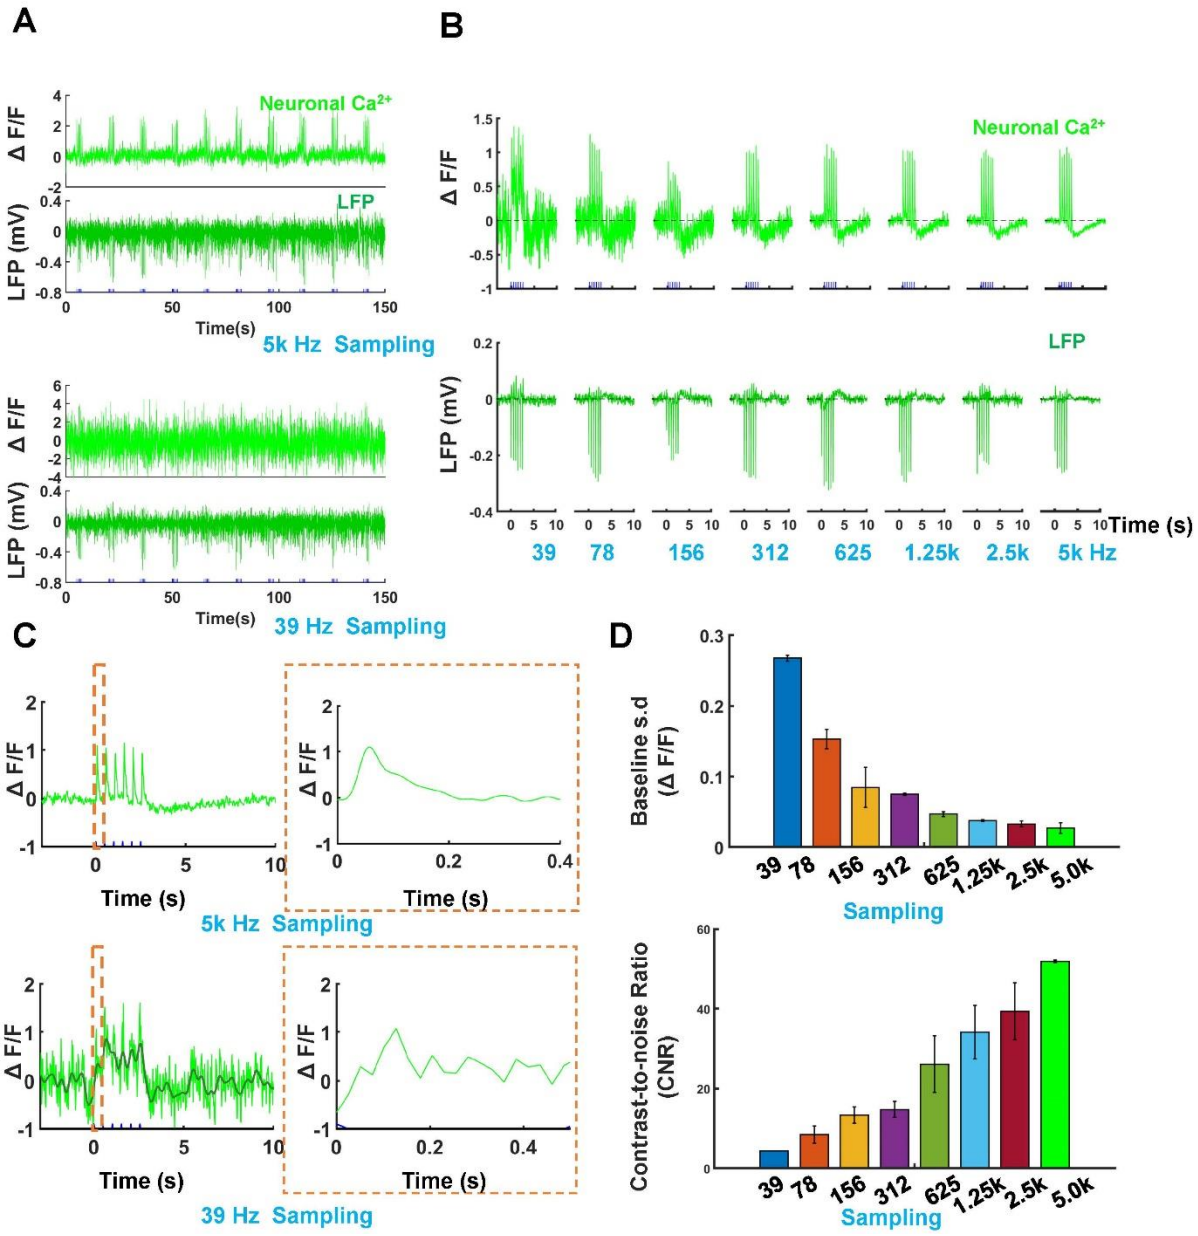

Figure 1. Characterizations of fiber photometry of neuronal Ca^{2+} responses acquired at different sampling rates. (A) The representative time course of neuronal Ca^{2+} signal acquired at 5000 and 39 Hz with simultaneous LFP. (B) Temporal features of one epoch sensory response at different sampling rates. (C) A zoomed-in view onto the initial seconds, exhibiting different neuronal Ca^{2+} transients. The dark green curve overlaid on the 39 Hz sampling (2 Hz low pass filter). Title: Custom-address serial holography for the measurement of spike correlations between neurons in mouse visual cortex

Authors: *W. AKEMANN[1], S. WOLF[2], V. VILLETTE[2], C. VENTALON[2], J.-F. LÉGER[2], S. DIEUDONNÉ[2], L. BOURDIEU[2];
[1]IBENS, École Normale Supérieure, Paris, France; [2]IBENS, Ecole Normale Supérieure, Paris, France

Abstract: Custom-address serial holography (CASH) is a new method for optical recording of indicator-reported neuronal activity in 3D cortical volumes at high speed *in-vivo*. Our current implementation allows random address sampling of 20 cells at 1 kHz up to 200 cells at 0.1 kHz in head-fixed behaving mice across a cortical space of 500 x 500 x 500 mm^3 size. Using fast acousto-optic spatial light modulation, every single laser pulse of a 40 kHz regenerative amplifier is individually patterned to serially address a selection of target cells with a square 5x5 spot excitation volume covering the cell body and, for the prevention of recording artefacts, the surrounding space in anticipation of the cell displacements during animal behavior. The recorded activity is corrected for neuropil signaling component by weighted subtraction of a neuropil reference signal obtained by interleaved sampling of neuropil activity close to each cell. We performed 3D-CASH recordings of GCaMP6f expressing neurons in layer 2/3 and 5 of mouse primary visual cortex in response to moving contrast gratings and applied MLspike and blind sparse deconvolution to estimate spike events. Pairwise correlation was higher between neuron pairs in the same layer versus neuron pairs in different layers. Principal component analysis of the correlation matrix revealed a principal component assigning weights of opposite sign to neurons in layer 2/3 versus layer 5. Furthermore, closest follower spikes occurred with higher probability in a neuron of the same layer than neurons located in a different layer with a mean latency of 17±60 ms. Following the temporal periodicity of the stimulus, the spike rate of the response features a phasic component (R_1) together with a non-phasic component (R_0). Measured R_1/R_0 values are broadly distributed with weak bimodality resembling the transition between pure non-phasic response of neurons with complex receptive field to phasic response of neurons with simple receptive field. Our data validate 3D-CASH as a method for assessing neuronal activity in small 3D-distributed cortical circuits at high sampling rate.

Title: Development of a Photonic crystal fiber (PCF)-based fiber photometry for multi-channel cellular-specific recording

Authors: *Y. JIANG[1], M. FROSZ[2], X. YU[1];
[1]Massachusetts Gen. Hosp., Charlestown, MA; [2]Max Planck Inst. for the Sci. of Light, Erlangen, Germany

Abstract: Given its MR compatibility and fast sampling of Ca^{2+} transients in millisecond scale, fiber photometry presents a powerful surrogate of *in vivo* electrophysiology when combining with fMRI to decipher the neuro-glio-vascular (NGV) coupling events. However, it remains challenging to distinguish NGV signaling at deep brain regions using fiber photometry. Here we proposed to develop a photonic crystal fiber (PCF) array-based multi-channel recording system, enabling the detection of cell-specific neuronal signals (e.g. GCaMP-based Ca^{2+} or GluSnFR-based Glutamate) from local NGV circuit. The PCF array has interleaved solid and hollow cores, allowing the optical signal transmission with little interference from adjacent ones using a light path designed in-house (**Fig 1A**). Each solid core has a diameter of 8-10 microns, matching the size of the neuronal soma, and the total PCF array tip covers cellular ensembles in a 250x250 μm^2 area. Here, we recorded the cellular specific neuronal signal using an sCMOS camera with ~1K sampling rate. In this work, we showed the multi-channel recording of the glutamate signals in the infragranular layer of the cortex. As shown in **Fig 1B**, the evoked Glu spikes can be detected from multiple solid cores through 36 channels upon forepaw electrical stimulation. In particular, we are detecting the different temporal dynamics of the evoked Glu signals from individual cores (e.g. Fig 1B, core 1, 7, 35), indicating the cellular-specific recording capability of the PCF-based imaging device. In summary, different from conventional fiber bundles, the PCF array enables multi-channel ultrafast cellular recording significantly reduces cross-talk, providing a unique recording device to measure distinct signaling events in the local NGV circut.

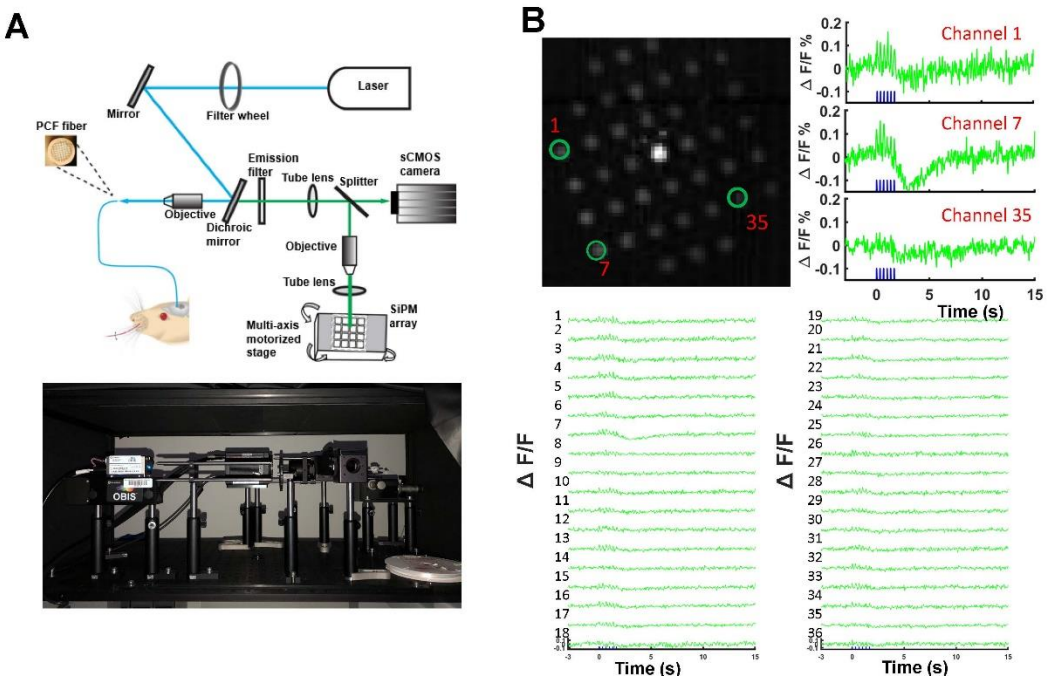

Figure 1. Multi-channel recording of Glu signal with PCF array. (**A**) The PCF-based imaging scheme and setup with 36 channels for in vivo parallel imaging. (**B**) The evoked Glu spikes from three channels (1, 7, 35) were represented to show the different temporal dynamics upon electrical stimulation of the forepaw (3 Hz, 2 s, 2mA).

Title: Dual color imaging in freely-behaving rodents using a head-mountable one photon miniscope.

Authors: *G. RIZZI, S. GULATI, K. ZITELLI, A. STAMATAKIS;
Inscopix, Palo Alto, CA

Abstract: We have developed a miniscope platform nVueTM that enables dual color imaging in freely-behaving rodents, thus greatly expanding the current range of in vivo imaging applications. The nVue system enables numerous applications, including simultaneous imaging of Ca2+ activity in two distinct populations of cells, imaging Ca2+ activity with static markers that can identify neurons based on projection, activity, or genetics, and imaging Ca2+ activity alongside blood flow. To enable dual color imaging, we have integrated two separate LEDs into the miniscope to image green and red indicators

without crosstalk. To correct for chromatic shifts in green and red focal planes, we have also developed novel GRIN lenses that minimize axial chromatic aberrations. Furthermore, we use electronic focusing capabilities of our miniscope to automatically correct for any residual color aberration. We have also developed an analysis algorithm that enables detection of colocalized red and green cells. We have performed a rigorous characterization of the miniscope performance on the benchtop and in vivo. To validate several features of this miniscope, we imaged medial prefrontal cortical neurons expressing GCaMP in addition to the contralaterally-projecting neurons labeled with TdTom using a novel retrograde transport agent (rAAV2-retro-CAG-tdTomato). Using this preparation, we have validated that we are able to 1) correct for chromatic aberrations in vivo to merge the red and green channels and, 2) register the co-localized neurons as a subset of projection-specific neurons.

Title: High throughput screening using QPatch II and Qube 384 systems: electrophysiological evaluation of primary neurons, glial cells and hiPSC-derived motor neurons

Authors: *B. BADONE, K. BODDUM, K. R. ROSHOLM;
Sophion Biosci. A/S, Ballerup, Denmark

Abstract: The QPatch II and Qube 384 are two automated patch-clamp (APC) systems useful for evaluating the electrophysiological properties of different cell models, with the possibility to perform high throughput compound screening for drug discovery. These systems provide high fidelity recordings which in combination with accurate, low volume applications, make them ideal for studying both voltage- and ligand- gated ion channels. With a rapidly increasing number of ion channels identified as potential therapeutic targets in neurological diseases, there is an urgency of finding valid neuronal cell models. Among these, primary brain cells and human induced pluripotent stem cells (hiPSCs)-derived neurons are promising physiological models for evaluating ion channels properties and potential drugs. Here we used our APC systems for studying both voltage-gated (Na_V, K_V) and ligand-gated ($GABA_A$) ion channels by comparing two different brain models: *i)* primary neurons and astrocytes dissociated from mouse and rat brains, respectively; and *ii)* hiPSC-derived motor neurons. Patch-clamp recordings require healthy membranes for high resistance sealing; however, different isolation methods may alter the membrane composition and change intracellular characteristics. Here we demonstrate that the electrophysiological properties of both brain cell models are maintained during APC recordings, confirming that both QPatch II and Qube 384 are powerful platforms for investigating brain cell models.

Abstract: Intracortical facilitation (ICF) is a common paired-pulse transcranial magnetic stimulation (TMS) measurement used to quantify interneuron activity in the primary motor cortex (M1). Due to the prevalence of the technique, most of the stimulation parameters to optimize quantification of ICF have been established. However, the underappreciated methodological issue of the time between MEP trials (inter-trial interval; ITI) has been rarely reported, unstandardized, and different ITIs have never been directly compared in a paired-pulse TMS study. This is important because a previous single-pulse TMS study found MEP amplitude reductions during the course of TMS trial blocks for short ITIs of 5 seconds and below, but not for a long ITI of 10 seconds (Julkunen et al. 2012). Similar overall effects of short and long ITIs were reported by (Moller et al. 2009) during the measurement of single-pulse recruitment curves. The purpose was to determine the influence of different ITIs on the measurement of ICF at rest. Sixteen young men and women completed a single experimental session. Surface EMG was recorded from the first dorsal interosseous (FDI) muscle of the right hand in response to TMS of the left M1. Each experiment involved: 1) resting motor threshold (RMT) quantification; 2) identification of the TMS intensity required to elicit a 1 mV MEP with a 10 second ITI; and 3) 4 separate ICF trial blocks presented in randomized order with each block utilizing one of 4 different ITIs (4, 6, 8, and 10 seconds). Each ICF trial block involved 52 trials (26 single-pulse MEP trials and 26 condition-test trials). ICF was always evoked using a 10 millisecond interstimulus interval, a conditioning stimulus intensity of 90% of RMT, and a 1 mV test stimulus intensity. The primary outcome was the amount of ICF (% facilitation). One-way ANOVAs indicated no significant differences in test MEP amplitudes ($P = 0.992$), conditioned MEP amplitudes ($P = 0.94$), and therefore ICF between the 4 ITIs ($P = 0.477$). The findings of this methodological study indicate that ITIs between 4-10 seconds provide nearly identical ICF values. Based on these results, it is recommended that an ITI of 4 seconds be utilized for quantification of ICF to optimize participant and investigator comfort as well as the time efficiency of TMS experiments.

Title: Adaptamaze adaptable and automated rodent behavior maze system

Authors: *J. OLSON[1], C. A. LEPPLA[1], J. H. BLADON[1], S. P. JADHAV[2];
[2]Psychology, [1]Brandeis Univ., Waltham, MA

Abstract: Mazes are a fundamental and widespread tool in behavior and systems neuroscience research due to rodents' natural proclivity to navigate towards rewards. Beginning in the early 20th century (Small, 1901), navigation experiments have uncovered landmark discoveries in learning & memory (Tolman et al., 1946) and its neural substrates (O'Keefe & Dostrovsky, 1971; Olton & Samuelson, 1976). Today, unique mazes are designed to test specific questions in these fields (Ainge et al., 2007; Böhm & Lee, 2020; Knierim et al., 2000; Nitz, 2006; Olson et al., 2017; Porter et al., 2018; Steiner & Redish, 2014; Tanila et al., 2018; Wilson et al., 2015), and standard maze designs are pervasive and underlie foundational tasks in learning and memory, decision-making, and even anxiety (e.g. Barnes, 1979; Frank et al., 2000; Handley & Mithani, 1984; Morris et al., 1982; O'Keefe & Dostrovsky, 1971; Olton & Samuelson, 1976). Facilitated by advances in neural data recording capabilities and machine learning analytical techniques, increasingly complex behavioral paradigms that include multiple environments are desired to investigate contextual memory and representations, spatial remapping, and adaptive decision making.

Unfortunately, current maze designs often limit potential experimental configurations. For simple or standardized designs, each maze is frequently one static piece with limited flexibility for configuration. This approach requires separate mazes to be made, stored, and positioned for any multi-environment recording. The demand on space and their inflexibility limits potential experiments. Alternatively, trainee scientists will spend months learning engineering skills to design and build complex, automated mazes to address a specific question. Despite the time invested, these mazes are rarely capable of flexible changes into novel maze configurations, and so the same cost in design and manufacturing recurs for each experiment.

To alleviate these issues, we developed an automated modular maze system to create flexible and scalable maze environments. The maze can be formed into multiple configurations in minutes. Reward wells integrated into the track pieces enable automated lick detection and reward delivery. Automated barriers can be placed between any track components, allowing additional environmental manipulations during a behavioral session. This maze system enables novel behavioral and neurophysiology experiments without the time and monetary costs that come with custom behavioral track design and with greater reproducibility and repeatability, potentially leading to greater advances in rodent behavior and neurophysiology knowledge.

Title: An improved system for simultaneous transcranial magnetic stimulation and single-unit recordings in non-human primates

Authors: *R. KOTHARE, S. M. GOETZ, R. HAMDAN, B. WANG, W. M. GRILL, A. V. PETERCHEV, M. A. SOMMER;
Duke Univ., Durham, NC

Abstract: Transcranial magnetic stimulation (TMS) is an FDA-cleared, non-invasive form of neuromodulation. While its effects in the human brain have been assessed at the macroscopic level (e.g. EMG, EEG, fMRI), there is a lack of understanding of finer-scale responses on the neuronal circuit level, and this limits the rational design of therapeutic TMS protocols. We aim to quantify the neuronal effects of TMS through single-unit recordings in the target region of stimulation in awake macaques. One of the main challenges of simultaneous recording during TMS is the presence of large, electromagnetically induced artifacts that hinder the isolation of small neuronal signals. We previously developed an electrophysiology system capable of resolving action potentials shortly after TMS pulses (Mueller et al. 2014). To improve on that system, which required manual tuning of artifact cancellation and used components that are now obsolete, we developed an updated, three-stage amplifier system that is more robust, automatic, and offers short recovery times after a pulse. To reduce capacitive coupling between the TMS coil and the recording system, we adapted a method from Li et al. (2017) involving the application of a grounded conductive coating to the coil. We also developed a low-inductance input connection that mitigates the inductive TMS artifact in the electronics, decreases leakage current into the brain, and reduces variability of the artifact across experiments better than the previous input connection. Additionally, we assessed the performance of three electrode materials - tungsten, platinum-tungsten, and platinum-iridium - with our system. Lastly, we developed post-processing methods to isolate better action potentials from the recorded signal. Overall, we present a new system capable of resolving neural signals within ~1-2 ms after the TMS pulse and reproducible for use in other laboratories.

Title: High throughput electrophysiological screen of large molecules: evaluating snake neurotoxins and the neutralization potential of recombinant antibodies

Authors: *K. BODDUM[1], L. LEDSGAARD[2], M. BUSK[1], D. BELL[1], A. H. LAUSTSEN[2];
[1]Sophion Biosci., Ballerup, Denmark; [2]Dept. of Biotech. and Biotherapeutics, Tech. Univ. of Denmark, Kongens Lyngby, Denmark

Abstract: Currently, more than 90% of approved drugs are small molecules, but large molecules (> 1.000 Da, also known as biologics) are rapidly rising in prominence and importance in drug discovery and already constitute the lion's share of top 10 selling drugs worldwide.
Large molecules have gained attention due to their mode of action, often achieving greater target specificity and potency than small molecule drugs. This, however, comes at a cost: often, they are expensive and scarce and can have unwanted polyreactivity ("stickiness"). In addition, they are more sensitive to their environment, as their three-dimensional structure is key to their function and relies on other, weaker interactions than covalent bonds. Two automated patch-clamp (APC) systems, QPatch II and Qube 384, have long been used in advancing drug discovery on ion channels, developing much-needed novel treatments, including large molecules targeting ion channels. Using APC, we have evaluated two groups of α-neurotoxins (7-8 kDa) and IgG antibodies (150-170 kDa).
Method
Snakebite is a highly neglected tropical disease, causing 100,000 yearly deaths and around 400,000 amputations. Each snake species has a unique venom, consisting of several dozen different toxins. One of the most medically relevant groups of snake toxins is α-neurotoxins, targeting the nicotinic acetylcholine receptor (nAChR). Evaluating the potential of recombinant monoclonal antibodies (mAbs) in the IgG format to neutralize α-cobratoxin (an α-neurotoxin from *Naja kaouthia*) and thereby prevent the inhibition of the nAChR response, planar whole-cell patch-clamp experiments were carried out on QPatch II, briefly: The human-derived Rhabdomyosarcoma RD cell line, endogenously expressing the muscle-type nAChR was patched, and the inhibitory effect of α-cobratoxin was evaluated, followed by a study of the concentration-dependent neutralizing effect of seven different IgGs. Next, the Qube 384 was employed for combinatory screening of both neutralizing potential and toxin cross-reactivity. In total, six different α-neurotoxins from four different elapid snake species were tested against 15 different IgGs.
Conclusion
The study demonstrated the potential of a range of IgGs to neutralize α-neurotoxins from several snake species. This is a critically important step toward enabling the design of novel, broadly-neutralizing recombinant antivenoms against snakebite envenoming. This work highlights the potential and advantages of using high-throughput electrophysiology systems to evaluate the functional activity of two large molecules, in this case, protein-based toxins and antibodies.

Title: Towards the perfect pipette: manufacture and reuse of high gigaseal, low noise electrodes for patch clamp electrophysiology

Authors: *M. C. YIP[1], C. R. LANDRY[2], M. M. GONZALEZ[1], C. R. FOREST[1];
[1]Woodruff Sch. of Mechanical Engin., [2]Wallace H. Coulter Sch. of Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Reuse of intracellular patch clamp electrodes was thought to be impossible due to accumulation of cellular debris in and around the tip of the electrode during patch clamp processes. However, in recent years, this fundamental limit of patch clamping has been overcome by trailblazing studies using detergents and oxidizers to remove cellular debris from the one micrometer diameter electrode aperture enabling immediate reuse in both single pipette and planar patch configurations. The innovation of cleaning a pipette has enhanced patch clamp automation such as the PatcherBot, an artificial intelligence-guided robot capable of performing 10-12 patch recordings per hour in cultured cells slices without human intervention. We have previously demonstrated that this technique can successfully clean and reuse a pipette over 100 times, and while such advances are noteworthy, all patch clamp experiments are limited by the original quality of the pipette and the need to constantly manufacture replacements. Improvements toward making the perfect pipette have been documented including the use of quartz electrodes for significantly low-noise recordings and the nano-machined tips of pipettes using focused ion beam (FIB) milling for high-resistance (>3 GΩ) junctions (or gigaseals) with the cell membrane. While fabricating these pipettes are laborious and time-consuming, the technology of cleaning pipettes enables greater efficacy and utilization out of each pipette. Here, we present an extension of the method for cleaning pipettes that enables re-uses towards perfect pipettes with no measurable change in yield or recording quality. Specifically, we will demonstrate cleaning of low-noise quartz pipettes and high gigaseal FIB-milled pipettes and show time-based scalability of pipette reuse by storing and reusing pipettes overnight (patch with the same pipette 10-12 hours later). This technology development will raise the high-quality recording capabilities of patch clamp electrophysiology, enabling repeatable high throughput experiments across neuroscience that can be readily adapted to fields ranging from *in vitro* phenotypic screening to single ion channel pharmacological screening.

