Abstract: A brain-computer interface (BCI) allows users to interact with a computer without any physical movement and could improve independence of paralyzed patients. By using neural data as direct input into a predictive model, one can control assistive technologies such as robot arms, spelling computers or speech synthesizers. A small but growing subgroup of BCIs use invasive stereotactic-EEG (sEEG) electrodes, often implanted for focal localization in patients with refractory epilepsy. These electrodes

provide high temporal and spatial resolution in a sparse brain-wide coverage, including deeper structures like the insula and hippocampus.
As sEEG electrodes are currently only implanted for clinical purposes, the contact locations are different for each patient and thus it is not straightforward to combine or compare data between patients. However, combining data would increase the amount of available data and could significantly decrease decoder calibration times. To combine data in the dispersed coverage of sEEG, we explore the use of Riemannian manifolds. By mapping the data to a higher dimensional manifold, large scale neural dynamics might be captured that are partially covered by implanted electrodes in each participant. Riemannian geometry is receiving increasingly more attention in scalp EEG, driven by state-of-the-art results in BCI decoding competitions and promising results in transfer learning. This work describes a first attempt to apply Riemannian Geometry in a movement decoder using sEEG recordings.
Ten epileptic patients undergoing presurgical assessment for resection surgery participated in our study. Participants were instructed to continuously open and close either their left or right hand for 3 seconds, followed by 3 second rest period. The experiments included 30 trials per hand in randomized order, resulting in a total of 60 trials. First, the neural data was detrended, demeaned and filtered for 50 Hz line noise. Then, we extracted the alpha, beta and high gamma band envelope and windowed the data. From the resulting [*windows* x *samples* x *channels*] matrix, we extracted the regularized sample covariance matrices (rSCM) per window. The Riemannian decoder was developed on a 3-class problem using 10-fold cross-validation. Predictions were made by calculating the minimum Riemannian distance of the rSCM to the class mean. Our results show that this approach achieves comparable results to previous work that uses a linear discriminant analysis classifier. These results implicate that a non-parametric approach can achieve similar performance as a parametric approach, reducing the risk of overfitting through hyper parameter estimation.

Title: Simultaneous decoding of reaching goals and task phases from medial parietal areas using a hidden Markov model

Authors: F. E. VACCARI[1], S. DIOMEDI[1], *M. GAMBERINI[1], M. FILIPPINI[1,2], P. FATTORI[1,2]; [1]Univ. of Bologna, Bologna, Italy; [2]Alma Mater Res. Inst. for Human-Centered Artificial Intelligence, Bologna, Italy

Abstract: The fronto-parietal network includes areas involved in generation and control of the motor behaviour. We recently showed that the activity of neurons of V6A and PEc areas, localized in the

posterior parietal cortex of macaque, progresses through a sequence of neural states during a reaching task similarly to what has been observed also for frontal regions. Here, we first investigated the neural states within the parietal PE area, contiguous to PEc, to test whether it shows the same sequence of activation patterns as the caudal areas PEc and V6A. To this purpose, we recorded neurons during a delayed reaching task in which the monkey had to reach 9 different targets placed at eye-level, the same task used to study V6A and PEc. Then, we explored the feasibility to embed an HMM algorithm as neural decoder for Brain Machine Interface (BMI) applications to simultaneously decode task phase and target position from these three areas. We found that a Hidden Markov model (HMM) was able to detect in PE the same main states that we previously found in V6A and PEc. To decode these common neural dynamics, we merged several HMMs separately pre-trained in a unique boosted model that was able to detect the initial phase of the task, in which the animal could freely move the eyes and it was not aware of the future target, plus the three main subsequent task phases (i.e., waiting time, movement execution and target hold period). With this model, we achieved epoch decoding accuracies up to 86 and 88% from V6A and Pec. This was significantly lower, but still above chance level, from PE (67%). Once estimated, the same state sequence could be exploited to also extract information about the reaching goal. In this case, the accuracy of the HMM algorithm was extremely good for V6A and PEc, whereas it decreased for PE (82 and 70% for vs 36%). Spatial information extracted by the three areas peaked during movement and rapidly decreased during the holding phase, suggesting a relative low influence of pure proprioceptive signals. Finally, we tested the algorithm in sub-optimal conditions simulating a neuron loss through several days of recordings without re-training the algorithm. HMM showed a reliable robustness losing on average only the 10% of performance against a 20% drop in the neural population. We demonstrated that HMM can be efficiently used to decode neural activity and to extract spatio-temporal information that could be used to drive a finite state BMI. Our work also confirms that the posterior parietal cortex is interesting to support BMI implants, but, due to the heterogeneity of these areas, careful investigations should be carried on to identify the best source of the information needed.

Title: Evidence for motor-related neural states in posterior parietal cortex

Authors: S. DIOMEDI[1], F. E. VACCARI[1], C. GALLETTI[1], K. HADJIDIMITRAKIS[1,2], *P. FATTORI[1,2];
[1]Univ. of Bologna, Bologna, Italy; [2]Alma Mater Res. Inst. for Human-Centered Artificial Intelligence, Bologna, Italy

Abstract: The parieto-frontal network enables us to perform optimal reaching movements by combining the multisensory integration and state estimation function of the parietal cortex with the muscular and motor planning functions of the motor and premotor cortices. Fundamental for these interactions are neural population patterns within the nodes of the network. In fact, whereas there are theoretically infinite possible activations, in practice, due to plasticity and anatomical connectivity, these patterns are reduced to only a small number of 'neural states', especially in typical, stereotyped laboratory tasks. Here, we examined whether in posterior parietal cortex it is possible to trace back the heterogeneity of neural discharges to a limited number of 'neural states'. We thus recorded from two *Macaca fascicularis* monkeys, 209 and 176 neurons from V6A and PEc areas respectively while the animals were performing a delayed reaching task toward 9 targets placed at different directions and depths in darkness. In addition, we also recorded 92 neurons from V6A area from 2 other animals during a delayed reaching task towards 3 targets placed on a fronto-parallel plane, both in light and dark conditions. To characterize different ensemble activity patterns, we applied an unsupervised machine learning method, the Hidden Markov Model. In the reaching task performed in the dark, both areas were found to encode several neural states. We divided the decoded states in 'micro and 'macro' based on their overall relevance on population activity. The three 'macro' states corresponded to the three main task epochs, already observed in motor and premotor cortices, i.e. waiting for the go signal, reaching execution and holding the target. 'Micro' states represented smaller task temporal intervals: the reaction time period before the action, an initial and a final part of the movement and the first part of the hold epoch. We further investigated the nature of these 'macro' states and tested whether they represented the pure motor plans processing and movement execution or whether they reflected underlying computation principles characteristic of the parietal cortex, invariant to task conditions. We found that visual input added in the reaching task performed in the light did not alter the state sequence, but rather, besides slight differences, a generalization analysis between light/dark conditions allowed to decode the same population patterns. These results suggest that dynamics in posterior parietal cortex are mainly shaped by motor and premotor cortices activity, reflecting the timing of action unfolding.

Abstract: Neural networks in the vertebrate hindbrain and spinal cord rely upon a balance of excitatory and inhibitory neurotransmitter systems to orchestrate locomotive behaviors. Classically inhibitory, GABA is recognized as a key regulator of these neural networks. Despite its importance, the precise roles and molecular mechanisms of GABA remain unclear due to the complexities of GABA signaling. $GABA_A$ receptors ($GABA_ARs$), which mediate the rapid responses to GABA, are ionotropic, ligand-gated heteropentamers, constituted from combinations of 19 and 22 different subunits in mammals and zebrafish, respectively. The molecular diversity, potential for compensatory mechanisms, and few isoform specific pharmacological agents have challenged efforts to better understand how $GABA_AR$, and hence GABA, regulate locomotor networks.In developing zebrafish, bath application of $GABA_AR$ antagonists results in hyperactive swimming by 48 hours post-fertilization (hpf) and all later stages of development, indicating that $GABA_ARs$ regulate locomotor behavior from early larval stages. We hypothesize that during these early larval stages, a limited number of $GABA_AR$ isoforms regulate locomotor networks. To test this hypothesis, we performed a CRISPR-Cas9 somatic mutation screen targeting individual or combinations of all 8 α subunit genes, which are obligatory receptor components, then we analyzed the escape behavior of these 'crispants' at 48 and 96 hpf. This analysis revealed that at 48 hpf, combinations that targeted α3, α4 and α5 generated different types of hyperactive behavior, suggesting that these subunits play a prominent and subtype-selective roles in regulating locomotion. At 96 hpf, a hyperactive phenotype due to this subset was drastically attenuated in both mosaic and germline lines, suggesting that homeostatic mechanisms are effective at later stages of development.α3 is expressed in discrete sets of cells in the hindbrain and spinal cord at 48 hpf, which provides the opportunity to identify specific cell types that are able to regulate swimming behavior. We are currently determining the identity of these α3 expressing cells and assessing the importance of the hindbrain versus the spinal cord in performing hyperactive swimming behavior. Taken together, these data provide a platform to identify how $GABA_ARs$ regulate vertebrate locomotion. Moreover, given that $GABA_AR$ dysfunction is a central aspect of epilepsy and larval zebrafish are an increasingly recognized epilepsy model, we are creating new resources to investigate this disorder.

Title: Role of Dopaminergic Descending Neuron in the control of locomotion in Drosophila

Authors: *N. WANG, V. BHANDAWAT;
Drexel Univ., Philadelphia, PA

Abstract: Neuromodulatory descending neurons (DNs) – neurons that project from the brain to the spinal cord/thoracic ganglia play an essential role in the control of locomotion. Their importance is well-established, in part, through the demonstration that exogenous applications of neuromodulators produce fictive locomotion. However, the mechanism of descending neuromodulation *in vivo* remains poorly understood: both how these DNs are recruited and how they affect the components of the motor circuit *in vivo* are unclear. This study aims to fill this critical gap by investigating the role of dopaminergic descending neurons (DADNs) in fly locomotion. Specifically, we will take advantage of the extensive genetic tools in flies, the availability of electron microscopy data for the entire fly brain and thoracic ganglia, *in vivo* electrophysiology, and calcium imaging in behaving *Drosophila* to elucidate the role of DADNs in the control of locomotion. In *Drosophila*, there are only two DADNs. We started by performing whole-cell patch-clamp recordings from these two neurons while tracking leg movements. We found that in the absence of leg movements, DADNs exhibit tonic activity, which transforms to burst activity during some but not all leg movements. There also exists a prolonged inhibition in DADNs after the termination of locomotion. Next, we measured the activity of DADNs when the fly was walking on a trackball; in this experiment, the activity in DADNs was highly correlated with yaw rotations. While these results establish the DADN activity is related to locomotion, it was also clear that the relationship between leg movements and DADNs' neuronal activity is complex. The complexity likely represents multiple diverse inputs into dopaminergic neurons. To further characterize presynaptic input into DADNs, we reconstructed DADNs in a publicly available electron microscopy dataset. The identified presynaptic partners suggested that DADNs receive 1) inputs from other descending neurons in the brain and 2) feedback from thoracic ganglia. By optogenetically stimulating presynaptic neurons in both the brain and thoracic ganglia, we found that both sets of presynaptic inputs can individually activate DADNs. Together, these studies show that DADNs integrate both feedforward and feedback signals to influence locomotion.

Title: Characterizing Chemical Synapses in the Cardiac Ganglion of Cancer Borealis

Authors: *N. K. BAAS-THOMAS, M. C. RUE, P. IYENGAR, E. MARDER;
Brandeis Univ., Waltham, MA

Abstract: The heart contractions in *Cancer borealis*, or the Jonah crab, are initiated by the cardiac ganglion (CG) which innervates the heart tissue. The CG is composed of only nine neurons, five large cell (LC) motor neurons and four small cell pacemakers. These neurons fire synchronously to produce stereotyped rhythmic impulses, which are stable yet flexible in response to perturbations. The CG is the direct target of multiple neuromodulators whose effects on the normal CG rhythm are well established. Characterizing the identity and location of the circuit's chemical synapses is key to understanding its flexible motor output. Using an antibody against synapsin, a presynaptic protein, we found that chemical synapses were clustered around the LC somata (Figure A) and at the neuropil (Figure B). This implicates the soma as a key site of synaptic integration which is unexpected in invertebrates like the Jonah crab. We next performed double immunostains for chemical synapses and several neuromodulators with different actions on CG output to understand the intersection between morphology and function in this circuit. Stains for inhibitory neuromodulators revealed GABA-like and AST-B-like immoreactivity which was nearly completely colocalized with chemical synapses near the LCs. We next looked at excitatory neuromodulators, proctolin-like, FMRFamide-like, and RPCH-like immunoreactivity, and found little or no overlap at the chemical synapses near the LCs. These results provide morphological evidence that inhibitory input is preferentially integrated at neuronal cell bodies. Conversely, all the neuromodulators studied only partially overlapped with the chemical synapses present at the neuropil. This suggests that there are specialized regions of integration for different modulatory inputs. For several of these neuromodulators, we have also identified which nerve provides afferent input into the ganglion. Our findings provide a topographical organization for multiple inhibitory and excitatory modulators that alter the rhythmic output of this semi-autonomous motor circuit.

Title: Alternating Rhythmic Finger Tapping is Strongly Correlated with Rudimentary Grasping Pattern

Authors: *S. MANOHARAN, H. PARK;
Electrical & Computer Engin., Texas A&M Univ., College Station, TX

Abstract: Neurotraumas often result in catastrophic loss of motor function. The retrieval of impaired grasping function is one of the major focuses of motor rehabilitation, since manipulation through grasping underlies most physical interactions with the world around us. In order to effectively accomplish this goal, there arise two distinct needs: 1) a deeper understanding of the driving neural mechanisms behind grasping and 2) a quantifiable physiological metric to evaluate the grasping function. Studies suggest that rudimentary grasping has a higher influence of subcortical control, while complex grasping has a higher influence of cortical control. Also, prior works indicate similarity between finger tapping patterns and rudimentary finger grasping patterns. Although the connection between the finger tapping and the rudimentary finger grasping has not been investigated with sufficient detail, finger tapping can provide a framework to evaluate the grasping capability, with a strong relationship in between. Notably, it is still challenging to quantitatively evaluate the grasping function, due to the variations caused by the complexity of grasping tasks and the varied levels of cognitive influence involved. In this study, we investigated factors and metrics to facilitate the quantitative evaluation of rudimentary grasping patterns using rhythmic finger tapping patterns. We employed alternating and simultaneous rhythmic finger tapping between two adjacent fingers among the thumb, index, and middle fingers. Ten healthy subjects were asked to tap neighboring fingers alternatingly or simultaneously as fast as possible while maintaining a clear trajectory, to minimize the cognitive intervention while maintaining the data reliability. We first identified that asymmetric patterns underlying alternating rhythmic finger tapping patterns for the Index-Middle and Thumb-Index pairs are skewed towards the rudimentary grasping pattern ($p<0.01$). Second, the degree of asymmetry during alternating rhythmic finger tapping is larger for Index-Middle pair than Thumb-Index pair ($p<0.01$), which is congruent to their respective temporal separation established in rudimentary grasping patterns. No such similarity between tapping and grasping was observed in simultaneous rhythmic finger tapping. Conclusively, we observe that alternating rhythmic finger tapping follows the rudimentary grasping pattern - therefore, we expect to apply these methods and metrics of alternating finger tapping in grasp diagnostics and rehabilitation.

Title: Effects of the paradoxical “freezing” response to stimulation in the Pedunculopontine nucleus (PPN) on the lumbar spinal interneurons in freely moving rat

Authors: *J. KAUR[1], N. BERTRAM[1], E. NAJARRO[1], R. W. BERG[2];
[1]Neurosci., Univ. of Copenahgen, Copenhagen, Denmark; [2]Neurosci., Univ. of Copenhagen, INF, KBH N, Denmark

Abstract: It is well-known that the mesencephalic locomotor region (MLR) plays an important role in initiating and regulating movement, and electrical stimulation can induce locomotion. Nevertheless, it was recently discovered that optically stimulating a subset of neurons in the pedunculopontine nucleus (PPN), which is a part of the MLR, paradoxically induces a whole-body halt of movement rather than movement initiation (Carvalho et al., 2020). To investigate this new phenomenon and the effect of this PPN stimulation on spinal motor circuits, we chronically implanted Multi-Electrode Arrays (128-channels) in the lumbar spinal cord of adult rats. Further, we stimulated the PPN using a photosensitive genetically expressed sodium channel (ChrimsonR), using CamKIIa as a promotor in an AAV virus, that was injected along with an implanted optical fiber. Contrary to the anticipated locomotor response, the photo-stimulation induced a strong arrest of movement where the whole body of the rat "completely froze". Measurements of motion were performed using accelerometers and video recording. The recordings of lumbar units indicated that PPN stimulation reduced the neuronal spiking activity in some of the spinal neurons. The PPN neurons inducing the "freezing behavior" were likely glutamatergic based on preliminary histology, which is still ongoing.

Pasteur, Paris, France; [6]Pediatrics, Univ. of Louisville Sch. of Med., Louisville, KY

Abstract: Swallow must be coordinated with breathing to prevent aspiration, but the mechanisms of this coordination are poorly understood. In the sagittally sectioned rodent hindbrain (SSRH) preparation, control networks for swallow are exposed at the dorsomedial edge of the preparation. In vitro swallow is defined as a burst at the hypoglossal nerve (XIIn) unaccompanied by phrenic (C4) motor output. Here we

used transgenic mice in which the genetically encoded Ca^{2+} indicator GCaMP6F was expressed in the germline, enabling optical recording from all cells exposed at or near the sagittal surface of the SSRH. At the end of each experiment, the tissue was fixed, and a 400 µm section was cut from the sagittal face, for immunohistochemical processing to identify $ChAT^+$, $phox2b^+$, and SST^+ neurons. Using this preparation, we identified a novel population of neurons rostral to the pre-Bötzinger complex (PBC) and dorsal to nucleus ambiguus (NA) that is immediately activated following stimuli. Seconds after stimulus offset, a discrete population of neurons in NA become active, and their activity is accompanied by a burst on XIIn unaccompanied by C4 activity, occurring immediately before or just after the inspiratory burst, consistent with adaptive intercalation of breath and swallow. Unlike the diffuse activity seen along the ventral respiratory column during fictive respiration, networks activated during swallow are spatially compact with sharp, well-defined borders, consistent with modularity. This functional anatomical organization is supported by immunohistochemistry: strong phox2b and ChAT expression with sharp boundaries was found to overlap with the population of neurons strongly activated during stimulation, and the delayed activity associated with fictive swallow overlapped precisely with the well-defined ChAT- and phox2b-positive populations within NA. These findings highlight divergent strategies between the swallow and respiratory pattern generators and lay the groundwork for a detailed investigation of adaptive central coordination of swallow with breathing.

Title: Shape and timing: using variational analysis to dissect motor robustness

Authors: *Y. WANG[1], J. P. GILL[2], H. J. CHIEL[2], P. J. THOMAS[3];
[1]Dept. of Mathematics, Univ. of Iowa, Iowa City, IA; [2]Dept. of Biol., [3]Dept. of Mathematics, Applied Mathematics, Statistics, and Biol., Case Western Reserve Univ., Cleveland, OH

Abstract: Motor systems show an overall robustness, but because they are highly nonlinear, understanding how they achieve robustness due to their different components such as sensory feedback and biomechanics is difficult. In many rhythmic systems, robustness against perturbations involves response of both the shape and the timing of the limit cycle trajectory. This makes the study of robustness even more challenging.
To understand how a motor system produces robust behaviors in a variable environment, we consider a

neuromechanical model of triphasic motor patterns in the feeding apparatus of the marine mollusk Aplysia californica developed by [Shaw et al., J. Comput. Neurosci 2015] and [Lyttle et al., Biol. Cybern. 2017]. We established in [Wang et al., SIADS 2021] the tools needed for studying combined shape and timing responses of both continuous and nonsmooth limit cycle systems under sustained perturbations and applied them to study robustness of the neuromechanical model against an increased mechanical load. Interestingly, we discover that nonlinear biomechanical properties confer resilience by immediately increasing resistance to applied loads. In contrast, while the sensory feedback also immediately responds to the perturbation, the effect of changed sensory feedback signal is significantly delayed by the firing rates hard boundary properties. Our analysis suggest that sensory feedback contributes to robustness primarily by shifting the timing of neural activation and specifically increasing the duty cycle of the neural pool involved in retraction. This enables the system to generate stronger retractor muscle force to compensate the increased force and hence achieve strong robustness.
The approaches that we are applying to understanding a neuromechanical model in Aplysia, and the results that we have obtained, are likely to provide insights into the function of many other motor systems that encounter changing mechanical loads and hard boundaries, both mechanical and in neuronal firing.