Title: Morpho-electric classification of single neurons in intact brain organoids

Authors: *C. R. LANDRY[1], W. NUI[3], Z. WEN[3], C. R. FOREST[2];
[1]Wallace H. Coulter Dept. of Biomed. Engin., [2]George W. Woodruff Sch. of Mechanical Engin., Georgia Inst. of Technol., Atlanta, GA; [3]Dept. of Psychiatry and Behavioral Sci., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Human brain organoids have been shown to contain a diverse range of cell types representative of the developing human brain. Understanding the diversity of these cell types in terms of structure, function, and genetics is critical for understanding human neurodevelopment. However, current cell type classification methods in brain organoids rely on RNA-seq and immunohistochemistry, in part because of the technical challenges and low throughput associated with patch clamp electrophysiology. Using fully automated and semi-automated methods developed in our laboratory to perform patch clamp recordings in large, intact human brain organoids, we are working to fills the gaps in cell type classification in human brain organoids. To this end, we have developed a pipeline to collect electrophysiological and morphological data from single brain organoid neurons without disrupting the fine neuronal structure or local synaptic network. To demonstrate the utility of this approach, we will show **1)** semi-automated patch clamp recordings of deep neurons from mature human brain organoids (i.e., 120 days in vitro), **2)** morphological reconstruction of deep neurons using biocytin-based labeling, **3)** and whole-mount imaging of intact brain organoids using CUBIC tissue clearing. Using this initial dataset from dozens of mature, intact human brain organoids, we will propose approaches for integrating morphological and electrophysiological cell types into current cell type models for human brain organoids.

Title: Fully automated fluorescence-guided patch clamp for cell type-specific electrophysiology in adult mouse cortex

Authors: *M. M. GONZALEZ[1], A. M. GOETTEMOELLER[2], M. J. M. ROWAN[2], C. R. FOREST[1];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Emory Univ., Atlanta, GA

Abstract: Recently, single-neuron RNA sequencing has allowed for the identification of an incredible diversity of neuronal cell types in the cortex. Characterizing the distinct electrophysiology of these cell types is an important step toward understanding the physiological properties across all cortical regions. Patch clamp electrophysiology enables the recording of single-cell behavior with unrivalled spatiotemporal resolution. While patch clamp can yield high fidelity electrophysiology data, the process is often challenging and time-consuming. Even with the development of automated patch clamp systems, many of these approaches cannot independently select and patch cells based on cell type. To enable targeted electrophysiological profiling of neurons in the cortex, we developed a fully automated, fluorescence-guided patch clamp electrophysiology rig which targets distinct cell types in ex vivo acute slices. By employing newly developed deep learning-based image processing methods and cleaning the patch pipettes for immediate reuse, the automated patch clamp robot could identify and patch 20 labeled GABAergic interneurons expressing green fluorescent protein from a single mouse, achieving quality of recording equivalent to a patch-clamp expert. The process reduces the time to patch and can be scaled to target other cell types by injecting multiple AAVs, using transgenic mice, and using additional filter cubes to filter different spectra. This advancement in automated patch clamp will enable a more efficient and robust characterization of neuronal behavior by programmatically targeting different cell types within the same slice while reducing the amount of time necessary to acquire high fidelity data.

Title: How much error is in your spiking data? Quantifying errors in spike sorting with ground truth.

Authors: *L. M. F. KLAVER, E. AKBAR, R. C. BULLINS, K. C. ARNDT, E. T. GILBERT, D. F. ENGLISH;
Sch. of Neurosci., Virginia Tech., Blacksburg, VA

Abstract: Mammalian brains encode information in the spiking activity of populations of neurons. To study population coding in behaving animals, spikes from ensembles of hundreds of neurons can be recorded with extracellular electrodes and assigned to their source neurons using spike sorting.
For decades, one problem has reduced the rigor and reproducibility of spike sorted data: it has been impossible to meaningfully quantify sorting accuracy because of insufficient empirically validated data, termed ‘ground truth’. Ground truth data for spike sorting consist of extracellular recordings in which a subset of neurons are also recorded with a second, unambiguous technique, such as a glass electrode.

Ground truth data are essential for quantifying spike sorting performance and developing automatic spike sorters to replace manual methods which are time-consuming and error prone. Such automatic sorters are urgently needed, as novel technologies will soon enable the recording of so many neurons that manual curation will no longer be possible.
We have generated a ground truth dataset in awake, behaving mice recorded from the hippocampus. Using SpikeInterface, we investigated performance and error sources of spike sorters on our data. Sources of error include different neuronal activity and signal artifacts; locomotion, electromyographic artifacts, local field potential oscillations, population synchrony, waveform changes during bursting, and electrode drift. We found that the contribution of these individual errors to overall error rates depend upon interactions between brain area, cell type, state, and upon choice of sorting algorithm and its parameters. These results will provide the neuroscience community with quantitative guidelines for spike sorting, and will aid in algorithm development. The resources presented will improve the rigor and reproducibility of all spike sorted data.

Title: Tace/ADAM17 dependent proteolytic processing of the Fra/Dcc receptor is required for commissural axon guidance

Authors: *Y. ZANG, K. CHAUDHARI, G. BASHAW;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Accurate axon targeting is a critical early step during the assembly of the neuronal network. This process requires signaling cascades that are coordinated across the growth cone plasma membrane by transmembrane axon guidance receptors. In particular, the conserved Frazzled (Fra)/Deleted in Colorectal Cancer (Dcc) receptor promotes axon growth and attraction in response to its ligand netrin. Fra can also function independently of Netrin in *Drosophila* commissural neurons to promote axon midline crossing. In this context, Fra undergoes gamma-secretase dependent cleavage to generate an intracellular domain that translocates to the nucleus to activate the transcription of Commissureless, a positive regulator of midline crossing. However, what signal activates the gamma-secretase cleavage of Fra and whether it is conserved for Dcc is currently unknown. Here we show that the Alzheimer's disease-associated ADAM family metalloprotease Tace/ADAM17 cleaves the extracellular domains of Fra and Dcc, and this step is required for Fra's transcriptional activity. Tace/ADAM17 is expressed in the developing *Drosophila* nerve cord and mouse spinal cord, and removal of *tace* in *Drosophila*

commissural neurons enhances *fra*-dependent axon projection deficits. In *Drosophila* ipsilateral neurons and in mouse dorsal spinal cord commissural explants, Tace/ADAM17 overexpression abrogates netrin-dependent axon growth and attraction. Our findings reveal a conserved role for Tace/ADAM17 in the Fra/Dcc signaling pathway during early development of the central nervous system. Further, as axon guidance receptors also function outside of the nervous system and play diverse roles in development and disease, the pathway defined here linking ADAM metalloprotease and gamma-secretase-dependent receptor cleavage to the nuclear import and transcriptional activity of an axon guidance receptor is likely be broadly important.

Abstract: Neurons are mechanosensitive cells that respond to direct application of force [1]. Recently, our team developed a method based on magnetic nanobeads to magnetize axons and pulling them through a precise and controllable magnetic field vector [2]. Pulled axons of hippocampal neurons were found to increase in length and branching and addition of new mass was confirmed [3]. Here, we focused on the local response evoked by this stimulus. Our results suggest that the nanobeads localise in close proximity of axonal microtubules (MT) and the pulling force promotes their polymerization. As MTs modulate axonal transport dynamics, it was not surprising to find an alteration of the trafficking vesicles and their accumulation in the pulled axons. Considering that some of these vesicular components, like RNA granules and late endosomes, are involved not only in axonal transport but also in local translation [4], we analysed ribosomes in active translation, confirming their accumulation under the stimulus. Collectively, these results gave rise to the idea of the pulling force coordinating, through the modulation of MT dynamics, a cross-talk between axonal transport and local translation and that this complex dialogue could be the basis for addition of new mass. The analysis of local transcriptome supports this idea and some genes involved in regulation of cytoskeletal dynamics were found dysregulated. However, the larger number of differentially expressed genes were involved in synaptic formation/maturation. At the synaptic level, we found alteration of the ultrastructure, increase in the co-localization of pre- and post-synaptic

elements and increase of neuronal excitability under the stimulus. Interestingly, our results were confirmed in both developing hippocampal neurons and neural precursor cells, providing another line of evidence that mechanical stimuli may play a fundamental role in shaping endogenous mechanisms of neural development. 1. Title: Nell2 and robo3 control axon guidance and neuronal migration in the developing spinal cord

Authors: *A. J. TULLOCH, Z. J. DELOUGHERY, J. ABOLAFIA, A. JAWORSKI;
Neurosci., Brown Univ., Providence, RI

Abstract: Guidance of migrating neurons and growing axons to their destinations is essential for proper nervous system wiring. The signaling pathways that control and cross-coordinate these steps in neural circuit development remain incompletely understood. In the embryonic spinal cord, the Robo3 receptor guides commissural axons across the floor plate at the ventral midline. Robo3 promotes midline crossing by executing three functions in parallel, as it inhibits repulsion from floor plate-derived Slit proteins, potentiates Netrin-1 attraction to the midline, and mediates NELL2 repulsion from the ventral horn. These varied signaling outputs of Robo3 synergize to steer commissural axons towards and across the floor plate with high fidelity, and they appear to be partially redundant. Consistent with this idea, inactivation of the repulsive Robo3 ligand NELL2 by itself does not appear to cause commissural axon guidance errors unless combined with loss of one *Robo3* allele, which partially impairs the two additional functions of Robo3. Here, we revisited the roles of NELL2 and Robo3 in commissural neuron wiring through detailed

phenotype analysis of knockout mice. We discovered that, early during spinal cord development, commissural pioneer axons aberrantly project into the ventral horn after loss of NELL2, even in the presence of both *Robo3* wild-type alleles. Further, we present evidence that NELL2 and Robo3 control neuronal cell body positioning in the ventral spinal cord. Finally, we show that Robo3 helps confine axons within the neural tube, as loss of Robo3 causes aberrant commissural axon growth into the body periphery. Together, these findings uncover novel functions for NELL2-Robo3 signaling in axon guidance and neuronal migration, thereby enhancing our understanding of mechanisms that control neural circuit assembly.

Abstract: Previously we showed that tectal EphA3 stimulates axon growth of nasal retinal ganglion cells (RGC) toward the caudal tectum preventing them from branching in the rostral tectum. GDNF participates in the formation of topographic connections of motor neurons of the spinal cord with the muscles of the lower limbs, stimulating axon growth interacting with Eph/ephrin system. However its effect on RGC axon growth and guidance is not clear and there is no evidence about the combinatorial effects of EphA3 and GDNF. We demonstrated that GDNF and EphA3 stimulate RGC axon growth.Our purpose was to study the individual and combinatorial effects of EphA3 and GDNF on RGC axon guidance.We cultured chicken embryo nasal retinal explants and dissociated RGCs on poly-L-lysine/laminin and exposed them to control conditions, to EphA3 ectodomain (aggregated EphA3-Fc), to GDNF or to EphA3-Fc plus GDNF to evaluate their effects on axon guidance.To confirm that EphA3 has a positive effect on the axon guidance of nasal RGCs, we developed the technique of Stripe assay using retinal explants. Nasal RGCs axons preferentially grow on a substrate with EphA3 instead of a permissive substrate of laminin in the stripe assay. This axonal preference is not modified with the addition of GDNF.
In order to evaluate the participation of soluble gradients of GDNF and EphA3 on the axonal guidance of nasal RGCs, we developed a chemotaxis test using the Dunn's chamber. This consists of two concentric rings in one glass slide face. An annular bridge lower than the rest of the slide separates both wells. The

external well contains a chemoattractant while the internal well contains culture medium. A linear gradient of chemoattractant is formed by diffusion across the bridge between two wells.
The results showed that RGC axons change their directions of growth toward gradients of EphA3 and GDNF. Besides, EphA3-Fc and GDNF together present the highest effects in comparison to the effects produced by any of them alone.
This demonstrates that GDNF and EphA3 not only stimulate RGC axon growth but their gradients also have chemoattractant effects on nasal RGC axons, suggesting that both of them present synergistic effects.

Title: A developmentally induced gene expression address space for axonal navigation

Authors: *S. KERSTJENS, G. MICHEL, R. J. DOUGLAS;
Inst. of Neuroinformatics, Zürich, Switzerland

Abstract: During brain development, billions of axons must navigate over multiple spatial scales in order to reach specific targets, and so form functional circuits. However, the genome has insufficient information capacity to encode all of these routes independently. Therefore, we are exploring mechanisms of development that could provide a compressive encoding of the global wiring task. One important aspect of our proposed mechanism is that development induces a global address space, analogous to a space of postal codes. Here we report experimental evidence for such an address space embedded in the gene expression patterns of mouse brain. We analysed expression data of 1240 genes in developing and adult mouse brains measured through *in situ* hybridization at 8 time points, and binned in 3D voxels of 80-200μm (larger voxels at later time points), by the Allen Institute for Brain Science. We found that gene expression covariance partitions the brain into a global spatial hierarchy of nested contiguous regions. The hierarchy is stable over at least the measured time points (accuracy of at least 80%, controlled baseline 67%), ranging from E11.5 to P56, and embedded reliably in the expression of any sufficiently large set of randomly chosen genes (accuracy of at least 80% with at least 50 genes). We explain mathematically, and confirm through simulation, that this global hierarchy can arise from two simple constraints on mitosis: That the mitotic daughter cells have, on average, a similar gene expression profile to their parent; and that, on average, they do not migrate too far from one another. With these features—hierarchical spatial structure, stability, and ease of induction—the hierarchy is consistent with a global address space for a global wiring mechanism.

Title: Notch is required for the completion of the late-developing avm branch at the c. elegans nerve ring

Authors: G. BROWN[1], A. LEONARD[2], R. GUERRERO[3], S. EMERSON[4], ***R. EL BEJJANI**[5]; [1]medical college of georgia, augusta, GA; [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Univ. of Florida, Gainesville, FL; [4]Neurosci., Vanderbilt Univ., Nashville, TN; [5]Davidson Col., Davidson, NC

Abstract: Most studies to date have examined axon growth and guidance during early development but less is known about these processes during later stages. The conserved Notch signaling pathway regulates key developmental processes and remains active after development is completed. We show that Notch is required for the growth of an axonal branch that connects the anterior touch neurons in *C. elegans* in the last larval stage, after most other neurons have completed their development. The late-developing AVM mechanosensory branch exhibits defects in all Notch pathway mutants tested. The defect is a failure in branch formation during late development and not a result of degeneration of a previously formed branch or of developmental delay. Tissue specific rescue experiments suggest that Notch functions non-autonomously, in tissues other than the adjacent body wall muscles. Interestingly, initial ventral guidance of the AVM neuron is not affected in Notch mutants, suggesting that Notch specifically affects the formation of the late, anterior branch.

Abstract: Our sense of touch is essential for life and relies on Low-Threshold MechanoReceptors (LTMRs) whose cell bodies reside in dorsal root and trigeminal ganglia. Interestingly, LTMR subtypes characterized by early embryonic expression of Ntrk2 (TrkB) exhibit morphological and physiological properties that are different depending on the skin region they innervate - hairy skin or hairless (glabrous) skin. In glabrous skin, $TrkB^+$ LTMRs terminate within Meissner corpuscles, while in hairy skin $TrkB^+$ LTMRs form longitudinal lanceolate endings around hair follicles. $TrkB^+$ LTMRs that innervate glabrous skin are Aβ RA1-LTMRs with fast conduction velocities and responsivity to vibration and gentle indentation. $TrkB^+$ LTMRs that innervate hairy skin, on the other hand, are Aδ-LTMRs (D hair cells) with intermediate Aδ conduction velocities and responsivity to indentation and also hair deflection in a directional manner. It is unclear whether embryonic neurons that share TrkB expression are genetically specified to become Aβ RA1-LTMRs and Aδ-LTMRs or whether the interaction of embryonic $TrkB^+$ neurons with different skin regions controls the development of skin region-specific $TrkB^+$ LTMR subtypes. Sparse genetic labeling experiments demonstrate that the morphological specializations of glabrous skin and hairy skin of paw innervating $TrkB^+$ neurons arise at nearly identical times during postnatal development. Interestingly, many $TrkB^+$ neurons terminate along the border of glabrous and hairy paw skin, and individual "$TrkB^+$ border neurons" exhibit branches that formed both lanceolate endings and Meissner corpuscles. Transcriptomic profiling and RNAscope experiments show that neonatal $TrkB^+$ DRG neurons that innervate glabrous skin and hairy skin are transcriptionally very similar, although they are distinct from other DRG neuron types. Lastly, using mouse mutants that have either ectopic glabrous skin or ectopic hairy skin we find that $TrkB^+$ neurons that innervate the ectopic skin regions of these mutants form ending types (either lanceolate or Meissner corpuscle endings) in accordance with the ectopic skin type. Together, these findings support a model in which embryonic $TrkB^+$ DRG neurons are poised to become either Aβ RA1-LTMRs of Meissner corpuscles or Aδ-LTMRs associated with hair follicles, and that glabrous skin and hairy skin differentially instruct the maturation of neonatal $TrkB^+$ neuron axonal endings. This model implies that neuronal identity in the peripheral nervous system is flexibly determined by target tissue.

Title: Role of Behavioral Timescale Synaptic Plasticity in Contextual Remapping

Authors: *S. P. VAIDYA, R. A. CHITWOOD, J. C. MAGEE;
Howard Hughes Med. Inst., Baylor Col. of Med., Houston, TX

Abstract: In rodents, the CA1 area of the hippocampus is known to manifest distinct maps or neural representations of the same environment based on reward contingencies, task requirements or subtle changes in background cues, a phenomenon known as contextual remapping. While contextual remapping remains a distinct signature of adaptive behavior in rodents, the cellular and network mechanisms underlying the emergence of these divergent maps remain unknown. In this study, we use longitudinal two-photon calcium imaging to characterize the neural dynamics and stability of the emergent maps over a duration of 7 days in the CA1 area of the rodent hippocampus. We show that mice foraging for rewards at distinct cued locations on a linear track form two orthogonal neural representations of the environment that stabilize over the first 2-3 days, after which the maps remain functionally stable across days. We identify distinct signatures of Behavioral Timescale Synaptic Plasticity (BTSP), a cellular plasticity mechanism known to underlie de novo place cell formation in the CA1 area of the hippocampus, in the formation of these divergent maps. To further confirm the role of this plasticity in contextual remapping, we directly manipulate the occurrence of BTSP by application of NMDA antagonist APV in behaving animals across the first two days when the maps emerge and show that in absence of BTSP, the divergence and resolution of the maps is severely impaired and key characteristics of the CA1 maps, like the overrepresentation of reward sites is distinctly absent. Our results suggest a causal role for BTSP in contextual remapping, a key signature of adaptive behavior.

Title: Critical brain dynamics emerge during development and are robust to sensory deprivation

Authors: *D. R. W. BURROWS[1], M. P. RICHARDSON[1], M. P. MEYER[1], R. E. ROSCH[1,2];
[1]MRC Ctr. for Neurodevelopmental Disorders, King's Col. London, London, United Kingdom; [2]Dept. of Bioengineering, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Different measures of neuronal function suggest that brain dynamics operate near a phase transition, known as criticality, which can optimise computation. Evidence from in silico studies suggests a role of synaptic plasticity in tuning brain networks to criticality. Given the presence of key

developmental windows during which brain networks are highly plastic and sensitive to sensory input, the stabilisation of networks to criticality may itself be a developmental process which depends on sensory input. However, whether critical dynamics emerge throughout development and are sensitive to sensory input, remains unknown. We perform in vivo 2-photon imaging of whole-brain dynamics in GCaMP6s larval zebrafish throughout development, with and without visual deprivation. We find that key markers of criticality, branching ratio and exponent relation, are subcritical at 3 days, but approach criticality around 6 days. Interestingly, we find that the emergence of criticality is brain region specific with the tectum exhibit faster emergence of criticality than other regions. Critical dynamics do not require visual input, as dark-reared fish also reach criticality at 6 days. These data suggest that critical dynamics emerge as a consequence of developmental network connectivity changes and are robust to sensory deprivation. This work demonstrates the developmental emergence of a balanced state in whole-brain networks in vivo.

Title: Regulation of hippocampal network and contextual memory by optogenetically-induced long term potentiation of pyramidal cell to somatostatin interneuron synapses.

Authors: *E. HONORÉ, A. ASGARIHAFSHEJANI, F.-X. MICHON, I. LAPLANTE, J.-C. LACAILLE;
Univ. of Montreal Dept. De Neurosciences, Montreal, QC, Canada

Abstract: Hippocampal dependent learning and memory originate from long term synaptic changes in hippocampal network. Somatostatin interneurons (Som-INs) display metabotropic glutamate receptor subtype 1a (mGluR1a) and mechanistic target of rapamycin complex 1 (mTORC1) dependent long-term potentiation (LTP) at their excitatory input synapses coming from local pyramidal cells (PC-Som synapses), that is elicited by fear learning. This PC-Som synapses LTP participates in the regulation of CA1 network metaplasticity and memory consolidation. However, whether LTP at PC-Som synapses is sufficient to regulate CA1 network plasticity and memory remains to be determined. In this work we use an optogenetic approach to examine this question. First, we used optogenetic silencing of Som-INs with dorsal CA1 injection of AAV9.flex.CBA.Arch-GFP.WPRE.SV40 in SOM-Cre mice and found that inhibition of Som-IN activity during memory acquisition impaired contextual fear memory. Thus, we

confirmed that CA1 Som-IN activity during the presentation of the aversive stimuli is necessary for contextual fear memory formation. Second, we developed a paradigm to elicit LTP at PC-Som synapses with optogenetic theta burst stimulation (optoTBS). Using dorsal CA1 injection of AAV-CaMK2a-ChR2 (E123T/T159C)-mCherry in SOM-Cre-eYFP mice and whole cell recordings from Som-INs in slices, we found that optoTBS elicited LTP at PC-Som synapses. This optoTBS induced LTP was dependent of mGluR1 and mTORC1 and regulated the metaplasticity of CA1 network. Third, at the behavioral level, otpoTBS given 30 minutes before contextual fear conditioning, resulted in an impairment of long-term contextual fear memory tested 24 h after. Whole cell recordings of Som-INs 24 h after contextual fear conditioning showed that optoTBS prior to fear conditioning reduced the spontaneous excitatory post synaptic currents (EPSC) frequency and amplitude, as well as evoked EPSC input-output function. Our results suggest that optogenetic induction of LTP at PC-Som synapses before learning may interfere with learning-induced PC-Som synapses LTP and result in contextual fear memory deficits. Thus, LTP at PC-SOM synapses appears sufficient for the regulation of hippocampal contextual memory.

Title: Conditional PTEN deletion in the adult dentate gyrus triggers robust de novo growth of granule cells and the formation of a seizure prone circuit

Authors: *J. M. YONAN, K. D. CHEN, T. Z. BARAM, O. STEWARD;
Univ. of California, Irvine, Irvine, CA

Abstract: Previous studies have documented that deletion of phosphatase and tensin homolog (PTEN) in early development leads to neuronal hypertrophy, aberrant circuitry and sometimes seizures, but consequences of deleting PTEN in mature hippocampal circuits are unknown. Here, we explore structural and functional consequences of PTEN deletion in mature dentate gyrus granule cells of adult mice. Experiments used male and female $PTEN^{f/f}$;$Rosa^{tdTomato}$ mice in which Cre activates expression of tdT and simultaneously deletes PTEN. Controls were $Rosa^{tdT}$ mice. Unilateral injections of AAV-Cre into the dentate gyrus at 2 months of age resulted in focal transfection of granule cells, leaving PTEN expression of input and target neurons intact. Mice survived for 2 weeks, 1, 2, 4 and 6 months following injection

(n=4-6 mice per timepoint). Quantitative analyses were un-blinded because anatomical consequences of PTEN deletion were dramatic, making blinding impossible. PTEN deleted granule cells exhibited approximately 2.3-fold increases in cell body size by 2 months after AAV-Cre injection, with growth occurring earlier in areas of more concentrated transfection. Quantitative assessments of tdT-positive dendrites revealed 1.5-fold increases in apical dendrite length, 1.8-fold increases in dendrite caliber and 1.5-fold increases in spine densities. Despite this dramatic dendritic growth, preliminary BDA tract tracing of perforant path and commissural inputs to PTEN deleted granule cells revealed that specificity of laminar input was maintained. Immunostaining for Znt3, a marker for mossy fibers, revealed that the lamina occupied by mossy fiber terminals from PTEN-deleted granule cells within CA3 increased in width by 150%, but mossy fibers were not evident in the stratum radiatum. Punctate labeling for Znt3 was present in the inner molecular layer in 2/5 mice at 4 months post AAV-Cre and 2/5 mice at 6 months after AAV-Cre indicating supra-granular mossy fibers. To assess for possible seizures in mice with unilateral Cre-mediated PTEN deletion, 7 mice were implanted with recording electrodes at 7 weeks post deletion to allow for intra-hippocampal EEG recordings and simultaneous video recording. Twenty-four hour monitoring revealed onset of electrographic and behavioral seizures beginning around 10 weeks after AAV-Cre injection in 5 mice, with one mouse dying during a seizure. Our results document dramatic *de novo* growth of fully mature dentate granule cells and establish that even unilateral focal deletion of PTEN in the dentate gyrus is sufficient to result in the development of electrographic and behavioral seizures.

Title: Examining how CXCL12/CXCR4 chemokine signaling affects cortical network function using in vitro microelectrode arrays.

Authors: *J. LUCHETTA[1,2], E. IROLLO[1,2], R. BRANDIMARTI[1,2], C.-T. HO[1,2], O. MEUCCI[1,2,3]; [1]Dept. of Pharmacol. and Physiol., [2]Ctr. of Neuroimmunology and CNS Therapeutics, Inst. of Mol. Med. and Infectious Disea, [3]Dept. of Microbiology and Immunol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The chemokine CXCL12 has numerous roles in the adult central nervous system including directing inhibitory neuronal axons, modulating neurotransmission, and promoting synaptic plasticity. Our previous reports demonstrate that CXCL12/CXCR4 G-protein signaling rescues dendritic spine density and cognitive flexibility deficits in an animal model of HIV-associated neurocognitive disorders, suggesting that this approach has therapeutic potential. CXCL12 primarily rescues thin spines, which are highly dynamic and associated with learning. Aligned with this, data from several neurological and psychiatric conditions and their respective animal models suggest that dendritic spines are anatomical correlates to cognitive function. Our studies indicate that CXCL12 regulates dendritic spines through a Rac1/PAK/cofilin signaling pathway, but we have not identified the cellular effectors responsible for CXCL12's beneficial outcomes. Previous reports suggest CXCR4 is only expressed on ~1% of neurons, which are mainly inhibitory. Because these cells have widespread control over network-level activity, we hypothesized that CXCL12/CXCR4 signaling mediates its effect on dendritic spines through consolidating neural network activity into synchronous network bursts in rat cortical neurons. To test this, we implemented a microelectrode array system and were able to measure neuronal culture activity beyond 100 days in vitro (DIV). Experiments in this system suggest that CXCL12 treatment (20 nM) at 28 DIV does not significantly alter synchronous network activity at 3, 6, 24, or 48-hours post-treatment and additional dose-response studies are underway. Ongoing experiments aim to test the possibility that CXCL12 either rescues and/or protects cortical network dysfunction during insult conditions such as APP overexpression or HIV-1 gp120 exposure. Initial results suggest APP overexpression does not alter synchronous network activity but may alter neuronal firing rates after 7 days of exposure. Future studies aim to directly test whether CXCL12's effects on dendritic spines are mediated through inhibitory neurons using a Cre-ON MiR30a shRNA construct combined with mDlx driven Cre expression to knock down CXCR4 specifically in inhibitory neurons in E17 rat cortical cultures. Together, these experiments aim to determine whether CXCL12 modulates neuronal network activity - an action that may be important for CXCL12's effect on dendritic spines and cognition in vivo.

Title: Effect of the chemokine CXCL12 on dendritic spines in a rodent model of HIV-associated neurocognitive disorder: is spine clustering involved?

Authors: *C. HO[1,2], E. IROLLO[1,2], O. MEUCCI[1,2,3];
[1]Dept. of Pharmacol. & Physiol., [2]Ctr. of Neuroimmunology and CNS Therapeutics, Inst. of Mol. Med. and Infectious Disea, [3]Dept. of Microbiology and Immunol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Several neurological disorders, including HIV-associated neurocognitive disorder (HAND), present with dendritic spine loss and synaptic pruning that can lead to cognitive impairment. Previous *in vitro* and *in vivo* work from our lab showed that the chemokine CXCL12 increases dendritic spine density in rat cortical neurons through activation of its cognate receptor CXCR4 and the downstream Rac1/PAK pathway. Importantly, this was correlated with improved cognitive flexibility in an operant learning task. However, it is not clear if CXCL12 regulates spine maturation, or simply stabilizes transient spines. Likewise, we do not know whether the chemokine promotes spine clustering, a phenomenon that has been often associated with learning and memory processes and that positively correlates with mice performance in a number of behavioral tests. To start addressing these questions, we examined the expression and distribution of postsynaptic proteins that are typically present in mature excitatory synapses, e.g. postsynaptic density protein 95 (PSD-95) and the AMPA receptor subunit, GluA1, and measured inter-spine distance in pyramidal neuron cultures treated with CXCL12. Though CXCL12 short-term treatments (20nM; 5 min up to 3hrs) did not significantly alter PSD-95 total protein levels in neuronal lysates, we observe a consistent and significant increase in the percentage of PSD-95^{+} thin spines in cultures exposed to 20 nM CXCL12 for 3hr. At this same timepoint, we observed a similar trend for GluA1^{+} spines and a significant increase in the overall spine density. These results suggest that CXCL12 may promote maturation of the highly dynamic thin spines. Additionally, time course experiments indicate that sustained CXCL12 action greatly depends on its continuous presence in the culture media. Our *in vivo* studies in a rodent model of HAND are in line with these data. Daily *in vivo* treatment with CXCL12 (i.c.v., 25ng/dose/day, 5 days) reduced the inter-spine distance in dendrites of the medial prefrontal cortex neurons with a pattern that is compatible with spine clustering. Ongoing live cell imaging studies in both cultured neurons and brain slices will shed more light on these findings and help determine CXCL12 effects in real time, thus advancing our understanding of CXCL12 regulation of dendritic spines and cognitive flexibility.

Abstract: Stress pervades modern life. It affects various brain functions, posing risks for many psychiatric disorders. However, few therapeutics are available to combat such deleterious effects of stress. One class of candidate drugs are psychedelics. With potent and fascinating effects on the human mind, these drugs have received renewed research interest in recent years. However, their hallucinogenic effects remain a concern for clinical applications. Using a mouse model of unpredictable mild stress, we investigated a novel compound called tabernanthalog (TBG), which is similar in structure to the psychedelic drug ibogaine but free from its hallucinogenic and toxic effects. We found that a single low dose of TBG can correct stress-induced behavioral deficits including anxiety, cognitive inflexibility, and defective sensory processing. In the stressed brain, TBG promotes the regrowth of stress-disrupted connections between cortical neurons and normalizes their baseline and task-associated activity patterns. Our study highlights the potential of using analogs of psychedelics to treat stress-related brain disorders, and provides novel insights into the neural mechanisms underlying their therapeutic effects.

Title: Evaluation of the therapeutic potential of ketamine in Rett syndrome and the role of brain derived neurotrophic factor (BDNF)

Authors: *M. K. PIAZZA[1], E. T. KAVALALI[2], J. L. NEUL[3], L. M. MONTEGGIA[1];
[1]Vanderbilt Brain Inst., Nashville, TN; [2]Vanderbilt Brain Inst., [3]Pediatrics, Vanderbilt Univ., Nashville, TN

Abstract: Rett syndrome (RTT) is primarily caused by mutations in the X-linked gene methyl-CpG binding protein 2 (MECP2), affecting roughly 1 in 10,000 live female births and representing the second leading cause of intellectual disability in girls and women worldwide. Multiple lines of investigation have implicated the N-methyl-D-Aspartate receptor (NMDAR) in the pathophysiology of RTT, as dysfunction of MeCP2 alters the developmental maturation of NMDARs, contributing to an imbalance of inhibitory and excitatory neurotransmission in the brain. Interestingly, both genetic manipulation and

pharmacological blockade with the noncompetitive NMDAR antagonist ketamine have shown efficacy in reversing such electrophysiological deficits, and a small number of studies have demonstrated an ability of systemic ketamine treatment to rescue behavioral symptoms of RTT and extend lifespan in an animal model. Despite these promising results, a more thorough characterization of ketamine's modulation of RTT symptoms and an investigation into the molecular underpinnings of this effect are warranted. Our lab has previously demonstrated that ketamine administration causes desuppression of brain derived neurotrophic factor (BDNF) protein synthesis in the hippocampus of mice, leading to an enhancement of glutamatergic activity and a reduction of depression-like symptoms. As BDNF is similarly down-regulated in animal models of RTT syndrome, it is plausible that this mechanism may be shared between these two disparate disorders. In this study, we utilized a combination of biochemical, electrophysiological and behavioral paradigms in *Mecp2* knockout mice as well as wild type littermate controls to explore this possibility. Indeed, our findings show an up-regulation of hippocampal BDNF protein expression in both wild type (WT) and *Mecp2* knockout (KO) mice following systemic ketamine treatment. Furthermore, an electrophysiological examination of field excitatory post-synaptic potentials (fEPSPs) revealed a concomitant potentiation of the fEPSP response in both WT and KO animals. Taken together, the results of this study will contribute to the growing investigation of ketamine's therapeutic efficacy and putative molecular action in Rett syndrome.

Title: A circuit-based approach to understand hypersexual behaviour in Parkinson's Disease.

Authors: *D. MATA MARÍN[1,3,4], J. A. PINEDA-PARDO[1,3], M. MICHIELS[1,3,4], C. PAGGE[1,3,4], R. MARTÍNEZ-FERNÁNDEZ[1,3], J. MOLINA[5], L. VELA[6], F. ALONSO-FRECH[7], I. Clínico San Carlos, Madrid, Spain

Abstract: BACKGROUND: The balance between cognitive control and enhanced desire towards sexual cues has been hypothesized to be biased toward the latter in individuals with hypersexuality, suggesting possible neurocognitive and connectivity changes along the mesocorticolimbic circuitry. Here, we provide evidence for this hypothesis by comparing the neurobiological substrate of sexual cues disturbance over cognitive control associated to a medication-induced hyperdopaminergic state in

Parkinson´s disease (PD) as a hypersexual acute model.METHODS: We assessed the effect of sexual cues on cognitive control using a novel erotic stop signal paradigm inside an fMRI in 16 hypersexual PD patients, 17 PD patients and 17 controls. Patients were assessed twice on and off medication. In a separate sample of 18 hypersexual patients, we also applied excitatory non-invasive brain stimulation – intermittent theta burst (iTBS) – following a randomized single blind sham-controlled design over the pre-supplementary motor area (pre-SMA).RESULTS: Compared with their non–hypersexual peers, patients with hypersexuality exhibited worse response inhibition in erotic trials, which correlated with medication effects. Inhibition of actions influenced by sexual cues recruited a network involving caudate, pre-SMA, VTA and ACC activity in hypersexual patients while medicated. Dynamic causal modelling revealed distinct best models to account for cortico-subcortical interactions showing reduced task-related inputs in pre-SMA and descending connectivity to caudate in hypersexual compared to non-hypersexual patients. This was sustained by enhanced fractional anisotropy and reduced mean diffusivity in the pre-SMA-caudate pathway. Importantly, excitatory intermittent theta burst stimulation (iTBS) over pre-SMA improved behavioural control when exposed to sexual cues. CONCLUSIONS: We identified a key fronto-striatal and mesolimbic circuitry underlying uncontrolled sexual behaviours in hypersexual PD. Moreover, we demonstrated beneficial acute effects of iTBS in improving inhibitory control in this population, providing valuable insight for future therapeutic options for better management of hypersexuality in PD without compromising patients' motor functioning.

Title: Dopaminergic medication remediates aberrant cognitive control circuit signaling in Parkinson's disease

Authors: *W. CAI, C. B. YOUNG, R. YUAN, B. LEE, S. RYMAN, J. KIM, L. YANG, V. W. HENDERSON, K. POSTON, V. MENON;
Stanford Univ., Palo Alto, CA

Abstract: Dopaminergic medication is widely used for alleviating motor symptoms in patients with Parkinson's disease (PD), but patients vary greatly in their cognitive responses to medication. It has been

hypothesized that dopaminergic medication impacts cognitive processing in PD by modulating frontoparietal-basal ganglia cognitive control circuits, but little is known about the underlying causal signalling mechanisms and their relation to individual differences in treatment response. Here we use a novel state-space computational model with high temporal resolution fMRI to investigate dynamic causal signalling in frontoparietal-basal ganglia circuits associated with working memory in 36 PD patients (69$\pm$7 yrs; 21F/15M) ON and OFF medication, as well as matched 44 healthy controls (71$\pm$6 yrs; 25F/19M). Our analysis revealed aberrant causal signaling in frontoparietal-basal ganglia circuits in PD patients OFF medication. Importantly, aberrant signaling was remediated by dopaminergic medication and a novel quantitative distance measure predicted individual differences in cognitive change associated with medication in PD patients. These findings were specific to causal signaling measures, as no such effects were detected with conventional non-causal connectivity measures. Our analysis also identified a specific frontoparietal causal signaling pathway from right middle frontal gyrus to right posterior parietal cortex that is impaired in PD (p<0.05). Unlike in healthy controls (r=-0.3, p=0.02), the strength of causal interactions in this pathway did not increase with working memory load and the strength of load-dependent causal weights was not related to individual differences in working memory task performance in PD patients OFF medication (p=0.4). However, dopaminergic medication in PD patients reinstated the relation with working memory performance (r=-0.4, p=0.01). Our findings provide new insights into aberrant causal brain circuit dynamics during working memory and identify mechanisms by which dopaminergic medication remediates cognitive control circuits.

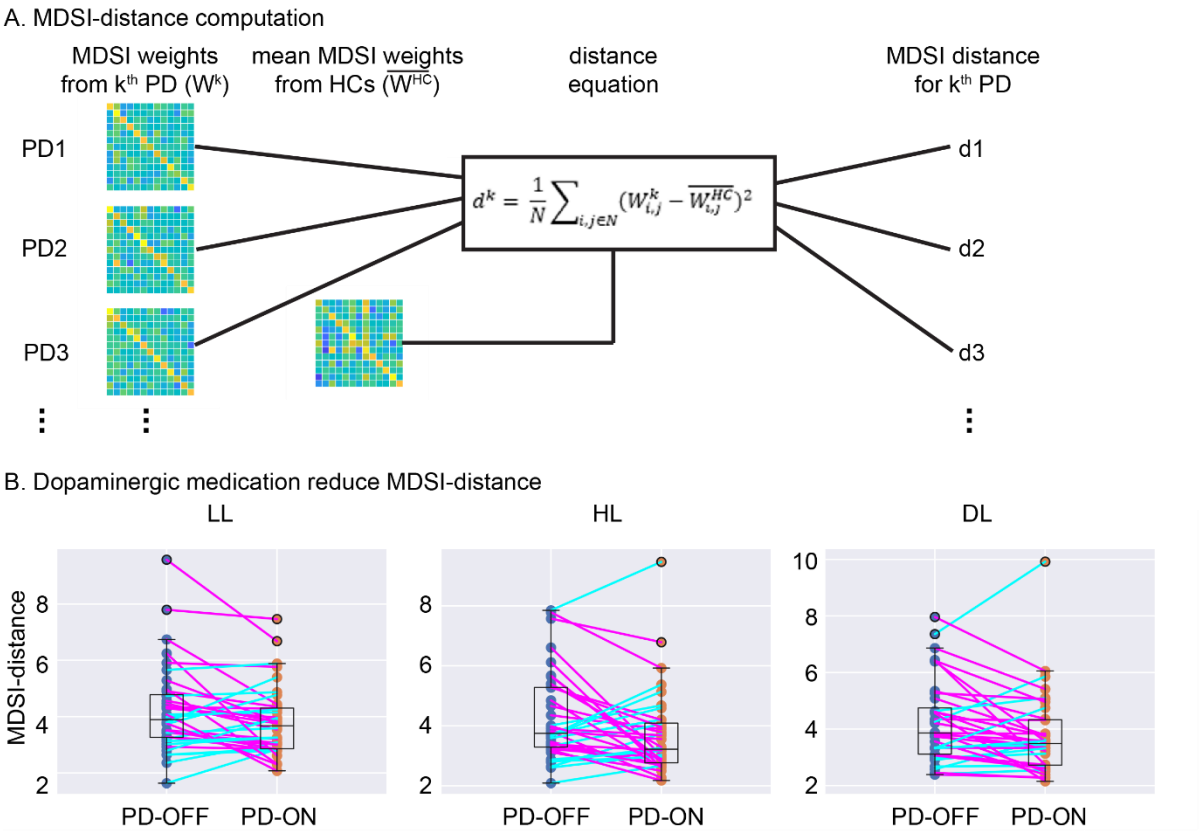

Figure 1. We used a novel multivariate dynamic state-space system identification (MDSI) method to estimate dynamic causal interaction between districuted cortical-subcortical systems during the Sternberg working memory task. (A) Schematic illustration of the algorithm used to compute MDSI-based network-level dissimilarity (distance) in each PD patient. The distance (d) is defined by the sum of the square of MDSI weight difference between each PD patient and the mean of the HC group. Note that d^k is the distance metric for k^{th} PD patient; N is the total number of non-diagonal edge (i,j) in MDSI weight matrix per condition; $W_{i,j}^k$ is the MDSI weight on edge (i,j) for kth PD patient; $\overline{W_{i,j}^{HC}}$ is the mean MDSI weight on edge (i,j) for all HCs. (B) Dopaminergic medication reduces MDSI-based distance, which quantifies the dissimilarity in network-level causal signaling between each PD patient and the HC group, in each task condition, e.g. low load (LL), high load (HL) and distractor load (DL) (all ps < 0.05).

Title: Everyday life motor habits alter striatal activity in early Parkinson's disease.

Authors: *P. GUIDA[1,2,3], M. H. MONJE[1,4], J. A. OBESO[1,2], I. OBESO[1,2];
[1]HM CINAC, Hosp. Universitario HM Puerta del Sur, Móstoles, Madrid, Spain; [2]Network Ctr. for Biomed. Res. on Neurodegenerative Dis. (CIBERNED), Inst. Carlos III, Madrid, Spain; [3]PhD program in Neuroscience, Autonoma de Madrid Univ., Madrid, Spain; [4]Dept. of Neurology, Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Humans can simultaneously and easily shift between automatic/habitual to voluntary/goal-directed modes of behavioural control. Habits (stimulus-response) allows us to perform well-practiced tasks with minimal or no conscious effort. In Parkinson disease (PD), there is a differential loss of dopamine (DA) along the caudal sensorimotor putamen initially transferring to more rostral regions as the disease progresses. Importantly, the sensorimotor putamen is primarily implicated in habitual control therefore possibly explaining some motor deficits in PD such as arm swinging, walking and writing.Our aim was to investigate loss of habitual writing after early dopaminergic cell loss in PD patients. We expected that everyday life motor habits (writing) would be impaired in automatic conditions associated to reduced striatal activities compared to controls. We developed a handwriting task (one of the most well-learned and automatic behaviour) that differentiates between habitual and goal-directed writing components. Writing conditions included automatic (e.g. signature, Spanish) and goal-directed conditions (e.g. Polish, Greek; 10 trials per condition). We considered the following general outcome parameters: writing duration (s), horizontal and vertical amplitudes (mm) of words. The quality and the level of handwriting automation was evaluated by means of the single stroke analysis. A behavioural (30 PD patients; 30 controls) and fMRI (18 PD patients; 25 controls) sessions were performed. Highly asymmetric and early (less than 2 year since diagnosis) PD patients were included and tested while off-medicated. Reduced automatism was seen in the execution of every writing condition compared to controls. This finding was especially true when the most affected side overlapped with hand-dominant side. Neural signals revealed great activity in bilateral posterior putamen in controls in habitual conditions ($p < 0.05$, FWE-corrected). In contrast, in goal-directed conditions, anterior putamen showed increased activity. A similar pattern was seen in PD patients, however, showing reduced posterior putamen activity ($p < 0.001$, uncorrected).Our results suggest that everyday life motor habits is executed with reduced automatic components in every writing condition in PD patients. This was accompanied by reduced posterior putamen recruitment in early PD. Our findings demonstrate a functional dysfunction in posterior putamen that plays a fundamental role in the origin of the characteristic habitual motor deficits of PD.

Title: Lstm decoding of tremor and movement speed in Parkinson's disease

Authors: *S. LEE, D. LIU, P. LAURO, D. AMAYA, W. ASAAD;
Brown Univ., Providence, RI

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder whose motor symptoms are principally characterized by tremor and bradykinesia. For severe PD, deep brain stimulation (DBS) is an effective treatment, and present efforts are concentrated on closed loop DBS that delivers stimulation in response to a biomarker of the disease. Yet patients often present with complex and specific symptoms, and state-of-the-art approaches to closed loop DBS leverage narrowband spectral estimates of local field potentials and do not yet address the wide variety of motor and non-motor symptoms observed.
Here we utilized full bandwidth recordings from multiple subthalamic and cortical regions in 27 patients with PD to predict moment-to-moment tremor and movement speed using convolutional long short-term memory (LSTM) artificial neural networks. Significant prediction of tremor and speed (empirical labels compared to shuffled) was achieved on a seconds-timescale from subthalamic nucleus (n=92/162 recordings), zona incerta (n=45/86), substantia nigra (n=15/40), as well as somatomotor cortices (30-50%, 25-50 total). We further performed spectral occlusion, in which we filtered the time series into narrowbands, trained new models, and assessed information carried by these bands, which demonstrated that unfiltered time series largely outperformed narrowband spectral estimates. We also demonstrate that multielectrode models could also significantly outperform single electrode models, highlighting the need for improvements in existing concurrent recording technology.
Our LSTM approach required little signal processing and no direct spectral estimation but still leveraged broadband oscillatory activity and may provide the basis for efficient closed loop DBS control policies to address both motor and non-motor symptoms in a patient specific framework.

Title: Posturography in patients with Parkinson´s disease and progressive supranuclear palsy

Authors: *M. SALING, **Z. KOSUTZKA**, P. MAJCHEROVÁ;
II. Neurolog. Depart., Derer's Univ. Hosp., Bratislava, Slovakia

Abstract: Introduction: Differential diagnosis of Parkinson's disease (PD) and progressive supranuclear palsy (PSP) might be difficult due to the shared pathophysiology. They might both present with deficits in postural control, even though, in the case of PSP it is typically earlier in the disease course. The pathophysiology of balance difficulties remains elusive, thus, challenging to target with therapy. Static posturography is used to examine a patient's balance and reflects the contributions of the visual, vestibular, and proprioceptive systems to a patient's balance.
Methods: We performed standard posturography in patients with PD (n=9, 3 men, mean age=67,4, range

56-81) and PSP (n=11, 3 men, mean age 69,6, range 58-82) with the history of at least one fall in the previous 3 months with matched disease duration. The posturographic protocol consisted of quiet standing with eyes opened, eyes closed, galvanic stimulation, vibration stimulation of Achilles tendon. Each trial lasted 50 seconds, the stimulation (vibration, galvanic) was applied between 10-20th second, if applicable. Amplitude and velocity of the postural response (separately medio-lateral, anterior-posterior direction), root mean square (RMS) and line integral (LI) was analyzed. The findings for left and right postural responses were combined. All patients were recorded in the best ON state with the absence of interfering dyskinesia. Peripheral neuropathy was excluded.
Results: Statistically significant difference in postural response was found between PD and PSP in the trial with the vibration stimulation of Achilles tendon. The difference was observed after the onset of stimulation (10-20th second of the trial) and reflected in the RMS and LI (p=0,038) with smaller postural responses in PSP. There was no other difference in the rest of the posturographic parameters.
Conclusion: The underlying pathophysiology of postural control might be different in PD and PSP, possibly due to the more pronounced deficit of the proprioceptive system in PSP patients. This might be also discriminative in the differential diagnosis of these entities.