Title: Differential activation of reflex motor pathways by 10kHz vs. single pulse spinal cord stimulation

Authors: *D. LEE, K. LEE, D. WANG, Z. KAGAN, K. BRADLEY;
Nevro, Redwood city, CA

Abstract: High frequency (10kHz) spinal cord stimulation (SCS) is well-established and expanding neuromodulatory technique for treating chronic pain as well as activating motor circuits to restore motor function. Despite clinical success, the cellular mechanism of 10kHz SCS for activating neurons is still not fully understood. We aimed to study the activation of reflex motor pathways by 10 kHz SCS vs. single pulses in the spinal circuits. SCS was applied via a micro-sized, in-line quadripolar electrode array positioned epidurally over the L5-L6 dorsal spinal segments (innervating the left hind paw). We applied 10kHz SCS (symmetric biphasic; pulse width: 20us; duty-cycled: 3ms ON with 5s OFF), as well as single pulse SCS (symmetric biphasic; pulse width: 200us; frequency: 0.2Hz). Both strategies were applied at different times on the same two stimulating contacts (configuration: bipole). Needle electromyograms (EMG) were taken of compound muscle action potentials (CMAP) from the hindlimb thigh (biceps femoris) and paw plantar toe flexor muscle (flexor digitorum brevis). We investigated the recruitment curve of these two different muscles by 10kHz SCS and single pulse SCS strategies, in terms of recruitment slope and peak-to-peak (PtP) CMAP amplitude. The recruitment curve was obtained by increasing stimulation amplitude from threshold (observable defection of EMG) to 130% of it. Within this range of amplitude, there was clear pattern that one muscle was more selectively recruited than the other

one. Using 10kHz SCS, the recruitment curve of the thigh muscle CMAP increased at a greater (slope:10.4±2.4 uV/uA, PtP:0.8±0.04 mV) than the toe muscle (1.5±0.15 uV/uA, 0.16±0.06 mV). Using single pulse SCS, the thigh muscle showed more gradual recruitment (4.5±2.1 uV/uA, 0.3±0.1 mV) than the toe muscle (21.8±14.8 uV/uA, 1.15±0.05 mV) We observed that 10kHz SCS activated the thigh muscle selectively, with very little activation by single pulse SCS. The toe muscle showed a similar but opposite selectivity, where single pulse SCS resulted in more selective activation of the toe than 10kHz SCS. Given that both strategies were applied to the same stimulating contacts, i.e., the same spatial location in the spine, these results suggest that 10kHz activates a different set of specific afferent fibers and/or reflex pathway different from that activated by a single pulse. This may represent a new tool for stimulation selectivity, and 10 kHz stimulation may expand potential targets in spinal circuits for pain and motor control beyond those commonly understood for conventional low frequency stimulation.

Abstract: The influence of proximal and distal muscle activation on bimanual interference Wang, Y.[1*], Pinto Neto, O.[2]; Davis, M.M.[1], Castro, R.J. [1], Wright, T.J.[1]. & Kennedy, D.M.[11]Department of Health & Kinesiology, Texas A&M University, College Station, TX[2]Center of Innovation, Technology and Education, Anhembi Morumbi University, São Paulo, SP
Neuroanatomical and neurophysiological differences between proximal and distal muscles suggest that the effects of neural crosstalk may be stronger in proximal than distal muscles. The current investigation was designed to compare coordination dynamics between bimanual force tasks performed with proximal and distal muscles. Right limb dominant participants (N=12, mean age = 21.9) performed rhythmic patterns of isometric force in 1:1 symmetric and 1:2 asymmetric patterns using proximal (triceps brachii (TRI)) and/or distal (First Dorsal Interosseous (FDI)) muscles. Lissajous plots and movement templates were provided to guide performance. Participants performed 10 trials per muscle combination (TRI-TRI, TRI-FDI, FDI-TRI, FDI-FDI) for each coordination pattern in a counterbalanced order. Muscle activity from the TRI and FDI were recorded using sEMG. The behavioral results indicated very effective temporal performance of the goal coordination patterns regardless of the muscle combination used to

perform the task. The results also indicated consistent perturbations in the forces exhibited by the non-dominant limb that could be attributed to the forces produced by the dominant limb during the asymmetric task. However, similar distortions were not observed in the symmetric task. The harmonicity results also indicated that more adjustments, hesitations, and/or perturbations in the left limb than the right limb during the 1:2 task regardless of the muscle combination used to perform the bimanual task. However, left limb harmonicity was significantly lower for the TRI-TRI condition than the other muscle combinations. These results are consistent with the notion that neural crosstalk exerts a stronger influence on the non-dominant limb than the dominant limb and this influence is greater with proximal than distal muscles activation.

Title: Optogenetic activation of 5-HT neurons in the raphe pallidus: effect on sensory-evoked responses in lumbar motoneurons of the neonatal mouse

Authors: *A. GIORGI[1], M.-C. PERREAULT[2];
[1]Emory Univ., Atlanta, GA; [2]Emory Univ. Dept. of Physiol., Atlanta, GA

Abstract: The brainstem raphe pallidus (RPa) is an important source of serotonin (5-HT). Many of the 5-HT-producing neurons in the RPa project to the spinal cord (raphespinal) and profusely innervate the ventral region of the spinal cord where motoneurons are located. Electrical stimulation of the RPa in the cat has been shown to depolarize and recruit lumbar motoneurons, both when given alone or in combination with sensory afferents stimulation (Fung and Barnes 1989). Because RPa also contains non-5-HT raphespinal neurons, it is still unclear whether motoneuron excitation can be attributed to the activation of 5-HT raphespinal neurons. In this study, we use channelrhodopsin-2 (ChR2) optogenetics for precise manipulation of RPa 5-HT neurons and calcium imaging for recording activity in individual lumbar motoneurons. We found that RPa activation did not recruit motoneurons and substantially reduced dorsal root (DR)-evoked responses in these motoneurons. The inhibitory effect of RPa activation on DR-evoked responses was completely abolished by spinal application of the 5-HT2 receptors antagonist ketanserin but not by application of the 5-HT1 receptors antagonist WAY-100135. These results unmask a previously unreported 5-HT2-dependent inhibitory role of RPa serotonergic neurons in the modulation of sensory-evoked responses in lumbar motoneurons, highlighting the need for a systematic re-evaluation of the serotonergic contribution of the different raphe nuclei to the modulation of spinal motor circuits.

Title: Diversity and specialization of brainstem V2a neurons in the control of orientation and locomotion

Authors: *G. USSEGLIO[1], E. GATIER[1], A. HEUZÉ[2], J. BOUVIER[2];
[1]Univ. Paris-Saclay, CNRS, Gif-sur-Yvette, France; [2]Paris-Saclay Inst. for Neurosci., CNRS, Gif-sur-Yvette, France

Abstract: The brainstem reticular formation (RF) is key for controlling and orchestrating motoractions. Indeed, reticular neurons interface multiple sensory and cognitive modalities upstream,with supra-spinal and spinal executive motor circuits downstream. However, their functionaldiversity is still poorly resolved. In particular, are reticular neurons an unified controller ofmultiple motor circuits, or do they comprise specialized subsets based on their inputs and/oroutputs to control component motor actions individually?We recently showed that a genetically-defined class of glutamatergic neurons in themedial reticular formation, the V2a neurons (Chx10-expressing), encompasses at least twodistinct spinally-projecting subsets: a cervical-projecting subset whose activation controls headrotation movements and imposes a change of locomotor trajectory, and a lumbar-projectingsubset that depresses locomotor speed (Usseglio et al., 2020). V2a reticular neurons thuscomprise distinct functional subsets defined by projection and whose functional outcome mayowe to the targeted cell type.Previous work suggested that lumbar-projecting V2a neurons exert a functionalinhibition on locomotion via local inhibitory neurons in the spinal cord (Bouvier et al., 2015).Using a rabies-based transsynaptic strategy on newborn mice, we demonstrate here that thecervical-projecting subset instead directly forms synapses with spinal motoneurons controllingthe axial musculature of the neck. Furthermore, using circuit optogenetics, we reveal that V2areticular neurons not only control head turning and locomotor velocity and trajectory, but alsoother inherent components of orienting behaviors whose executive circuits are located in thebrainstem. These include conjugate eye movements, snout deflections and breathingmodulation. Importantly, we show that these latter functions are not dependent on spinally-projecting V2a neurons but are supported by brainstem-projecting V2a subsets.Our work highlights that V2a neurons in the gigantocellular reticular nucleus act as anorchestrator of orienting motor actions and can be subdivided in two macro-categories,anatomically and functionally, i) one that controls ocular, orofacial and respiratory movementsthrough supra-spinal projections, and ii) another one that controls trunk and limb movementsthrough spinal projections. Within each, a further specialization by projection site andpostsynaptic targets supports the control of individual motor components.

Title: Uncovering the descending dopaminergic inputs to the medullary reticular formation

Authors: *J. R. GRAMS[1,2], T. L. NELSON[4], M. A. TRAN[3], D. A. ELLIOTT[1], P. J. WHELAN[1,3]; [1]Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada; [2]Dept. of Neurosci., [3]Dept. of Comparative Biol. and Exptl. Med., Univ. of Calgary, Calgary, AB, Canada; [4]Cumming Sch. of Medicine, Univ. of Calgary, Calgary, AB, Canada

Abstract: Dopamine is a key neurotransmitter involved in motor control, which has been shown to mediate locomotor behaviors through the nigrostriatal pathway. Although this pathway is well understood, a growing body of literature suggests that parallel descending pathways contribute to the modulation of locomotion. Dopamine neurons have been shown to project directly to motor circuits within the mesencephalic locomotor region (MLR). Neurons within the medullary reticular formation (MRF) also contribute to locomotor control and integrate modulatory input. However, the dopaminergic projections to the MRF have not been well documented. We used a combination of immunohistochemical and viral tracing techniques in DAT-IRES-Cre;td-Tomato and TH-IRES-Cre transgenic mice to map dopaminergic inputs to the MRF. Retrogradely labelled neurons were identified across numerous dopaminergic brain regions including the A13 and A11 nuclei, the periaqueductal grey (PAG) and the locus coeruleus (LC). Our preliminary results suggest that the primary source of dopaminergic input to the MRF originates from the A11 region. Intriguingly, projections from the substantia nigra pars compacta (SNc) and ventral tegmental area (VTA) to the MRF were sparse. Next, using an anterograde viral approach, we found that dopaminergic neurons from the A11 region project to and form putative synaptic connections with neurons in the MRF. We compared the overall fiber length and synaptic density across the rostrocaudal extent of the MRF and found multiple projection sites in the caudal pontine reticular nucleus (PnC) and Gigantocellular Reticular Nucleus (GRN), which are key sites involved in locomotor control. Putative synaptic connections were formed with excitatory reticulospinal neurons. Lastly, using D1-IRES-Cre;td-Tomato transgenic mice, we found evidence of D1 dopamine receptor expression in the MRF. Altogether, our study suggests that the primary source of dopaminergic input to the MRF originates from non-canonical neurons in the A11 region. These preliminary findings support the idea that dopaminergic neurons of the A11 region contribute to the modulation of locomotor behaviour through descending projections to motor circuits in the MRF.

Title: Spinal cord injury-induced plasticity of sensory afferent input pathways to Shox2 interneurons following epidural stimulation in mouse

Authors: *D. GARCIA-RAMIREZ, N. J. STACHOWSKI, S. J. ATOCHE, L. YAO, S. GISZTER, K. J. DOUGHERTY;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Lumbar spinal neuronal circuitry generates the locomotor rhythm and pattern even in the absence of descending input from the brain and sensory afferent inputs. However, the initiation and adaptation of locomotion to the environment requires descending and sensory afferent control. Most spinal cord injuries (SCIs) occur above the location of the spinal locomotor neurons so descending modulation is disrupted but the spinal circuitry remains relatively intact. Therefore, stimulation of afferent fibers, such as with epidural stimulation (ES), is used as a strategy to counteract the deficit of the descending modulation after SCI and subsequently gain locomotor control. In mice, lumbar interneurons (INs) expressing the transcription factor Shox2 have been linked to locomotor rhythm generation and patterning. Therefore, studying the effects of ES on Shox2 INs represents an opportunity to understand the therapeutic mechanisms and further improve current strategies to recover locomotor function after SCI. Previously, we stimulated dorsal roots while performing whole cell patch clamp recordings targeting Shox2 INs in lumbar spinal slices from uninjured adult Shox2::Cre;Rosa26-lsl-tdTomato mice and found that Shox2 INs received inputs mediated by both excitatory and inhibitory sensory pathways. In slices from mice 6+ weeks after complete thoracic spinal transection, Shox2 INs received almost exclusively excitatory inputs in response to dorsal root stimulation. However, in mice in which ES wires were implanted at lumbar spinal level L2 and sub-motor-threshold ES was delivered while mice were weight-supported on a treadmill starting 1 week after SCI and electrode implantation surgery, afferent-evoked inhibitory inputs to Shox2 neurons were observed more often than excitatory inputs. The aim of this study is to identify whether sub-motor-threshold ES alone is sufficient to revert or prevent the SCI-induced changes in afferent pathways to Shox2 neurons, as observed with ES during weight-supported treadmill sessions. We compared the SCI-induced plasticity of sensory afferent input to Shox2 INs in groups of mice receiving sub-motor-threshold ES in the home cage, weight-supported treadmill sessions without ES, and ES on the treadmill, with that of untreated SCI mice. We found afferent-evoked inhibitory and excitatory inputs to Shox2 INs in mice that received ES in their home cage, while Shox2 INs from mice placed on the treadmill with weight support but no ES received mainly excitatory input, similar to the untreated SCI group. This suggests that ES alone is sufficient for the recovery or maintenance of inhibitory sensory pathways to locomotor-related neurons.

Title: Impaired feedback auditory processing despite extensive single-neuron responses during human sleep

Authors: *H. HAYAT[1], A. MARMELSHTEIN[1], A. J. KROM[2], Y. SELA[1], A. TANKUS[3], I. STRAUSS[3], F. FAHOUM[3], I. FRIED[4], Y. NIR[1];

Abstract: Reduced behavioral responsiveness to environmental stimuli is a hallmark of sleep, yet how responses along cortical sensory pathways during sleep compare to those during wakefulness remains unclear. Specifically, previous studies have yet to resolve where along the sensory hierarchy, in which signals, and what factors affect sensory responses during sleep. Here, we recorded intracerebral EEG, microwires LFPs, and neuronal spiking activity along with polysomnography in 13 drug-resistant epilepsy patients implanted with clinical depth electrodes, while intermittently presenting auditory stimuli (e.g. words, click-train, music) during wakefulness and sleep. We found that auditory spiking and LFP induced high-gamma (80-200Hz) power showed robust auditory responses during sleep across the temporal lobe well beyond the primary auditory cortex, exhibiting moderate attenuation in response magnitude while maintaining their selectivity profiles and their tight locking with soundwave envelopes. By contrast to spiking/gamma responses, LFP alpha-beta (10-30Hz) power decrease was prevalent in wakefulness but strongly disrupted in sleep. Entrainment to 40 Hz click-trains was comparable across REM sleep and wakefulness but reduced in NREM sleep. In conclusion, our results establish the presence of extensive and robust auditory responses during sleep while LFP alpha-beta power decrease, likely reflecting top-down processes, is deficient. More broadly, our findings suggest that feedback signaling is key to conscious sensory processing.

Title: Reduction of the glutamate concentration in the ventromedial prefrontal cortex during human sleep

Authors: *T. YAMADA[1], M. TAMAKI[2], B.-D. TYLER[1], S. KHAN[1], J. WATERS[1], T. WATANABE[1], Y. SASAKI[1];
[1]Brown Univ., Providence, RI; [2]Cognitive Somnology RIKEN Hakubi Res. Team, RIKEN Cluster for Pioneering Res., Saitama, Japan

Abstract: Neurochemical mechanisms underlying wake-sleep regulations in the human brains are poorly understood. It has been suggested that regions that span from the subcortical regions to the medial prefrontal region are involved in arousal systems in humans (Maquet et al., 2000; Nofzinger et al., 2004, 2005), possibly through glutamatergic signaling (Weigend et al., 2019). Animal models have suggested that circuits using glutamate and GABA neurotransmitters in the subcortical regions regulate wake and sleep (Brown et al., 2012; Saper & Fuller 2017). In the rats' cortex, glutamate levels increased during prolonged wakefulness and during REM sleep, whereas glutamate levels decreased during NREM sleep (Dash et al., 2009). However, to our knowledge neurochemicals processing regulating wake and sleep in the human brain has never been clearly revealed. As an initial work to address this question, specifically we measured the concentrations of glutamate (Glx) in the ventromedial prefrontal cortex (vmPFC) and early visual areas (EVA) during sleep to test whether the Glx concentration changes in these regions, using simultaneous magnetic resonance spectroscopy (MRS) and polysomnography (PSG). Healthy young adults, ranging 18-30 years old, participated in the experiment. Approximately one week after an adaptation session conducted for them to be familiarized with sleeping inside an MRI bore, the subjects were again asked to sleep inside the MRI bore for about 90 min. During this 90-min sleep session, a 10-min MRS scan was repeated 9 times to collect Glx concentrations from the vmPFC in one group or EVA in the other group. We then calculated how much Glx concentrations changed during NREM sleep and REM sleep relative to wakefulness in the vmPFC or EVA region. While the Glx concentration was decreased during NREM sleep and REM sleep in the vmPFC, it was not decreased during either NREM sleep or REM sleep in EVA. The relative Glx concentration in the vmPFC was significantly lower than that in EVA during both NREM sleep ($p=0.001$) and REM sleep ($p=0.012$). Moreover, the amount of reduction of Glx concentration in the vmPFC during NREM sleep was significantly correlated with the sleep onset latency ($p=0.015$): Namely, the larger amount of reduction of Glx concentration in the vmPFC, the shorter the sleep onset latency. However, in EVA, the Glx concentration was not correlated with the sleep onset latency. These results are consistent with the hypothesis that the vmPFC is a part of the human arousal system, in which reduction of the glutamate level plays a role in initiating sleep, whereas the glutamate level in EVA is not involved in the human arousal system.

Title: Consistent Temporal Patterns of Thalamocortical Activity during Slow Global Events detected with High Resolution EEG-fMRI

Authors: *Z. DIAMANDIS[1], B. SETZER[2], L. D. LEWIS[1];
[1]Biomed. Engin., [2]Grad. Program for Neurosci., Boston Univ., Boston, MA

Abstract: Sleep reflects a state of decreased arousal important for cognitive function and memory consolidation. Sleep is marked by specific oscillatory interactions across cortical and thalamic structures as well as large fluctuations in the global fMRI signal that are coupled to both neural activity and autonomic arousal. While previous studies have shown that brain-wide propagated activity reorganizes during sleep, the fine-grained thalamocortical dynamics that underlie these global events remain unknown. In the past, studies have been limited by the spatiotemporal resolution of conventional imaging methods, which cannot capture dynamics in individual thalamic nuclei. We used previously published simultaneous electroencephalography (EEG) and fast functional magnetic resonance imaging (fMRI) (TR=367ms) data to investigate the interaction between thalamocortical dynamics and EEG activity during slow global cortical events. Then, we used ultra-high field fMRI at 7 Tesla (TR=247ms) to specifically examine the dynamics of individual thalamic nuclei during these events. We found a consistent sequence of cortical EEG and thalamocortical fMRI activity associated with troughs in the global cortical fMRI signal, wherein EEG slow waves precede cortical fMRI troughs which are in turn followed by analogous thalamic activity with a 1-2s lag. Further, we found evidence of a specific sequence of activation across individual thalamic nuclei, subsequent to the dip in the cortical signal. These results demonstrate a specific, consistent pattern of thalamocortical activity coupled to the global cortical fMRI signal and shed further light on how fMRI signal fluctuations relate to electrophysiology and arousal state.

Title: Analysis of the disruption of DMN synchronicity under effects of Sevoflurane and contributions of VTA-DMN FC to the emergence from general anesthesia

Authors: *J. ZIMMERMANN[1], R. NUTTALL[2], D. GOLKOWSKI[3], G. SCHNEIDER[2], A. RANFT[2], R. ILG[4], C. SORG[2], A. WOHLSCHLÄGER[2];
[1]Technische Univ. München, Munich, Germany; [2]Technische Univ. München, München, Germany; [3]Univ. Heidelberg, Heidelberg, Germany; [4]Ludwig Maximilian Univ., München, Germany

Abstract: Disruption of the intrinsic connectivity of the Default Mode Network (DMN) has been associated with Sevoflurane general anesthesia. However, whether its integrity or disruption is the key for consciousness remains unclear. Studies in rodents suggest that the dopaminergic ventral tegmental area (VTA) might be involved in the process of emergence from general anesthesia with a halogenated ether. We propose that a sevoflurane-induced unconscious state is characterized by the loss of synchronization in the DMN, and that a dopaminergic VTA functional connectivity towards the DMN is crucial for reestablishing its synchronization. We used rs-fMRI data from 15 male volunteers (mean, 26yr), under Sevoflurane general anesthesia. Then, we calculated the Fano Factor (FF) and its distribution across 34 regions of the DMN. The FF captures higher order correlation and global synchrony between discrete events and allows to quantify if the observed neural variability compares with the expected variability for a Poisson process. Gamma distributions were fitted to the FF distributions yielding shape and scale factors for each subject and session. We conducted a VTA seed-based functional connectivity (sb-FC) analysis, as a proxy of the dopaminergic interaction between VTA and DMN. To control for anatomical accuracy and RSN specificity, we added 8 further midbrain nuclei and 5 further resting state networks. Finally, we used a mediation analysis to test whether the recovery of synchronicity in the DMN can be explained by first the recovery of VTA-DMN connectivity. Our results showed that the scale factor of the FF distribution as well as sb-FC of the VTA to the DMN were significantly reduced under sevoflurane. Furthermore, the effect of anesthesia on the scale factor was totally mediated by the sb-FC: **Indirect Effect: -0.49** CI: [-0.9185 - -0.0368], **Direct Effect: -0.14** CI: [-0.2956 - +0.0202], **Total Effect: -0.24**CI: [-0.3808 - -0.1066], which is suggested by the mediation analysis. Our findings suggest that the FF distribution is sensitive for detecting resting state fMRI signal changes in synchronicity related to sevoflurane general anesthesia. We could also demonstrate that large-scale synchronization patterns were disrupted, specifically in the DMN. This implies that a well-organized and integrated DMN is a signature for consciousness and that its recovery might depend on an intact dopaminergic VTA-DMN interaction.