Title: Parkinson's Advance with DART and DANNCE

Authors: *I. A. WEAVER[1], J. M. ROACH[1], J. R. RAVENEL[2], S.-X. LIM[1], H. YAN[2], B. C. SHIELDS[1], T. W. DUNN[1], M. R. TADROSS[1,2];
[1]Biomed. Engin., [2]Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Parkinson’s Disease (PD) is a devastating movement disorder caused by the degeneration of dopamine afferents to the striatum. It is known that chronic loss of dopamine alters excitatory (AMPA-R) and inhibitory (GABA-R) synapses in the striatum, and produces a wide range of motor deficits. However, it has been difficult to establish causal relationships between synaptic changes and the behavioral phenotype. One issue is a mismatch in resolution; synaptic changes have been studied in a fine-grain manner, revealing dozens of synaptic alterations in the striatal connectome. In contrast, behavioral assays have been coarse-grain, limited to metrics like velocity, turning, and freezing. Here, we present Compact-DANNCE (Compact 3 -Dimensional Aligned Neural Network for Computational Ethology), which features a floating behavioral arena, a single high-resolution camera mounted below the

arena looking upwards, and optical-grade IR mirrors positioned at the level of the animal chamber to provide 5 angles of view. This system builds upon DANNCE (Dunn, et. al., Nature Methods, 2021), which required multiple cameras in a 10' x 10' room. Here we have compressed the design to a 2' x 2' profile, enabling scalability of the approach. Other key features include observing mice during the active dark phase of their circadian cycle (via IR illumination); visualizing the paws, mouth, and tongue of the animal (via bottom-up view); localizing each body part in 3D space (via concurrent side views), and improved temporal synchronization across views enabling accurate tracking of rapid movements up to 90 Hz (owing to the single-camera design). We are combining Compact-DANNCE with DART (Drugs Acutely Restricted by Tethering), a tool we previously developed to deliver clinical drugs to genetically defined cells (Shields et. al., Science, 2017). Thus far, we have performed a head-to-head comparison of two treatments in a unilateral 6-OHDA mouse model of PD, comparing L-DOPA (replacing dopamine without correcting synaptic pathologies) to AMPAR antagonism of indirect pathway spiny projection neurons (iSPNs) with DART (correcting one synaptic pathology without replacing dopamine). Whereas both treatments qualitatively improve coarse-grain metrics, we resolve pronounced fine-grain differences. L-DOPA restores hunched idling and grooming behaviors but fails to restore rearing. In contrast, iSPN-AMPAR antagonism restores low rearing behaviors similar to those seen in healthy mice. While the results are preliminary, they reveal the power of fine-grain kinematic quantification, and set the stage to examine movement disorders from the perspective of a connectome pathology.

Title: Effects of exercise on heart rate variability in Parkinson's disease

Authors: *A. A. MEMON[1], **E. B. GEORGE**[2], Y. SUNKARA[3], M. POGWIZD[4], C. CATIUL[5], J. PILKINGTON[5], S. M. POGWIZD[4], A. W. AMARA[5];
[1]Univ. of Alabama Hlth. Services Fndn. P, Birmingham, AL; [3]Neurosci., [4]Cardiol., [5]Neurol., [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Parkinson's disease (PD) is the most common neurodegenerative motor disorder of aging. Although clinical diagnosis requires motor features, non-motor symptoms, including autonomic dysfunction, can present early and adversely affect quality of life in persons with PD (PwP). Indeed, sympathovagal imbalance is present in more than half of PwP. Unfortunately, pharmacological therapies for autonomic dysfunction in PD have limited efficacy and are associated with side effects. Excitingly, exercise rehabilitation has shown potential to enhance autonomic regulation in adults. However, whether exercise improves autonomic modulation in PwP is unclear. Heart rate variability (HRV) is a noninvasive marker of autonomic derangement. Novel insights can be gained from studying this marker during different stages of sleep. Therefore, we hypothesize that exercise will restore sympathovagal balance

during sleep in PwP. To test this hypothesis, we leveraged an existing sleep dataset collected during a recently completed, randomized, controlled clinical trial (RCT) of exercise on objective sleep in PD. In this RCT, 55 participants were randomized to exercise rehabilitation (N=27) or a sleep hygiene, no-exercise control (N=28). All participants underwent laboratory-based nocturnal polysomnography (PSG) at baseline and post-intervention. We analyzed 10 min electrocardiographic recordings (ECG's) during deep sleep (Non-rapid eye movement (NREM) stage 3) and during REM sleep. ECGs were sampled at 512 Hz and exported for analysis using a specially designed Matlab-based program that uses a point process model to assess instantaneous (rather than time-averaged) HRV using a history-dependent inverse Gaussian process. We will use parametric autoregressive modeling to determine power spectral density. We will evaluate frequency domain measures as low-frequency power (LF, 0.04-0.15 Hz), high-frequency power (HF, 0.15-0.40 Hz), and LF/HF ratio. HF reflects parasympathetic/vagally mediated modulation of heart rate, while LF/HF ratio reflects sympathovagal balance. This novel work in progress allows investigation of sleep ECG signatures, a noninvasive and widely accessible measure, as a potential marker to evaluate the effects of exercise on HRV in PwP.

Title: Spinal Cord-Chips from sporadic ALS patients reveal disease-specific biomarkers

Authors: *B. ONDATJE[1], D. LALL[1], S. SANCES[1,3], M. LUKASIAK[1], D. WEST[1], A. LAPERLE[1], R. HO[1], M. WORKMAN[1], V. VAIBHAV[2], J. VAN EYK[2], C. SVENDSEN[1];

[3]Translational Sci. and Drug Discovery, Insitro, Inc., South San Francisco, CA

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a complex neurodegenerative disorder, with the vast majority of cases being sporadic in nature with unknown genetic cause. ALS is characterized by progressive loss of cortical and spinal cord motor neurons, resulting in muscle weakness and death from respiratory failure typically within 3-5 years of diagnosis. Using induced pluripotent stem cell (iPSC) technology, patient-specific cells can be differentiated into cell types relevant to ALS. Microphysiological systems (MPS), also known as organ-chips, have microengineered three dimensional compartments that enable the co-culture of different iPSC-derived cell types to recapitulate conditions of human physiology *in vitro.* Here we developed an MPS-based model incorporating patient-derived spinal cord motor neurons **(SC-Chip)** to study young onset sporadic ALS. The SC-Chip top channel contains disease-relevant neuronal cells, and the bottom channel contains brain microvascular endothelial cells (BMECs). The porous membrane between the two channels allows for the establishment of a blood-brain barrier.

The primary goal of this project is to establish robust and reproducible biomarkers of this disease by identifying metabolomic, transcriptomic, and proteomic signatures, as well as to test efficacy of candidate therapeutics to ameliorate disease-specific phenotypes. We have detected several biomarkers of sporadic ALS that are consistent across multiple studies in RNA-seq, proteomics, immunohistochemical staining and western blot analysis. These biomarkers were initially detected in a cohort of 5 patient-derived iPSC lines, compared to 5 control lines, and are currently being confirmed in an additional 10 ALS/ control lines. Identified biomarkers for sporadic ALS include increased expression of heavy, medium, and light chain neurofilaments as well as peripherin, an increase in calmodulin binding substrate neurogranin, and a decrease in neural RNA-binding protein ELAV3. We will next administer experimental therapeutics to the vascular side of the SC-Chip to determine (i) transport across the blood-brain barrier and (ii) reversal of disease-specific phenotypes on the neuronal side.

Title: Multi-omics approach on spinal cord organoids to assess new candidate genes/pathways in C9orf72-Amyotrophic Lateral Sclerosis

Authors: N. GALLI[1], B. FRIZZI[1], I. FARAVELLI[1], M. RIZZUTI[2], G. COSTAMAGNA[1], F. BIELLA[2], M. GARBELLINI[2], G. GARRONE[3], M. NIZZARDO[1], P. RINCHETTI[1], E. PAGLIARI[1], M. MENERI[4], G. COMI[1], *S. CORTI[1];

Abstract: Amyotrophic lateral sclerosis (ALS) is a rare, idiopathic neurodegenerative disease involving motor system that controls voluntary movement. It is characterized by upper and lower motor neuron (MN) loss, resulting in progressive and relentless muscle paralysis that ultimately leads to death from respiratory failure within a few years. Unfortunately, no effective treatments are available to slow, halt or reverse disease progression. Therefore, improving our knowledge on ALS pathophysiology is crucial for the development of novel therapeutics. Recent evidence indicates that gliosis and mitochondrial dysfunction affect MNs, possibly meaning that alterations in immune and energy metabolism related genes/pathways are associated with ALS. Since 2D cultures are limited in their capability to mimic intercellular interactions, 3D models represent a new tool that recapitulates the complexity of tissue architecture. The primary goal of this proposal is to 1) generate and characterize spinal cord organoids from C9orf72-ALS patient-derived iPSCs and their relative isogenic controls; 2) harness “omics” approaches (with particular focus on transcriptomics and proteomics) to outline the ALS phenotype in this cellular system; 3) identify and validate candidate genes/pathways related to the pathophysiology of the disease. On this basis, we generated spinal cord organoids with a protocol recently optimized in our laboratory and we verified the presence of neural progenitors, post-mitotic neurons, motor neurons, and glia. Organoids were harvested, fixed, and cryosectioned at three time points (day 30, day 45, day 80) and evaluated for their morphology and neurodevelopmental features by immunohistochemistry and qPCR. Specifically, day 80-organoids expressed markers such as MAP2, DCX, OLIG2, PAX6, SMI32, TUBB3, and GFAP. Terminally differentiated spinal cords organoids underwent mass spectrometry to reveal proteins differentially expressed in ALS samples compared to controls. The obtained results showed a number of significantly dysregulated proteins that we are currently evaluating with western blot and qPCR. Preliminary gene ontology analysis displayed alterations associated with cytoskeleton, energetic metabolism, and astrocyte population. Finally, organoids at day 80 were dissociated and cryopreserved to investigate possible aberrant transcriptomic profile related to ALS pathogenesis through single-cell RNA-sequencing. Overall, this project might allow the assessment of novel candidate genes/pathways linked with C9orf72-ALS pathogenesis and their potential as therapeutic targets.

Abstract: Frontotemporal dementia (FTD) is a common dementia syndrome in patients under age 65, and amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease with the loss of spinal cord and cortical motor neurons leading to paralysis and death from respiratory failure typically within 3-5 years of diagnosis. FTD and ALS have significant overlap clinically, pathologically and genetically. Aggregates of TDP-43 protein are the defining pathology of FTD (FTLD-TDP variant) and nearly all cases of ALS, and the most common genetic cause of both FTD and ALS are repeat expansions in the C9orf72 gene. C9orf72 is expressed in multiple cell types in the brain including in microglia and neurons, and there is strong evidence that disrupted interactions between different cell types underlie pathogenesis in C9-FTD/ALS. In order to model C9-FTD/ALS forebrain, we have developed a microphysiologic system (MPS) that permits the 3D culture of human induced pluripotent stem cell (iPSC)-derived cortical neurons (CNs), astrocytes and microglia in one chamber and brain microvascular endothelial cells in a separate chamber, separated by a porous membrane that provides a blood brain barrier component. Our goal is to validate the robustness of this forebrain MPS (fMPS) model and to identify C9-FTD/ALS-specific biomarkers, which we will then cross validate with the clinical data and pathology from the C9-FTD/ALS patients used to generate the patients iPSCs. In the future, the established fMPS model can be used to discover and validate translatable biomarkers for preclinical efficacy testing, and to assist in patient stratification for clinical trial design.

Title: Phosphomimetic TDP-43 shows increased propensity to undergo aberrant liquid-liquid phase separation

Authors: *W. M. TENNANT, J. R. MANN, A. M. GLEIXNER, J. C. MAUNA, C. J. DONNELLY; Univ. of Pittsburgh, Pittsburgh, PA

Abstract: TDP-43 is a predominantly nuclear DNA/RNA binding protein (RBP) where it plays a keyrole in RNA processing, including alternative splicing and RNA trafficking, and is an underlyingneuropathological feature in nearly all Amyotrophic Lateral Sclerosis (ASL) patients. In ALS,TDP-43 is depleted from the nucleus and mislocalized to the cytoplasm where it formshyperphosphorylated and p62 positive insoluble inclusions that strongly correlate with regionsof CNS degeneration. The upstream mechanisms leading to TDP-43 proteinopathy and itscontribution to neurotoxicity remain unresolved and existing approaches to model thispathological event are unreliable. We and others previously showed that TDP-43 undergoesaberrant liquid-liquid phase transitions driven by the C-terminal Low Complexity Domain (LCD)when the protein does not bind its cognate RNA sequences (Mann et al 2019; Gassett-Rosa etal 2019; French et. Al 2019). While hyperphosphorylation of TDP-43 is a hallmark pathology ofALS and other neurological disorders, the physiological and pathological effects ofphosphorylated TDP-43 remain unknown. Here, we generated a 5S>D construct to mimichyperphosphorylated TDP-43 sites in postmortem tissue and found expression results inenriched cytoplasmic localization of the phosphomimetic construct. We next tested the effectof a phosomimetic TDP-43 LCD using the photokinetic optoDroplet approach to study the effecton LLPS of the protein fragment (Mann et al, 2019; Shin et al, 2017) and found repeatedstimulation promotes irreversible protein droplet assembly when compared to WT TDP-43 LCDdisassembly. Furthermore, we find that this optodroplet formation is highly concentrationdependent in the case of the WT TDP-43, however the threshold for LLPS is greatly reduced inthe 5SD construct. Lastly, we also demonstrate that blue light stimulation of full length 5SDoptoTDP-43 results in larger cytoplasmic inclusions when compared to the WT protein. Takentogether these studies indicates that phosphorylation plays a pivotal role in the regulation ofTDP-43 LLPS which could have far reaching implications for TDP-43 both physiologically andpathologically.

Title: Nuclear accumulation of CHMP7 initiates nuclear pore complex injury and subsequent TDP-43 dysfunction in sporadic and familial ALS

Authors: *A. COYNE[1], V. BASKERVILLE[1], B. ZAEPFEL[1], D. W. DICKSON[2], F. RIGO[3], F. BENNETT[3], P. LUSK[4], J. ROTHSTEIN[1];
[1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Pathology & Neurosci., Mayo Clin. Jacksonville, Jacksonville, FL; [3]Ionis Pharmaceuticals, Carlsbad, CA; [4]Yale Sch. of Med., New Haven, CT

Abstract: Alterations in the nucleoporin (Nup) components and function of the nuclear pore complex (NPC) have been implicated as contributors to the pathogenesis of genetic forms of neurodegeneration including *C9orf72* Amyotrophic Lateral Sclerosis/Frontotemporal Dementia (ALS/FTD). We hypothesized that Nup alterations and the consequential loss of NPC function may lie upstream of TDP-43 dysfunction and mislocalization widely observed in ALS, FTD, and related neurodegenerative diseases. Here, we provide evidence that CHMP7, a critical mediator of NPC quality control, is increased in nuclei of *C9orf72* and sporadic ALS induced pluripotent stem cell (iPSC) derived spinal neurons (iPSNs) and postmortem human motor cortex prior to the emergence of Nup alterations. Inhibiting the nuclear export of CHMP7, triggered Nup reduction and TDP-43 dysfunction and pathology in human neurons. Knockdown of CHMP7 alleviated disease associated Nup alterations, deficits in Ran GTPase localization, defects in TDP-43 associated mRNA expression, and alleviated downstream glutamate induced neuronal death. Thus, our data support a role for altered CHMP7 mediated Nup homeostasis as a prominent initiating pathomechanism for familial and sporadic ALS and highlights the potential for CHMP7 as therapeutic target.

Title: Expression of ALS-linked profilin-1 alters the phagolysosomal pathway in iPSC-derived microglia-like cells

Authors: *S. FUNES[1], F. N. U. SHANKARACHARYA[1], J. A. MCDONOUGH[3], W. C. SKARNES[3], J. E. LANDERS[1], D. P. SCHAFER[2], D. A. BOSCO[1];

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disorder characterized by loss of motor neurons. Cumulative evidence shows that microglia contribute to disease progression, but the mechanisms underlying this effect are unknown. Several ALS genes are highly expressed in microglia compared to neurons, including profilin-1 (*PFN1*), which encodes an actin-binding protein involved in microglia activation and phagocytosis. To interrogate whether ALS-linked PFN1 mutations affect the intrinsic functions of microglia, we generated mutant human inducible pluripotent stem cells (iPSCs) using CRISPR-Cas9. iPSCs were differentiated into microglia-like cells (iMGs) by a protocol that mimics primitive hematopoiesis in the yolk sac. Isogenic control and ALS-PFN1 iMGs express microglia-enriched markers including P2RY12, TMEM119, and IBA1. Further, iMGs are reactive to LPS and phagocytose disease-relevant material such as human synaptosomes and aggregated mutant PFN1 protein. Using this model, we discovered that ALS-PFN1 iMGs accumulate phagocytosed pHrodo-labeled material over time compared to isogenic control iMGs. Human-synaptosome washout studies indicate that control and ALS-PFN1 iMGs exhibit similar engulfment capacities, but that ALS-PFN1 iMGs retain a higher amount of undigested material at later time points post-washout. ALS-PFN1 iMGs also exhibit an accumulation of CD68 positive structures detected by immunofluorescence, consistent with alterations in the phagolysosomal pathway. To gain mechanistic insight into how mutant PFN1 affects phagocytosis, we performed RNAseq analysis and uncovered an upregulation of *TBC1D15* in ALS-PFN1 iMGs compared to isogenic control iMGs. TBC1D15 regulates the activation state of RAB7, a canonical late-endosomal protein crucial in endosomal/lysosomal pathways. Together, these observations implicate that the degradation machinery of ALS-PFN1 iMGs may be compromised during phagocytosis, leading to an accumulation of undigested material. Our findings provide insight into PFN1 biology and open new perspectives regarding microglia cell-autonomous defects in ALS that may contribute to motor neuron death.

Title: Investigating the convergence of altered neuronal activity and C9orf72-linked molecular mechanisms in ALS/FTD

Authors: *L. GHAFFARI, A. BOEHRINGER, T. WESTERGARD, D. TROTTI, A. R. HAEUSLER; Thomas Jefferson Univ., Philadelphia, PA

Abstract: The (GGGGCC)n nucleotide repeat expansion (NRE) in the C9orf72 gene (C9) is the most common genetic cause of ALS and FTD. The presence of the NRE is proposed to lead to neurodegeneration in three ways that may not be mutually exclusive: 1) repeat RNA transcribed from can sequester essential RNA-binding proteins, 2) dipeptide repeat proteins (DPRs), which are unconventionally translated through non-AUG repeat-associated (RAN) translation mechanism in both sense and antisense directions, can produce five distinct DPR species; poly(GA), poly(GR), poly(GP), poly(PA), and poly(PR), and 3) loss of C9ORF72 protein from the NRE-affected allele. Studies using C9-ALS/FTD patient-derived human induced pluripotent stem cell (hiPSC) differentiated into neurons indicate diseased neurons exhibit hyper-excitability, which transitions to hypo-excitability with longer culture time. Furthermore, cortical hyper-excitability is a commonly observed phenotype in ALS patients that typically precedes the onset of lower motor neuron dysfunction. However, the underlying cause and consequence of changes in excitability remain unclear. Since C9-NRE expression can alter neuronal excitability, this could trigger a feed-forward loop of activity-dependent C9-NRE product expression. Our laboratory has recently shown that repetitive trains of depolarization at high frequency (100 Hz) and glutamate-induced excitotoxic stress can trigger RAN translation of DPRs. The effect of altered neuronal activity and C9-NRE products and disease pathogenesis, including DPRs, has just begun to be elucidated by our laboratory and others. However, there is still a critical need to further understand this relationship as it might unravel novel therapeutic targets to ameliorate the DPR burden in C9-ALS/FTD. With these initial findings in mind, I hypothesize that neuronal activity serves as a C9-ALS/FTD pathology modifier. I will dissect the impact of excitatory and inhibitory neuronal activity on molecular mechanisms of C9-ALS/FTD using patient-derived hiPSCs differentiated into glutamatergic cortical neurons.

Title: Altered expression of angiogenesis and proteinopathy molecules in North Indian ALS patients and their effects on NSC34 cell line.

Authors: *R. KHOSLA, S. MODGIL, A. TIWARI, K. SHARMA, A. ANAND;
Post Grad. Inst. of Med. Educ. and Res., Chandigarh, India

Abstract: Altered expression of angiogenesis and proteinopathy molecules in North Indian ALS patients and their effects on NSC34 cell line.**AuthorsRadhika Khosla***, Shweta Modgil, Abha Tiwari, Kaushal Sharma, Akshay Anand.
Disclosures Radhika Khosla: None, Shweta Modgil: None, Abha Tiwari: None, Kaushal Sharma: None, Akshay Anand*: None .**Abstract**Amyotrophic Lateral Sclerosis (ALS) is a devastating motor neuron disease which leads to paralysis and total loss of movement with increasing severity of the disease. The diagnostic and prognostic markers are limited. Proteinopathy and angiogenesis (and neuroprotection) have been studied in respect to the disorder. The objective of the study was to analyse the expression of molecules involved in the angiogenesis and proteinopathy as prospective biomarkers in plasma of ALS patients. 89 ALS patients and 98 non neurological controls were recruited in the study. The plasma levels of Vascular Endothelial Growth Factor (VEGF), VEGF Receptor 2 (VEGFR2), Angiogein (ANG), Tar DNA Binding Proetin 43 (TDP 43), Optineurin (OPTN) and Chemokine Ligand 2 (CCL2) were analysed among ALS using ELISA and compared with healthy individuals. Correlation analysis was done for all the markers. To further analyse the effect of the patients' plasma and these molecules on neurons, *in-vitro* analysis was done. NSC34 hybridoma cell line was used as a model. The cell line was stimulated using the patients' plasma to prepare *in-vitro* model of ALS. Appropriate controls were used for cell line experiments in the form of healthy participants' plasma as well as unstimulated cells. The same molecules expression was analysed in the cell line using RT-PCR and ICC experiments. The molecules were found to be significantly reduced in the patients' plasma and were found to be significantly correlated to one another. The plasma caused significant loss of cells after stimulation in *in-vitro* studies. Also the shape of cells was significantly altered. The cells lost their extensions and took circular shape. The expression of the molecules tested was also found to be altered in cell line. The results indicate the importance of the molecules to be studied as prospective biomarkers as a panel as all the molecules were correlated to one another. Studying the effects of plasma on neuronal cell line and study of the neuroprotective and proteinopathy molecules in patients' plasma can be useful in developing appropriate biomarkers for prognosis of the disease. However a limitation of the study is that along with plasma these molecules expression in CSF and plasma-CSF relation are also warranted to be studied as the neurons are in direct vicinity of the CSF.

Title: Transcriptome analysis using ALS patient iPSC-derived skeletal myocytes reveals Bet1L as a new molecule possibly linked to neuromuscular junction degeneration

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neuromuscular disease in which patients gradually become paralyzed due to loss of motor function. While many genetically inheritable mutations have been linked to ALS, the majority of ALS cases are considered sporadic. Therefore, there is a need for a common therapy that is effective for all ALS patients. Although there is evidence of the disease beginning in the periphery at the neuromuscular junction (NMJ), the specific processes involved in skeletal muscle and at the NMJ are still largely unknown. To study common disease mechanisms in ALS skeletal muscle, we performed RNA sequencing of skeletal myocytes differentiated from induced pluripotent stem cells (iPSCs) of familial ALS (with *C9ORF72*, *SOD1*, or *TARDBP* mutations) and sporadic ALS patients. Compared to healthy control lines, the myocytes from all ALS lines showed downregulation of four genes: *BET1L*, *DCX*, *GPC3*, and *HNRNPK*. We next measured the expression levels of these four genes in hind limb muscle samples from a rat model of familial ALS ($SOD1^{G93A}$ transgenic). Notably, only the Bet1L gene, which encodes Bet1 Golgi Vesicular Membrane Trafficking Protein Like, was commonly downregulated. Bet1L protein appeared to be localized to the basal lamina of the NMJ, with decreased expression over time following disease progression in $SOD1^{G93A}$ transgenic rats. Our results indicate that loss of Bet1L at the NMJ could be of interest for better understanding ALS disease progression.

Title: Cortical and Hippocampal Reductions in Synaptic Glycoprotein 2 Isoforms in a Rat Model of Traumatic Brain Injury

Authors: K. M. FRONCZAK, Y. LI, M. PARRY, E. HOLETS, J. J. HENCHIR, C. DIXON, ***S. W. CARLSON**;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Traumatic brain injury (TBI) can result in chronic cognitive impairments and greatly impact the quality of life for patients living with an injury. Alterations in hippocampal function, including changes in neurotransmission, have been shown to contribute to the manifestation of cognitive impairments in preclinical models of TBI. Neuronal communication is facilitated by the controlled release of neurotransmitters from vesicles in the presynaptic terminal. Synaptic vesicular glycoprotein 2 (SV2) isoforms SV2A and SV2B have been shown to be critical for maintaining the presynaptic vesicular pool and coupling of calcium signaling to the N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex, two presynaptic properties we have recently shown to be altered after TBI. The effect of TBI of SV2 isoforms has not been examined. To investigate this, cortical and hippocampal abundances of SV2A and SV2B were assessed at 1, 3, 7 and 14 days after 2.7mm controlled cortical impact (CCI) or sham control injury in rats. Immunoblotting revealed that SV2A and SV2B levels (n=6 / group / time point) were significantly reduced at multiple time points in the cortex and all time points in the hippocampus after CCI. Hippocampal immunohistochemical staining at 14 days post-injury (n=6 / group) revealed significantly reduced immunoreactivity for each isoform in several hippocampal subregions. Overall, reduced SV2 abundance was observed at time points in which injured animals exhibited impaired motor function, as tested by a beam walking task on days 1-5 post-injury, and impaired spatial learning and memory performance, as assessed by the Morris water maze task on days 9-14 post-injury. These findings provide new evidence for the effect of TBI on SV2 isoforms and novel insight into potential contributors to impaired neurotransmission and associated neurobehavioral dysfunction after TBI.

Title: Prophylactic activation of Shh attenuates TBI sequela by regulation of EAAT2 in adult zebrafish

Authors: *J. HENTIG, D. R. HYDE;
Univ. of Notre Dame, Notre Dame, IN

Abstract: Traumatic brain injuries (TBI) have tremendous and lasting impacts on survivors as these injuries can result in various sequelae. Secondary injury begins within minutes after TBI, with alterations in cellular function, metabolism, chemical signaling contributing to neuro-deterioration. Sonic hedgehog (Shh) is a key signaling pathway that is upregulated following central nervous system (CNS) damage in adult zebrafish and aids in injury-induced regeneration. The Smo agonist purmorphamine, which activates Shh signaling, attenuates various TBI sequelae. Using a modified Marmarou weight drop on adult

zebrafish, we examined post-traumatic seizures (PTS) following blunt-force TBI and Shh modulation. We demonstrate that purmorphamine-induced activation of Shh signaling attenuates TBI-induced sequelae. The inhibition of Shh signaling, by the Smo antagonist cyclopamine, significantly increased the number of TBI fish that experienced PTS, prolonged the timeframe PTS was observed, and significantly decreased survival across all TBI severities compared to severity-matched counterparts. qRT-PCR and immunoblots revealed purmorphamine increased EAAT2 expression in undamaged brains compared to untreated controls. Exposing undamaged fish to 5 mM glutamate in their tank water for 30 mins induced 90% of the fish to experience seizures, with the first seizure recorded as early as 5 mins after exposure. Purmorphamine treatment suppressed the glutamate-induced seizures, with the first recorded seizure at 20 mins and only 25% of the treated fish experiencing seizures. In contrast, cotreating glutamate-bathed fish with purmorphamine and cyclopamine resembled controls, with rapid seizure onset and the majority of the fish experiencing seizures. In contrast, triple-treating (purmorphamine, cyclopamine, and ceftriaxone to transcriptionally upregulate EAAT2) glutamate-bathed fish, rescued the glutamate-induced seizures, with delayed seizure onset and low percentages of fish experiencing seizure activity. In an analogous manner, purmorphamine treatment reduced post-traumatic seizures, edema, and cognitive deficits in TBI fish. In contrast, cyclopamine treatment increased seizure activity, and prolonged elevated edema and cognitive deficits in TBI fish. The increased severity of TBI phenotypes with cyclopamine was significantly reduced by cotreating the TBI fish with cyclopamine and ceftriaxone. Collectively, these data suggest that Shh signaling induces EAAT2 transcription and plays a role in regulating TBI-induced glutamate excitotoxicity and therefore reduces TBI-sequelae.

Title: Repeated concussions heightens the vulnerability of brain to blast exposure

Authors: *P. ARUN, D. M. WILDER, A. BATUURE, Y. WANG, J. B. LONG;
Walter Reed Army Inst. of Res., Silver Spring, MD

Abstract: A history of repeated concussions is known to cause long-term neurological problems. Typically as a result of contact sports or training exercises, significant numbers of military service members are reported to have a history of concussion before exposures to blast during deployment. No systematic studies have been carried out to determine whether concussion history heightens or decreases the brain vulnerability to blast exposure. In the present study, we have evaluated the effect of repeated concussions on the vulnerability of brain to blast exposure using neurobehavioral functional assessments in rats. Anesthetized rats were subjected to either repeated concussions (two concussions in one week apart using a modified Marmarou weight drop model) or single blast exposure (19 psi peak total pressure,

4-5 msec duration using an advanced blast simulator) or single blast exposure one day after the second weight drop. Sham control rats were not subjected to weight drop or blast exposure. Neurobehavioral changes were monitored at acute, and sub-acute time points using rotating pole test for vestibulomotor functions, open field exploration test for anxiety/depression, and novel object recognition test for short-term memory. Rotating pole test results indicated that the vestibulomotor functions were most disrupted in blast-exposed rats having prior concussions compared to the sham controls or rats exposed to either repeated concussions or blast. The deficits were evident from day 1 post-blast and persisted till one month. Total distance travelled, horizontal/vertical activity, center time and margin time measurements in the openfield exploratory activity test indicated that the rats exposed to both concussions and blast develop more anxious and depression-like behaviors compared to the other groups of rats at both acute and sub-acute time points. The novel object recognition test revealed short-term memory loss at 1 month post-blast in rats exposed to both repeated concussions and blast. The results obtained indicated that the concussion history exacerbated the neurobehavioral functional deficits after blast exposure.

Title: Repetitive Mild Head Trauma Induces Age-Dependent Sexually Dimorphic Long-term Brain Deficits in a Novel Drosophila Model

Authors: *C. YE[1], J. A. BEHNKE[1], K. H. MOBERG[1], J. Q. ZHENG[2];
[1]Cell Biol., Emory Univ., Atlanta, GA, [2]Cell Biol., Emory Univ., Atlanta, GA

Abstract: Traumatic head impacts, including mild ones such as concussion, represent an environmental risk factor linked to the development of chronic brain dysfunction that can occur years after initial exposure. However, the underlying mechanisms remain poorly understood. A better understanding of the brain's response to mild physical insults and the long-lasting detrimental effects can lend new insight towards the development of neuroprotective strategies. *Drosophila melanogaster* represents an excellent tractable model organism to dissect fundamental cellular and molecular disease mechanisms, including neurodegeneration. With their relatively short lifespan, *Drosophila* enables long-term outcome analyses after initial exposure to mild head trauma. To investigate the life-long effects on brain function and structure after the initial exposure to mild head trauma and the underlying mechanisms, we developed the **H**ead **I**mpact **FL**y **I**njury model (HIFLI) model, in which mild repetitive headfirst impacts to multiple

(10-15 at a time) awake and unrestrained adult flies can be delivered. We showed that young flies (3-5 days old) subjected to our mild and nonlethal injury immediately exhibited concussive-like behaviors such as temporary uncoordinated and seizure-like movements but recovered within 24 hours. However, these injured flies progressively developed impaired startle-induced climbing, brain degeneration, and shortened lifespan throughout their lifetime. Importantly, the behavioral deficits and brain degeneration were more profound in female flies than male flies, indicating that female flies have a heightened vulnerability to mild head trauma. Interestingly, we found that head impacts elicited elevated brain activity, and its acute blockage abrogated some of the detrimental effects in female flies. Lastly, we assessed age as a risk factor for head trauma-induced chronic brain dysfunction by delivering mild head impacts to fly cohorts of different ages (3 days, 2 weeks, and 4 weeks old). We observed substantially worse sensorimotor decline and brain degeneration in the older cohorts, indicating that aging increases vulnerability to mild head injury. Together, our findings validate *Drosophila* as a suitable model system for investigating the long-term effects of head trauma, suggest an increased vulnerability in females and older adults for head trauma-induced brain dysfunction and degeneration, and indicate that early altered neuronal excitability may be a key mechanism linking mild brain trauma to chronic degeneration.

Title: Traumatic Brain Injury Alters Contextual Fear Extinction But Not Pattern Separation

Authors: *E. R. HALTER[1], C. D. ADAM[2], M. SERGISON[3], O. FRUCHET[3], J. A. WOLF[2];
[1]Univ. of Pennsylvania, PA, PA; [2]Neurosurg., [3]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Traumatic Brain Injury (TBI) and Post-Traumatic Stress Disorder (PTSD) are two of the most common ailments afflicting Veterans. However, little is known about the comorbidity of these two disorders, or how they interact and progress over chronic time points. To study the effect of injury on fear memory acquisition and extinction, we subjected rats to a lateral fluid percussion injury (FPI) of 1.8atm or 2.1atm, creating a unilateral mild to moderate TBI. These animals were run through a contextual fear-conditioning and pattern separation paradigm at an acute time point two weeks post-injury (1.8atm n=5, 2.1atm n=3) or sham surgery (n=7). All groups showed an equal affinity for the creation of contextual fear memories as evidenced by similar overall acquisition curves and corresponding high freezing levels in the acquisition context, context A, during the first extinction trial. Similar pattern separation abilities between groups were also displayed by significantly lower freezing levels in a similar, but novel context B, used only for extinction 2, and completed 5min after extinction 1. When a third extinction trial was completed one day later back in context A, sham animals showed a significant reduction in freezing as

compared to extinction 1. This suggests sufficient extinction memory creation and consolidation had occurred. At this same time point, both groups of injured animals did not show decreased freezing but instead displayed freezing at levels statistically similar to the first extinction trial in context A. In the 2.1atm injured group, this high level of freezing in extinction 3 was much more pronounced than the 1.8atm injured animals, suggesting a corresponding larger injury effect. Both groups of injured animals did not show significant extinction in context A until extinction 4, one trial later than seen in the sham group. Our findings suggest that TBI slows the creation and consolidation of fear extinction memories but does not appear to affect the acquisition of contextual fear memories or pattern separation abilities on a short temporal scale. The mild to moderate injury may be disrupting the extinction process due to sleep deficits preventing the consolidation of the extinction memory. This effect appears to increase with injury size. Our data gives us a behavioral basis to further explore the mechanisms underlying this dysfunction using *in vivo* electrophysiological and explore more chronic injury time points using this behavioral paradigm.

Title: Studying the regeneration of the zebrafish telencephalon in response to blunt force traumatic brain injury.

Authors: *K. CLOGHESSY, J. HENTIG, D. R. HYDE;
Biol. Sci., Univ. of Notre Dame, Notre Dame, IN

Abstract: Blunt force traumatic brain injuries (bfTBIs) result in global and diffuse damage to the central nervous system (CNS) and are associated with increased risk of long-term side effects, like memory loss, speech issues, and seizures. Currently, treatments for TBI are focused on managing chronic damage, rather than regenerating cells lost during injury. Activation of endogenous quiescent stem/progenitor cells is a possible therapy for TBI, necessitating a deeper understanding of the genetic mechanism of neuronal regeneration. While the regenerative capacity of mammals is limited, zebrafish (*Danio rerio)* has a robust neurogenic capacity in the CNS, making it ideal to uncover mechanisms involved in endogenous neuronal repair. Our lab modified the Marmarou weight drop model, allowing us to deliver scalable blunt force injury that is centered on the zebrafish telencephalon, homologous to the hippocampus, the center of learning and memory. Following bfTBI, we found that zebrafish recapitulate many of the phenotypes commonly seen in human TBI patients, including an increase in both the number of fish experiencing

seizures and the time required to recover from the bfTBI. There was an increase in the severity of subdermal hematomas, which correlated with the disruption of the blood brain barrier (BBB) as measured with Evan's Blue dye. We also observed cognitive deficits, such as learning in a shuttle box assay, which utilizes an associative-learning test with an adverse electric shock stimulus. Following the bfTBI, we found that both short-term and long-term recall of a learned behavior in the shuttle box were significantly impaired. We determined that the bfTBI induced a gradient of cell death across the entire neuroaxis of the brain, with the maximum numbers of dying cells centered on the region underlying the impact site. Most importantly, we found that the bfTBI also induced cell proliferation in the telencephalon. Thus, zebrafish represents a useful model that recapitulates many of the clinical symptoms described in human bfTBI patients, but unlike mammalian models, also exhibits a robust cell proliferation and neuronal regeneration response. This will allow us to study the genetic mechanisms that induce the quiescent stem/progenitor cells to reenter the cell cycle and regenerate lost neurons following a bfTBI, which could ultimately lead to inducing an analogous regeneration response in humans.

Abstract: Mechanisms of Secondary Injury and Auditory Deficits Following Mild Blast Induced Trauma

Joseph Fernandez[1,4], Emily Han[1], Edward Bartlett[1,3], Riyi Shi[1,3,41]Weldon School of Biomedical Engineering, Purdue University, West Lafayette, IN[2]School of Medicine, Indiana University, Indianapolis, IN[3]Purdue University Interdisciplinary Life Science (PULSe) Program, Purdue University,West Lafayette, IN[4]Dept. Basic Medical Sciences, College of Veterinary Medicine, Purdue University,West Lafayette, IN

Blast-induced hearing difficulties affect thousands of veterans and civilians each year. The long-term impact of blast exposure on the central auditory system (CAS) can last months, even years, without major external injury, and is hypothesized to contribute to many behavioral complaints associated with mild blast traumatic brain injury (bTBI). However, the mechanisms that underlie these long-term impairments are still poorly understood. Although initial mechanical injury likely plays a role in central auditory damage, a secondary molecular mechanism of damage likely results in the chronic auditory deficits following mild bTBI. Oxidative stress has been suggested as a key player in secondary molecular damage

in other models of CNS injury, including other TBIs, and may underlie functional auditory deficits in mild bTBI as well. Here, we examined the underpinnings of auditory deficits following bTBI and compared these results to molecular and anatomical changes observed following injury. We examined changes in markers for cellular membrane damage and acrolein protein adducts for oxidative stress. Additionally, we examined GAD65/67 for changes in cellular inhibition/excitation patterns. These markers were assessed along the auditory pathway, namely, within the superior olivary complex (SOC), inferior colliculus (IC), and auditory thalamus (AT). Increased TMR and acrolein protein adducts staining in blast animals indicate initial mechanical injury within the SOC and ventral axon streams in the brainstem at the 2 day post injury time point. Staining for GAD65/67 shows a reversal of inhibition/excitation within these auditory systems over the course of 14 days. Comparisons of ABR wave amplitudes/ratios and middle latency response, suggest functional changes correlated with these anatomical results. Taken together, our results suggest that an acute cascade of (axonal) membrane damage and oxidative stress results in a temporally dependent inhibition/excitation imbalance over the course of two weeks that is correlated with slight changes in auditory processing.

Title: Serotonin sensitivity across injury severities

Authors: *O. SHELTON[1], D. V. BIRCH[2], M. JIANG[1], V. M. TYSSELING[2];
[2]Dept. of Physical Therapy and Human Movement Sci. and Physiol., [1]Northwestern Univ., Chicago, IL

Abstract: Spinal cord injuries disrupt messages between the brain and the body distal to the injury. This results in paralysis below the injury level and makes daily function very difficult. In addition, most people with spinal cord injury develop hyperreflexia and involuntary muscle contractions, or spasms, that cause even more movement dysfunction as well as pain, contractures, and safety issues. Multiple neuronal tracts are interrupted by SCI. Descending projections from the raphe nuclei innervate the spinal cord and release 5-HT onto spinal neurons. 5-HT alters the excitability of neurons via persistent inward currents. In chronic SCI with long-term deprivation of 5-HT input motoneurons and several species of spinal interneurons change their response to 5-HT by becoming constitutively active or increasing their sensitivity to 5-HT, respectively. In this study we examine whether the difference in intensity of spasms varies with/can be explained by the degree of increase of 5-HT sensitivity of the spinal cord. We used a chronic impact injury mouse model of SCI. We assessed the amount of functional locomotor recovery at 10wks and compared this recovery to the electrical outputs from muscle and nerve tissue in the SCI mice.

To compare how muscle contractions were impacted by our drug interventions we tested spasticity *in vivo* by recording the flexor withdrawal EMG response to an electrical stimulus three months post injury. To directly measure the spinal reflexes, we removed the sacral section of the spinal cord, stimulated the dorsal roots, and then recorded the ENG response through the ventral roots.

Title: Mitochondrial Adaptations to Diaphragm Muscle Inactivity Imposed by Cervical Spinal Cord Injury

Authors: *A. D. BROWN[1], M. J. FOGARTY[2], G. C. SIECK[3];
[1]Dept of Physiol. and Biomed. Engin., [2]Dept. of Physiol. & Biomed. Engin., [3]Physiol. & Biomed. Engin., Mayo Clin., Rochester, MN

Abstract: Mitochondrial Adaptations to Diaphragm Muscle Inactivity Imposed by Cervical Spinal Cord InjuryAlyssa D. Brown, Matthew J. Fogarty, Gary C. Sieck
2101/2300 characters Type I and IIa diaphragm muscle (DIAm) fibers comprise fatigue resistant slow and fast motor units that are recruited to accomplish breathing. In contrast, type IIx/IIb fibers comprise more fatigable fast motor units that are infrequently recruited only during airway protective and straining behaviors. Thus, there are marked differences in the activity and energetic demand for type I and IIa DIAm fibers compared to type IIx/IIb fibers. Cervical spinal cord hemisection at C_2 (C_2SH) removes excitatory drive for inspiratory activity of the DIAm and thereby imposes prolonged inactivity of type I and IIa fibers. We hypothesize that mitochondrial structure and function in type I and IIa DIAm fibers differs from type IIx/IIb fibers and adapts in response to inactivity induced by C_2SH. After C_2SH, inactivity was confirmed by the absence of DIAm EMG, and after 14 days, the effect of inactivity on mitochondrial structure and function was assessed in type identified fibers. Mitochondria in DIAm fibers were labeled using MitoTracker Green and imaged in 3-D by fluorescence confocal microscopy. Mitochondrial volume density and morphometry were analyzed using ImageJ. In alternate serial sections of the same DIAm fibers, the maximum velocity of the succinate dehydrogenase reaction (SDH_{max}) was determined using a quantitative histochemical technique. Overall, mitochondrial volume density was higher in type I and IIa DIAm fibers and mitochondria were more filamentous compared to type IIx/IIb fibers. Inactivity reduced mitochondrial volume density in type I and IIa DIAm fibers and induced mitochondrial fragmentation. The SDH_{max} values normalized for fiber volume and for mitochondrial volume were both higher in type I and IIa DIAm fibers compared to type IIx/IIb fibers. After 14 days of

inactivity induced by C_2SH, SDH_{max} (normalized for fiber volume and for mitochondrial volume) decreased in type I and IIa. These results are consistent with mitochondrial structural and functional adaptions to the marked reduction in the energetic demand of type I and IIa DIAm fibers imposed by C_2SH.

Title: Timeline of changes in key hormones and their receptors associated with spinal cord injury-induced polyuria

Authors: *J. H. GUMBEL, C. YANG, L. E. ZIPPERER, C. H. HUBSCHER;
Univ. of Louisville, Lousiville, KY

Abstract: Timeline of changes in key hormones and their receptors associated with spinal cord injury-induced polyuria
Jason H Gumbel, Cui Bo Yang, Lindsey E Zipperer, Charles H Hubscher
Spinal cord injury (SCI) results in upper and lower urinary tract function deficits, which includes detrusor overactivity, urinary incontinence, detrusor-sphincter dyssynergia, and polyuria. Together, these are among the leading issues that affect quality of life. As the overproduction/passage of urine (polyuria) after SCI has previously been associated with an imbalance in key regulators of body fluid homeostasis, this current study examined the timing of changes in levels of these hormones, peptides, receptors, and channels post-contusion injury in adult male Wistar rats. The results of this study demonstrate significant up or down regulation at various time points, beginning at 7 days post injury, in the levels of urinary atrial natriuretic peptide (ANP), serum arginine vasopressin (AVP), kidney natriuretic peptide receptor-A (NPRA), kidney vasopressin-2 receptor (V2R), kidney aquaporin-2 channels (AQP2) and kidney epithelial sodium channels (ENaC, β and γ but not α subunits). Additionally, the number of AVP-labeled cells/area in the hypothalamus were also significantly decreased at one or more time points, particularly in the suprachiasmatic nucleus which deals with circadian rhythms. Together, the observed significant fluctuations in key components involved in body water/solute homeostasis post-SCI suggests therapeutic interventions (for example, desmopressin, a synthetic analogue of AVP - a hormone known to lose its diurnal rhythmicity post-SCI in humans) should be considered early post-SCI.

Title: Sci in aged mice exacerbates neuropathological changes in both spinal cord and brain leading to worsened neurological dysfunction

Authors: *Z. LEI, Y. LI, R. M. RITZEL, H. LI, A. I. FADEN, J. WU;
Anesthesiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Approximately 20% of all spinal cord injuries (SCI) occur in persons aged 65 years or older. Older patients with SCI have different features with regard to neurological characteristics after injury. Recent large-scale longitudinal population-based studies showed that patients with SCI are at a higher risk of developing dementia than non-SCI patients, indicating that SCI is a potential risk factor for dementia. Age is known to potentiate inflammation and neurodegeneration at the injured site leading to impaired recovery from SCI. However, no research has been aimed at studying the mechanisms of SCI-mediated cognitive impairment in the elderly. In the present study, young adult (3-month-old) and aged (18-month-old) male mice were subjected to moderate contusion SCI at T10 and their functional outcomes were evaluated using a battery of neurobehavioral tests including motor function [Basso Mouse Scale (BMS)], cognition [Y-maze, novel object recognition (NOR)], and depression [novelty-suppressed feeding (NSF) and social recognition (SR)]. BMS assessment of locomotor function showed marked impairment in aged mice compared to young animals, which were correlated with reduced spared white matter and increased lesion volume. At 2 months post-injury, aged mice displayed worse performance in neurobehavioral tests, as evidenced by lower % of spontaneous alteration in Y-Maze task, reduced novelty preference in NOR test, increased sociability deficits in SR, and elevated latency to detect food in NSF, indicating exacerbated impairment of cognition and depressive-like behavior in aged mice compared to young animals. NanoString analysis with the neuropathology panel identified several age- and injury-specific genes that were differentially expressed in the brain after SCI, including those involved with the inflammation, neurodegeneration, and autophagy pathways. These findings were further validated by qPCR and microscopy. Flow cytometry demonstrated increased microglia and myeloid and lymphocytes infiltration at the injured site from young mice which was exacerbated with age. Moreover, SCI in aged mice altered microglial function and dysregulated autophagy function in both microglia and neurons of the brain, resulting in neurodegeneration compared to young animals. Taken together, our data indicate that aging exacerbates neuropathological changes in both injured spinal cord and remote brain region that is associated with poorer functional outcome. Thus, our studies provide innovative cellular and molecular perspectives on the pathophysiology of age-related deficits after SCI.

Title: Spinal dopamine synthesis, release, and regulation of micturition reflexes in female rats with spinal cord injury

Authors: *J. H. DEFINIS[1], E. OATMAN[1], Z. D. BRODNIK[2], C. T. TRUEBLOOD[1], R. A. ESPAÑA[2], S. HOU[1];
[1]Marion Murray Spinal Cord Res. Center, Dept. of Neurobio. and Anat., [2]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Spinal cord injury (SCI) often results in urinary dysfunction. Although an involuntary micturition reflex can be established to elicit voiding, bladder hyperreflexia and detrusor-sphincter dyssynergia arise to cause incontinence and inefficient expulsion of urine. To date, the mechanisms that underlie the regulation of micturition after SCI are not well understood. We recently observed an increase of a population of tyrosine hydroxylase (TH)+ cells in the rat lumbosacral cord following SCI, which could contribute to the sustention of a low level of dopamine (DA) that modulates the recovered micturition reflex. To further elucidate this spinal endogenous machinery, we employed multiple approaches in female rats with SCI, including qPCR and Western blot to determine the expression of DA-related genes and proteins, fast-scan cyclic voltammetry (FSCV) to test in situ DA release, injection of Bromodeoxyuridine (BrdU) and immunostaining to identify the origin of TH+ neurons, as well as bladder cystometrogram (CMG) and external urethral sphincter (EUS) electromyography (EMG) to examine DA-modulated detrusor-sphincter activity. Three weeks after T10 spinal cord transection, mRNA and protein levels of TH and dopamine decarboxylase (DDC) were decreased, but detectable in the L6/S1 spinal cord segment. Focal electrical stimulation of the region where TH+ cells reside in spinal cord slices evoked DA release. In BrdU injected rats, labeling of mitotic cells showed that no TH+ cells incorporated BrdU. Alternatively, a portion of spinal TH+ cells express PAX2, a transcription factor of inhibitory interneurons. During bladder CMG and EUS EMG, intrathecal (i.t.) administration of the DA precursor, L-DOPA, reduced the number of bladder non-voiding contractions in the filling phase and increased the EUS bursting period during voiding, illustrating the precursor's ability to decrease bladder hyperactivity and improve voiding efficiency. Thus, spinal TH+ cells undergo injury-induced plasticity and are capable of synthesizing and releasing DA following SCI. Newly emerged TH+ cells may develop from a phenotypic switch rather than neurogenesis. Ultimately, increasing DA signaling in the lower cord enhances recovered micturition function after SCI.