Title: Getting a good night's sleep: Sleep duration is associated with default mode network connectivity in youth

Authors: *A. HEHR[1], A. MORALES[1], B. BORG[1], J. EVANSKI[1], E. HUNTLEY[2], H. A. MARUSAK[1]; [1]Dept. of Psychiatry and Behavioral Neurosciences, Wayne State Univ. Sch. of Med., Detroit, MI; [2]Survey Res. Center, Inst. for Social Res., Univ. of Michigan, Ann Arbor, MI

Abstract: Sleep plays an integral role in healthy development. Inadequate sleep has been linked to poorer emotion regulation and increased risk of psychopathology. Alarmingly, 58% of middle school children are sleeping less than the recommended amount of 9-12 hours based on guidelines from the American Academy of Sleep Medicine. Prior neuroimaging studies in adults link poor sleep to variation within and between key neurocognitive networks, particularly connectivity of the default mode network (DMN). The DMN is implicated in self-reference and rumination, and disruptions in DMN connectivity are associated with risk of psychiatric disorders. Importantly, many psychiatric disorders begin during childhood and adolescence, and functional connectivity within and between neurocognitive networks undergo dramatic changes across childhood and adolescence. However, few studies have examined the impact of sleep on DMN connectivity in youth. This study included 3798 youth (11.9±0.6 years, 47.5% female, 78.9% White, 12.3% Black American, 4.5% Asian) from the Adolescent Brain Cognitive Development (ABCD) study, a longitudinal experiment across 21 sites in the United States. To maximize sample size with both neuroimaging and objective sleep data (Fitbit watch activity tracker), we included data from the ABCD 2-year follow-up time point. Within and between network resting state functional connectivity (rsFC) was measured between the DMN and core neurocognitive networks (i.e., dorsal attention network [DAN], frontoparietal network [FPN], and salience network [SN]). Average sleep duration was measured over 13.1±6.5 days. Pearson's R correlations were used to test for associations between sleep duration and within and between network rsFC of the DMN. On average, youth slept 7.4±0.7 hours (range: 3-14.1 hours), which is below the recommend 9-12 hours. Total sleep duration was positively correlated with within-network DMN rsFC and negatively correlated with rsFC between the DMN and the DAN and FPN. Sleep duration was not associated with rsFC between DMN and the SN. These findings are consistent with a previous neuroimaging study of sleep deprivation in adults, showing similar patterns of altered within and between network connectivity of the DMN. Given that altered DMN connectivity has been associated with risk of psychopathology, altered DMN connectivity during development may play a role in the link between poor sleep and the development of psychiatric disorders. This study contributes to a growing body of research demonstrating the importance of healthy sleep habits in youth. Future directions will include behavioral indices and additional measures of sleep quality.

Title: Evidence of a supplementary role of monoaminergic disfacilitation in the suppression of hypoglossal motoneuron activity during hypoxic REM sleep

Authors: C. D. TOBIN[1,2], S. J. FUNG[1,2], *M. XI[1,2], M. H. CHASE[1,2,3];
[1]Websciences Intl., Los Angeles, CA; [2]VA Greater Los Angeles Healthcare Syst., Los Angeles, CA; [3]UCLA Sch. of Med., Los Angeles, CA

Abstract: The present study was undertaken to explore the neurochemical mechanisms that control motor activity during REM sleep under hypoxic conditions, such as those that arise during obstructive sleep apnea. Specifically, we aimed to determine whether monoaminergic disfacilitatory mechanisms (withdrawal of excitatory noradrenergic and serotonergic inputs) participate in the suppression of hypoglossal motoneuron activity during REM sleep under hypoxic conditions. Accordingly, noradrenergic and serotonergic antagonists were microinjected into the hypoglossal nucleus, and their effects on the hypoglossal nerve activity were examined during hypoxic REM sleep. Adult cats were prepared for monitoring behavioral states of sleep and wakefulness, and for extracellular recordings from the hypoglossal nerve. A breathing mask was placed over the animal's nose and mouth to induce single episodes of hypoxia (SpO2 = 70-75%) via a ventilator that regulates on-off flows of nitrogen gas and air into the mask. The real-time oxyhemoglobin saturation level (SpO2) was continuously monitored and recorded. A mixture of prazosin (a noradrenergic antagonist) and methysergide (a serotonergic antagonist) were microinjected, ipsilaterally, into the hypoglossal nucleus during hypoxic non-REM sleep and wakefulness. Prior to the microinjection of drugs, hypoglossal nerve activity decreased by 23.4±2.6% (n=13) during REM sleep versus non-REM sleep under hypoxic conditions (pretreated hypoxia). Following the microinjection of prazosin+methysergide, there was a mean decrease of 12.2±1.3% (n=17) in the nerve activity during hypoxic REM sleep (treated hypoxia). The effect of drug treatment during hypoxic REM sleep was statistically significant compared to pretreated hypoxia ($p<0.001$; unpaired t-test). After 50 minutes of postinjection, recovery from drug effect occurred with a decrease of 19.0±2.3% (n=12) during hypoxic REM sleep (recovery hypoxia), which was significantly different from that of treated hypoxia ($p=0.009$), but not different compared to pretreated hypoxia ($p=0.217$). Our data demonstrates that blockade of hypoxia-induced monoaminergic drives attenuates the suppression of hypoglossal nerve activity during REM sleep. This validates our hypothesis that monoaminergic disfacilitation contributes partially to the suppression of hypoglossal motoneuron activity during hypoxic REM sleep. Therefore, we propose that monoaminergic disfacilitation, in addition to glycinergic postsynaptic inhibition, are responsible for atonia during REM sleep under hypoxic conditions (e.g., obstructive sleep apnea).

Title: Parabrachial nucleus glutamatergic neurons are not necessary for wakefulness

Authors: *F. GRADY[1], S. GRAFF[1], J. C. GEERLING[2];
[1]Univ. of Iowa, Iowa City, IA; [2]Neurol., Univ. of Iowa (hospital and Clinics), Iowa City, IA

Abstract: Lesions in the brainstem tegmentum can cause coma in humans and experimental animals, but the specific cell types and neural connections that sustain wakefulness have not yet been identified. Coma-causing lesions overlap the parabrachial nucleus (PB) and disrupting glutamatergic PB neurons decreases wakefulness. We hypothesized that glutamatergic parabrachial neurons are necessary for wakefulness. We selectively ablated Vglut2-expressing PB neurons by injecting a Cre-conditional apoptotic vector (AAV-DIO-Casp3-TEVP), bilaterally into the PB of Vglut2-IRES-Cre mice that also had a GFP Cre-reporter (R26-LSL-L10GFP). This approach deleted glutamatergic neurons in the PB region, while leaving neighboring neuronal populations in the laterodorsal tegmental nucleus and locus coeruleus intact. As controls, mice with the same genotype were injected with a Cre-conditional mCherry vector (AAV-DIO-TVA-mCh). Bilateral stereological counts of GFP-expressing neurons remaining in the PB revealed that this approach was highly effective (2,770 ± 2,732 versus 19,072 ± 2,003 GFP+ neurons in ablation versus control mice).
In our first cohort, we used a novel infrared camera-based assay to measure the locomotor activity of mice. We found no statistical difference between our ablation and control groups (p=.73, 41.5 ± 7.2% versus 37.5 ± 8.0% epochs with movement in n=10 ablation versus n=7 control mice). In a replication cohort, we used video-electroencephalography and electromyography (vEEG/EMG) to more rigorously measure wakefulness. Once again, we found no statistically significant difference (p=0.90, 50.1 ± 6.6% versus 53.3 ± 6.9% wakefulness in n=9 ablation versus n=8 control mice), and wakefulness did not correlate with the number of remaining PB neurons (r^2=0.06). We also did not find statistically significant differences in amount of time spent in non-REM sleep (p=0.65). Several mice in the ablation group had unusually short bouts of REM sleep, and this group spent significantly less time in REM sleep (p=0.042, 4.8 ± 2.8% versus 6.2 ± 1.2%). These results are not consistent with our hypothesis that glutamatergic parabrachial neurons are necessary for wakefulness.

Title: Spectral features of limbic network activity during cataplexy in narcoleptic mice

Authors: *Z. SABRA[1], A. A. ROGERS[2], L. M. AIANI[2], J. T. WILLIE[3], N. AU YONG[1];
[1]Neurosurg., [2]Emory Univ., Atlanta, GA; [3]Neurosurg., Washington Univ. in St. Louis, St. Louis, MO

Abstract: Introduction: Orexin-deficient narcolepsy type 1 (NT1) is characterized by sudden attacks of REM sleep with associated loss of muscle tone (cataplexy) triggered by strong emotional stimuli. Although autoimmune-mediated loss of orexin neurons in the lateral hypothalamus causes NT1, the precise circuit-level disturbances that link emotional triggers to precipitous lapses into REM sleep remain unknown.**Methods**: Using orexin/ataxin-3 transgenic mice, a model of NT1, we studied the dynamic variation of limbic network activity during wake, sleep, and cataplexy by recording local field potentials (LFPs) in the infra- and prelimbic (IL/PrL) cortex and amygdala in freely behaving mice. Continuous video recording was performed in 6 mice for 24-48h while collecting frontal-parietal neocortical EEG, nuchal EMG, IL/PrL LFPs, and amygdala LFPs. Spectral analysis was performed to determine oscillatory features associated with behavioral transitions.**Results**: We demonstrate that transition from wakefulness to cataplexy is associated with 1) enhanced low frequency oscillations (1-30Hz) with a prominent theta (4-8Hz) component and 2) simultaneous attenuation of high frequency oscillations (30-100Hz). These changes appear earlier in the IL/PrL cortex compared to neocortex. Analysis of coherence between the amygdala and IL/PrL cortex showed highest coherence in the theta range. Using spectral Granger causality analysis, the spectral changes associated with cataplexy in the IL/PrL cortex precede and predict those in the amygdala and neocortex. **Conclusion:** Cataplexy in narcoleptic mice is associated with an increase in low frequency oscillations within the IL/PrL cortex that precedes and possibly drives subsequent responses within the amygdala and neocortex. Characterization of circuit-level biomarkers of narcolepsy may be used to inform novel neuromodulatory interventions.**Support**: Sleep Research Society Foundation, Career Development Award to JTW.

Title: Spectral electroencephalic features of a slow propofol induction in mice

Authors: D. KILLING, T. HAPPE, D. P. OBERT, M. KREUZER, F. NOWAK, G. SCHNEIDER, *T. FENZL;
Tech. Univ. Munich, Muenchen, Germany

Abstract: Despite the vast use of anesthetics, many questions regarding the underlying mechanisms leading to loss of consciousness remain, upon today, unanswered. While working towards better understanding, rodents have become the predominant animal model. Yet there is only minimal knowledge on the effects of propofol, one of the most commonly used intravenous general anesthetics, on the mouse

brain. In the present study we investigated spectral EEG changes during slow induction of propofol anesthesia in mice in order to improve face validity and constructive validity of this animal model. Seven adult, male mice (C57BL6) were included in this study. We established a chronic central venous access via the right external jugular vein, and implanted 9 chronic epidural electrodes (ECOG), one of them serving as grounding. After 14 days of recovery, we performed a propofol anesthesia (propofol 2%), increasing the flow rate every two minutes by 0,5µl/min. After loss of righting reflex (LORR) the infusion rate was held constant for 5 minutes before stopping. Observation periods were split into two phases: start of anesthesia to LORR; and LORR to EEG burst suppression. We used descriptive statistics and a paired Wilcoxon test for analyses. Mice lost righting reflex 1320 s [IQR: 204] after start of anesthesia at a flow rate of 5.7 µl/min [IQR: 1.0]. Around LORR, delta power increased in all cortical areas, as did alpha, especially in the somatosensory cortex. When comparing the EEG at the start of induction vs. the EEG shortly before burst suppression, we found a decrease in delta power in all cortical areas. The alpha power decreased as well, except in the somatosensory cortex. In this work we show mouse-specific spectral electroencephalographic changes upon induction of propofol anesthesia. However, these changes differ in some points from observations in humans. While, around LORR, an increase in delta power, reflecting a slowing of the EEG, can also be found in humans and other primates, we could not observe an increase in alpha power in the frontal cortices only, but a global increase. These differences may be due to different species, but also could be attributed to the induction speed. We performed a slow induction, to optimally observe EEG changes, which stands in contrast to bolus injections in humans. This study depicts advantages and potential limitations of a mouse model for propofol anesthesia. As many questions regarding neuroscientific features of anesthetic induced loss of consciousness can only be answered using animal models, our data, including the newly established vein access, provides important basis for further research.

Title: Chemogenetic activation of GABAergic neurons in the rostromedial tegmental nucleus decreases arousal and increases sensitivity to general anesthetics

Authors: *O. A. MOODY, K. F. VINCENT, R. KATO, E. R. ZHANG, K. SOLT;
Anesthesia and Critical Care, Massachusetts Gen. Hosp., Boston, MA

Abstract: During states of unconsciousness, like sleep and general anesthesia, the brain has multiple areas that are actively suppressed to reduce wakefulness. The rostromedial tegmental nucleus (RMTg) is

one GABAergic midbrain nucleus that sends inhibitory projections to the ventral tegmental area (VTA). Previous research has shown that activating dopaminergic neurons in the VTA increases wakefulness, and inhibiting these neurons can increase non-rapid eye movement (NREM) sleep. We hypothesized that activating GABAergic neurons in the RMTg would decrease wakefulness and make the brain more susceptible to anesthetic-induced unconsciousness. Excitatory designer receptors exclusively activated by designer drugs (DREADDs) expressed in transgenic Vgat-ires-cre mice were used to target the GABAergic RMTg neurons specifically. Mice expressing excitatory M3Dq receptors in the RMTg travelled significantly shorter distances and spent more time immobile in the open field test after receiving CNO (3 mg/kg, i.p.) compared to saline ($p < 0.05$, n=8). These mice also took more time to recover the righting reflex after 50 minutes of 2.5% isoflurane after receiving CNO (3 mg/kg, i.p.) compared to saline. Finally, mice given CNO (3 mg/kg, i.p.) before propofol (100 mg/kg, i.p.) had increased time to return of righting compared to when given saline prior to propofol. In addition, several mice that did not lose righting after saline and propofol, did lose righting for over 40 minutes after receiving CNO and propofol. Together these data suggest that activating GABAergic neurons in the RMTg reduces overall motor activity and makes the brain more susceptible to anesthetic-induced unconsciousness. The RMTg may play an important role in actively suppressing arousal during states of unconsciousness.

Title: The Portal System of the Suprachiasmatic Nucleus

Authors: *Y. YAO[1], A. B. TAUB[2], J. LESAUTER[2], R. SILVER[1,2,3];
[1]Dept. of Psychology, Columbia Univ., New York City, NY; [2]Dept. of Neurosci. and Behavior, Barnard Col., New York City, NY; [3]Dept. of Pathology and Cell Biology, Grad. Sch., Columbia Univ. Med. Sch., New York City, NY

Abstract: Transplantation of the suprachiasmatic nucleus (SCN) into the third ventricle (3V) restores circadian rhythms in an SCN-ablated animal. Even when placed within a semipermeable polymeric capsule, which allows diffusion of hormonal signals but prevents neural outgrowth, the SCN restores circadian rhythmicity with the period of the donor rather than that of the recipient host (Silver et al., 1996) demonstrating that the brain clock produces effective diffusible signals. Ex vivo studies confirm that diffusible signals can set the phase of SCN oscillators in organotypic slices (Maywood et al., 2011). However, a challenge raised by Schibler et al. (2003), is how the small SCN can produce sufficient amounts of humoral signals to set the phase of extra-SCN oscillators unless the target is very nearby. To

explore the possibility of nearby targets, we examined the SCN's vascular organization in male C57BL/6NJ mice (n=27) to explore possible output pathways for humoral signals. The SCN lies at the base of the brain, adjacent to the fluid-filled 3V, making it difficult to study its vasculature in sectioned material. To acquire whole mount images of SCN vasculature we combined iDISCO+ brain clearing and light sheet microscopy using antibodies type IV collagen, smooth muscle actin, and arginine vasopressin to label blood vessels, arteries and the SCN respectively. Surprisingly, we discovered portal vessels connecting the capillary beds of the SCN and the organum vasculosum lamina terminalis (OVLT), a circumventricular organ (CVO). The portal vessels join the rostral-most SCN and the ventral-most aspect of the OVLT superficial plexus. Additionally, the SCN shell has a significantly higher branch density of capillaries ($8.7\pm0.7\times10^{-6}$ nodes/μm^3, n=6) than the core ($4.6\pm1.8\times10^{-6}$ nodes/μm^3). This clock-OVLT portal system enables high concentrations of diffusible signals from the SCN to reach nearby targets without being diluted by returning to the systemic circulation. Prior to this report, the only known portal system in the mammalian brain was the pituitary portal system, first described by Popa & Fielding (1933). Unravelling the function of the pituitary portal system and the neural signals it carries took decades, and continues to be a topic of investigation (Harris, 1948; Guillemin & Schally, Nobel Prize 1977; Trudeau & Somoza, 2020). Like the pituitary portal system, the SCN-OVLT portal system encompasses a highly fenestrated CVO and provides "a window" to the brain. These findings of a new portal system expand opportunities to explore how the SCN communicates with target brain regions and helps to explain how this small nucleus can impact rhythms throughout the body.

Title: Rapid state reversibility from deep dexmedetomidine sedation induced by photoactivation of lateral preoptic GAD2 neurons in mice

Authors: *T. YAMAGATA[1,3], S. N. PEIRSON[1], E. O. MANN[2], R. G. FOSTER[1], V. V. VYAZOVSKIY[1,2];
[1]Sleep and Circadian Neurosci. Institute, Nuffield Dept. of Clin. Neurosciences, [2]Dept. of Physiology, Anat. and Genet., Univ. of Oxford, Oxford, United Kingdom; [3]Fac. of Med., Toho Univ., Tokyo, Japan

Abstract: Dexmedetomidine (Dex) is an agonist of alpha2-adrenergic receptor hence it acts as a powerful sedative by counteracting noradrenaline-mediated arousal. Dex-induced sedation is characterized not only by EEG patterns characteristic of NREM sleep, but also reduced body temperature. Here we investigated whether the probability of awakening from Dex sedation is related to the degree of hypothermia, assessed

using thermal imaging of skin temperature in freely behaving mice. To induce awakenings from Dex sedation, we used an established paradigm which consisted in optical activation of GAD2 neurons in the lateral preoptic area in mice ($GAD2^{LPO}$, n=6), which we and others have shown to reliably result in an immediate awakening from physiological sleep. As expected, shortly after Dex administration (100 mg/kg), the animals stopped moving, assumed a prone position, and the frontal EEG was dominated by high amplitude slow waves, concomitantly with a progressive reduction of skin temperature. During the early phase of sedation (first 1h after administration), photoactivation of GAD2 neurons using 10Hz stimulation for 2 min initially provoked a drop in SWA without behavioral arousal and eventually induced behavioral awakening, while the latency to awakening was still substantially higher during stimulation under sedation as compared to spontaneous NREM sleep (NREM: 5.3 ± 1.6 s, Dex: 31.4 ± 5.5 s, n=6, $p<0.05$, two-tailed paired t-test). Once the 2-min stimulation was terminated, the animals returned to a sedated state within 0.5 ± 0.3 min and high amplitude SWA was re-established. We observed that stimulation during the late phase of sedation (2-3 hours after administration), when the peripheral body temperature dropped to nearly room temperature and the EEG amplitude was very low, still resulted in rapid behavioural awakening, and, unexpectedly, the latency to awakening was significantly shorter as compared to trials performed during the initial Dex sedation ($p=0.0021$). These results indicate that GAD2 neurons in the lateral preoptic hypothalamus have a wake-promoting role during both sleep and Dex-induced sedation. Intriguingly, depth of sedation reflected in elevated threshold for awakening was not associated with the degree of hypothermia, suggesting that reduced metabolism is not incompatible with behavioural wakefulness and arousal.