Title: Characterizing age-dependent alterations in neuron-extrinsic responses after spinal cord injury

Authors: *T. C. SUTHERLAND, D. HORVAT, A. SEFIANI, O. A. GARCIA, M. RIVERA, P. HUNG, C. G. GEOFFROY;
Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Spinal Cord Injury (SCI) is the second most common cause of paralysis, following stroke, and places a significant life-long burden on patients. In the western population, the average age of incidence for SCI has increased, as has the length of survival of SCI patients. This places great importance on understanding SCI in middle-aged and aging patients. Experimentally, SCI is commonly modeled in young adult animals in stark contrast to the aging human population, likely hampering translation of research to the clinic. Axon regeneration after injury is an area of study that has received substantial attention and made important experimental progress, however our understanding of how aging affects this process, and any therapeutic effort to modulate repair, is incomplete. The growth and regeneration of axons is mediated by both neuron intrinsic and extrinsic factors, and both may play a significant role in the age-dependent decline of this capability. Key extrinsic influences on axon regeneration in the include inflammation and astrogliosis, components of the extracellular matrix, and myelin proteins. Alterations in neuron-extrinsic factors with age have received little attention, however, and how the age factor can impact these responses is not well characterized. Alterations in these elements have been observed in the naïve aging CNS and also after SCI. These may compound to result in worse outcomes after SCI in aging populations. Age-dependent alterations in astroglial dynamics are likely to impact the efficiency of astrogliosis, and diminish the ability of astrocytes to quickly sequester the fibrotic scar and inflammatory lesion. There is also evidence of altered inflammation and fibrosis, as well as increases in inhibitory ECM molecules in aging animals. These elements lead to a more severe SCI lesion and will likely result in subsequent decreases in functional recovery. Understanding these age-dependent changes in acute and sub-acute phases of SCI is highly significant to provide strategies to target this early neuron-extrinsic response in aging populations. This will be vital to the development of potential therapeutic avenues to improve injury outcome in an increasingly older SCI population and improve functional recovery after SCI in patients of all ages.

Title: May the force be with regeneration

Authors: *Y. SONG;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Axons in the mature central nervous system (CNS) fail to regenerate after injury, due to the loss of neuronal intrinsic growth potential and the extrinsic inhibitory environment constituted by reactive glial cells. We aim to identify, characterize and manipulate programs in and out of the neurons to achieve axon regeneration and behavioral recovery. We identified a neuronal intrinsic program acting as a brake on axon regeneration by sensing the mechanical force. During axon regeneration, the growth cone physically interacts with the environment such as the glial cells, resulting in the activation of the mechanosensitive ion channel Piezo at the growth cone tip. Opening of the Piezo channels leads to local calcium influx and the activation of Nos (Nitric oxide synthase), which then produces NO. NO functions as a second messenger and propagates to the nucleus where it activates Atr (ataxia telangiectasia and Rad3 related) and its associated complex non-canonically, causing regeneration failure. Atr is a serine/threonine kinase, known to sense single-stranded DNA breaks and activate the DNA damage checkpoint by phosphorylating Chek1, which inhibits Cdc25, causing cell cycle arrest. This pathway has not been implicated in neuroregeneration. We show that in *Drosophila* sensory neurons removing Atr or Chek1, or overexpressing Cdc25 promotes regeneration, whereas Atr or Chek1 overexpression, or Cdc25 knockdown impedes regeneration. Inhibiting the Atr-associated checkpoint complex in neurons promotes regeneration and improves synapse/behavioral recovery after CNS injury. Independent of DNA damage, Atr responds to the mechanical stimulus elicited during regeneration, via the mechanosensitive ion channel Piezo and its downstream NO signaling. Sensory neuron-specific knockout of Atr in adult mice, or pharmacological inhibition of Atr-Chek1 in mammalian neurons *in vitro* and in flies *in vivo* enhances regeneration. Our findings reveal the Piezo-Atr-Chek1-Cdc25 axis as an evolutionarily conserved inhibitory mechanism for regeneration, and identify potential therapeutic targets for treating nervous system trauma.

Title: Combination of viral BDNF and daily epidural stimulation to activate locomotor circuits and limit spasticity after complete spinal cord injury in mouse.

Authors: *N. J. STACHOWSKI, D. L. GARCIA-RAMIREZ, S. J. ATOCHE, L. YAO, S. F. GISZTER, K. J. DOUGHERTY;
Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: SCI disrupts motor control below the level of injury, often resulting in paralysis and/or hyperreflexia which remain intractable to current rehabilitation strategies. However, spinal locomotor circuits can be activated to mediate functional stepping in the absence of descending control and serve as therapeutic targets for locomotor rehabilitation. Although excitation of silent pathways is often the focus of SCI studies, a restoration of inhibitory gating of sensory information is essential to prevent aberrant signaling and ensure smooth motor control. BDNF-TrkB signaling has known roles in inhibitory circuit formation and neuronal excitability, and viral overexpression of BDNF after SCI has been associated with locomotor improvements but also pain and spasticity. Epidural stimulation (ES) reduces hyperalgesia and hyperreflexia but additional excitatory modulation is needed to maximize locomotor function. The goals of our study are first to determine if locomotor outcomes can be improved by combining these potentially complementary strategies and then to identify a cellular target by which these strategies exert their beneficial effects for future leveraging. Recent intersectional genetic manipulations have linked inhibitory interneurons (INs) expressing the retinoid orphan receptor β (RORβ), and more specifically expression of TrkB receptors on RORβ INs, with sensory gating of proprioceptive input. Therefore, we hypothesize that exogenous BDNF and ES converge on RORβ INs to enhance inhibition in order to counterbalance concomitant non-specific excitatory effects of BDNF. Here, we use a complete thoracic transection model with viral BDNF treatment alone and in combination with daily ES in adult RORβcre;lsl-tdTomato mice to determine chronic rehabilitative effects *in vivo* and changes in RORβ cellular excitability *in vitro*. We perform weekly measures of locomotor performance and hyperreflexia for 6 weeks post-SCI followed by whole cell patch clamp recordings from RORβ INs in spinal slices. Mice receiving BDNF display weight-supported, alternating stepping but also greatly exacerbated hyperreflexia, but the latter is reduced by ES. RORβ INs from SCI mice have more depolarized voltage thresholds for action potential generation and higher rheobase, whereas cellular properties in neurons from BDNF-treated mice are similar to those of uninjured controls. Taken together, our results suggest that BDNF and ES may have synergistic effects to enhance locomotor improvements when combined and identify RORβ INs as a potential target for restoration of inhibitory counterbalance in sensorimotor pathways after SCI.

Abstract: The acute phase of spinal cord injury (SCI) is marked by loss of motor function. However, uncontrolled muscle spasms develop in the chronic phase and can interfere with rehabilitation efforts and daily activities. Current pharmacological approaches to manage these spasms depend on global suppression of motor circuit excitability which can equally hinder motor recovery after SCI. To identify more specific therapeutic targets, we investigated chronic changes in synaptic excitation and inhibition in spinal motor circuits, as well as motoneuron intrinsic excitability. We used mouse models of both complete (transected) and incomplete (impact) chronic SCI. Following recovery, animals with incomplete injury were further divided into either low-function or high-function groups based on their BMS score. The whole-tissue sacrocaudal spinal cord along with its ventral and dorsal roots was then extracted and maintained *ex-vivo* and used to evaluate spasm-like activity and its underlying synaptic inputs. Tissue from age-matched animals with no prior spinal injuries was used as a control. Electrical stimulation of the dorsal roots elicited prolonged activity (spasm-like activity) in the ventral roots in all injury models as compared to very brief responses in the control preparations. To study the mechanisms of this activity, we evaluated changes in synaptic inhibition, synaptic excitation, and motoneuron excitability. Synaptic inhibition was estimated indirectly by measuring rate-dependent depression (RDD) of the dorsal root reflex. All SCI groups showed decreased synaptic inhibition compared to control. To evaluate excitatory synaptic currents and motoneuron persistent inward currents (PICs) underlying spasm-like activity, synaptic inhibition was first pharmacologically blocked. Then, individual motoneurons were recorded using single-electrode voltage clamp to measure membrane currents during sensory-evoked spasms. There was no difference in the amplitude of synaptic excitatory currents measured in the injury models compared to control. In addition, motoneuron PICs were slightly increased after injury. Interestingly, when the three chronic injury models were compared to each other, there was no difference in either excitatory synaptic currents or PICs. These results indicate that decreased synaptic inhibition and increased motoneuron PICs drive spasm-like activity in different animal models and thus could serve as better therapeutic targets for managing muscle spasms following SCI.

Title: The BDNF Val66Met genetic polymorphism increases vulnerability of human motor neurons derived from pluripotent stem cells to an in vitro stretch injury

Authors: S. HE[1], *A. TOGLIATTI[2], K. Y. COTTON[2], Y. BOURICHA[2], I. E. JONES[3], J. D. FINAN[3], C. K. FRANZ[2];

Abstract: Traumatic spinal cord injury (SCI) results in various neurological impairments. Most research emphasizes the white matter (axons) loss after the injury. But emerging treatments of SCI like neuromodulation techniques also rely on preserved gray matter (neurons) in the spinal cord. In previous clinical studies, motor neurons loss after SCI varies a lot between patients for several segments above and below the level of injury. Individual patient genetic variation is an elusive factor that may contribute to variable outcomes after SCI. To understand how genetic variation may affect outcomes, we focus on the brain-derived neurotrophic factor (BDNF) since it is an important growth factor in neural development and neural regeneration. The single nucleotide polymorphism (SNP) in the BDNF gene, which results in the substitution of valine by methionine at the 66th residue in the protein (i.e., BDNF Val66Met), has decreased activity-dependent release of BDNF and is associated with altered outcomes in neurological injury such as stroke or traumatic brain injury. It is unknown how Val66Met polymorphism influences outcome after SCI, but approximately 1/3rd of the US population carry it. To test the hypothesis that carriers of the Met allele are more susceptible to motor neuron degeneration after mechanical injury, we use an *in vitro* stretch injury model employing human induced pluripotent stem cell (iPSC)-derived motor neurons from two patients (both are gene-edited to differ by just the presence or absence of the Met allele). We apply different strain levels to isogenic iPSC-motor neurons, then measured the cell viability and neurite length after the injury. The results show that the Met allele carrying motor neurons are more susceptible to neurodegeneration than the Val allele carrier after the injury. Attempts to rescue this phenotype by adding back different amounts of recombinant BDNF could only partially rescue the difference between genotypes before adding even higher amounts resulted in worsening outcomes in both Val and Met groups. Transcriptomic analysis of isogenic iPSC-motor neurons by RNA sequencing reveals differential expression of 1491 genes (613 upregulated, 878 downregulated) with gene ontology enrichment analysis identifying novel cellular processes that may contribute to why the BDNF Val66Met polymorphism is associated with greater susceptibility to neurodegeneration after injury.

Title: The MAP3ks Dlk and Lzk direct diverse responses to axon damage in zebrafish peripheral neurons

Authors: *K. ADULA[1], A. SAGASTI[2];
[2]MCDB, [1]UCLA, Los Angeles, CA

Abstract: The MAP3Ks Dual Leucine Kinase (DLK) and Leucine Zipper Kinase (LZK) play diverse roles in axon damage responses. To characterize their functions in axon injury at the single cell level, we generated zebrafish mutants of each gene, labeled single motor neurons (MN) and Rohon-Beard (RB) touch-sensing neurons in live zebrafish, precisely cut their axons with a laser, and assessed the ability of mutant axons to regenerate. DLK and LZK were required redundantly and cell autonomously for axon regeneration in MN neurons, but not in larval RB or adult dorsal root ganglion neurons. Surprisingly, in dlk lzk double mutants, the spared branches of wounded RB axons grew excessively, suggesting that these kinases inhibit regenerative sprouting in injured axons. Uninjured trigeminal sensory axons also grew excessively in mutants when neighboring neurons were ablated, indicating that these MAP3Ks are general inhibitors of sensory axon growth. These results demonstrate that zebrafish Dlk and Lzk promote diverse injury responses, depending on the neuronal cell identity and type of axonal injury.

Title: Sensory STIM1 is coupled to TRPA1 contributing nociception

Authors: *Y. MEI, B. LEE, N. KAUSHAL, T. ROHACS, H. HU;
Rutgers New Jersey Med. Sch., Newark, NJ

Abstract: The transient receptor potential (TRP) channels play critical roles in sensory modalities, including nociception. TRPA1 is a member of the TRP superfamily. It serves as a noxious chemical sensor and is involved in nociception and chronic pain. TRPA1 is a Ca^{2+} permeable ion channel and located on the plasma membrane. It has been shown that activation of TRPA1 induces intracellular Ca^{2+} release. However, the functional significance of TRPA1-mediated Ca^{2+} release remains unclear. STIM1 is a single transmembrane-spanning Ca^{2+} binding protein and is a Ca^{2+} sensor in the ER to initiate store-operated Ca^{2+} entry (SOCE) when ER Ca^{2+} level is reduced. Our previous studies have shown that STIM1 is expressed in the majority of nociceptors. Whether TRPA1-mediated Ca^{2+} release can activate STIM1 is unknown. In this study, we investigated the involvement of STIM1 in TRPA1-mediated Ca^{2+} response and nociceptive behavior. We transfected the DRG neurons with an ER Ca^{2+} indicator, G-CEPIAer1, and

loaded the transfected neurons with Fura-2 to simultaneously monitor cytosolic and ER Ca^{2+} concentration changes. Our Ca^{2+} imaging data showed that DRG neurons responded to 100 μM AITC, a TRPA1 agonist, in the Ca^{2+} free solution, leading to Ca^{2+} release from the ER, suggesting TRPA1 is likely located in the ER. Using TIRF microscopy, we observed STIM1 puncta formation and translocation after treatment of AITC in the co-transfected STIM1-YFP and TRPA1 HEK cells, suggesting that TRPA1-mediated ER Ca^{2+} release activates STIM1. Moreover, AITC-induced SOCE was significantly reduced in STIM1 KO neurons. To determine whether STIM1 contributes to TRPA1-mediated nociception, AITC-induced nociceptive behavior was examined in WT and STIM1 KO mice. STIM1 KO mice showed a marked reduction of AITC-induced nociception, especially at later time points. Our findings reveal the functional link between intracellular TRPA1 and STIM1. Our study also provides insights into the TRPA1-mediated nociception.

Title: Store-operated calcium channels are modulated by prostaglandin via the EP1-PKC pathway

Authors: *H. HU[1], D. WEI[2], Y. MEI[1], V. WHITEHEAD[1], A. BEKKER[1];
[1]Rutgers New Jersey Med. Sch., Newark, NJ; [2]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Store-operated calcium channels are modulated by prostaglandin E2 via the EP1-PKC pathway Huijuan Hu, Dongyu Wei, Yixiao Mei, Victoria Whitehead, Alex BekkerDepartment of Anesthesiology, Rutgers New Jersey Medical School Newark, NJ 07103Chronic inflammatory pain is often caused by peripheral tissue inflammation. Peripheral sensitization is one of the primary mechanisms underlying the pathogenesis of chronic inflammatory pain. However, candidate molecules involved in peripheral sensitization remain unclear. We have shown that store-operated calcium channels (SOCs) are expressed in the dorsal root ganglion (DRG). Whether SOCs contribute to peripheral sensitization associated with chronic inflammatory pain is elusive. Here we report that global deletion of Orai1, a major component of the SOC family, attenuates CFA-induced pain hypersensitivity. To determine the peripheral role of Orai1 in inflammatory pain, we performed patch clamp and Ca^{2+} imaging recordings in wild type (WT) and Orai1 knockout (KO) DRG neurons. We found that thapsigargin (TG, an ER Ca^{2+}-ATPase inhibitor)-induced SOC entry (SOCE) and SOC currents were significantly increased in WT, but not in Orai1 KO DRG neurons from CFA injected mice. Interestingly, the expression level of the Orai1 in L3/4 DRGs was not altered, suggesting that the increased SOCE in DRG neurons is attributed to the functional change of Orai1. To understand how the Orai1 is modulated under inflammatory pain conditions, prostaglandin E_2 (PGE_2), a major inflammatory mediator, was used to sensitize DRG neurons. TG-induced SOCE in DRG neurons was potentiated by PGE_2 in WT, but not Orai1 KO neurons. This

effect was attenuated by a PGE_2 receptor 1 (EP1) antagonist, a Gq/11 inhibitor, PLC and PKC selective inhibitors, indicating PGE_2-induced SOCE enhancement is mediated by EP1 and its downstream Gq-PKC cascade. Consistently, Orai1 deficiency diminished PGE_2-induced thermal hyperalgesia and mechanical allodynia, suggesting that Orai1 is a novel downstream target of PGE2 signaling. Taken together, our findings demonstrate that peripheral Orai1 plays an important role in mediating peripheral sensitization. Our study also provides new insight into molecular mechanisms underlying chronic inflammatory pain.

Title: Kv7.2 is the functionally dominant Kv7 subunit in peripheral nociceptors

Authors: *F. JONES, S. MILNE, N. GAMPER;
Univ. of Leeds, Leeds, United Kingdom

Abstract: Pain is a regular and unavoidable experience that dramatically impacts people's quality of life. Current treatments are often inadequate, expensive or invasive, thus, despite advances, the clinical need is still left unmet and new therapeutic targets are needed. Kv7 ('M') channels may represent such a target as these impose strong control over neuronal excitability. Functional M channels are present in peripheral somatosensory neurons but there is currently no consensus as to what the functionally dominant subunit is. This knowledge is necessary to guide selective therapeutic approaches as various sets of Kv7 subunits express in the brain, muscle and vasculature. Here we combine measures of gene and protein expression with functional patch clamp analysis, behavioural testing and genetic manipulations to ascertain functionally dominant Kv7 subunit(s) in the peripheral nerves. We demonstrated that all but Kv7.1 are expressed in rat and mouse sensory neurons and that Kv7.2, Kv7.3 and Kv7.5 are abundantly expressed. Kv7.2 showed a bias to small-diameter neurons and Kv7.5 toward larger neurons with significant overlap between the various subunits in rats and mice. Effects of Kv7.2/Kv7.3 selective agonist, ICA-27243, and *kcnq2* knockdown on M currents in DRG neurons in vitro suggest Kv7.2 is the predominant subunit controlling M current in TRPV1 positive nociceptors. Thus, *Kcnq2* knockdown significantly reduced the M current amplitude and rheobase in TRPV1 positive neurons and significantly increased the excitability of these neurons. This translated to a reduction in thermal and mechanical pain thresholds and an increased response to acute hyperalgesia when *kcnq2* was knocked down *in vivo.* ICA-27243 also significantly attenuated acute and inflammatory pain with comparable efficacy to retigabine. Knockdown of *Kcnq5* had marginal effects on DRG neuron excitability *in vitro* and on nociceptive transmission *in vivo*. These findings identified Kv7.2 as the functionally dominant Kv7 subunit in nociceptors.

Title: Pain provoked by a scorpion toxin that targets voltage-gated sodium (NaV) channel 1.3

Authors: *J. SALVATIERRA[1], J. M. BRAZ[2], G. TREVISAN[4], M. SADEGHI[5], M. DEWAARD[6], X. YU[7], F. BOSMANS[8], A. I. BASBAUM[3];
[1]Univ. of California, San Francisco Sch. of Med., San Francisco, CA; [2]Anat., [3]Dept Anat, UCSF, San Francisco, CA; [4]Federal Univ. of Santa Maria, Santa Maria, Brazil; [5]Univ. of California, San Francisco, San Francisco, CA; [6]French Inst. of of Hlth. and Med. Res., Paris, France; [7]Anesthesiol., Univ. of California San Francisco, San Francisco, CA; [8]Ghent Univ., Ghent, Belgium

Abstract: Voltage-gated sodium (Na_V) channels are critical for the excitability and transmission of noxious stimuli of sensory neurons. Although previous studies on nociceptive (pain) processing by sensory neurons focused on $Na_V1.7$, $Na_V1.8$, and $Na_V1.9$, here we provide new evidence for a significant contribution of $Na_V1.3$. To reinvestigate the contribution of $Na_V1.3$ to pain processing we identified and synthesized Tf2, a selective $Na_V1.3$ ß-scorpion activator from venom of the Brazilian scorpion Tityus fasciolatus. To identify $Na_V1.3$-expressing dorsal root ganglion (DRG) neurons and to explore their function in pain processing, we performed *in situ* hybridization, immunhistochemistry, *in vitro* calcium imaging, leveraged human-derived iPSC sensory neurons, and conducted a battery of behavioral assays in C57BL/6J mice of both sexes. In contrast to previous reports of minimal expression of $Na_V1.3$ in sensory neurons, we found substantial $Na_V1.3$ mRNA in tyrosine hydroxylase (TH)-mRNA-expressing DRG neurons, a subpopulation generally associated with the transmission of low threshold mechanical inputs (namely CLTMRs). Intradermal hindpaw injection (1µM) of Tf2 in mice induced significantly more nocifensive behaviors (i.e., licking of the hindpaw) than vehicle alone. Injection of Tf2 also induced significant Fos expression in superficial layers of the dorsal horn. Interestingly, the toxin also provoked vigorous behavioral responses indicative of pain of the hindlimb contralateral to the injection, suggesting a rapid development of central sensitization in the spinal cord. Application of Tf2 to dissociated DRG neurons increased Ca^{2+} signals in small- diameter neurons. Importantly, Tf2-induced nocifensive behaviors persisted after ablation of the $TRPV1^+$ nociceptor population with resiniferatoxin. Tf2 (1nM) also significantly and reversibly increased the firing rate of human-derived iPSC sensory neurons. Lastly, injection of Tf2 provoked significant hindpaw swelling and plasma extravasation of Evans Blue albumin, but surprisingly only after ablation of the $TRPV1^+$ population. Taken together our findings suggests that Tf2 induces profound, sensory neuron-mediated effects, possibly via CLTMR afferents, by its binding to and facilitating opening of $Na_V1.3$. It should be noted that previous work by Israel M.R. et al. also reported pain-like behaviors evoked by Tf2, in addition to swelling, but we do not see significant swelling or extravasation in naïve mice with our synthesized Tf2. Future studies will investigate the contribution of $Na_V1.3$ in injury-induced ongoing pain conditions, as well as effects of selective blockade of the channel.

Title: Peripheral voltage gated calcium channels in skin are essential for transient heat hypersensitivity in mice

Authors: *E. J. LOPEZ SOTO[1], D. M. DUBREUIL[2], S. DASTE[1], R. MEIR[1], D. LI[1], A. FLEISCHMANN[1], D. LIPSCOMBE[1];
[1]Brown Univ., Providence, RI; [2]Massachusetts Gen. Hosp., Charlestown, MA

Abstract: $Ca_V2.2$ voltage-gated calcium channels are the dominant Ca_V channel expressed in nociceptors. $Ca_V2.2$ channel blockers applied to the spinal cord relieve pain in humans and rodents, especially during pathological pain. $Ca_V2.2$ channels are expressed at nociceptor pre-synaptic terminals, soma, and peripheral axons, but a biological function of nociceptor $Ca_V2.2$ channels outside pre-synaptic terminals is rarely considered. In this study, we demonstrate that $Ca_V2.2$ channels at nociceptors free nerve endings in skin are required for heat hypersensitivity. We used Hargreaves and automatic von Frey assays to evaluate heat and mechanical sensitivities in female and male wild-type and $Ca_V2.2$-KO mice. Experiments were performed blinded to genotype and treatment. Paw withdrawal latencies to heat and mechanical stimuli were longer in $Ca_V2.2$-KO mice compared with WT controls ($p = 0.001$ and $p = 0.021$, respectively). This is expected as $Ca_V2.2$ channels at nociceptor afferent pre-synaptic termini in spinal cord regulate neurotransmitter release and the transmission of nociception. We then assessed the role of peripheral $Ca_V2.2$ channels in skin, in particular in capsaicin-induced heat and mechanical hypersensitivity. Intraplantar injection of capsaicin (0.1%), a TRPV1 channel agonist, induces transient hypersensitivity to mechanical and heat stimuli at 15 mins which returns to pre-capsaicin baseline responses within 30 mins. Capsaicin-induced heat, but not mechanical, hypersensitivity was 60% reduced in $Ca_V2.2$-KO as compared to WT mice ($p = 0.001$ and $p = 0.994$, respectively). To assess the role of peripheral $Ca_V2.2$ channels in skin we used intraplantar ω-conotoxin MVIIA (1 μM). In wild-type mice, capsaicin-induced heat hypersensitivity was consistently reduced by co-injecting conotoxin with capsaicin, compared to capsaicin alone ($p = 0.041$). By contrast, capsaicin-induced heat hypersensitivity was not altered by intradermal ω-agatoxin IVA, a selective inhibitor of $Ca_V2.1$ channels ($p = 0.130$). Our data reveal that local activation of peripheral $Ca_V2.2$ channels in nociceptor termini in skin *in vivo* are required for capsaicin-induced heat hypersensitivity, but not mechanical hypersensitivity.