Title: Responding to predicted and surprising foot shock outcome in ventral pallidum and nucleus accumbens core

Authors: *M. MOADDAB, M. H. RAY, M. A. MCDANNALD;
Psychology and Neurosci., Boston Col., Chestnut Hill, MA

Abstract: The ventral striatopallidal system, a basal ganglia network, includes the ventral pallidum (VP) and the nucleus accumbens. The involvement of different nodes within the ventral striatopallidal system in mediating reward has been well-studied, yet little is known about the contribution of such circuitry to threat processing. Recently, we reported the VP and nucleus accumbens core (NAcc) as neural sources of threat signals. We did this using a discrimination procedure consisting of cues predicting unique foot shock probabilities: danger (p = 1.00), uncertainty (p = 0.25), and safety (p = 0.00). We showed dynamic

relative threat signaling during cue presentation within the VP, and specific threat signaling within the NAcc. Here, our aim was to examine firing patterns following the delivery and omission of foot shock outcomes in each region. We observed diverse neural signals for aversive outcome in each region. Further, we found the VP and NAcc to be composed of very similar functional neuron types. Many VP and NAcc neurons are shock responsive, showing equivalent responding following danger and uncertainty shock. However, many other VP and NAcc show differential firing to surprising and predicted foot shock on uncertainty shock and danger trials. This firing pattern is indicative of positive prediction error - a signal to strengthen cue-shock associations. Additionally, both the VP and NAcc contain neurons showing differential firing to surprising and predicted foot shock omission on uncertainty omission and safety trials. This firing pattern is indicative of negative prediction error - signal to weaken cue-shock associations. Neither regions contain a substantial number of neurons showing a fully signed prediction error. Our observation of similar aversive outcome responding raises the possibility that both the VP and NAcc receive inputs from the same areas involved in foot shock-related processing. A complete analysis of VP and NAcc outcome firing will be presented.

Title: Dissecting the amygdalar microcircuitry

Authors: *Á. BABICZKY, F. MÁTYÁS;
Res. Ctr. For Natural Sci., Budapest, Hungary

Abstract: The amygdala is a central hub in the brain circuit that controls behavioral responses to the environmental changes via the well-accepted lateral (LA)/basal(BA)→central amygdala (CeA) route. Accordingly, CeA controls a line of motor and autonomous brain centers regulating behavioral responses. In addition, recent discoveries have refined this canonical functional organization by identifying valence-specific LA/BA pathway avoiding the CeA suggesting that CeA is not the only output region of the amygdalar complex. Therefore, our main goal was to provide a comprehensive anatomical map with connectivity principles of the amygdalar subregions participating in emotional response. First, we combined anterograde and retrograde tracer microinjections with fluorescent immunohistochemistry to investigate the afferent and efferent connections of different amygdala subnuclei. We selectively labelled the LA, BA, the basomedial (BM), centrolateral (CeL) and centromedial (CeM) subnuclei, as well as the amygdalostriatal transition area (Astr) and the intercalated inhibitory cells. Then we investigated the

localization of labelled axons and neurons and compared their relative densities in each subnuclei. Our results indicate that there are several, rather non-overlapping pathways within the amygdala which contradicts the traditional serial information flow model. For example, there is no prominent connection between LA and BA, and their intra-amygdalar targets are also different (BM, Astr and CeM, respectively). Notably, both LA and BA projections avoid CeL and only weakly target CeM, suggesting only a limited intra-amygdalar connection between the cortical-like and striatal like amygdala. Next, we investigated the major excitatory, namely the cortical and thalamic inputs to the amygdala. Furthermore, using cortical layer- and thalamic subnuclei-specific cre mouse lines, we further detailed these pathways in a cell type-specific manner. We found that the cortical and thalamic afferents selectively innervate amygdalar subnuclei, suggesting the existence of functional link between cortical/thalamic input and the separate intra-amygdalar routes. Specifically, LA and BA as well as CeL and CeM connectivities largely differ. Taken together, our findings highlight the existence of separate (rather than serial) information flow within the amygdala defined by their intra-amygdalar and cortical/thalamic innervation which could provide a framework for future studies on understanding amygdalar function.

Title: A posterior insular cortex - lateral amygdala circuit in fear learning

Authors: S. PALCHAUDHURI, D. OSYPENKO, A. KHUBIEH, O. KOCHUBEY, *R. SCHNEGGENBURGER;
Brain Mind Inst., Ecole Polytechnique Federale de Lausanne (EPFL), Lausanne, Switzerland

Abstract: Associative learning allows animals to evaluate environmental cues, and to generate appropriate behavioral responses. During aversively motivated learning, a neutral sensory cue like an auditory stimulus (the conditioned stimulus, CS) acquires an aversive meaning when paired with an aversive reinforcing stimulus (the unconditioned stimuli, US). The lateral amygdala (LA) is a convergence point for CS-US association, and for plasticity of a CS representation. Nevertheless, the role of specific long-range afferents to the LA in these processes still remain elusive. The posterior insular cortex (pInsCx) is a multimodal sensory area which processes auditory, somatosensory / nociceptive, as well as interoceptive information; in rats, the pInsCx projects to various amygdalar regions including the LA (McDonald 1998; Shi & Cassell 1998). Using retrograde and anterograde tracing techniques, we provide anatomical evidence in mice that the granular and dysgranular regions of the pInsCx project to the anterior LA. Optogenetically-assisted circuit mapping shows robust glutamatergic EPSCs in principal neurons of the anterior LA after the expression of Chronos in the pInsCx, providing evidence for a functional glutamatergic pInsCx → LA connection. Furthermore, optogenetically-evoked EPSCs at this

connection showed increased AMPA/NMDA ratios in mice that received paired CS-US stimulation as compared to various control groups, suggesting an involvement of this pathway in fear learning. *In-vivo* optrode recordings showed that a subpopulation of pInsCx neurons develop a CS response which persists on the fear memory retrieval day, suggesting a role of the pInsCx in fear learning. Optogenetic silencing of LA-projectors in the pInsCx during the US (using retrogradely-expressed Arch1.0), showed a moderate, but significant decrease of fear memory when tested one day later. *In vivo* Ca^{2+} imaging experiments, combined with optogenetic and/or chemogenetic silencing of pInsCx neurons, are underway to study the impact of pInsCx afferents on LA neuron activity during the transmission of US information, as well as for the transmission of learned CS information. In summary, our study suggests a role of pInsCx afferents to the LA in fear learning, and begins to unravel the mechanistic role of this afferent connection to the LA during key phases of fear learning.

Title: Stress Enhanced Fear Learning in Juvenile and Adult Male and Female Rats

Authors: *S. R. HETHERINGTON[1], A. M. POULOS[2];
[1]Psychology, [2]Dept. of Psychology, Univ. At Albany, SUNY, Albany, NY

Abstract: Stress Enhanced Fear Learning (SEFL) is a paradigm used to investigate key characteristics of Post-Traumatic Stress Disorder (PTSD) such as exaggerated fear expression that does not rely on associative learning. There are few studies that have investigated the effects of age and sex in reference to SEFL. To further explore how stress intensity, developmental age, and sex affects the development of SEFL, we used the SEFL method developed by Fanselow and colleagues under three levels of stress in rats. Using no, low, moderate, and high stress groups, rodents at either P24 or P90 underwent four days of SEFL training and testing. Our preliminary findings for P24 rats showed that females exhibited SEFL under moderate and high levels of stress, while age- and litter-matched males only exhibited SEFL under high levels of stress. However, in stark contrast, we observed the opposite effect in high stress P90 rats where males, but not female rats exhibited SEFL.

Title: Acute restraint stress enhances context encoding in fear conditioning

Authors: *E. GROOM[1], E. PERU[2], L. M. COLON[3], A. M. POULOS[4];
[2]Biol. Sci., [1]Univ. At Albany, Albany, NY; [3]Psychology- Behavior Neurosci., Univ. At Albany State Univ. of New York, Albany, NY; [4]Dept. of Psychology, Univ. At Albany, SUNY, Albany, NY

Abstract: Various forms of stressors have the capacity to influence cognitive and emotional processing in ways that can enhance learning in mammals ranging from humans to rodents. Context fear learning is a task that requires the use of cognitive systems to create a context representation that can then be associated to a fear response through affect-based processing systems. This type of learning has been seen to potentiate with acute stressors in mice and rats, however, these observations have not yet determined if the potentiation is due to affect-based changes or if this effect could in part be mediated by enhanced context encoding. In the current study we aim to determine if a brief restraint stressor can alter contextual-spatial encoding by using a modified context fear conditioning procedure in adult C57Bl/6J mice and Long Evans rats. Mice were either restrained or transferred to a novel cage for 15 minutes then placed back into their homecage for 15 minutes before being exposed in varying amounts of time to Context A. After 24 hours mice were placed back into Context A for a brief period followed by a single footshock, then immediately removed, and placed back into their homecage. On days 3 and 4 half of the mice were exposed to either the context in which they were shocked or a novel context in a counterbalanced way to test for generalization. Our data demonstrates that presentation of an acute stressor immediately prior to context pre-exposure can enhance contextual-spatial encoding as seen by the enhancement in freezing of stressed mice with little to no generalization. Use of a similar procedure in Long Evans rats will also be conducted to determine if the effect that is seen in mice can also be observed in rats. Preliminary experiments suggest that the same brief restraint stress used in mice is also able to enhance fear learning in rats.

Title: Long Term Retention of Juvenile and Adult Context Fear Memory in Female and Male Rats

Authors: N. ODYNOCKI[1], Z. ISSACS[1], L. BARON[2], S. HETHERINGTON[1], ***A. POULOS**[3]; [2]Psychology, [1]Univ. at Albany, SUNY, Albany, NY; [3]Univ. At Albany, SUNY, Albany, NY

Abstract: While the long-term retention of context fear memories has been largely described in adult male rodents, relatively little is known about the dynamic nature of these memories in juvenile male and female rats. In the small but growing body of research aiming to characterize juvenile long-term memory, the results from these studies have identified that young animals are more prone to forgetting. However, the extent to which these juvenile memories can be recovered in both male and female rats is not well understood. Our laboratory has recently shown that as juveniles, female rats exhibit greater context fear conditioning (CFC) than males, but this pattern shifts in adulthood when males exhibit greater CFC than females. In the current set of experiments, Long-Evans male and female rats were context fear conditioned at 24 (juvenile) and 90 (adult) days of age and tested for retrieval at 1 or 60 days later. Adults displayed stable levels of freezing across retention intervals with males exhibiting higher levels of freezing compared to females at both intervals. Juvenile animals, irrespective of sex, showed moderate levels of conditional freezing at the 1-day retrieval test, but showed little freezing at 60 days. We then tested the hypothesis that the forgetting evident in juvenile male and female rats could still be recovered with a test of savings. We found that animals who exhibited forgetting displayed higher levels of context fear expression in a sex dependent manner after a savings trial compared to animals who were not shocked as juveniles. Overall, our results highlight the importance of studying learning and memory processes in both male and female subjects, which are not stagnant across development. Furthermore, we provide evidence that fear memories forgotten as juveniles can be recovered in adulthood after a savings trial. These results may help lay a foundation into further understanding sex differences and development in context fear conditioning.

Title: A comparison of ventral CA1 and medial prefrontal cortex efferents in the male and female rat

Authors: L. M. COLON[1], ***E. PERU**[2], V. I. NAVARRO[3], A. M. KHAN[4], A. M. POULOS[5]; [1]Psychology- Behavior Neurosci., Univ. At Albany State Univ. of New York, Albany, NY; [2]Psychology, Univ. At Albany SUNY, Albany, NY; [3]Biol. Sci., Univ. of Texas At El Paso, El Paso, TX; [4]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX; [5]Dept. of Psychology, Univ. At Albany, SUNY, Albany, NY

Abstract: In rodents the medial prefrontal cortex (mPFC) and the hippocampus are inter-connected and project to the basolateral amygdalar nuclei (BLA) and constitute a major portion of the neural circuit mediating context-mediated fear expression. While these regions associated with context fear conditioning have been well characterized and anatomically defined, the vast majority of research in this area has been conducted in the adult male rat. Mounting evidence suggests that male and female rats differentially recruit distinct regions of this neural circuit during associative learning (Maren et al., 1994, Kudo et al., 2004, Gresack et al., 2009, Keiser et al, 2017). These findings raise the intriguing possibility that sex differences in context fear mediated retrieval result from differences in the neural connectivity of this circuit. Here we characterize and explore the densities and distributions of mPFC and ventral hippocampal (vH) efferent projections in both male and female Long Evans rats using the anterograde tracer *Phaseolus vulgaris-leucoagglutinin* (PHA-L). Transport of PHA-L was visualized using 3,3'-diaminobenzidine immunoperoxidase staining while an adjacent series of Nissl-stained tissue sections were used for cytoarchitectural analysis with reference to atlas templates from 2018; *Brain Maps (BM) 4.0, J Comp Neuro*. Spatial registration of fibers with PHA-L transport in reference to *BM 4.0* allowed for an initial qualitative comparison of densities and distributions across the male and female rat brain. For the comparisons presented here, we have chosen to mainly focus on major regions involved in context fear conditioning, namely prelimbic, infralimbic, anterior cingulate, ventral hippocampus, and amygdalar nuclei. PHA-L injection sites were observed within the boundaries of the prelimbic area and ventral CA1 resulting in visible transport of axonal fibers within basolateral amygdalar nuclei.

Title: Direct prefrontal cortical projections to the central amygdala regulate high fear states in mice

Authors: *C. BORKAR[1], X. FU[2], M. DOROFEIKOVA[1], Q.-S. LE[3], R. VUTUKURI[3], C. VO[3], S. BASAVANHALLI[3], A. DUONG[3], E. BEAN[3], A. RESENDEZ[1], J. G. PARKER[4], J. G. TASKER[2], J. P. FADOK[1];

Abstract: Exaggerated responses to perceived threat are associated with several mental illnesses including generalized anxiety, post-traumatic stress and panic disorders. Neuronal circuits in the central nucleus of the amygdala (CEA) are necessary for fear learning and expression of defensive behavior, with a mutually inhibitory circuit motif in the CEA regulating freezing and flight responses. The sources of

excitation to the GABAergic CEA that drive intense fear responses are unsolved. Cortical dysfunction is observed in clinical populations with panic disorder, raising the possibility that direct projections from cortex to CEA could modulate high intensity fear responses. Here, we describe a projection to the CEA from the dorsal peduncular (DP) subdivision of the ventromedial prefrontal cortex. DP-->CEA neurons are glutamatergic and mainly target the medial subdivision of the CEA. Mice were subjected to a Pavlovian fear conditioning paradigm that elicits freezing and flight responses to distinct components of a serial compound stimulus, and Ca^{2+} activity was recorded using open-source miniscopes. We show that DP-->CEA projectors are activated specifically by high-intensity threats. Optogenetic and chemogenetic manipulation experiments demonstrate that inhibition of this pathway is anxiolytic and leads to reduced flight, suggesting that the DP-->CEA pathway is necessary for avoidance behavior. Finally, results from *in vitro* recordings demonstrate that these DP-->CEA projectors have excitatory effects on both corticotropin-releasing factor and somatostatin cells in the CEM. These results are the first demonstration that the prefrontal cortex exerts direct top-down control over CEA neuronal circuits that generate fear-related behavior.

Title: Neuropixels recordings reveal distributed signaling of threat probability and threat-elicited behaviour across rodent midbrain and pons

Authors: *J. A. STRICKLAND, M. A. MCDANNALD;
Boston Col., Chestnut Hill, MA

Abstract: The generation of suitable threat signals in response to threat stimuli is generally considered to be the domain of the forebrain. These signals are then thought to be relayed to midbrain/pons regions to organize the behavioural aspects of fear and adaptive fear responding. Recording from the ventrolateral periaqueductal gray, a midbrain region commonly implicated in generating fear behavior, our lab has found signals for both threat probability and behavioural output. This suggests that threat probability signaling is not exclusive to forebrain regions. To more comprehensively map midbrain and pons threat signaling, we devised a system for multi-region, high-density recording using Neuropixels probes during a fear discrimination procedure in rats. The one-centimeter Neuropixels probe was implanted such that its path coursed through the superior colliculus, most periaqueductal gray subregions, all dorsal raphe subregions, median raphe and additional regions enroute. We recorded 1812 neurons across 21 regions from 10 rats. Analysis of firing during cue presentation showed that neurons could be clustered into

discrete functional types, with each type distributed across at least several regions. Every functional cluster showed a unique temporal pattern of differential cue firing. From these clusters, a small functional network emerged: consisting of clusters showing short latency firing increases to danger, strong differential firing of danger and safety with firing patterns tightly correlated across clusters. Regression revealed these neurons to initially and rapidly signal threat probability, then giving way to signaling of threat-elicited behaviour. Additional analysis of the period following the outcome indicates these regions also play a role in threat outcome and prediction error signals, expanding even further the potential role of midbrain/pons networks in threat signaling and behaviour. These results suggest that networks of midbrain/pons regions not only generate threat-elicited behaviour in response to threat stimuli, but may also play a role in the generation of threat signals themselves.

Title: Activity and modulation of ventrolateral periaqueductal gray neurons during innate freezing

Authors: *C. E. VAAGA, I. M. RAMAN;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Appropriate behavioral responses (i.e. freezing and flight) to threats within the environment are critical for survival. Such innate defensive behaviors require activation of the midbrain periaqueductal gray (PAG), however, the extent to which distinct sub-columns within the PAG are involved in conditioned vs. innate freezing remains controversial. Our recent work has demonstrated that putative freezing-related neurons (expressing the transcription factor Chx10) in the ventrolateral column of the PAG (vlPAG) are subject to modulation by local dopaminergic neurons, which receive input from cerebellar circuits. Whether these neurons in the vlPAG mediate innate freezing, however, is not known. Here we have begun to test the necessity and sufficiency of activity in vlPAG Chx10 neurons during innate fear responses evoked by visual looming stimuli. Under control conditions, both male and female mice responded to visual looming stimuli with prolonged freezing responses (males: 31.4 ± 4.0 seconds, females: 38.5 ± 3.6 seconds, unpaired t-test $p = 0.2$). In response to repeated stimuli, freezing responses showed robust habituation, but the pattern of habituation depended on the interval between successive stimuli. Habituation was slowed when stimuli were presented within the same behavioral session (inter-trial interval: ~5 minutes), as compared to when stimuli were presented across behavioral sessions (inter-trial interval: 24-48 hrs). To test necessity of vlPAG Chx10 neurons during innate freezing, we optogenetically inhibited these neurons during the presentation of a looming visual stimulus. Optogenetic inhibition significantly reduced the percent time spent freezing during the first 20 seconds post stimulus

(WT: 87.2 ± 2.3%; Chx10::Arch: 41.3 ± 9.3%). These results suggest silencing Chx10 neurons occludes freezing responses, suggesting that vlPAG circuits are responsible for generating innate freezing behaviors. Freezing could also be elicited in head-fixed mice running on a treadmill, setting the stage for electrophysiological recordings of vlPAG neurons during behavior.

Title: Medial prefrontal cortex represents ordinal position within a sequence of events

Authors: *G. A. ELIAS[1], A. H. TRAN[1], M. P. SARAF[1], K. W. COOPER[1], B. SHAHBABA[2], N. J. FORTIN[1];

Abstract: The prefrontal cortex is a key region within a larger network that supports the temporal organization of memory. Our recent work suggests the prefrontal cortex is necessary for animals to track their ordinal position within a sequence of events, but precisely how prefrontal cortex accomplishes this remains unclear. To elucidate the computational and representational mechanisms underlying ordinal position tracking, we recorded single-unit ensembles from the medial prefrontal cortex (mPFC) of rats as they performed an odor sequence memory task. In this task they had to determine whether a presented odor (4x odors, A-D) occurred in the correct ordinal position (4x trials per sequence) or not. First, we observed that individual neurons were selectively active during distinct epochs during trials (individual odor presentations) and modulated their activity levels during these periods according to the trial's ordinal position. Next, using a Bayesian decoding algorithm, we quantified the information contained in the ensemble activity. We found that prefrontal ensembles represented time and ordinal information throughout the sequence, though some moments and positions were more strongly represented than others. Specifically, temporal coding was more accurate during trial periods compared to inter-trial periods and, while ordinal position was reliably decoded throughout the entire sequence, it was strongest for the first and last positions in the sequence. Finally, to disambiguate odor from ordinal coding, we decoded the activity during "out of sequence" trials, in which odors were presented at an incorrect ordinal position (e.g. odor B in position 4). We found that ordinal position was more strongly decoded than the

odor identity throughout these trials. These findings suggest that the prefrontal cortex supports the temporal organization of memory by preferentially representing the ordinal position of sequential events.

Title: The sequential organization of hippocampal ensemble activity provides a key temporal signal supporting the memory for the order of events

Authors: *M. SARAF[1], D. HAGHVERDIAN[2], K. COOPER[1], G. ELIAS[1], B. SHAHBABA[2,3], F. NORBERT[1];
[1]Neurobio. and Behavior, [2]Statistics, [3]Computer Sci., Univ. of California, Irvine, Irvine, CA

Abstract: The hippocampus is critical to the temporal organization of our experiences. Although this fundamental capacity is conserved across modalities and species, its underlying neuronal mechanisms remain unclear. Previous studies found that hippocampal ensemble activity exhibits sequential firing fields during the presentation of individual stimuli or inter-stimulus intervals (i.e., “time cells”). Although this type of activity has been shown to provide a strong temporal signal within such task events, it remains unclear whether it supports the temporal organization of event sequences. To address this important issue, we recorded CA1 ensemble activity as rats performed a nonspatial sequence memory task. Briefly, the task involved repeated presentations of a sequence of five odors, and rats had to determine whether each odor was presented in the correct order to receive a water reward. We adapted a Bayesian algorithm to quantify the degree of temporal information contained in the spiking activity of simultaneously recorded neuronal ensembles. Consistent with previous reports, we found that hippocampal ensembles provided significant temporal information not just during inter-stimulus intervals, but also during individual stimulus presentations. Importantly, we discovered that this temporal organization was primarily stimulus-specific, reflected sequential relationships among stimuli through a lag effect, and was stronger on correct than incorrect order judgments. We also report that this temporal coding extended across the full sequence of stimuli unfolding over several seconds. Collectively, these findings offer compelling evidence that the sequential organization of hippocampal ensemble activity provides a key temporal signal supporting our ability to remember the order of events within a sequence.

Ongoing analyses are examining whether this form of temporal coding was also present in a compressed form during sharp wave ripple (SWR) events observed during inter-stimulus intervals.

Abstract: The hippocampus is critical for our ability to remember the sequence of daily life events. Although this capacity is conserved across species and modalities, its underlying neural mechanisms remain unclear. Considerable data from spatial exploration paradigms in rodents indicates that capturing the sequential nature of trajectories is a fundamental coding property of hippocampal neurons. This view is supported by evidence that hippocampal activity can represent sequences of past, present, and future spatial locations during running or a pause at a decision point. To determine whether this function extends beyond the processing of spatial information, we recorded hippocampal activity as rats performed a challenging odor sequence memory task, wherein they had to correctly identify whether each item was presented in the correct sequence position. Using novel statistical decoding methods that account for the graded nature of odor coding in the hippocampus, we quantified the information contained in the activity of simultaneously recorded hippocampal ensembles during odor presentations. To maximize decoding accuracy, we first used a convolutional neural network model and found that, within individual odor presentations, hippocampal ensembles reliably reactivated the sequence of odors experienced. To decode neural activity during specific theta cycles within odor presentations, we then used a logistic regression model, which had better temporal resolution but weaker decoding accuracy. We found that information about past, present and future stimuli was compressed within individual theta cycles, and that this sequential information was linked to the accuracy of order judgments and flexibly incorporated trial-specific contingencies. Finally, at the level of individual neurons, we found a significant proportion of

neurons that exhibited phase precession during odor presentations, as well as neurons that tended to fire in a specific sequence within theta oscillations. Collectively, these results suggest a fundamental function of the hippocampus is to encode, preserve, and predict the sequential order of experience across modalities.

Abstract: Schemas capture patterns across multiple experiences, accumulating information about common event structures that guide decision making in new contexts. Previous behavioral work suggests that schematic knowledge based on the temporal regularities of events affects reasoning about non-temporal properties of event elements. Using fMRI, we measured neural representations of temporal schemas and examined how these representations relate to reasoning behavior. Participants were presented with object sequences that were generated from an underlying temporal community structure and were then asked to make inferences about properties of the objects. Temporal schema representations in perirhinal cortex predicted the subjective similarity of the objects, suggesting that high-level object representations are shaped by temporal schema learning. Furthermore, we found that temporal schemas also affected reasoning about non-temporal properties; participants were more likely to infer that objects in the same temporal community were associated with the same environment. We contrasted different models of schema-mediated reasoning behavior and found that reasoning is influenced by both abstract knowledge of temporal schemas (i.e., whether two objects were associated with the same community or a different community) and detailed knowledge of temporal statistics, as simulated based on a successor representation model of statistical learning. We found that the fidelity of temporal schema representations in hippocampus and precuenus predicted the degree to which temporal schemas affected reasoning behavior. Our results suggest that temporal schemas are represented at multiple levels of abstraction, and that hippocampus and precuneus may support reasoning based on these temporal schemas.

Title: Quantifying individual differences in latent-cause inference

Authors: *D.-M. MIREA[1], Y. SHIN[3], S. DUBROW[4], Y. NIV[2,1];
[1]Dept. of Psychology, [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [3]Dept. of Psychology, Yale Univ., New Haven, CT; [4]Dept. of Psychology, Univ. of Oregon, Eugene, OR

Abstract: Every day, humans are subject to a combination of new and familiar experiences, in the face of which we need to behave appropriately. To do this, we must continuously trade off learning new things with generalizing from prior knowledge. This problem can be solved optimally through inferring the latent causal structure of the environment, so that we can generalize appropriately across experiences that we infer to originate from the same cause. Failure in this process could underlie psychopathological deficits in generalization, such as the tendency to form new, idiosyncratic beliefs based on little evidence, characteristic of schizotypy. Latent-cause inference has been shown to support a wide array of cognitive processes, from fundamental learning and memory to social judgements. Computationally, this process can be parametrized in a formal Bayesian model with three parameters: how likely it is that a new cause occurs (concentration), how variable are the events that a cause tends to create (size prior), and how long each cause is active (decay rate). Designing a task that allows confidently estimating these parameters at the individual level is crucial for mapping psychopathology dimensions such as schizotypy onto the latent-cause inference process. Here, we developed such a task, in which participants are shown ambiguous stimuli resembling microbes, which they need to cluster according to two perceptual features (the length and number of spikes on the microbe). Across three studies conducted online (N = 187 after quality filtering), we found that participants vary widely in their clustering behavior, forming anywhere between 2 and 22 clusters spanning variable portions of the perceptual space. We estimated model parameters using hierarchical fitting, and saw that these correlate in a meaningful way to task behavior - for example, a higher decay rate was associated with fewer assignments to old clusters, suggesting a higher turnover of latent causes ($r_s < -0.6$, $p < 0.001$ in all studies). In addition, we performed parameter recovery, by simulating behavior using the estimated parameter values and fitting the model to this simulated data, and found strong correlations between actual and recovered values ($r_s > 0.9$, $p < 0.001$ for all parameters). Lastly, we found that latent-cause inference models provide a superior fit to the task behavior compared to other classes of models such as reinforcement learning. Overall, our task successfully captures the latent-cause inference process and allows quantifying individual differences in

model parameters, being therefore well-suited for both computational psychiatry and neuroimaging studies of latent-cause inference.

Title: Towards examining event segmentation in mental disorders

Authors: *N. WOLF[1], L. BEUGELSDYK[2], D.-M. MIREA[3], Y. NIV[4], O. BEIN[3];
[1]Queens College, CUNY, New York, NY; [2]Oklahoma State Univ., Stillwater, OK; [4]Princeton Neurosci. Inst., [3]Princeton Univ., Princeton, NJ

Abstract: Event segmentation theories posit that continuous experience is segmented into discrete events when changes in context occur. These changes, termed event boundaries, lead to ending one event representation in our mind and starting a new one. Event segmentation seems to be a fundamental process in perception and cognition, underlying our ability to make sense of our experiences. Chunking our experiences inappropriately can lead to incoherent representations of our external world and impair everyday functioning, and is potentially at the heart of some mental disorders. We therefore adapted an event-segmentation paradigm to examine event segmentation in mental disorders. Previous research has shown that response times are slower at event boundaries, and can be interpreted as a marker of event segmentation. For example, when reading naturalistic stories, reading times are longer for sentences that include an event boundary compared to sentences that do not include a boundary (non-boundary sentences). Here, participants read stories of everyday life events online while their reading times were recorded. In Study 1 (N=25), we replicated the boundary effect: reading times were longer for boundary compared to non-boundary sentences. Next, to understand individual differences, we estimated the relative boundary effect per participant, and examined its stability. Split-half reliability analysis found that, across participants, the magnitude of the boundary effect in the first half of the experiment significantly correlated with the magnitude in the second half, indicating that the boundary effect was stable across the two halves of the study. This suggests that individual differences in the magnitude of the boundary effect are meaningful. In Study 2, we used a novel approach: rather than comparing between separate boundary and non-boundary sentences, we used identical boundary and non-boundary sentences, counterbalanced across groups of participants, as well as structurally similar boundary and non-boundary sentences within participants. The goal was to ensure that differences in the magnitude of the boundary effect across individuals would reflect differences in event segmentation rather than differences in processing of the sentences themselves. Analyses focused on validating this set of stories, as well as

correlating the boundary effect with self-report measures of mental disorder symptoms. Together, these studies aim to examine implicit event segmentation in populations with clinical and subclinical mental health impairments such as anxiety, depression, schizotypy, and ADHD.

Title: What happens next: Complementary time-resolved neural signal of temporal expectations in hippocampus and cortex

Authors: *V. VAN DE VEN, B. LI, P. DE WEERD;
Fac. of Psychology and Neuroscience, Maastricht Univ., Maastricht, Netherlands

Abstract: Using functional magnetic resonance imaging study, we provide evidence for complementary spatiotemporal neural representations in hippocampal and visual cortical areas that are associated with when visual events are expected to appear. The human brain learns temporal structure from experiences to predict what will happen when. We investigated the evolution of neural representations of audio-visual temporal expectations across different multi-second delays. During 3 Tesla fMRI, participants (N=20) learned to uniquely associate each of three different auditory cues with one of three delays (3s, 6s or 9s) and subsequent visual outcomes (faces, scenes or objects). For audio-visual pairs with 3s and 6s delays, participants also saw "catch trials" in which the expected visual class was never shown over a 9s delay (for which the 9s audio-visual pairs acted as baseline condition). Using time-resolved support vector machine (SVM) multivariate pattern analyses (MVPA), we analysed at which moment during the delay the hippocampus and visual cortex represented the cue-dependent expected visual classes during catch trials. We found that MVPA classification accuracy (3s vs. 9s; 6s vs. 9s) of catch trials in hippocampal CA1 and visual cortex was highest ($p<0.001$, permutation test) across the delay at the moment that the visual classes were expected to appear. Further, spatiotemporal patterns for visual classes could be classified in CA1 (3s vs. 6s; $p < 0.01$) but not in visual cortex. Higher CA1 classification accuracy correlated with faster task response times, suggesting behavioral relevance of the spatiotemporal hippocampal representations in temporal expectancy. Finally, we aimed to describe the spatiotemporal nature of the representations in CA1 and visual cortex, for which we developed new MVPA approaches. We found that CA1 representations included a sequence of non-overlapping voxel sets with peak classification accuracy for different moments during the delay, while visual cortical patterns became more similar to the expected visual classes as delay time progressed (prospective coding). Our findings reveal that temporal expectancy of "what will happen when" includes the time-resolved integration of complementary representations in hippocampus and cortex.

Abstract: Multimodal Temporal Pattern Discrimination in Awake-Behaving Mice
Sam Post, Craig Carlan, Anubhuti Goel
Timing is a critical ability across species, enabling judgment of whether to stop or go through a yellow light or when best to feint a predator. Timing behaviors involve perception and discrimination of intervals, prediction, and enaction of timed movements, all of which likely necessitate complex interactions between primary sensory cortices and downstream higher order areas. Here, we investigate discrimination of temporal intervals using a multimodal sensory guided task in which mice learn to discriminate between sequences of 4 synchronous visual and auditory stimuli. Each stimulus's duration within the set is either 200 ms (preferred) or 900 ms (nonpreferred). A water reward, associated with the preferred condition, is dispensed at 1.2 to 1.4 s, and a time out period of 6.5 s is given if the mouse incorrectly responds. Following learning, we then test the mice on a unimodal paradigm to determine if there is transference of learning between stimulus modalities.
Using a discriminability index to determine performance, we find that there is robust learning in the multimodal task and moderate transference of learning to a visual-only version of the task. We find that with improved performance across sessions, mice's lick rates and the variability of their lick rates immediately preceding reward and punish windows correlate with correct and incorrect responses. Prior to learning, there is little difference in lick rates classified by response type. With learning however, correct rejection lick rates slightly depress prior to the reward window and substantially depress prior to the punishment window; false alarm lick rates do not consistently depress at either interval and display less variability across the trial period.
These licking trends are reliably observed in the multimodal and unimodal paradigms and indicate that mice indeed learn to time reward and punishment windows in dependence on stimuli and discrimination of them. We hypothesize that mice discriminate the two conditions via intrinsic mechanisms in which neural networks encode temporal information locally. At present we are using in-vivo 2 photon calcium imaging in primary visual cortex (V1) layer 2/3 to test this hypothesis. Our previous in-vitro work shows that cortical networks are capable of 'learning' to time by broadly disinhibiting the network at learned intervals. We expect to find similar mechanisms in V1 in mice in which an increased excitation-inhibition ratio is temporally coordinated with reward and punishment windows following learning.

Title: Neural circuitry of time orientation: a lesion study

Authors: *J. D. SKYE[1], A. D. BOES[2], D. TRANEL[3];
[1]Neurology, Pediatrics, [2]Pediatrics, Neurol. & Psychiatry, Univ. of Iowa, Iowa City, IA; [3]Neurology, Psychological & Brain Sci., Univ. Iowa, Iowa City, IA

Abstract: What time is it? We are frequently called upon to compare our internal representation of time against a common reference. Assessing orientation to time is a cornerstone of neurological and psychiatric mental status exams. Focal brain damage can disrupt this ability, but the underlying circuitry supporting time orientation is unclear. In this study, we sought to localize the most critical neuroanatomical substrates of time orientation based on impairments following focal, acquired brain damage. We used behavioral and neuroimaging data from the Iowa Neurological Patient Registry. Registry patients are screened for premorbid psychopathlogy, significant medical history, and neurodegenerative disease prior to enrollment. We used the Benton Temporal Orientation Scale (BTOS) to assess time orientation in N=132 ($n_{impaired}$=33) neurological patients with focal, stable brain lesions from the Iowa Neurological Patient Registry. Assessments were performed 3 months or more after lesion onset. We used proportional subtraction to compare the relative frequency of lesions at each voxel in patients with time disorientation and in brain damage comparisons who are temporally oriented. Scores of 5 or more were considered impaired for time orientation, which corresponds with errors in identifying the year, the month, and/or multiple durations of time including the day of the month, day of the week, and/or time of day. We found that damage to the hippocampus bilaterally, left fusiform gyrus, left parahippocampal gyrus, and right ventromedial prefrontal cortex was associated with impaired performance. Then, we created 5mm spherical regions of interest (ROIs) around peak clusters in the proportional subtraction statistical map to seed a structural lesion network mapping (sLNM) analysis. sLNM uses white matter tractography data from healthy adults to identify tracts connecting lesion-derived seeds with other brain areas. This analysis implicated lesions of the left inferior longitudinal fasciculus, left inferior fronto-occipital fasciculus, forceps minor, right cingulum, and right anterior thalamic tract in association with time disorientation. Taken together, we conclude that impaired time orientation is associated with damage to the temporal lobe and ventromedial prefrontal cortex, regions in the default mode network (DMN). This evidence derived from patients with focal, acquired brain lesions supports prior literature implicating the hippocampus and DMN in time orientation and extends this literature by showing that patients with DMN lesions are at a higher risk of time disorientation following brain injury.

Title: Spatial Navigation to Unrewarded and Unmarked Goal Locations

Authors: J. R. WIELAND[1], B. GERKEN[1], *J.-M. FELLOUS[2];
[1]Univ. of Arizona, Tucson, AZ; [2]Univ. of Arizona, Tucson, AZ

Abstract: The CA1 region of the hippocampus encodes locations and rewards using place cells and reward cells. We studied the roles of auditory and visual cues on the rats' ability to learn unmarked (no marked boundary) positive and unmarked (no boundary, small mark on the floor) negative zones on an open field arena. When the rat entered the positive zone, it was rewarded at a random feeder along the circumference of the arena, away from the zone. For negative zones, rather than actively punishing the rat, we used reward withdrawal to avoid fear and stress which are known to significantly depend on non-hippocampal structures such as the amygdala. When the rat entered the negative zone, the feeder that was cued was de-activated and a 10-second delay was initiated before another reward location became active. When auditory cues were used, distinctive sounds were played when the rat entered the positive or negative zone. The experiments consisted of four conditions: positive zone only; negative zone only; positive zone then halfway through the experiment, the area switched to becoming a negative zone; and simultaneous positive and negative areas at different locations on the maze. When visual cues were used, each experimental session was divided into two halves; learning and manipulation. During learning, a local cue on the arena wall and a distal cue on the curtain surrounding the arena were on the side closest to the zone. Three manipulations were tested: the cues and the zone moved together to a new location in the arena, the cues moved but the zone remained unchanged, or the zone moved and the cues remained unchanged.
Behaviorally, we found that the rats quickly learned to enter the positive zone and receive a subsequent reward elsewhere on the maze. They also learned to avoid the negative zone by adjusting their trajectories. In the visually cued experiments, rats were able to navigate more accurately into the positive zone and avoid the negative zone when the cues and zone moved together, but less so when the cues and zone were moved separately. These results show that pairing the zone and distal cues had a significant effect on the rats' behavior. Pilot tetrode recordings in CA1 of the dorsal hippocampus during the auditory cue experiment showed place fields accumulation around the reward locations and near the positive and negative zones. We also observed place field remapping in response to manipulations, and significant changes in their firing rate, especially in the consecutive positive-negative conditions.

Title: Place Field Repetition in Hippocampal CA1 in a Novel City-block Maze

Authors: *W. HOCKEIMER, R.-Y. LAI, J. J. KNIERIM;
Zanvyl Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: The mammalian brain solves the problem of navigation via a distributed network of regions centered on the medial temporal lobe, supported by the spatially selective firing properties of place cells of the hippocampus. Place field firing activity is known to be affected by variables related to movement and trajectory (Markus et al., 1995; Wood et al., 2000; Frank et al., 2000; Ferbinteanu et al., 2003) as well as the border configuration around the place field (Skaggs and McNaughton, 1998; Barry and Burgess et al., 2007). Further, in environments with repeating structural motifs, place cells have been observed with repeating fields at many or all of the analogous regions (Spiers et al., 2015; Grieves et al., 2016; Cowan and Nitz, 2014). However, many of these apparatuses featured a limited number of repeated regions and restricted behavior to access such regions. To explore whether and how place fields exhibit repetition in a more complicated environment, tetrode recordings were taken from CA1 as rats navigated a city-block maze consisting of rectilinear passageways arranged in a grid. Place fields with single fields were observed, as expected, as well as cells with repeating fields. Across 11 days of recording from four animals, an average of 41.9% of cells (+/- 20.1%) exhibited place field repetition, defined has having two or more fields in geometrically similar locations. Within six of these days, the number of repeating cells was significant (6/11 days with significant amount of repetition, $p < 5.8*10^{-6}$). Repeating place fields were typically observed in alleys sharing a common orientation, consistent with earlier findings on the role of head direction on repeating firing fields (Harland et al., 2017). Further, repetition within each cell was not observed in all maze locations that shared a common geometry, but was gated by a particular region of the maze, suggesting a role for global, allocentric inputs on the firing. These data show that place field repetition can be observed in complex environments in which the animal can take a variety of routes through each field.

Title: A comparison of spatial and contextual coding in the hippocampus and retrosplenial cortex.

Authors: *D. SUBRAMANIAN, Z. HE, A. M. P. MILLER, D. M. SMITH;
Cornell Univ., Ithaca, NY

Abstract: The hippocampus (HPC) and retrosplenial cortex (RSC) are involved in spatial navigation and context coding, but they appear to encode this information differently. For example, CA1 neurons exhibit compact place fields while RSC neurons fire reliably at higher rates across wide areas of the environment. Recently, we discovered that RSC neurons exhibit a rate code for the context, even without spatial specificity (Miller et al, 2021, Cerebral Cortex, 31). We examined the mechanisms of spatial/contextual coding by analysing individual neuronal responses and population level activity patterns of neurons in dorsal CA1 and the granular b subregion of RSC while the rats (n=7) foraged in two different contexts - black and white square boxes. To characterize the spatial encoding of the context, we computed pixel-by-pixel spatial correlation for each neuron as a measure of the similarity of spatial firing patterns across trials. The spatial firing patterns were more similar for visits to the same context than for visits to different contexts in both regions. However, this difference was greater in the HPC than in the RSC. Specifically, the spatial firing patterns were more similar for visits to the same context and more distinct across visits to different contexts in the HPC as compared to RSC. We also used a decoding approach in which we predicted the rat's location based on population level spatial firing patterns and found that decoding success was greater in the HPC. Thus, spatial firing patterns in the HPC distinguished the contexts better than spatial firing patterns in the RSC. In contrast, the RSC was better at differentiating contexts via rate coding. We used a population level decoding approach where we repeatedly sampled the firing rates of all the neurons (250 msec bins) and classified which context they were drawn from. Again, firing rates in both regions clearly distinguished the two contexts. However, classification accuracy was higher in the RSC as compared to HPC. We also compared various firing characteristics in both regions and found that HPC firing was sparse while RSC firing was more distributed. We also used a Linear-Nonlinear (LN) model (Hardcastle et al, 2017, Neuron, 94) to examine which variables were encoded by the neurons. Both regions encoded several navigation-related and contextual variables simultaneously (multiplexing), but head direction was more prominently encoded in the RSC. These results suggest that in an open field, the HPC preferentially employs a sparse spatial coding mechanism for distinguishing contexts while the RSC preferentially employs a more distributed rate coding mechanism which includes egocentric head direction information.

Title: Animal-to-animal variability in hippocampal context identification

Authors: P. NILCHIAN[1], M. A. WILSON[2], ***H. SANDERS**[3];
[1]Florida Intl. Univ., University Park, FL; [2]Picower Inst. Learn/Memory, [3]MIT, Cambridge, MA

Abstract: Hippocampal place cells represent an animals' environment. When animals are moved to a different context, hippocampal place cells change their spatial response patterns, known as hippocampal remapping. However, there is variability in the extent of hippocampal response change across animals when presented with the same experiences. In this work, we analyzed electrophysiological recordings from Alme et al., 2014, in which five rats were exposed to 11 different environments. To compare the hippocampal maps in two rooms, we computed average rate map correlation coefficients. We found that many place cells remap in repeated rooms. Furthermore, we discovered that the heterogeneity in animals' remapping behavior is structured: some animals consistently remap to a greater extent in response to a variety of contextual changes, whereas other animals consistently remap to a lesser extent. In summary, our findings emphasize the role that animal-specific factors play in hippocampal context identification.