Title: Contribution of T-type calcium channels to nociceptors' hyperexcitability and chronic neuropathic pain following spinal cord injury in rats.

Authors: *M. PUOPOLO, H. LIU, J. LAUZADIS, M. KACZOCHA;
Anesthesiol., Stony Brook Med., Stony Brook, NY

Abstract: A hyperexcitable state and spontaneous activity of nociceptors following spinal cord injury (SCI) have been suggested to play a primary role in the development of SCI-induced neuropathic pain (SCI-pain). Previous work showed that the increased activity of T-type calcium channels induced by the injury is responsible for triggering nociceptors' hyperexcitability and for promoting their spontaneous activity. These observations suggest that the increased activity of T-type calcium channels following SCI may play a critical role in the development of SCI-pain. The aim of this project was to test the hypothesis that TTA-P2 (a blocker of T-type calcium channels) will reduce the hyperexcitable state of SCI-nociceptors and rescue SCI-pain. Sprague Dawley rats (male, 300-350 g) were used in this study. SCI was performed by a midline spinal cord contusion at T10 by using an Infinite Horizon Impactor (150 kilodynes, 1-s dwelling time). The patch clamp technique was used in dissociated dorsal root ganglia (DRG) neurons isolated from SCI, sham, and naïve rats. For voltage-clamp experiments, the external solution was (mM): 151 NaCl, 2.5 KCl, 2 $CaCl_2$, 1 $MgCl_2$, 10 HEPES; the internal solution was (mM): 125 CsCl, 10 NaCl, 2 $MgCl_2$, 10 HEPES, 10 EGTA, 4 MgATP, 0.3 NaGTP, 14 phosphocreatine, pH=7.2 with CsOH. For current clamp experiments, the external solution was (mM): 151 NaCl, 2.5 KCl, 2 $CaCl_2$, 1 $MgCl_2$, 10 HEPES; the internal solution was (mM): 125 K-methanesulfonate, 10 NaCl, 2 MgCl2, 0.1 EGTA, 10 HEPES, 14 Tris-creatine PO4, 4 Mg-ATP, and 0.3 Na-GTP; pH 7.2 with KOH. The mechanical allodynia following SCI was assessed with the von Frey filaments by using the up-down method with the 50% threshold. The conditioned place preference (CPP) paradigm was used to assess spontaneous pain. In SCI-nociceptors, we found that T-type calcium channels sustains the bulk (~60%) of the inward current active during the interspike interval. In current-clamp recordings, inhibition of T-type calcium channels with 1 μM TTA-P2 reduced both the spontaneous and the evoked firing in SCI-nociceptors to a level similar to sham-nociceptors. The 50% mechanical threshold dropped from 26.1 ± 3.2 g (pre-injury) to 14.3 ± 1.6 g (post-injury). Intraperitoneal injection of 10 mg/kg of TTA-P2 rescued the to 50% threshold to 26.3 ± 2.4 g (n=6). The difference score measured with the CPP paradigm was 46.4 ± 40.8 s for the drug-paired chamber and -30.8 ± 34.1 s for the vehicle-paired chamber. Taken together, our data suggest that the increased activity of T-type calcium channels induced by the injury

plays a primary role in driving SCI-nociceptors to a hyperexcitable state and contributes to chronic neuropathic pain following SCI.

Title: Localization of Adaptin α2-Subunit to Large Dense Core Vesicles in Mice and Humans

Authors: *R. POWELL[1], V. YOUNG[2], **A. BHATTACHARJEE**[3];
[1]SUNY Univ. at Buffalo, Buffalo, NY; [2]SUNY - Buffalo, Buffalo, NY; [3]Univ. at Buffalo - The State Univ. of New York, Buffalo, NY

Abstract: Clathrin-mediated endocytosis (CME) is a critical cellular process that underlies signaling cascades, protein turnover, and general cellular homeostasis. A key facilitator of CME is the heterotetrameric Adaptor Protein Complex 2 (AP2). The AP2 complex is a comprised of α-, β-, σ-, and μ-subunits that display comparable levels of expression across different cell types; however, the α-subunit is unique in that it has two distinct genetic isoforms: AP2α1 and AP2α2. The first characterization of the subneuronal localizations of the two α-subunit isoforms, which showed that AP2α1 was primarily synaptic and AP2α2 was primarily cytoplasmic, occurred over 26 years ago by Ball et al. (PMID: 7593326). Herein, we have expanded upon the work presented in Ball et al. through an immunofluorescent approach to characterize the expression of AP2α2 in mouse and human dorsal root ganglion (DRG) neurons. In mice, surprisingly, we observed a high degree of colocalization of AP2α2 and the neuropeptide calcitonin gene-related peptide (CGRP) at large dense core vesicles (LDCVs) within somas, indicating AP2α2 localizes to LDCVs. In sciatic nerve immunohistochemical analyses, AP2α2 and CGRP co-localization was maintained at mature LDCVs transported down the axon. However, the AP2α2/CGRP colocalization was lost at peripheral terminals where AP2α2 was observed at the very distal neuronal endings within the epidermis, dissociated from CGRP containing LDCVs. Immunofluorescent staining in human DRGs (from one donor) showed similar immunoreactivity patterns that were observed in mice, where AP2α2 colocalized with CGRP as well as TRPV1 at LDCVs. Altogether, we have described an expression profile of AP2α2 in mouse and human DRGs that suggests that AP2α2-CME is functionally distinct from AP2α1-CME in nociceptive peptidergic neurons.

Title: Sensory neuron transcriptomes reveal complex neuron-specific regulation and function of mec-2/Stomatin splicing

Authors: *X. LIANG, C. CALOVICH-BENNE, A. NORRIS;
Southern Methodist Univ., Dallas, TX

Abstract: Alternative splicing (AS) plays a major role in development and function of the nervous system by increasing the diversity and complexity of cellular components. RNA binding proteins are important regulators that control alternative splicing by binding to specific sequences on pre-mRNA. Recent studies from our lab as well as others have showed the alternative splicing is regulated by RNA binding proteins in a cell-specific manner, but it remains unknown to what extent AS contributes to the function of single neurons. MEC-8 is a conserved RNA binding protein, with an essential role in the function of touch neurons in *C. elegans*. However, it is unclear how MEC-8 executes its regulatory function in touch neurons. To this end, we exploited RNA-Seq to profile the transcriptome to get a clear view of MEC-8 regulatory networks in touch neurons. Current single-cell sequencing techniques are limited by low coverage depth, making it difficult to study things like lowly-expressed genes or alternative splicing regulation. By taking advantage of invariant *C. elegans* cell lineage, we isolated thousands of same cells and then performed neuron specific RNA-Seq of wild-type and *mec-8* mutant touch neurons. With this increased depth of coverage in single-neuron profiles we could investigate splicing regulatory in specific neuron type. We noticed a few genes showing different splicing pattern in touch neurons compared to whole animals in wild-type and *mec-8* mutant worms, which suggests their potential roles in touch neurons. Among those genes, a conserved stomatin-related protein MEC-2 was strongly regulated by MEC-8, and *mec-2* mutants show a strong phenotype in touch assays. Furthermore, we found canonical long *mec-2A* isoform is only expressed in six touch neurons while non-canonical short *mec-2B* isoform are expressed in many other neurons in addition to touch neurons. Based on the expression patterns of two *mec-2* isoforms, we uncovered an olfactory role for *mec-2* in addition to its mechanosensory role. Using CRISPR-Cas9 system to force the expression of one or the other isoform of *mec-2* shows that *mec-2A* is functional in touch sensation and olfaction, but *mec-2B* is only functional in olfaction. Putting long isoform of *mec-2* back to *mec-8* mutant can rescue the *mec-8* touch insensitivity phenotype, which indicates the *mec-2* is the primary functionally relevant target of MEC-*8* in touch neurons. Interestingly, by looking carefully of RNA-Seq data, we identified an additional extra-long *mec-2E* isoform, which co-localizes with *mec-2A* isoform, and needs to work together with *mec-2A* to function mechanosensation in touch neurons.

Title: The role of $\alpha_3\beta_4$* nicotinic acetylcholine receptors in modulating the excitability of VIP neurons in the mouse inferior colliculus

Authors: *L. M. RIVERA-PEREZ, J. T. KWAPISZEWSKI, M. T. ROBERTS;
Dept. of Otolaryngology-Head and Neck Surgery, Univ. of Michigan - Kresge Hearing Res. Inst., Ann Arbor, MI

Abstract: The inferior colliculus (IC), the midbrain hub of the central auditory system, receives extensive cholinergic input from the pontomesencephalic tegmentum (PMT). Activation of nicotinic acetylcholine receptors (nAChRs) in the IC can enhance auditory performance by altering the excitability of neurons. However, how nAChR activation affects the excitability of specific neuron classes in the IC remains unknown. Our lab identified a distinct class of glutamatergic principal neurons in the IC that expresses vasoactive intestinal peptide (VIP). Using VIP-Cre x Ai14 mice and immunofluorescence, we found that cholinergic terminals are commonly located in close proximity to the somas and dendrites of VIP neurons. By using whole-cell electrophysiology combined with pharmacology in brain slices, we found that acetylcholine (ACh) drives a strong, long-lasting excitatory effect in VIP neurons. Application of the muscarinic antagonist atropine did not affect the excitation elicited by ACh. Instead, application of nAChR antagonists revealed that ACh excites VIP neurons via the activation of $\alpha_3\beta_4$* nAChRs, a subtype that is relatively rare in the brain. Furthermore, by blocking the receptors for the main neurotransmitters expressed in the IC, we determined that cholinergic excitation of VIP neurons occurs by activating post-synaptic nAChRs located in VIP neurons themselves and does not require activation of presynaptic inputs. Finally, we found that trains of ACh puffs elicited temporal summation in VIP neurons, suggesting that cholinergic inputs can affect activity in the IC for prolonged periods in an in vivo setting. These results uncover the first cellular-level mechanisms of cholinergic modulation in the IC and a novel role for $\alpha_3\beta_4$* nAChRs in the auditory system, and suggest that cholinergic inputs from the PMT can strongly affect auditory processing in the IC by increasing the excitability of VIP neurons. Since VIP neurons project to the auditory thalamus, the superior olivary complex, and other brain regions, these results further suggest that cholinergic excitation of VIP neurons is likely to have widespread effects on auditory processing and its downstream effects.

Title: The contribution of GlyT2$^+$ PnC neurons to prepulse inhibition of the acoustic startle reflex during aging

Authors: *W. HUANG[1], K. FENELON[2];
[2]Biol., [1]Univ. of Massachusetts Amherst, Amherst, MA

Abstract: BACKGROUND:
Prepulse inhibition (PPI) of the acoustic startle reflex (ASR) refers to the inhibition of the startle response by presenting a weak stimulus ("prepulse") prior to the startling stimulus ("pulse"). PPI is a standard operational measure of sensorimotor gating. Reduced PPI is found in patients with schizophrenia, obsessive compulsive disorder and Huntington's disease, and PPI impairments are often associated with deficits in attention (Braff et al, 2001).
The brainstem caudal pontine reticular nucleus (PnC) is at the core of the PPI pathway. Within the PnC, glycinergic neurons are widely distributed among the startle-mediating glutamatergic giant neurons (Lingenhöhl and Friauf, 1992; Koch and Friauf, 1995; Rampon et al., 1996; Zeilhofer et al., 2005). We recently showed that inhibiting these glycinergic PnC neurons reduces PPI (Cano et al., 2021). However, the contribution of these neurons during aging has not been investigated.
Therefore, we used young and old mice to investigate the role of PnC neurons expressing the glycine transporter type 2 (GlyT2) during aging, to determine if the age-related reduction in PPI is associated with a decline in PnC inhibitory function.
METHODS:
Experiments were performed in mice expressing the Cre enzyme in GlyT2$^+$ neurons (i.e., GlyT2-Cre mice), and their control littermates. Animals were classified into two categories: 1- young adults (3-6 months old) or 2- older adults (9-12 months old). To photo-manipulate GlyT2$^+$ PnC neurons, Cre-dependent viral vectors driving the expression of the inhibitory optogenetic tool Archaerhodopsin or the excitatory optogenetic tool Channelrhodopsin, were injected in the PnC. The ASR and PPI were measured 4 weeks after injections, both in the absence and in the presence of neuronal photo-manipulation, in all animals. PPI was used as a behavioral readout of sensorimotor gating and PPI values were compared between genotypes.
RESULTS:
Photo-manipulating GlyT2$^+$ PnC neurons had no effect on ASR in young GlyT2-Cre mice, their control littermates and older GlyT2-Cre mice. In young adult mice, photo-activating GlyT2$^+$ PnC neurons significantly increased PPI ($p=.005$) at 100-1000ms interstimulus intervals (ISI) between the prepulse and the pulse. While photo-inhibiting these neurons resulted in the reverse effect ($p=.033$): PPI was decreased at shorter ISI of 50-100ms. Interestingly, in older adult mice, photo-inhibition of GlyT2$^+$ neurons did not affect PPI.
DISCUSSION:
The findings suggest that: 1) GlyT2$^+$ PnC inhibitory neurons contribute to PPI in young adult mice and 2) such contribution declines with age, providing a possible explanation for age-related PPI alterations.

Abstract: The integration of synaptic inputs to generate an action potential is a complex process with multiple control points. These factors include the relative placement of excitatory and inhibitory inputs, the dendritic surface area, and innervation and dimensions of the axon initial segment (AIS). We performed high-resolution, volume electron microscopy (EM) and reconstruction of bushy cells (BC) in the mouse cochlear nucleus in order to quantify these factors. These structural data were converted into compartmental biophysical models and the integration of synaptic inputs was measured using the NEURON simulation environment. 3D reconstructions of cellular compartments were processed to create so-called computational meshes for accurate measurement of surface areas. Dendrite to soma surface area ratios ranged from 2.8-3.6. For the reconstructed BCs (n = 26), somatic surface area ranged in a tight distribution from about 1200 to about 1500 µm² for all except one cell. For dendrites that were completely or nearly completely contained in the image volume (n = 10), surface areas ranged from 3100 to 4700 µm². Large somatic inputs were reconstructed (range 5-12 per cell) and activated individually in the model. Most inputs were subthreshold, but nearly all became suprathreshold following removal of dendrites. For one cell, we mapped every dendritic and somatic synapse, and noted that entire dendritic branches were not innervated but were instead wrapped by glial cells. We also investigated innervation of the axon hillock and axon initial segment (AIS). Large somatic inputs could extend from the cell body onto the hilllock and AIS in most (20/21) cells. The AIS ranged in length from 14.2 to 21.4 µm (n = 16). By assuming a constant density of sodium channels along the initial segment we identify the initial segment length as a contributing factor to cellular excitability. The initial segment was innervated not only by excitatory but also small, likely inhibitory inputs, which ranged a number from 4 to 19. Thus, we identify dendrite to soma surface area ratio, and length and innervation of the axon initial segment as factors controlling neuron excitability. We also suggest that growth of non-innervated dendrites presents another homeostatic mechanism by which individual neurons regulate their excitability.

Title: Synaptic representation of infant distress cries in the auditory cortex

Authors: *J. SUNDARARAJAN[1], D. NEOPHYTOU[2], R. HUSZAR[4], H. V. OVIEDO[3], R. C. FROEMKE[5];
[1]NYU Sch. of Med., New York, NY; [3]Biol., [2]The City Col. of New York, New York, NY; [4]Ctr. for Neural Sci., New York Univ., New York, NY; [5]Otolaryngology, NYU Med., New York, NY

Abstract: The ability of parental animals to accurately process and respond to infant-related sounds is critical for providing appropriate caregiving responses (Dulac et al., Science 2014). In mice, recent work from our lab and others has shown that maternal experience is accompanied by lateralized auditory cortical plasticity, including enhancement of neuronal responses, and correlation of excitatory and inhibitory inputs in the left auditory cortex (Cohen & Mizrahi, J Neurosci 2015; Marlin et al., Nature 2015). Additionally, responses of individual auditory cortical neurons are enhanced to pup call tempos that occur with higher probability following maternal experience (Schiavo et al., Nature 2020). However, it remains unclear how single auditory cortical neurons reliably compute the behavioral meaning of an infant distress cry, and how infant cries are represented at the level of individual dendritic branches and synapses.Here we use structural and functional 2-photon imaging to ask how populations of synaptic inputs can shape single-neuron responses to infant distress cries in the maternal mouse auditory cortex. We observe that individual auditory cortical neurons exhibit differential tuning to various sounds including pup distress cries with different spectrotemporal characteristics. Additionally, in line with prior work, somatic responses to different pup call tempos are broadened following maternal experience. At the dendritic spine level, our data suggest that individual spines exhibit varying tuning profiles to different pup distress cries, with most individual spines displaying narrow tuning to pup call tempo. We observe that overall somatic response strength is proportional to the number of dendritic spines responding to individual pup calls and pup call tempos suggesting a mechanism by which collective spine responses can influence somatic tuning. We are examining structural synaptic changes that accompany functional changes by tracking excitatory and inhibitory synaptic dynamics during maternal experience. Finally, we are recording from neurons in brain slices that we have imaged in vivo (Ko et al., Nature 2011), to determine the circuit motifs that provide specific auditory inputs to left vs right auditory cortical neurons in male and female mice following parental experience.

Title: Using Microprisms, the 2P Calcium Imaging Revealed a functional distinction between the Dorsal & Lateral Cortices of The Mouse Inferior Colliculus.

Authors: B. IBRAHIM, Y. SHINAGAWA, G. XIAO, A. R. ASILADOR, D. LLANO;
Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The inferior colliculus (IC) is a critical midbrain structure for the processing of auditory stimuli. The IC is a hub that permits widespread convergence of both bottom-up & top-down projections involving auditory, somatosensory, visual, motor & arousal-related brain regions. Dorsal (DC) & lateral (LC) cortices form the non- lemniscal division of the IC and receive most of the descending projections directed to the IC. LC only contains periodic modules of GABAergic cells & terminals which stain for a range of metabolic markers. Interestingly, the auditory inputs from the auditory cortex or central nucleus of the IC strongly avoid these inhibitory modules & instead form dense projections to the matrix areas that surround the modules. This anatomic distinction between DC & LC could implicate a functional distinction between the two subdivisions. Two-photon imaging was used here to characterize the functional activity of the GABAergic & non-GABAergic cells in the LC as well as in the DC. Consistent with a previous report (Wong and Borst 2019), imaging the surface of the IC showed that both GABAergic & non-GABAergic cells of the DC showed mirror-image tonotopic mapping of high to low & then from low to high frequency along the medial to lateral axis. In contrast, side view imaging of the LC using 45^0 microprisms showed that both GABAergic and non-GABAergic cells were less responsive to the pure tone sound, were not tonotopically organized and were more responsive to amplitude modulated broad band noise. This finding implicates a functional distinction between DC and LC, which functions more to process complex sound.

Title: Activation of basal forebrain parvalbumin neurons exerts frequency dependent effects on auditory processing and behavior in the rat.

Authors: *H. AZIMI, K. THOMAS, M. NADERI, P. VACA SANCHEZ, M. HARVEY, G. RAINER; Dept. of Med., Univ. of Fribourg, Fribourg, Switzerland

Abstract: The basal forebrain (BF) encompasses a collection of deep brain nuclei that have been implicated in higher cognitive functions, such as attention and memory, (Rye et al., 1984), the processing of sensory information, (Bhattacharyya et al., 2013), and sleep and arousal, (Jones, 2003). BF projections to the sensory cortex have now been shown to be segregated according to sensory modality (Kim et al. 2016), with visual, somatosensory, and auditory areas organized along an anterior-posterior axis. While the BF provides the main cholinergic input to the cerebral cortex, it also harbors substantial GABAergic and glutamatergic populations. The diversity of cells types and projections must be taken into account in order to understand how the BF modulates cognitive and sensory processing. We have previously shown that electrical activation of the posterior nucleus basalis (pNB), a BF nucleus associated with auditory processing, enhances response reliability of rat A1 neurons to complex auditory stimuli. Electrical stimulation is expected to activate all pNB projection neurons, so in order to disambiguate the contribution of different BF neuronal subtypes, we utilized a PV-Cre rat line to express channel rhodopsin (ChR2) uniquely in pNB PV neurons. We recorded local field potential and single unit activity simultaneously in the pNB, the thalamic reticular nucleus (TRN), the medial geniculate nucleus (MGN), and the primary auditory cortex (A1), during 40Hz pulse optogenetic activation of the pNB paired with the presentation of complex auditory stimuli in an anesthetized preparation. We have preliminary data from 12 animals. While optogenetic activation of pNB PV neurons had no effect on response reliability, it did result in a frequency specific modulation of firing rates in both MGN and A1. Spiking activity of single neurons at their preferred frequency was suppressed in both A1 and MGN, while responses to non-preferred frequencies in A1 were enhanced. As auditory responses recorded within pNB showed a rough tonotopic organization, we postulate that frequency selective effects of pNB activation on MGN and A1 might regulate neural responses in the auditory pathway via a tonotopic projection pattern. A frequency specific performance deficit in rats that we observed during an auditory detection task for high amplitude targets is consistent with this hypothesis. Both findings support the idea that pNB may modulate auditory processing in a tone-frequency dependent manner according to behavioral demands, selectively dampening high amplitude auditory inputs in a manner opponent to cholinergic BF circuit activity.

Title: A cellular level analysis of the interface between motor and sensory networks in Drosophila

Authors: *K. N. BOONE[1], H. S. J. CHEONG[2], M. M. BENNETT[1], F. A. SALMAN[1], J. F. PHELPS[3], B. MARK[5], J. C. TUTHILL[5], W.-C. A. LEE[4], K. C. DALY[1], G. M. CARD[2], A. M. DACKS[1];
[1]Biol., West Virginia Univ., Morgantown, WV; [2]Howard Hughes Med. Institute, Janelia Res. Campus, Ashburn, VA; [4]Kirby Neurobio. Ctr., [3]Harvard Med. Sch., Cambridge, MA; [5]Univ. of Washington, Seattle, WA

Abstract: The ability for motor and lower order networks to relay information to sensory centers about the behavior state of the animal represents a critical interface between sensory and motor systems. Here, we undertake a circuit analysis of such a sensorimotor interface. Two pairs of ascending histaminergic neurons (AHNs) project from the ventral nerve cord (VNC) of many arthropods to innervate sensorimotor regions in the brain and VNC, and have been demonstrated to function as a corollary discharge circuit in the moth, *Manduca sexta*. However, little is known comprehensively about the connectivity and functionality of these morphologically conserved motor-to-sensory circuits. Using connectomics, transcriptomics and neuroanatomy techniques in *Drosophila melanogaster*, we begin to resolve the connectivity of the mesothoracic and metathoracic AHN pairs (the MsAHNs and MtAHNs, respectively). We demonstrate that each AHN cell pair innervates mostly non-overlapping brain regions (within which they are the sole source of histamine) that process distinct sensory modalities, including auditory and mechanosensory networks. The AHNs receive most of their synaptic input within the tectulum of the VNC with a large proportion of this synaptic input originating from descending neurons. Based on connectomic analyses, the AHNs synapse upon more neurons than were observed to express histamine receptors, suggesting that the AHNs co-release additional transmitters. Transcriptomic and transgenic approaches reveal that the AHNs co-release neuropeptides, including Diuretic Hormone 44 (DH44), implying that these neurons likely have effects over multiple timescales as insect histamine receptors are ionotropic whereas neuropeptide receptors are metabotropic. Downstream targets of the AHNs include several well-characterized cell types including sensory afferents which broadly express the HisClB receptor and second-order auditory neurons which express DH44 receptor 1. Interestingly, there is little overlap in receptor expression of downstream targets, suggesting that the AHNs can have distinct functional roles by way of different transmitter release. Finally, we demonstrate that the AHN pairs differ from each other in a variety of ways including receptor expression, synaptic connectivity, and baseline levels of intracellular calcium regardless of behavioral context. Taken together, this suggests that the AHN pairs likely receive and relay distinct information to downstream targets. Our results provide a detailed circuit-level understanding of a sensorimotor interface that allows descending motor commands to provide feedback to distinct sensory modalities.