Engin., [7]Djawad Mowafaghian Ctr. for Brain Hlth., Univ. of British Columbia, Vancouver, BC, Canada; [8]Dept. of Biol., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Place cells are neurons in the mammalian hippocampus that fire when the animal is in a particular location in the environment. This activity involves integrating self-motion information over time (path integration), combined with landmark information. Optic flow is often proposed to be an important idiothetic cue for path integration (Sharp et al, 1995; Wiener et al, 2013; Mao et al, 2020), but the ability of optic flow to control the firing locations of hippocampal place cells has not been directly demonstrated. Previous work in our lab (Jayakumar et al, 2019) has shown that place fields in rats remain locked to a set of reliable landmarks even when the landmarks are moved as a function (experimental gain) of the rat's velocity. Here we show that place cell activity can be similarly controlled using optic-flow cues.
We trained rats to run on a circular track placed in the center of a virtual reality dome. During running, we

projected a set of 80 uniformly spaced, vertical stripes onto the interior of the dome. These stripes were designed to create a non-polarizing optic-flow cue. We moved the stripes at an experimental gain either >1 or <1, creating the illusion of running faster or slower, respectively, relative to the optic flow pattern. We recorded place cells from CA1 during each session. In 5 rats, the experimental gain manipulation was predetermined (open-loop trials). We found that the place fields drifted around the circular track with respect to the laboratory even when the stripes were stationary, likely due to accumulated error from path integration in the absence of landmarks. In the majority of experiments, the rate of drift increased or decreased in response to >1 or <1 experimental gain values, respectively, showing that optic flow influences path integration and the firing locations of place cells.
To further demonstrate the strength of this influence, we placed 4 of the rats under neural closed-loop control, modifying the speed of the stripe pattern in real time based on CA1 place cell activity. Using a decoding algorithm, we estimated the rate of place field drift in real time and fed this into a novel feedback control system that adjusted the experimental gain of the stripes so as to drive the hippocampal drift rate towards a desired setpoint. Using this feedback control loop, we achieved more robust control over the activity of place fields, successfully maintaining the desired drift rate over extended periods of time with only optic flow manipulations in a majority of sessions. These results demonstrate that optic flow can exert powerful control over the hippocampal cognitive map and confirm its hypothesized role as a major idiothetic cue for path integration in mammals.

Title: Dorsal hippocampus retrieves category representations in rats

Authors: *M. BROSCHARD[1], J. KIM[2], B. C. LOVE[3], J. H. FREEMAN[2];
[2]Psychological and Brain Sci., [1]Univ. of Iowa, Iowa City, IA; [3]Univ. Col. London, London, United Kingdom

Abstract: Categorization is an essential process that organizes experiences according to perceptual similarity. Recent neuroimaging experiments suggest that the hippocampus plays a central role in category learning by building and storing category representations. This is supported by *in vivo* studies demonstrating that single units in the hippocampus track changes along non-spatial feature spaces. In the current experiment, we assessed the role of the rat dorsal hippocampus in storing category representations through inhibitory DREADDs and computational modeling. Using a touchscreen apparatus, rats were trained to categorize distributions of artificial stimuli containing black and white gratings that varied along two continuous dimensions (i.e., spatial frequency and orientation). For some rats, categorizing the

stimuli required selective attention to a single stimulus dimension (i.e., 1D task). For other rats, categorizing the stimuli required attention to both dimensions (i.e., 2D tasks). Inactivating the hippocampus impaired learning for both 1D and 2D tasks but had no effect on a control discrimination task with the same trial structure as the categorization tasks. We then fit the neural network model SUSTAIN (Supervised and Unsupervised STratified Adaptive Incremental Network) to the learning data to examine the role of the hippocampus in storing category representations. Model simulations suggest that the hippocampus uses pattern completion mechanisms to retrieve relevant category representations to make category decisions.

Title: Testing for Odor Discrimination and Habituation in a rat model of Fragile X Syndrome

Authors: *D. OKWUBODU[1,2], D. ASHADE[1,2], E. ROBSON[1,2], U. SALEEM[1,2], S. KIM[1,2], L. L. COLGIN[1,2,3];

Abstract: Fragile X Syndrome is the most common monogenetic cause of autism spectrum disorders. A common symptom of autism spectrum disorders is impaired social interactions, and CA2 is a subregion of the hippocampus that is thought to play a key role in social cognition. The principal neurons of the hippocampus are place cells, neurons that have receptive fields for particular locations in space. Previously published research showed that place cell firing patterns in CA2, a hippocampal subregion hypothesized to be important for social memory, changed in response to social experiences (Alexander et al., *Nature Communications* 2016). Our preliminary data indicate that CA2 place cells responded specifically to the olfactory component of social stimuli (Mably et al., *SfN abstracts* 2018). Preliminary data also suggest that CA2 place cell responses to social odors were absent in a rat model of Fragile X syndrome (Fmr1 knockout rats, or "FXS rats") (Robson et al. *SfN abstracts* 2019). Here, we aimed to determine whether the lack of CA2 place cell responses to social odors in FXS rats was due to dysfunctional olfaction. Olfactory habituation and dishabituation tests were performed to determine whether FXS rats detected and discriminated odors as well as age-matched wildtype control rats. Preliminary results suggest that FXS rats habituated to social and non-social odors presented across sessions and were able to discriminate between different social and non-social odors. However, preliminary results suggest that FXS rats explored social stimuli, but not non-social stimuli, less than

wildtype rats. This pattern of results suggests that deficient CA2 place cell responses to social odors in FXS rats are not explained by deficits in basic olfactory function but may be related to impaired social behaviors.

Title: Investigating awake replay in a rat model of Fragile X Syndrome

Authors: *M. M. DONAHUE[1,2], E. ROBSON[1,3], L. L. COLGIN[1,2,3];
[1]Ctr. for Learning and Memory, [2]Inst. for Neurosci., [3]Dept. of Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: Fragile X Syndrome (FXS) is a neurodevelopmental disorder that can cause impairments in spatial cognition. The hippocampus is thought to support spatial cognitive functions through the activity of place cells, neurons that fire selectively in particular regions of space. The reactivation or "replay" of previously active place cell sequences during sharp wave-ripples (SWRs) is believed to be important for spatial memory-guided planning and spatial memory consolidation. Previous research has shown that SWRs are abnormal in a mouse model of FXS (Boone et al. 2018), but to our knowledge the replay of place cell sequences during SWRs has not been examined in a rodent model of FXS. Here, we examined whether SWR-associated replay was impaired in preliminary data from a rat model of FXS (*Fmr1* knock-out rats or "FXS rats"). We recorded CA1 place cells in FXS rats and wildtype (WT) control rats during unidirectional running on a circular track and subsequent waking rest periods. We then used a Bayesian decoding algorithm to estimate angular positions on the circle track represented by ensembles of CA1 place cells during replay events. Our preliminary results suggest that replay fidelity was similar between WT and FXS rats. However, the temporal compression of sequences of locations represented during replay events was observed to be lower in preliminary data from FXS rats. Additionally, preliminary results suggest that FXS rats had a higher proportion of reverse replay events than WT rats. These results raise the possibility that impairments in SWR-associated replay contribute to aberrant spatial cognitive functions in FXS.

Abstract: The hippocampus is important for spatial learning and memory. Hippocampal place cells receive sensory information from internal and external sources to form a representation of space by localizing their firing to specific locations of an environment ("place fields"). We and our colleagues previously reported that place cells in the CA2 region of the rat hippocampus change their firing patterns ("remap") after a social interaction with a familiar conspecific (Alexander et al., *Nature Communications* 2016). Further experiments have suggested that CA2 place cells remap specifically to the olfactory content of the social experience (Mably et al., *SfN abstract* 2018). Here, our preliminary data show that while CA2 place cells respond to social odors they do not respond to non-social, or neutral, odors. A differential pattern of results was observed for preliminary data from CA3, with CA3 place cells responding to neutral, but not social, odors. Moreover, CA1 place cell activity seemed unaffected by both neutral and social odors. These data suggest that social and non-social olfactory stimuli are processed differently by different hippocampal subregions. Insights gained from our ongoing studies may aid the understanding of disorders associated with specific sensory processing and integration deficits, and impaired social behaviors, such as Fragile X syndrome.

Title: Hippocampal neuronal firing in the air-lifted T-maze alternation task

Authors: *Y. LI, M. A. GO, S. V. PRADO, S. R. SCHULTZ;
Imperial Col., London, United Kingdom

Abstract: The hippocampus is essential for spatial working memory. The continuous T-maze alternation task is widely used for assessing short-term spatial working memory in rodents. Behavioral performance and recording of hippocampal neuronal firing under head-fixation during the T-maze alternation task in the real-world environment has however not been demonstrated to date. Here we present the assessment of spatial working memory while imaging hippocampal CA1 neurons by two-photon calcium imaging in an air-lifted T maze in head-fixed mice. Methods: We injected AAV-jGCaMP7s into hippocampal CA1 subregion (pyramidal layer) in the mouse (Chat-ires-Cre, male, 3-4 months, N=4), then implanted a glass craniotomy imaging window by aspirating cortex above the injection site. A metal head-plate was glued to the skull. Animals were allowed to recover for at least one week after surgeries. Water restriction was used to motivate animals navigation and learning in the maze. Animals were trained under head-fixation in the air-lifted T maze cage for 2 sessions daily on 8-12 consecutive days. Animals were started running from the stem arm and allowed to choose one of reward arms for the first trial. In subsequent trials, rewards were only given when animals entered the goal arm opposite to the arm visited on the previous trial. After the mouse was well trained (the percentage of alternation is above 70% in consecutive 3 training sessions), we employed two-photon microscopy to record hippocampal CA1 neurons activities via calcium imaging when the head-fixed mouse was been testing in the floating T-maze. Calcium imaging videos were processed by motion correction and ROI segmentation via CalmAn. Results: Head-fixed mice can be well-trained in the floating T maze for continuous alternation tasks after 15 sessions. We observed both hippocampal place cells encoding the reward location and the return arm. In addition, we analysed the alternation navigation into two trial types (right-left turn trials and left-right turn trials), finding trial type-specific firing hippocampal neurons (“splitter cells”) that were selectively active on the stem arm and strongly predicted the future path. Our results provide the first demonstration of hippocampal place cells and splitter cells representations in head-fixed mice performing alternation in the air-lifted T maze by combining two-photon calcium imaging.

Title: Time-varying gamma balance in CA1 distinguishes between differential spatial coding regimes

Authors: *M. GUARDAMAGNA, F. STELLA, F. P. BATTAGLIA;
Donders Inst. for Brain, Cognition and Behavior, Radboud Univ., Nijmegen, Netherlands

Abstract: In the CA1 subfield of the hippocampus, converging inputs at different layers provide complementary streams of information and independently shape the activity of local pyramidal cells (Colgin et al., 2009; Schomburg et al., 2014, Fernandez-Ruiz et al., 2016). Fine scale spike timing phenomena within this circuitry are found both at the single cell (phase precession) and population levels (theta sequences). To which extent these processes are related to each other and influenced by the same or different set of converging inputs remains still unknown.
Here we investigate the association of oscillations at distinct gamma frequency ranges with the appearance of phase precession and theta sequences in the CA1 place cells population. To this purpose, we take advantage of a new chronic implant device (the Hybrid Drive) combining linear silicon probe recordings with high density tetrode arrays in freely moving mice. We describe for the first time how phase precession selectively appears in a sub-population of CA1 place cells in association with dominant medium gamma (60-90 Hz) power from the stratum lacunosum moleculare (SLM) - Figure A-B. Conversely, theta sequences are increasingly present as the slow gamma (20-45 Hz) from the stratum radiatum (SR) becomes more dominant.
Our findings, indicating a substantial complementarity between phase precession and non-local coding in the hippocampus, point to the existence of functionally distinct collective-activity states in CA1. As CA1 pyramidal cells receive two anatomically segregated, excitatory inputs: the Schaffer collaterals, tagging the SR from CA3, and the perforant path tagging the SLM from the entorhinal cortex (EC Layer 3), we hypothesize that such states depend on the competition between these two inputs. Gamma oscillations, rooted in the layer-specificity of these inputs, would then reflect their instantaneous balance.

Title: Hippocampal neural dynamics of spatial navigation in the Morris water maze

Authors: *R. RESHEF, M. SHAHI, D. AHARONI, P. GOLSHANI;
UCLA, Los Angeles, CA

Abstract: Learning and memory enables the organism to acquire, store, retrieve, and update knowledge of the world through experience as well as to use this knowledge to navigate through a myriad of stimuli to facilitate survival. Lesions or inactivation of the hippocampus impair the encoding and retrieval of spatial memories. Hippocampal place and head direction (HD) cells activity has long been proposed to be related to the representation of one's location in space and the heading direction in that space. Yet, how place and HD neuronal population dynamics change with spatial learning and how this activity drives navigation to a learned goal is poorly understood. To address these questions, using wire-free miniaturized microscopy of genetically encoded calcium indicator GCAMP7f**,** we imaged the activity of CA1 neurons during spatial learning of a target oriented two-dimensional navigational task, the Morris Water Maze - a gold standard task for spatial navigation. Using generalized linear models (GLM) we were able to disentangle the activity of place cells and HD cells in CA1 as animals navigate in the maze. Our results demonstrate that the tuning of space and HD cells becomes more selective as animals learn to navigate to the goal. As we were able to track the activity of cells across days, we also found that tuning selectivity of individual neurons increases. Thus, cells become more tuned to location and heading direction as learning continues. Future work will determine whether this increased selectivity in tuning is essential for learning.

Title: Recognition and approximate reconstruction of exponentially many arbitrary patterns leading to a Content-Addressable Memory Continuum.

Authors: *S. SHARMA, S. CHANDRA, I. FIETE;
MIT, CAMBRIDGE, MA

Abstract: How does the hippocampus, vastly outnumbered by the number of potential patterns in cortical neurons, store memories of experiences encoded by cortex? It is assumed to act as an associative memory, but classical models such as the Hopfield network store and robustly recall only up to N arbitrary patterns in a network of size N. Recently proposed associative memory architectures enable robust reconstruction of an exponential number of patterns (Hillar & Tran, 2018; Chaudhuri & Fiete, 2019; Krotov & Hopfield, 2016); however, these networks involve biologically implausible assumptions about synapses (Krotov & Hopfield, 2016) or the amount of information recalled per pattern is small because they are highly structured (Hillar & Tran,2018; Chaudhuri & Fiete, 2019).
We construct an entorhinal-hippocampal (EC-HC) attractor network using the theme of modular input structures with random feedforward EC-HC projections and associatively learned return weights that exhibits exponentially many robust (large-basin) fixed points. Training the HC to EC weights (hebbian learning) over only a small subset of contiguous grid cell states results in the formation of a large number of additional HC fixed points with large basins that can be reconstructed robustly from unseen grid cell states. In other words, these untrained hippocampal patterns can be robustly reconstructed in the presence of large amounts of noise from grid inputs. Further, the addition of hetero-associative recurrent synapses within HC leads to learning of the grid state transition matrix and the potential for high-capacity sequence memory.
Because place cells construct conjunctions between sensory experience and abstract spatial coordinates (Manns & Eichenbaum, 2006), we add a sensory input stream to HC. The combination of structured and unstructured inputs enables storage and robust recollection of a large number of arbitrary sensory patterns from partial cues. This allows us to span a content-addressable memory continuum with varying degrees of recovered information that depends on the number of stored patterns, with complete recovery of a small number of patterns (recall) and partial recovery (recognition) for an exponentially large number of patterns. Thus, our proposed model supports high-capacity associative memory, essential for interference-free episodic memory and spatial learning across time.

Title: Atomically thin platinum ditelluride cortical neural probes

Authors: *D. KIREEV[1], G. JEANPIERRE[1], R. T. JAYANTH[1], S. HAN[5], Y. JUNG[5,6,7], S. R. SANTACRUZ[1,2,3], D. AKINWANDE[1,4];

Ctr., [6]Dept. of Materials Sci. and Engin., [7]Dept. of Electrical and Computer Engin., Univ. of Central Florida, Orlando, FL

Abstract: Based on the decades of research progress in implantable electrodes, we recognize that three features make an effective implantable electrode material: high conductivity, low interface impedance,

and small thickness or softcore. Atomically thin two-dimensional (2D) materials are unique constructs that fit the application explicitly due to their intrinsic flexibility and tissue imperceptible thinness. In this work, we report on platinum ditelluride ($PtTe_2$) as the active material of choice. Unlike graphene and most other transition metal dichalcogenides, $PtTe_2$ is a highly metallic 2D material with superior conductivity properties and attractively low (~400°C) synthesis temperature. *In vitro* studies show that $PtTe_2$ exhibits superior interface capacitance and area-normalized impedance compared to gold and platinum. An ultrathin ~10 µm polyimide is used as a supporter for the $PtTe_2$ cortical probe where the $PtTe_2$ is thermally converted from the thin (~5 nm) Pt film pre-deposited on the polyimide. This $PtTe_2$ growth is performed at a low temperature of 400°C directly on the polyimide, making the probe fabrication easy and attractive. The resulting $PtTe_2$ is confirmed to be ~20 nm thick in a 2D multi-layered structure. the probe is passivated with another layer of a thin (~5 µm) polyimide yielding a stack of polyimide/$PtTe_2$/polyimide with 32 measurement sites with 200 µm pitch and 400 μm^2 electrode opening. *In vivo* studies are performed by acutely implanting the $PtTe_2$ cortical probe into the frontal eye fields (FEFs) in the left hemisphere of a rhesus macaque monkey using a guide tube and polyethylene glycol to acutely increase stiffness during penetration into neural tissue. We examine signal stability and signal-to-noise ratio (SNR) of the recorded local field potentials and single unit spiking activity across daily sessions. Recordings are compared with signals from standard metal (tungsten) microwire electrodes. The $PtTe_2$ cortical probe's conductive properties, low impedance, and thinness make it a desirable invasive electrode that will contribute to the next generation of soft, biocompatible electrodes.

Title: Multifunctional fiber-based neurotechnology enables cortical neuromodulation in non-human primates

Authors: *I. C. GARWOOD[1], A. J. MAJOR[2], M.-J. ANTONINI[1], J. CORREA[3], M. K. MAHNKE[2], E. K. MILLER[2], E. N. BROWN[1], P. ANIKEEVA[4];
[1]HST, [2]PILM, [3]Brain and Cognitive Sci., [4]MSE, MIT, Cambridge, MA

Abstract: Local modulation of cortical neural receptors in-vivo provides important insight into cortical circuit dynamics. In recent years, there has been significant innovation in multifunctional neural interfaces for rodents, enabling direct receptor modulation with simultaneous electrophysiology monitoring. Microscale flexible devices have enabled intracranial neuromodulation while reducing damage to delicate neural tissues. We translated multifunctional fiber-based neurotechnology for use in non-human primate (NHP) studies for the first time. The intracranial portion of the device, the fiber, is 150-200 um in diameter and contains four electrodes and two microfluidic channels in polyetherimide cladding. The devices are smaller and more flexible than commercial multifunctional devices used in NHP research. The backend connectors of the device are highly modular and compatible with common NHP setups (see fig below). We implanted these fibers in the premotor cortex and recorded single unit and local field potential activity. We demonstrated that a local 5-minute infusion of muscimol, a $GABA_A$ receptor agonist, reduced firing rates. The distribution of interspike intervals (ISIs) prior to injections were estimated with an inverse gaussian model. We compared post-injection ISI distributions with baseline ISI distributions. At infusion rates of 10 nl/min, there was a significant decrease in firing rate 3.8-4.1 min (Pr(ISI > baseline) > 0.99) after the injection, which recovered 0.3 min after the injection was stopped. At 50 nl/min, there was a significant decrease in firing rate 0.64-1.29 min after the injection began, which partially recovered over 20 minutes after the injection stopped. An infusion of saline at 50 nl/min did not reduce the firing rate. In summary, we translated and validated multifunctional fiber-based devices in NHPs.

Title: Characterization of Recording Electrodes to Measure Evoked Compound Action Potentials (ECAPs)

Authors: *N. VERMA, B. KNUDSEN, A. SKUBAL, J. FRANK, K. LUDWIG;
Univ. of Wisconsin - Madison, Madison, WI

Abstract: Appropriately designed electrodes to make *in vivo* recordings of neural activity have been essential to the understanding of the nervous system. Recording electrode design has been extensively explored for use in measurement of naturally occurring neural activity in the brain. Recently, recording of evoked compound action potentials (ECAPs) in the periphery has garnered interest due to their relevance in neuromodulation therapies for determining target engagement and enabling closed-loop operation. Here, we compare several types of recording electrodes - microelectrodes, cuff electrodes, and longitudinal interfascicular electrodes (LIFE) - and their ability to make *in vivo* recordings of spontaneously occurring, sensory evoked, and electrically evoked neural activity in the peripheral nerves of a large animal.

The great auricular nerve, innervating the auricle, and cervical vagus nerve of domestic pigs were instrumented with several recording electrodes. Spontaneous neural activity, sensory evoked neural activity induced by gentle brushing of the skin, and electrically ECAPs delivered through non-invasive and implanted electrodes were recorded. A finite element model (FEM), implemented in COMSOL, was used to further explore the parameter space for the design and performance of these recording electrodes. We show that the recording cuff has superior performance in measuring implanted stimulation cuff ECAPs while the tungsten microelectrodes, routinely used for microneurography in humans, have superior performance in measuring naturally occurring action potentials and transcutaneous electrical stimulation (TES) ECAPs. Further, we show how choice of reference electrode position may be optimized depending on target fiber type to be recorded. Additionally, we show that TES paired with microneurography recordings can be used to functionally map sensory innervation areas of the auricle for individual subjects, allowing individualized placement of stimulation electrodes in non-invasive neuromodulation therapies, such as auricular vagus nerve stimulation (aVNS), to achieve on-target neural fiber activation.

We present *in vivo* recordings from the peripheral nerves of domestic pigs paired with finite element models to explore recording electrode design for recording of peripheral neural activity, particularly ECAPs. These findings provide a basis to optimize recording electrode design and configuration for measurement of *in vivo* ECAPs in the development and deployment of neuromodulation therapies.

Title: Polysaccharide-based bioactive coating for intracortical recording microelectrodes

Authors: *V. DHAWAN[1], T. CUI[2];
[2]Dept. of Bioengineering, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Invasive neural electrodes offer high spatial selectivity in recording neural activity, stimulating neurons, and sensing neuroactive species. However, their implantation in the brain initiates a foreign body response (FBR) which hinders device function for chronic applications. Bioactive coatings are promising in camouflaging electrode surfaces and promote seamless integration with nearby tissue while maintaining device performance. Existing protein-based coatings are susceptible to denaturation during processing and are not active players in reducing FBR, despite their neurite growth-promoting properties. Chondroitin sulfate (CS) is a naturally occurring polysaccharide in the brain, is commercially available, and offers a more stable, hydrophilic alternative with specific bioactivity for novel neural electrode interface application. Negatively charged sulfate groups in CS are implicated in neurite growth-promoting properties, shown by many *in vitro* studies. Immobilized CS was also shown to bind to key player MCP-1 chemokine. As a surface coating, CS can be utilized to sequester MCP-1 and dampen the downstream inflammatory cascade. The abundant hydroxyl groups in CS impart hydrophilicity to the surface, which is critical for preventing non-specific protein adsorption, the first step in FBR. CS was immobilized on SiO_2 glass coverslips for *in vitro* testing via divinyl sulfone linker. Preliminary surface characterization with Fourier-transform infrared spectroscopy confirmed successful CS immobilization indicated by the addition of S=O, C-O/C=O, and O-H groups. The CS-coated surface also showed reduced non-specific protein adsorption, compared to uncoated control. Primary cortical neurons were grown on CS and control samples (n = 3 cultures) and total neurite outgrowth (υm) was normalized to control. The CS samples had significantly higher mean neurite growth (145%±51, Welch's t-test, $p<0.0001$) compared to control (85%±36). Additionally, a significantly higher mean cell count was observed in the CS samples (119±36, Welch's t-test, $p<0.0001$) than the control (29±11). Primary microglia had smaller morphology with drastically reduced cellular extensions when grown on CS samples compared to controls which promoted normal growth with branching. Future work will investigate the interaction between activated microglia and CS using lipopolysaccharide and phorbol 12-myristate 13-ester simulation models. This work utilizes the untapped potential of polysaccharide-based coatings which can aid seamless integration of neural electrodes for optimal device performance with applications for neuroscience and clinical translation.

Title: Steeltrode: a microfabricated stainless steel neural interface for high spatio-temporal resolution recording in non-human primates

Authors: *Z. AHMED[1], I. KIMUKIN[1], J. REDDY[1], V. JAIN[1], T. TEICHERT[2], M. CHAMANZAR[1]; [1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Dept of Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Translational neuroscience research can greatly benefit from tools for high-resolution neural recording from deep structures within the non-human primate (NHP) brain. While high-density neural probes have been devised for rodents, mainly leveraging well-established nanofabrication techniques for silicon-based devices, the inherent brittleness of silicon renders such devices vulnerable to fracture as the aspect ratio is made larger to investigate deep brain regions of larger non-human primate brains. As a result, the silicon-based microfabrication processes for rodent probes cannot be directly translated to realize implantable NHP neural interfaces meant for deep brain interrogation. To address this outstanding issue and the unmet demand for such tools in primate electrophysiology, we have developed a novel neural probe platform in flexible polymers and stainless steel. Stainless steel has great mechanical robustness and biocompatibility making it suitable for ultra-high aspect ratio NHP neural devices. Our new hybrid flex/rigid device architecture, called steeltrode, uses a stainless steel shank to allow robust insertion, while benefiting from a flexible polymer cable to relieve tethering forces and leave the device freely floating in the brain after implantation. We have optimized a novel microfabrication process to implement high-density electrical interconnects on stainless steel platform to fabricate devices with upto 102 channels. The long aspect ratio stainless steel probes feature 8-cm long shanks with a small cross section of 250 um x 150 um with densely packed microelectrodes with customizable diameters (15-50um) and arrangements of electrodes. We have conducted benchtop experiments to characterize the probe functionality using artificial action potential signals to measure the yield, crosstalk and SNR and also test chronic viability with accelerated lifetime testing. We have also recently validated the functionality of the probes in both macaque and rodent models. Isolated single units and multi-unit activities from different depths of the cortical laminae were recorded from the macaque motor cortex. With a shorter variant (~1 cm shank length) of the stainless steel probe, we have recorded multi-channel single unit data from Hippocampus (~2 mm depth) of wild-type mice, which demonstrates the versatility of our neural probe platform. Robustness and customizability of our microfabricated steeltrodes can facilitate distributed simultaneous volumetric recording from different depths across cortical regions in large animals and enable development of novel tools for translational research.

Title: Multi-layer Metallization in Ultra-Microelectrode Arrays for Neural Interfaces

Authors: *N. GERAMIFARD, S. COGAN;
The Univ. of Texas at Dallas, Richardson, TX

Abstract: Microelectrode arrays (MEAs) are used in the neural recording and modulation of neural activity. Ultra-microelectrodes may improve the selectivity of stimuli by enabling the stimulation of small tissue volumes. Ideally, to achieve the desired performance, higher electrode densities, large channel counts with effective encapsulation and small array footprints are required. However, increasing the electrode density and scaling down the interconnects may lead to high capacitive coupling between channels, hence increase in signal crosstalk and interference in the stimulation or signal recording. Here, we introduce amorphous silicon carbide (a-SiC) based UMEAs featuring two layers of patterned metallization sandwiched between a-SiC dielectric layers suitable for neural interface devices and provide electrical and electrochemical characterization. UMEAs with a total of 4 shanks with a cross-sectional area of less than 120 μm^2 and 4 to 8 electrodes on each shank were developed for densely packed electrodes. Some electrodes were fabricated with high capacitance and low impedance sputtered iridium oxide film (SIROF) with 200 μm^2 area whereas other channels were left encapsulated for electrical characterization. Voltage transient, electrochemical impedance spectroscopy and DC current measurements were used to evaluate leakage current and capacitive coupling between the adjacent channels. Scanning electron microscope images of cross-sectional cuts made by focused ion beam (FIB) milling of fabricated devices suggest that the two-metal-layer interconnects have a good structural integrity with a 2 μm traces interspacing and a 2 μm a-SiC interlayer encapsulation. Leakage currents between metal traces was measured as a function of steady state voltage bias between -1 and 1 V using a Keithley acquisation system and were found to be approximately $1x\ 10^{-13}$ A, both in air and PBS. Parasitic capacitance between parallel traces was calculated from voltage transient measurements in response to 1-10 μA current pulses with a pulse width of 50-200 μs and was found to be an order of magnitude smaller than the charge injection capacity of the SIROF electrodes. These results indicate that parasitic capacitive coupling is unlikley to substantively affect stimulation current pulse. Using the a-SiC as a base and interlayer insulator enables the development of ultramicroelectrode arrays with multi-layer metallization that permits an increase in the number of electrode sites with a desirably low shank cross-sectional area.

Title: Chromos probes: toward the development of minimally invasive high-channel count si cmos probes

Authors: *J. F. RIBEIRO, A. PERNA, L. GIANTOMASI, G. ORBAN, F. BOI, G. N. ANGOTZI, L. BERDONDINI;
Italian Inst. of Technol., Genova, Italy

Abstract: The chronic stability and the signal quality of intracortical implantable multielectrode array probes is tightly linked to the level of the brain tissue inflammatory response to the implant. To improve performances, free-floating devices assembled on flexible connectors, probes integrated on flexible polymeric substrates approaching the stiffness of the brain tissue and advances in implantation methods were demonstrated. More recently, it was shown that the reduction of the cross-sectional size of probes realized by rigid materials, such as silicon, plays a major role to improve the recording performances after weeks from the implant. However, downscaling the cross-sectional shank size of conventional Si-probes implies a drastic reduction of the number of integrated microelectrodes due to spatial constraints in electrically wiring each microelectrode to individually contact pads for external connection. Active dense implantable neural probes based on CMOS technology, such as Neuropixels, Neuroseeker or, more recently, the SiNAPS-probes developed in our lab, might allow to overcome this limitation in the number of integrated electrodes over small cross-sectional shank sizes. Indeed, although realized with different circuit's architectures and functionalities, such devices introduced the combined use of standard CMOS and MEMS technologies to realize monolithic active probes that integrate into the same substrate hundreds of closely spaced microelectrodes together with electronic circuits required for recording extracellular neural signals. In particular, the solution introduced by SiNAPS uses in-pixel amplifiers integrated beneath each microelectrode and on-probe multiplexing circuits to reduce the number of output lines. Differently than other CMOS neural probes that integrate low noise neural amplifiers in the probe base, the SiNAPS technology allows to avoid most of the connection lines in the shanks. By leveraging the high modularity nature of this technology, here we report the first results toward the realization and characterization of implantable probes, named ChroMOS probes, with 64 electrodes-pixels integrated in a 23 µm wide shank. We will present and discuss preliminary results obtained from passive silicon neural probes with shank cross-sections from 23 to 83 µm wide, 15 to 20 µm thick and 3 to 5 mm long. These passive neural probes were used to study the mechanical stability, materials resilience, tissue inflammation and the insertion protocol. Also, this passive neural probes allowed to develop and optimize the necessary CMOS compatible microstructuring process to realize ChroMOS probes.

Title: Neuroroots, minimally invasive, bioinspired probes for long term recordings

Authors: *V. SHAUTSOVA[1], E. ZHAO[2], M. D. FERRO[2], S. JAYABAL[4], J. L. RAYMOND[5], N. MELOSH[3];
[1]Stanford Univ., Palo Alto, CA; [3]Materials Sci., [2]Stanford Univ., Stanford, CA; [4]Dept. of Neurobio., [5]Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Chronic neural technologies have enormous potential for clinical neuroprosthetic and neuromodulation devices and for fundamental neuroscience enabling research on how the computations performed by a neural circuit change over time, during development, experience-dependent learning and memory, aging, or disease progression. Recent research efforts have identified several key aspects for chronic devices to establish a reliable and glial scar-free neural-probe interface: (i) neural probes dimensions on the cellular scale (10µm) to minimize their perturbation to the host biological matrix, (ii) high probe flexibility to ensure complete compliance with the host tissue, (iii) minimal surgical damage (100µm shuttle size) to allow efficient tissue recovery and destruction of local circuits and (iv) mechanical and electrical stability during long-term operation under physiological conditions. To address these stringent conditions, we developed bio-inspired flexible neural probes, NeuroRoots, mimicking natural axons. The individual dimensions of the neural probes are cellular size, while the probes are centimeter long and organized in axon-like tendrils. This enables seamless device integration with brain tissues by matching the neural probe physical properties, in particular the dimensions and the mechanical flexibility, with that of the cellular networks in living brain. A significant aspect of this design is its internal potential for easy scalability coming from mechanical separation of individual probes. The probes are delivered in the brain using a microwire shuttle making it compatible with existent surgical instruments. Our results demonstrate high quality of the signal and long-term stability of the electrodes being chronically implanted in rats to record the neural activity during 7 weeks. A key goal of the current study is to create miniaturized probes with even smaller dimensions that can be used in parts of the nervous system that are difficult to access with existing technologies including the spinal cord, parts of the brain stem, and the cerebellum.

Abstract: The challenging demands of investigating dopamine (DA) neurotransmission in the brain have led to numerous advancements, including the development of multi-site sensors capable of monitoring the highly complex nature of DA signaling. University of Michigan engineers have recently focused on developing minimally invasive carbon-fiber multielectrode arrays (CF-MEAs) for the purpose of multisite electrical and chemical recording. The latest iteration of CF-MEAs utilizes individuated silicon support shanks with the goal of insertion into deep subcortical structures of the rodent brain without the need for a shuttle such as polyethylene glycol or guide cannula. These novel devices feature sixteen Parylene C-insulated carbon fibers (d=8.4 μm) with a 100-μm pitch, an overall width of 1.5 mm, and a shank length of 6.0 mm. The silicon support structure for each fiber decreases in size stepwise from 55.5 to 15.5-μm with a ~20-μm depth. A 300-μm length of fiber extends beyond the silicon support, and laser ablation of insulation at the tip yields a 50-μm length of bare carbon fiber (d= 7.0-μm) as the sensing region. Here we evaluate these CF-MEAs for the purpose of measuring the neurotransmitter dopamine (DA) using fast-scan cyclic voltammetry (FSCV), a state-of-the-art electroanalytical technique for measuring neurochemicals that provides a voltammogram (i.e., a plot of measured current versus applied potential) at each 100-ms measurement for chemically identifying the analyte. We utilize flow injection analysis (FIA), an automated “beaker” technique that directs a timed bolus of analyte to the sensing surface, to characterize CF-MEAs for DA measurements. Through statistical analysis of sensor performance metrics, including speed of response, sensitivity, signal-to-noise ratio, total background current, and electrochemical variation, we show that performance of CF-MEAs compares favorably with the single carbon-fiber microelectrode, the longstanding gold-standard sensor for FSCV. Moreover, we demonstrate that CF-MEAs are amenable to chemometrics analysis using principle component regression in order to resolve individual analytes from a mixed signal. The favorable DA-sensing metrics of CF-MEAs coupled with the ability to effectively separate and quantify interfering signals suggests that CF-MEAs are well-suited for spatially resolved neurotransmitter analysis across a broad mediolateral span of the brain.

Title: Carbon fiber electrodes for intracellular recording and stimulation

Authors: *Y. HUAN[1], J. P. GILL[1], J. B. FRITZINGER[1], P. R. PATEL[2], E. DELLA VALLE[2], J. D. WEILAND[2], C. A. CHESTEK[2], H. J. CHIEL[1];

Abstract: To understand neural circuit dynamics, it is critical to manipulate and record from many neurons, ideally at the single neuron level. Traditional recording methods, such as glass microelectrodes, can only control a small number of neurons. More recently, devices with high electrode density have been developed, but few of them can be used for intracellular recording or stimulation. Carbon fiber electrodes (CFEs) are 8 micron-diameter electrodes that can be organized into arrays with pitches ranging from 100 to 200 microns. They have been shown to have good signal-to-noise ratios (SNRs) and are capable of stable extracellular recording during both acute and chronic implantation in vivo in neural tissue such as rat motor cortex. Given the small fiber size, it is possible that they could be used for intracellular arrays. We tested this using the large identified and electrically compact neurons of the marine mollusk *Aplysia californica*. The cell bodies of neurons in *Aplysia* range in size from 30 to over 250 microns. We compared the efficacy of CFEs to glass microelectrodes by impaling the same neuron's cell body with both electrodes and connecting them to a DC coupled amplifier. We observed that intracellular waveforms were essentially identical, but the amplitude and SNR in the CFE was lower than in the glass microelectrode. CFE arrays could record from 3 to 8 neurons simultaneously for many hours, and many of these recordings were intracellular as shown by recording from the same neuron using a glass microelectrode. Stimulations through CFEs coated with platinum-iridium had stable impedances over many hours. CFEs not within neurons could record local extracellular activity. Despite the lower SNR, the CFEs could record synaptic potentials. Thus, the stability for multi-channel recording and the ability to stimulate and record intracellularly make CFEs a powerful new technology for studying neural circuit dynamics.

Title: Characterization of silicon-supported carbon-fiber microelectrode arrays for dopamine measurements in vivo

Authors: *R. L. CHICOSKY[1], B. M. SMITH[1], P. R. PATEL[2], J. M. RICHIE[2], C. A. CHESTEK[2], P. A. GARRIS[1];
[1]Sch. of Biol. Sci., Illinois State Univ., Normal, IL; [2]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: The ability to monitor brain neurotransmitters with high fidelity is critical for establishing the neural underpinnings of behavior and pathology. New carbon-fiber microelectrode arrays (CF-MEAs), with individuated silicon supports designed to insert into sub-cortical structures in the rat brain, have compared favorably to the gold standard carbon-fiber microelectrode (CFM) for fast-scan cyclic voltammetry (FSCV) dopamine (DA) measurements with flow injection analysis (see companion abstract). Here we evaluate these new CF-MEAs for DA recordings in the striatum of the urethane anesthetized rat. DA is a neurotransmitter critical for locomotion, motivation, and cognition that also plays a role in the pathologies of Parkinson's disease, substance use disorder, and schizophrenia, and the striatum is a brain region strongly implicated in reward learning. Striatal DA levels are readily measured by conventional CFMs coupled to FSCV. Electrically evoked DA measured in the striatum by a CF-MEA were both stable over time and pulse number dependent, indicating a broad dynamic [DA] measurement range. Moreover, DA signals collected from a 1.5-mm by 1.0-mm grid (100-μm mediolateral and dorsoventral resolution) suggest striatal heterogeneity in terms of both DA signal amplitude ([DA]max) and dynamics. Striatal DA signals were categorized into fast and slow, with fast DA signals further subdivided into four different types based on temporal profile (Types 1-4). The effects of amphetamine (AMPH), a potent inhibitor of the DA transporter combining high abuse potential and clinical efficacy in treating attention deficit hyperactivity disorder, were assessed using a three-parameter (DA release or [*Rp*], DA uptake or [*kU*], and DA diffusion or [*kT*]) restricted diffusion kinetic model. Post-AMPH electrically evoked DA signals, while kinetically heterogeneous, showed an increase in both [DA]max and *Rp*, and a decrease in both *kU* and *kT* in all channels of the CF-MEA. AMPH-induced non-electrically evoked DA transients, sub-second to second increases in extracellular DA resulting from burst firing of DA neurons, were observed both synchronously across all channels of the CF-MEA and asynchronously across just four channels of the CF-MEA in a time-dependent fashion. Our results demonstrate that CF-MEAs afford a similar utility as CFMs for monitoring brain DA signals in a temporally, chemically, and spatially resolved manner while providing the transformative advantage of substantively expanded spatial coverage for superior characterization of kinetically heterogeneous DA signal types that have previously been underexplored.

Title: Carbon Fiber Electrode Arrays: Past, Present, and Future

Authors: *P. R. PATEL[1], J. G. LETNER[1], E. DELLA VALLE[1], Y. HUAN[2], B. M. SMITH[3], J. M. RICHIE[1], J. P. GILL[2], P. A. GARRIS[3], H. J. CHIEL[2], D. CAI[1], J. D. WEILAND[1], C. A. CHESTEK[1]; [1]Univ. of Michigan, Ann Arbor, MI; [2]Case Western Reserve Univ., Cleveland, OH; [3]Illinois State Univ., Normal, IL

Abstract: Our group has developed multiple platforms and processes that have enabled minimally invasive carbon fiber electrodes to detect electrical or chemical activity in various animal models and target regions. Our most widely used platform centers around a flexible polyimide board with 16 carbon fibers in a compact 2x8 configuration. With this device, we have acutely recorded neural activity from rat cervical vagus nerve (blowtorched tips with a poly(3,4-ethylene-dioxythiophene) (PEDOT) coating) and *Aplysia* (blowtorched or laser cut tips with PEDOT). In addition, we have ablated the insulation at the tips and chronically implanted this device into rat nucleus accumbens to record extracellular dopamine levels using fast scan cyclic voltammetry. We are currently ramping up production and distribution of an improved 16-channel array that utilizes thin, individuated silicon shanks as supports for the carbon fibers. The devices come in various lengths, useful for targeting a variety of brain regions. We have used longer devices to map the heterogeneity of both electrically evoked and amphetamine-induced phasic dopamine signals in rat striatum. The shorter devices have recorded chronic neural activity in rat motor cortex with a tip plating of either PEDOT or platinum iridium (PtIr). Additionally, the device tips can be localized within the tissue either by slicing through them *in situ* or by localizing their tract after explant. Our chronic results show that these newest devices still have little to no detriment to the surrounding tissue. We are also exploring the use of these arrays for stimulating and recording in *Aplysia*, by blowtorching and plating the tips with PtIr. The previous arrays have been adapted for acute use in targets outside of the rat brain; however, they are not suitable for chronic use in those targets. To alleviate this we have developed a silicone encased carbon fiber array with small form factor and recorded acute unit activity from feline dorsal root ganglion. Our goal is to build on this design to create chronically implantable variants for other models such as octopus and *Aplysia*. Lastly, we have begun preliminary work on transitioning towards a wireless package that can record or stimulate via carbon fiber electrodes. This would enable us to interface with new targets, such as the retina, along with those previously mentioned, but with no tethering forces and maximum flexibility in electrode placement.