Title: Correlating transcriptomic markers and morphological features of neurons in the zebrafish startle circuit

Authors: S. A. SEMENOVA, *H. A. BURGESS;
Eunice Kennedy Shriver Natl. Inst. of Child Hlth. and Human Develop., Bethesda, MD

Abstract: The acoustic startle response is a robust quantifiable behavior that is frequently used to assess the effects of gene mutations on neuronal connectivity and neural circuit function in model organisms. In larval zebrafish, the acoustic startle response starts with statoacoustic ganglion (SAG) neurons receiving an impulse from hair cells of the inner ear and transmitting it to the Mauthner cells, large reticulospinal neurons which trigger body movements by activating motor neurons and interneurons in the spinal cord. Our behavior tests after targeted neuron ablation revealed that populations of neurons in both the anterior and posterior parts of the statoacoustic ganglion contribute to the escapes responses. Tracing of individual fluorescently labeled SAG neurons with subsequent registration to a reference brain revealed a topographic arrangement of cell bodies correlated with the efferent projection pattern. On average, anterior SAG neurons had longer axonal branches than posterior SAG neurons, and suggesting a possible segregation of central targets between these subpopulations. Both anterior and posterior populations had connections to all five hair cell patches. In order to develop new markers for SAG neurons projecting to different central targets, we manually isolated SAG neurons and Mauthner cells and performed transcriptomic analysis using the SMART-Seq v4 protocol. Strong and specific expression of several genes in these neurons was in concordance with previous in situ RNA hybridization data. The neurotransmitter receptor profiles of anterior and posterior SAG neuron populations were distinct, raising the possibility of differential modulation of SAG neuron activity by neuropeptides and serotonin. This data now enables us to develop new transgenic lines for manipulating activity in genetically defined SAG neurons for testing segregation of auditory afferent information to central targets.

Ashburn, VA; [5]Princeton Neurosci. Inst., Princeton, NJ; [6]Inst. of Neuroinformatics UZH/ETHZ, Zurich, Switzerland

Abstract: A key task for auditory systems is recognizing behaviorally relevant acoustic features to drive appropriate reactions. How feature detection emerges along auditory pathways has been difficult to solve due to challenges in mapping the underlying circuits and characterizing responses to behaviorally relevant features. Here we study auditory activity in the *Drosophila melanogaster* brain and investigate feature selectivity for the two main modes of fly courtship song, sinusoids and pulse trains. We identify 24 new cell types of the intermediate layers of the auditory pathway, and using the new connectomic resource FlyWire, we map all synaptic connections between these cell types, in addition to connections to known early and higher-order auditory neurons. This represents the first map of the auditory pathway. We also determine the excitatory vs. inhibitory nature of most synapses in the auditory connectome. We find that auditory neurons display a continuum of preferences for courtship song modes, and that neurons with different song mode preferences are highly interconnected in a network that lacks hierarchical structure. Among this network, frequency tuning is centered on the range of frequencies present in song, whereas pulse rate tuning extends to rates outside of song, suggesting that these neurons form a basis set for downstream processing. We evaluate a linear model for predicting neural responses to acoustic stimuli from a given neuron's synaptic inputs. Ongoing efforts will probe the roles of key nodes in the network by inactivating individual cell types in females during natural courtship behaviors and while imaging from downstream neurons.

Title: Cytology and connections of nucleus angularis in the Western ratsnake (Pantherophis obsoletus)

Authors: *D. HAN[1], B. A. YOUNG[2], C. E. CARR[1];
[1]Dept. of Biol., Univ. of Maryland, College Park, MD; [2]Kirksville Col. of Osteo. Med., A.T. Still Univ., Kirksville, MO

Abstract: Snakes lack a tympanum; instead, their columella connects the oval window to the quadrate bone of the jaw. Despite this adaptation, the function and connections of their central auditory system has received little attention. Here we describe a well-defined first order cochlear nucleus, nucleus angularis (NA), in the auditory brainstem of the Western ratsnake (*Pantherophis obsoletus*). Injections of Neurobiotin were made in the basilar papilla, superior olivary nucleus, and torus semicircularis of 16 snakes. NA was identified by location, and by retrograde label following injections into the torus

semicircularis. NA occupies the most dorsal and lateral portion of the acoustic tubercle. It extends rostrally to the cerebello-medullary junction, and caudally borders nucleus vestibularis ovalis. In contrast to lizards, NA does not extend to the medial edge of the medulla. The dorsal part of the posterior branch of the VIIIth nerve terminates in bouton-like terminals in NA. This terminal field is separated into a larger, more medial region and a smaller extension close to the entry of the auditory nerve. NA contains a heterogeneous population of projection neurons which project to the ipsilateral superior olive, the contralateral superior olive and torus semicircularis. The ipsilateral superior olive projects back to NA. Our results reveal similar projections to those observed in lizards. Although snakes are insensitive to airborne sound, and respond best to low-frequency vibrations, the well-defined NA provides a potential substrate for encoding sound intensity as in other reptiles.

Abstract: The transformation of sensory inputs into behavioral outputs is characterized by an interplay between feedforward and feedback operations in cortical hierarchies. In primary sensory cortices, this is observed when stimulus presentation triggers an early response component (driven by thalamic bottom-up input) and, often, a late component thought to result from reverberating activity through areal interactions. This late phase is engaged by attention and stimulus complexity, and also encodes sensory-independent factors, including movement and report-related variables. However, despite its pervasiveness, the nature and function of late activity in perceptual decision-making remain unclear. Here, we tested whether the function of late activity depends on the complexity of a sensory change-detection task. We trained three cohorts of mice in an audiovisual change detection paradigm with the same stimulus configurations, but different reward contingencies: noncontingently exposed (untrained), unisensory trained (detecting visual, but not auditory), or multisensory trained (detecting both visual and auditory). While visual hit rates were

similar for both trained cohorts, multisensory-trained mice responded more slowly to the same visual stimuli than unisensory-trained mice. Laminar recordings in V1 revealed that early-latency, sensory-related activity was similar across cohorts, whereas late, report-related activity only emerged in trained mice and was associated with decreased noise correlations in V1. To test whether this late activity was causal to perception, we optogenetically silenced V1 bilaterally either at stimulus onset (0 ms) or after a delay (200 ms). Early silencing indiscriminately abolished perceptual report, but delayed silencing selectively affected experimental sessions (primarily in multisensory-trained mice) with slow reaction times and a late onset of report-related activity in V1. We confirmed this result in a second multisensory task with different requirements. The temporal window in which V1 is necessary for perceptual decision-making was therefore extended when we increased task complexity, independently of the presented visual stimulus. Thus, although early visual response components encode all sensory information necessary to solve the task, V1 is not simply relaying information to higher-order areas transforming it into behavioral responses. Rather, task complexity determines the temporal extension of a loop of recurrent activity, which overlaps with report-related activity and determines how perceptual decisions are built.

Title: Cortico-tectal circuits involved in motor preparation and navigation

Authors: *T. LUPASHINA[1,2], R. BERGMANN[3], K. SEHARA[3], S. DOMINIAK[4], J. SIBILLE[1,2], M. LARKUM[3], R. SACHDEV[3], J. KREMKOW[1,2];

Abstract: Cortico-tectal interactions are thought to mediate a range of multimodal behaviors, including navigation, attention, orientation and decision making. Layer 5 pyramidal neurons distributed in

widespread cortical areas connect cortex to superior colliculus (SC) and collicular output targets higher order thalamic nuclei. The thalamo-cortical neurons then generate feedback in cortex. How and when these circuits interact to generate complex behavior is not known. When head-fixed mice navigate a plus-maze, they orient their body to the maze. They coordinate the movement of their torso and limbs with the movement of their whiskers and eyes (Dominiak 2019; Bergmann 2021), with the whiskers and eyes moving in a look ahead fashion, and separately predicting the turn direction that mice impose on the maze. Here we begin to test the hypothesis that the cortico-collicular loop is causal in planning and execution of these behaviors. Our first aim was to look for activity in motor cortical areas (secondary motor cortex, MOs) and colliculus that was related to these behaviors. Activity recorded in all layers of SC and in MOs with high density Neuropixels probes showed that neurons in both areas fire in relationship to movement direction of the mouse. Furthermore, neurons in sensory and motor layers of colliculus fire when eye movement was elicited by whisker stimulation with air puffs. We are currently assessing whether activity in the superior colliculus or cortex is associated with motor preparation or is causal in generating the entire sequence of movements associated with navigation.

Title: Weber, Fechner and Stevens can co-exist under Fisher's roof

Authors: *J. ZHOU[1], L. R. DUONG[2], E. P. SIMONCELLI[3,4];
[1]Flatiron institute, center for computational neuroscience, NYC, NY; [2]Ctr. for Neural Sci., New York Univ., New York City, NY; [3]New York Univ. / HHMI, New York, NY; [4]Flatiron Inst., New York City, NY

Abstract: In 1834, Weber observed that just-detectable stimulus perturbation (perceptual threshold) for many sensory attributes is proportional to stimulus intensity. Fechner later proposed that this lawful behavior arose from a logarithmic internal representation of stimulus intensity, which when differentiated gives rise to Weber's observation. In apparent contradiction to Fechner’s logarithmic proposal, Stevens showed that observers' rated stimulus intensity are typically power functions of stimulus intensity, with exponents that vary substantially for different stimulus attributes. These two conflicting descriptions of the relationship between stimulus intensity and internal representation are each supported by different types of experimental evidence, and the discrepancy remains unresolved. We show that this quandary can be resolved in a framework that incorporates the joint effects of mean and variance of an abstract internal stimulus representation. Specifically, we propose that magnitude ratings (as used by Stevens) reflect the mean internal representation of stimulus intensity, whereas discrimination thresholds (as well as super-threshold distances) depend on both the mean and variability, as captured by the measure of Fisher Information. Under this interpretation, Weber's Law is fully consistent with Stevens' Power Law (for all

exponents) when variance of the internal representation grows as the square of the mean, a property that has been observed or proposed for a variety of neural representations.

Title: Diverse coding of visual and movement signals in V1 of freely moving mice

Authors: *P. R. L. PARKER[1], D. M. MARTINS[2], E. S. P. LEONARD[2], S. L. SHARP[2], N. M. CASEY[2], M. SIDIKPRAMANA[2], E. T. T. ABE[2], C. M. NIELL[2];

Abstract: Studies of visual processing have traditionally been performed in stationary subjects viewing artificial stimuli on a two-dimensional screen. However, this is vastly different from the typical domain in which our visual system operates, as we constantly move through a complex and three-dimensional environment. Furthermore, recent studies have demonstrated a range of movement-related signals in visual cortex, but the computational role of this modulation is unclear due to the constrained conditions under which visual physiology experiments are generally performed. In order to address this mismatch, we have developed a system to perform visual physiology in freely moving mice. A key challenge in this is determining the visual input, which is no longer under experimenter control but depends on the animal's head and eye position. We solve this by using two head-mounted cameras, one recording the visual scene from the mouse's perspective, and one measuring the eye position. By combining this information with high density silicon probe recordings of up to 100 simultaneous neurons, we are able to measure visual receptive fields during free exploration through a three-dimensional environment. In addition to this visual coding, we also find that a large fraction of neurons in V1 encode combinations of eye or head position, as well as saccadic and compensatory eye movements. Finally, recording from the same neurons under head-fixed conditions allows us to relate these freely moving measures to standard measures of visual processing, such as orientation and direction selectivity.

Title: Robust representations of 3D motion in macaque FST, but not MT

Authors: *L. W. THOMPSON[1], B. KIM[1], B. ROKERS[2], A. ROSENBERG[1];
[1]Neurosci., Univ. of Wisconsin-Madison, Madison, WI; [2]Psychology, New York University-Abu Dhabi, Abu Dhabi, United Arab Emirates

Abstract: Determining the movement of objects through three-dimensional (3D) space is a critical function of the visual system. Recent work identified activity in the macaque superior temporal sulcus that potentially reflects 3D motion processing. However, such modulations could alternatively reflect lower-level selectivity for 2D retinal motion that naturally covaries with 3D motion. To distinguish these possibilities, we measured the responses of macaque middle temporal (MT) and fundus of the superior temporal sulcus (FST) neurons to 3D motion during a 'towards'/'away' discrimination task. The stimuli consisted of dots that moved towards or away from the cyclopean eye within a volume (3° diameter; ±1° of disparity) and contained: (1) combined stereoscopic and perspective cues, (2) stereoscopic cues only, or (3) perspective cues only. Critically, the left- and right-eye perspective cues had opposite net 2D retinal motion directions for both directions of 3D motion. We found that roughly 50% of both MT and FST neurons showed significant direction tuning in the combined and stereoscopic cue conditions. To distinguish if that tuning reflected 2D or 3D motion selectivity, we compared the combined and stereoscopic cue responses to those in the perspective cue conditions. In MT, preferences for the combined and stereoscopic cue stimuli were positively correlated with the perspective cue preferences measured from the dominant eye and either negatively correlated or uncorrelated with those from the non-dominant eye. In contrast, the combined and stereoscopic cue preferences of FST neurons were positively correlated with both eye's perspective cue preference. These results suggest that MT neurons largely represent 2D retinal motion signals, whereas many FST neurons represent 3D motion. To further test if 3D motion could be robustly decoded from either neuronal population, we trained linear decoders using the combined-cue responses and then tested the decoders on each of the cue conditions. In MT, cross-cue testing revealed that 3D motion was conflated with the 2D motion signals and ocular dominance, such that only responses to the dominant eye's perspective cues could be accurately decoded. Decoding performance using MT responses to the non-dominant eye's perspective cues was at chance level. In stark contrast, cross-cue decoding from FST was accurate across all cue conditions. Thus, robust decoding of 3D motion was possible in FST, but not MT. These results suggest that a crucial 2D-to-3D visual motion transformation occurs along the MT to FST pathway.

Title: Topological and dynamical features of source localized EEG networks in presaccadic visual processing

Authors: *A. GHADERI[1], M. NIEMEIER[3], J. D. CRAWFORD[2];
[1]York Univ., Toronto, ON, Canada; [2]Ctr. for Vision Res., York Univ., North York, ON, Canada; [3]Dept. of Psychology, Univ. of Toronto Scarborough, Toronto, ON, Canada

Abstract: The topology and dynamics of cortical networks involved in the generation of presaccadic neural signals remain poorly understood. In particular, how they interact with simultaneously presented visual stimuli. Here, we used different approaches in graph theory analysis (GTA) and electroencephalography (EEG) to evaluate topology and dynamics of functional brain networks in the perisaccadic interval. EEG was recorded via 64 channels in two behavioral conditions (fixation or saccade). Participants (N=21) were pre-cued with a series 1-3 grids (three horizontal lines, 10° by 10°) located 5° below the central fixation-point. 100ms later, a stimulus (three vertical lines; same size/location) was briefly presented (for 70ms). In the saccade condition, a left/right shift of the fixation-point during the interstimulus interval triggered a saccade after the second stimulus. Source localization (SL) was performed on the 200ms period following the saccade cue, or the equivalent time during fixation trials. Lagged coherences were calculated between all pairs of 84 Brodmann areas. SL/GTA both identified major network hubs near the frontal and parietal eye fields, with widespread cortical connectivity. Other GTA measures (clustering coefficient, global efficiency, energy, entropy) showed that network segregation, integration, synchronizability, and complexity were enhanced during the perisaccadic interval. Further, these network properties significantly interacted with stimulus repetition, altering both hubs and network topography. These data suggest a network mechanism for enhanced visual information processing and propagation in the presaccadic interval. Title: Quantifying the effects of saccadic eye movements on visual responses and receptive field measurements in V1 of the awake mouse.

Authors: *A. NWANKPA[1], C. BARNES[2], D. BARSON[2], J. A. CARDIN[2], M. J. HIGLEY[2];
[1]New York Univ., New York, NY; [2]Dept. of Neurosci., Yale Univ., New Haven, CT

Abstract: In the visual system, many species possess the ability to move their eyes rapidly in order to scan their surroundings. For mice, which lack a foveal region of the retina, the function of these saccades in visual processing is not well understood. In addition, neurons in the mouse primary visual cortex (V1) respond preferentially to relatively large stimuli, in contrast to primates and carnivores, potentially reducing the impact of small changes in eye position on visually evoked neural activity. Thus, the consequences of saccades for visual processing in the mouse are unclear. Here, we developed a novel method for calculating gaze shifts in awake, head-fixed mice presented with visual stimuli comprising either sinusoidally drifting gratings or filtered noise patterns. We used 2-photon calcium imaging of GCaMP6s-expressing neurons in V1 to quantify visually-evoked single cell response magnitudes and receptive field structure. We simultaneously monitored spontaneous variation in the animal's behavioral state, measured by pupil diameter, facial movements, and locomotion. We then asked whether including estimates of eye position significantly improved response measurements. Our results suggest that saccades are temporally coupled to changes in behavioral state. Moreover, changes in eye position are capable of altering the response to visual inputs, suggesting a behaviorally relevant function for these movements. Overall, these findings indicate that eye position should be considered in experimental studies of visually-evoked activity in the mouse and that, as in other species, mouse vision represents an active process of acquiring information about the external environment.

Title: Low-dimensional neural manifolds describing natural behaviors

Authors: *E. ALTAN, S. A. SOLLA, L. E. MILLER, E. J. PERREAULT;
Northwestern Univ., Chicago, IL

Abstract: Across many brain areas, the activity of populations of neurons is constrained to low-dimensional subregions of the neural space known as neural manifolds. Recent studies of the primary motor cortex (M1) suggest that the population activity on the low-dimensional neural manifold represents the computations required for planning and executing motor behaviors. However, low dimensional manifolds have only been studied in constrained laboratory settings. Is the underlying simplicity suggested by the low dimensionality of M1 manifolds simply a byproduct of the constrained laboratory

environment? If so, is the dimensionality of M1 manifolds corresponding to natural behaviors such as crawling and feeding higher than that of grasping tasks in the laboratory? The dimensionality of the neural manifold determines the number of neurons that need to be sampled to construct accurate brain-to-behavior decoders: the higher the dimensionality of the neural manifold, the more neurons need to be sampled to faithfully represent the behavior. Therefore, establishing the dimensionality of the neural manifold corresponding to natural behaviors is crucial to the design of brain-machine interfaces, a rehabilitative technology that converts neural signals into control commands to restore movement to paralyzed patients. In this study, our first objective was to establish the dimensionality of the M1 manifolds across a range of motor behaviors in different contexts. Our second objective was to use dimensionality reduction to find the neural manifolds and assess whether it is possible to decode EMGs from them. We used Parallel Analysis and Two Nearest-Neighbors as linear and nonlinear estimators of dimensionality, respectively. We found that the linear dimensionality of neural manifolds associated with unconstrained natural behaviors ranged between 7 and 13, while the nonlinear estimates were between 5 and 6. The linear dimensionality of manifolds associated with laboratory tasks ranged between 7 and 15, while the nonlinear estimates were between 5 and 6. Our results suggest nonlinearity in both contexts and that the dimensionality of laboratory behaviors is similar to that of natural tasks. Next, we used two common dimensionality reduction tools, PCA (linear) and UMAP (nonlinear), to find the neural manifolds. EMG prediction accuracies were similar when we used all recorded neurons, PCA embeddings, and UMAP embeddings. Our results suggest that low-dimensional neural manifolds exist in richer, natural behavioral contexts as they do for the constrained laboratory environment, and that these low-dimensional manifolds are associated with motor behaviors across contexts.

Title: Tracking long-term changes in high-dimensional ECoG BCI control using deep autoencoders

Authors: *N. NATRAJ[1], R. ABIRI[2], S. SEKO[1], Y. GRAHAM[1], N. HARDY[3], E. F. CHANG[4], K. GANGULY[5];
[2]Dept. of Neurol., [1]Univ. of California, San Francisco, San Francisco, CA; [3]Neurol., [4]Neurosurg., [5]UCSF, San Francisco, CA

Abstract: For individuals with paralysis, Brain Computer Interfaces (BCIs) have the potential to restore lost function through the decoding of neural activity to control external assistive devices. Typically, the control signal in BCIs are low-dimensional as they comprise the imagined motor movements of a single end-effector (such as imagined right arm movements). However, recent work in invasive, spike-based

intracortical recordings has shown that the whole-body can be represented from a single cortical region such as the “hand-knob area”. This suggests that BCI recordings can allow decoding of much higher-dimensional representations, with the potential to translate to complex control of assistive devices with higher degrees of freedom. In this study, we sought to understand whether high-dimensional BCI control signals can be decoded using mesoscale electrocorticography (ECoG). We first established separable control signals using diverse discrete imagined actions, resulting overall in a 12D control signal from the single ECoG grid. A discrete classifier was initialized on these imagined data to classify individual imagined actions using the envelope of three neural oscillations: delta band (0.5-4Hz), beta band (12-30Hz) and high-gamma (70-150Hz), all binned at 8Hz. Then, by leveraging the stability of ECoG, we tracked the consolidation of the high-dimensional control signal with practice over many weeks. Specifically, stable decoding of the high-dimensional control signal was achieved through closed-loop decoder batch updates from online sessions over many sessions of practice. As a result, our subject was able to robustly control a high-degree of freedom virtual robotic device. To understand how neural activity evolved to consolidate the control signals, we used a deep autoencoder to uncover the latent space that captured the refinement of the high-dimensional control signals with long-term BCI training. Overall, our results show that high-dimensional control signals can be stably represented in mesoscale ECoG recordings, without any rigid somatotopy and outside of the hand-knob area of primary motor cortex. Notably, we are able to track changes in the latent space representations; this allowed the user to more easily control the BCI system.

Abstract: Intracortical brain-computer interfaces (iBCIs) can restore voluntary movement to people with paralysis by translating brain activity into a control signal for an external device. Currently, iBCI performance declines over time due to instabilities at the neural interface, such as shifts in electrode position. Such instabilities result in a degradation of decoding performance that can only be recovered by retraining with additional data. To solve this problem, an emerging class of methods seeks to find a population-level latent manifold structure that has a stable mapping between brain activity and behavior. In recent proofs of concept, Farshchian et al (2018) and Degenhart et al (2020) found that unsupervised manifold alignment can achieve stable iBCI decoding without supervised decoder recalibration. However, these methods do not incorporate nonlinear dynamics models, which have outperformed other methods in retaining the behavioral information necessary for high-performance iBCI decoding (Pandarinath et al., 2018). Thus, we developed a platform for nonlinear manifold alignment with dynamics (NoMAD) that seeks to stabilize iBCI decoding following discovery of nonlinear neural population dynamics. In NoMAD, manifold discovery is performed by latent factor analysis via dynamical systems (LFADS), a deep learning approach that uncovers manifold structure by modeling the shared dynamics underlying population activity. NoMAD combines LFADS with unsupervised distribution alignment (Dyer et al., 2017; Farshchian et al., 2018) to produce consistent manifold estimates that are robust to changes in the recorded neurons. We tested whether NoMAD could improve the stability of offline decoding for motor cortical activity from a monkey performing an isometric wrist force task throughout 20 sessions spanning over three months. NoMAD achieved stable, high-performance decoding of the monkey's exerted force over all sessions without supervised recalibration. On days where a static decoder applied to smoothed spikes achieved positive decoding performance, NoMAD achieved a mean improvement over the static decoder of 0.48±0.16 R^2. Comparatively, ANMA (Farshchian et al., 2018) and FA-based stabilization (Degenhart et al., 2020) gave average improvements of 0.26±16 R^2 and 0.028±0.19 R^2, respectively. Of the days that had negative decoding performance with a static decoder, NoMAD restored positive performance to 7 of 8, while ANMA restored 3 and Degenhart 4. By combining accurate, nonlinear manifold discovery with unsupervised manifold alignment, NoMAD improves upon current methods, potentially enabling high-performing, stable iBCIs.

Title: Intrinsic and nonlinear geometric dynamical modeling of neural population activity

Authors: *H.-L. HSIEH[1], H. ABBASPOURAZAD[1], B. PESARAN[2], M. M. SHANECHI[1];
[1]Electrical Engin., USC, Los Angeles, CA; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Neural population activity during naturalistic behavior may evolve on nonlinear low-dimensional geometric manifolds. Thus, identifying this intrinsic geometry and incorporating it explicitly in the dynamical model are critical for investigating neural representations but remain elusive. We develop a novel data-driven framework to learn a nonlinear geometric dynamical model for the temporal evolution of neural population activity. Prior work has shown that a prevalent feature of cortical dynamics across datasets is rotational patterns that can be seen with various dimensionality reduction techniques. Motivated by this broad observation, we hypothesized that neural population activity may evolve on nonlinear manifolds containing holes, which may explain why linear projections of this activity onto hyperplanes show rotations in time. We thus developed our framework to identify multi-dimensional nonlinear manifolds with holes, learn an intrinsic coordinate system for the manifold, and then learn a dynamical model for the temporal evolution of population activity on top of the manifold. We applied this framework to motor cortical population dynamics in non-human primates performing motor tasks. We found that the manifold underlying neural population dynamics was indeed nonlinear and contained a hole yet was multi-dimensional. Moreover, our derived manifold-based intrinsic coordinates described the population activity better than the linear embedding coordinates. This geometric dynamical modeling framework for neural population activity has the unique ability to identify the underlying intrinsic geometry and to build the dynamic model on top of it. Thus, it provides a novel tool to explain and model neural population activity and its intrinsic geometric dynamics.