Title: Subcellular Resolution Localization of Carbon Fiber Electrodes in Rat Motor Cortex

Authors: *J. G. LETNER[1], P. R. PATEL[1], L. A. WALKER[2], D. CAI[3], C. A. CHESTEK[1];
[1]Biomed. Engin., [2]Biophysics, [3]Cell and Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: Brain machine interfaces (BMIs) can restore motor function to individuals with neurological deficits such as spinal cord injury and are commonly enabled by the implantation of neural electrodes in motor cortex. Chronic implantation of carbon fiber electrodes has shown to elicit a minimal foreign body response due to their subcellular diameter (8.4 µm) (Patel *et al.*, 2016; Welle *et al.*, 2020), making the electrodes possible candidates for clinical BMIs and characterizing nearly healthy tissue with electrophysiology and histology. However, the "slice-in-place" protocol that we developed to retroactively localize the tip recording sites with micrometer resolution (Patel *et al.*, 2020) proved not applicable to implants in cortical regions because cryosectioning was prohibited by the remaining headcap mounting screws. Recent changes in electrode design and protocol enabled us to localize the recording sites after explant to analyze the surrounding tissue with subcellular resolution. We implanted one male Long-Evans rat with a 16-channel high density carbon fiber array in layer V motor cortex for 3 months and recorded electrophysiology throughout the implant's lifetime. We stained the implant and contralateral control sites for neurons, astrocytes, and microglia, then imaged the sites with a confocal microscope in 3D. Using histological biomarkers, we located the tips with subcellular accuracy, typically in the absence of glial accumulation at the tips. 3D scaffolds of somae were reconstructed to measure neural morphologies, derive neural locations relative to the electrodes, and measure neuronal densities. We found that the distance of the closest neuron to the tip is 16 ± 5 µm (mean ± SD) and that of the second closest is 22 ± 5 µm; both were not different from control via two sample t-tests. Compared to control with two sample t-tests, neuron density was significantly reduced at 20-30 µm ($p=0.004$) and 30-40 µm ($p=0.01$) radial bins from the fibers, but was not significantly different at the 40-50 µm bin. Neuron density within 50 µm was 84% ± 20% that of control, a small but significant change ($p=0.004$, two sample t-test). Elliptical fitting to neurons (Du *et al.*, 2017) suggests they were stretched compared to control via a Kolmogorov-Smirnov test ($p=1.1 \times 10^{-67}$). N=16 fibers from 1 device. Overall, we found that these high-resolution analyses elucidated effects of carbon fiber electrode implantation that were previously obfuscated from array-scale analyses. These effects render carbon fibers biocompatible with further room for design improvements. Also, high resolution scaffolds of the surrounding neurons may prove useful in electrophysiological modelling.

Title: Event detection is a main determinant of spike sorting in human intracranial single unit recordings

Authors: *P. N. STEINMETZ;
NeurTex Brain Res. Inst., Dallas, TX

Abstract: Four different spike sorting techniques have largely been used to identify the firing activity of single neurons in human intracranial microwire recordings. As previously shown, these 4 techniques have a low level of agreement between them (AMIall ranging from 0.041 - 0.16 on a 0-1 scale) and lead to different estimates of the fraction of neurons responsive to different stimuli (0.08 - 0.31).
Spike sorting requires two distinct steps: detecting periods of time which may contain an action potential waveform (events) and subsequently grouping these events into clusters of similar waveform shape. While prior studies have examined the effects of different clustering techniques on a fixed set of waveform events, this study measures agreement for both event detection and clustering using adjusted mutual information (AMI). Use of AMI allows the joint computation of agreement in events detected (AMIevent), agreement when sorting common events (AMImatch), and agreement in sorting overall (AMIall). These 3 measures were computed for 2752 channels of recording previously performed at the Barrow Neurological Institute.
There are six possible pairs of four sorting techniques. The distribution of AMIevent had grossly different patterns depending on the pair of spike sorting techniques considered. The Brain Modeling Laboratory (BML) techique was the most different from the OSort or Combinato techniques, while agreeing more closely with the WaveClus technique.
The values of AMIevent and AMImatch for each channel were used in a linear model to predict AMIall. AMIevent was a significant predictor (p<0.05) for all 6 of the possible pairs of spike sorting, while AMImatch was a significant predictor for 4 of the 6 pairs. While one might expect that increasing noise in the passband (300-3000 Hz) would decrease AMIall, noise was significantly negatively correlated for only the BML-Combinato pair. AMImatch was not significantly correlated with noise level for any pair. Overall these results suggest that different spike sorting techniques identify different aspects of the underlying signal which reflect a common responsiveness to experimental stimuli. They also show that further work is needed to understand the relationship of these signals to single neuron firing.

Title: Exploring disease similarities and dissimilarities using structural attributes of genes and proteins

Authors: *R. MOUSSA[1], S. CHANDRASENA[2], M. ELADAWI[2], X. ZHANG[2], R. E. MCCULLUMSMITH[2], R. SHUKLA[2];
[1]Univ. of Toledo Col. of Med. Neurosci. & Neurolog. Disorders, Toledo, OH; [2]Univ. of Toledo, Toledo, OH

Abstract: Similarities and dissimilarities between disorders are not well understood. High-throughput omics technologies have revealed multifactorial associations between different diseases. However, these studies are limited to studying a few diseases at a time. Furthermore, the selection of disorders is limited by the biased selection of comparable disorders, datasets/cohort availability, and challenges with data normalization. Recently, we showed that disease specific gene-sets (aka disease-signatures) can be leveraged to mitigate these issues and can be used to understand disease similarities and dissimilarities at a functional level using biological pathways, cell-types, and drug targets. In our present work, we are now extending this approach to understanding disease similarities and dissimilarities at a structural level, involving several gene attributes, such as length, GC content, and IRES, as well as protein attributes such as amino acid composition, conserved domains, and prosite patterns. Disease signatures were obtained from DisGeNET and structural attributes from Ensembl BioMart. Different machine learning models (decision trees, logistic regression, random forest, and lasso methods) were evaluated for their ability to reveal associations between diseases and structural attributes. Different coefficients of structural attributes for a given disease were revealed. The coefficients will be further used to generate a penalty matrix which will be used to fine-tune a disease-disease interaction network. Our approach provides a promising lead to compare different diseases and to explore novel pharmacological interventions based on structural attributes.

Title: Understanding Cortical Function with Novel Modeling Approaches of C. elegans Neuronal Activity

Authors: *W. G. RYAN, V[1], A. S. IMAMI[2], S. M. O'DONOVAN[3], R. SHUKLA[4], B. BAMBER[5], R. E. MCCULLUMSMITH[1];
[2]Bioinformatics, [3]Neurosci., [1]Univ. of Toledo, Toledo, OH; [4]Neurobio. of Aging and Depression, CAMH, Toronto, ON, Canada; [5]The Univ. of Toledo, Toledo, OH

Abstract: Cortical function comprises the gestalt of sensory interpretation mechanisms in the brain that form the foundation of consciousness. Traditional feed-forward theories of cortical function to date have failed to fully capture the complexity between interactions in the neural connectome. Recent work challenging this paradigm posits recurrent and generative theories better model the architecture of the neocortex. The *C. elegans* model permits assessment of neuronal activity across all 302 neurons simultaneously, as well as temporal kinetics of neuronal activation in response to external stimuli. It follows that this is an ideal system to facilitate learning about neuronal networks and to test our assumptions about the theories of cortical function. To that end, we performed whole-brain neuronal activity recordings of behaving *C. elegans* in response to an aversive stimulus that elicits backward

locomotion. Data from neuronal Ca^{2+} imaging profiles were processed and normalized to generate activity pattern heatmaps. Activity patterns revealed highly dynamic neurons wherein the feed-forward model does not drive all neuronal activity in response to stimuli. To better assess the complexity of neuronal network dynamics and sensory plasticity within *C. elegans*, we sought to apply recent approaches in deep learning systems neuroscience able to better model non-linear interactions within these activity patterns. We demonstrated successful deconvolution of activity within *C. elegans* neuronal activity using OASIS. Re-convolved calcium imaging traces were generated with fidelity to the ground truth data for our proposed novel generative model, permitting the detection of the most statistically functionally relevant temporospatial features within neuronal activity patterns. Work is ongoing to optimize the generative model in order to generate importance maps. Importance maps express the effect of simulated temporal perturbations to infer these features. Ultimately, we propose these novel approaches as an ideal avenue to better our understanding of the underlying mechanisms of cortical function and how they could give rise to sentient systems.

Title: Incorporating single cell transcriptomic data into a hippocampal computer model to understand epilepsy pathophysiology

Authors: *V. REDDY[1], M. A. SHERIF[2], R. MCCULLUMSMITH[1], R. SHUKLA[1];
[1]Univ. of Toledo, Toledo, OH; [2]Psychiatry, Brown Univ. / Carney Inst. of Brain Sci. / Lifespan Physician Group, Providence, RI

Abstract: Temporal Lobe Epilepsy (TLE) is one of the most common neurological disorders and is characterized by recurrent seizures. Although TLE genetic and electrophysiological markers such as gamma oscillations are well characterized, alteration of the interactions between neurons predisposing a cortical region to seizures are not fully understood. To study these non-linear interactions, we incorporated RNA expression changes into a microcircuit computer model of the hippocampus, an area strongly implicated in TLE. Cellular deconvolution of bulk RNAseq data with single cell transcriptomic data from pilocarpine-induced temporal lobe epilepsy mouse model hippocampus revealed three distinct cell clusters characterized as pyramidal (PYR) cells, oriens-lacunosum moleculare (OLM) interneurons, and parvalbumin-positive (PV) interneurons. We used the differential expression (log fold change) of genes coding for the AMPA, NMDA, and $GABA_A$ receptor subunits in the control and epileptic conditions for each cell cluster to guide scaling of receptor density in the model. The model was composed of 800 PYR, 200 PV and 200 OLM neurons. PYR cells of the model activate PV, OLM, and other pyramidal cells via NMDA and AMPA receptors; in return, the PV and OLM interneurons inhibit PYR cells by acting on their $GABA_A$ receptors. Guided by the RNA expression data, we ran simulations

where we increased the density of both PYR AMPAR and PV $GABA_AR$. Increasing pyramidal AMPAR density increased gamma power generated by the model, suggesting increased seizure susceptibility. However, the magnitude of increase was modulated by the PV $GABA_AR$ density scaling. Our work illustrate how microcircuit computer modeling can maximize information gained from single-cell and bulk RNAseq experiments. Single-cell transcriptomics provides cellular and molecular characteristics of brain changes in great detail, but this information is merely a snapshot of cell states. To more accurately estimate the molecular contribution of neurons in disease phenotypes, we propose the integration of single-cell transcriptomic data with biophysically-realistic microcircuit models. Applying this integrative approach to a penetrant phenotype such as epilepsy will aid our understanding of the non-linear interactions between different cell types resulting in seizure onset.

Title: Topographically detailed computational model of the motor and somatosensory thalamic circuits

Authors: *J. V. S. MOREIRA[1], F. S. BORGES[1], D. DOHERTY[1], W. W. LYTTON[1], S. DURA-BERNAL[1,2];
[1]Physiol. and Pharmacol., SUNY Downstate Hlth. Sci. Univ., BROOKLYN, NY; [2]Ctr. for Biomed. Imaging and Neuromodulation, Nathan Kline Inst. for Psychiatric Res., Orangeburg, NY

Abstract: The thalamus is a key router of information going in and out of the cerebral cortex, and has been widely studied at the cellular and circuit levels. However, in recent years, computing power enabled large-scale simulations of these circuits. In this study, we developed a large-scale model of the motor and somatosensory thalamus, with ~2250 neurons, incorporating recent data on projection targets and circuit architecture. Our objective was to reconcile the single cell dynamics of thalamic relay and reticular nuclei cells with circuit-level observations. The model was built using the NetPyNE tool and the NEURON simulator. It is composed of four first-order excitatory nuclei: the motor cortex projecting ventral anterior/ventrolateral and ventromedial nuclei; and the somatosensory cortex projecting ventral posterolateral and ventral posteromedial nuclei. It also includes a higher-order excitatory posterior medial nucleus with separate motor and somatosensory projecting sectors. First-order nuclei present topographical connectivity, whereas higher-order nuclei are connected via divergence rule, as literature shows. All excitatory nuclei are interconnected within the thalamus through projections to the reticular nucleus, represented here by a single-layered motor sector and a three-layered somatosensory sector. We

used single compartment cell models based on Destexhe (1996) with adjusted parameters. Both cell types feature Hodgkin-Huxley-type mechanisms, including Na+ and K+, low-threshold transient Ca2+, and K+ leak currents, and relay cells also have a hyperpolarization-activated cationic current and a rapidly-inactivating and transient K+ current. The connectivity rules were based on data of axonal and dendritic footprints for each nuclei, and probability and weight of connections were tuned within biological constraints to match dynamics observed experimentally. The results show our model reproduces the key features, such as tonic- and burst-firing behavior at single-cell level; rhythmic bursting and spindle oscillations at circuit level; stable self-sustained rhythmic activity; and responsiveness to driver inputs, shifting its dynamics and being susceptible to external modulation. We are currently integrating this model with existing models of motor cortex and somatosensory cortex. This will provide a framework to study neural coding, information flow and learning mechanisms in the cortico-thalamo-cortical circuits of the sensorimotor pathway with an unprecedented level of detail, allowing us to make predictions about the mechanisms underlying physiological and pathological sensorimotor dynamics in the brain.

Title: Convergent Cross Sorting for Estimating Dynamic Coupling

Authors: L. BRESTON[1], E. J. LEONARDIS[3], L. K. QUINN[2], M. TOLSTON[4], J. WILES[5], *A. A. CHIBA[6];
[1]Neurosci., [2]Univ. of California San Diego, La Jolla, CA; [3]Cognitive Sci., UC San Diego, San Diego, CA; [4]Air Force Res. Lab., Wright Peterson Air Force Base, Dayton, OH; [5]The Univ. of Queensland, Brisbane, Australia; [6]Cognitive Sci. and Program in Neurosci., UCSD, La Jolla, CA

Abstract: Natural systems exhibit diverse behavior generated by complex interactions between their constituent parts. To characterize these interactions, we introduce Convergent Cross Sorting (CCS), a novel algorithm based on convergent cross mapping (CCM) for estimating dynamic coupling from time series data. CCS extends CCM by using the relative ranking of distances within state-space reconstructions to improve the prior methods' performance at identifying the existence, relative strength, and directionality of coupling across a wide range of signal and noise characteristics. In particular, relative to CCM, CCS has a large performance advantage when analyzing very short time series data and data from continuous dynamical systems with synchronous behavior. This advantage allows CCS to better uncover the temporal and directional relationships within systems that undergo frequent and short-

lived switches in dynamics, such as neural systems. In this paper, we validate CCS on simulated data and demonstrate its applicability to electrophysiological recordings from interacting brain regions.

Title: Spiking neural network based on hippocampal circuitry

Authors: *S. COPPOLINO, M. MIGLIORE;
Italian Natl. Res. Council, PALERMO, Italy

Abstract: Learning to navigate a complex environment is, in general, not a difficult task for humans. Finding the correct path to follow to exit from a maze does not require a long training session; in most cases, just a single exploration of the environment is sufficient to recall the correct trail to the exit. This ability is in contrast with the performances of any deep learning algorithm in learning a trajectory through an arbitrary sequence of objects or places. Although artificial network architectures such as Long Short-Term Memory or Bidirectional Recurrent neural networks have reached impressive practical results, they require an exponentially long time for an appropriate learning phase. This suggests that something is missing in the artificial reproduction of basic cognitive functions.
In this work we present a model based on cell types and circuitry observed in the hippocampus, a brain region well known to integrate space, time, and memory to solve a spatial navigation task. Place-cells, head-direction cells, and other neurons types are wired together with plastic synapses to form a self-organizing network able to learn, in a single learning trial, the correct sequence of objects to follow toward an exit. The learning process is controlled by a spike-time-dependent plasticity rule, with excitatory and inhibitory neurons modulating the learning/forgetting cycle during the exploration of the environment. This allows the spiking neurons network, implemented in PyNN, to control the navigation of a virtual robot connected through a set a python-ROS transfer functions. The results suggest a new generation of explainable artificial intelligence algorithms for spatial navigation.

Title: Development of an unsupervised Spiking Neural Network for vocal and speech patterns classification

Authors: *S. POKALA[1], B. YVERT[2];
[1]Inserm and Univ. Grenoble Alpes, Saint-Martin-d'Hères, France; [2]INSERM, Saint-Martin-d'Hères, France

Abstract: One of the fundamental tasks that human beings do on a daily basis is pattern recognition and the human brain performs this very efficiently. Taking inspiration from the human brain, Artificial Neural Networks (ANNs), or Deep Neural Networks (DNNs), to be specific, are making significant progress in reproducing this ability and are successfully used for various static and sequential pattern recognition applications today such as Natural Language Processing (NLP), Image Recognition and Automatic Speech Recognition (ASR), just to name a few. However, they come with their limitations - they usually require rigorous training on very large datasets and heavy computations. An alternative, aimed at addressing these issues, are Spiking Neural Networks (SNNs) which are more biologically plausible and need fewer data to train. Moreover, developing new SNN architectures dedicated for complex pattern recognition tasks is crucial as they could be implemented in energy-efficient neuromorphic hardware. In this context, we developed a potentially energy-efficient SNN with Spike-Timing-Dependent-Plasticity (STDP) for unsupervised classification of audio patterns. We built a simple network using Low Threshold Spiking (LTS) neurons. The input audio is converted into spike trains across several frequency bands using 'time-to-first-spike' encoding method and these spike trains modulate the membrane potentials of the LTS neurons in the output layer causing them to spike. We assessed the performance of our network on synthetic spectrotemporal patterns mimicking vocal spectrograms which allowed us to evaluate the network's output with respect to the known ground truth. Such a network could perfectly classify 8 different patterns (f-score = 1) and remained very robust when noise was added to alter the patterns (f-score of 0.75 for 25% perturbation of the encoding spike trains). The next step will be to evaluate the network on vocal and speech datasets. The ability to classify vocal patterns in a completely unsupervised manner with a rather simple network architecture is interesting and opens new avenues for more complicated pattern detection with SNNs.

Title: Investigation of synaptic communication through Interluminescence by patch-clamp recordings from cultured neurons

Authors: *M. PRAKASH[1], A. BJOREFELDT[3], M. TREE[1], N. C. SHANER[5], C. I. MOORE[4], D. LIPSCOMBE[4], U. HOCHGESCHWENDER[2];

Abstract: In BioLuminescent OptoGenetics (BL-OG) a genetically encoded light source, a luciferase, activates a light-sensing optogenetic element, a channelrhodopsin or a pump. When light emitter and light sensor are tethered, as in luciferase-opsin fusion proteins (luminopsins, LMO), application of the luciferin coelenterazine (CTZ) and subsequent light production will change the membrane potential of the cell expressing the LMO. Here, we leverage this coupling strategy across the synapse by placing the luciferase in the presynaptic neuron and the opsin in the postsynaptic neuron. In the presence of CTZ, light emitted from the luciferase activates the opsin of synaptically connected neurons. We previously demonstrated the effects of this 'Interluminescence' on synapse-specific circuit control in multi electrode array recordings of cortical and striatal neuron co-cultures. Here we tested BL-OG effects across the synapse by patch clamp recordings from individual postsynaptic neurons. E18 rat cortex and striatum neurons were nucleofected with a luciferase-dTomato construct and an excitatory opsin-EYFP construct, respectively, and were plated on glass coverslips as a mixed culture. At DIVs 28-40, synaptic pairs were located by visualizing the reporter expression for the luciferase (red) on presynaptic cortical neurons and for the opsin (yellow) on postsynaptic striatal neurons. Whole cell patch configuration was achieved on the opsin-expressing postsynaptic neuron and synapse-specific modulation of the postsynaptic neuron was recorded in current clamp mode. Generation of action potentials was compared in the presence of CTZ and vehicle. Depolarization in postsynaptic neurons was robustly elicited with bioluminescence from presynaptic partners and was likely due to trans-synaptic communication. Such biological light activation across genetically determined synaptic partners offers the potential to optogenetically dissect synaptic communication non-invasively.

Title: A bioluminescent optogenetic synapse drives robust, dynamic changes in mouse thalamocortical circuits in vivo

Authors: *J. MURPHY[1], N. FRIEDMAN[1], M. PRAKASH[2], R. ST. LAURENT[1], D. LIPSCOMBE[1], N. SHANER[3], U. HOCHGESCHWENDER[2], C. I. MOORE[1];

Abstract: Current opto- and chemogenetic tools generically modify cellular excitability, or require gene expression to target specific synaptic junctions. The ability to selectively regulate the impact of afferents on a specific subset of their synaptic targets, and only when these afferents are active, would be a powerful asset to understanding dynamic neural circuits. Here we present a bioluminescent optogenetic tool that provides a high degree of synaptic selectivity and is capable of regulating circuits based on their intrinsic activity. This intersectional dynamic goal is achieved by packaging bioluminescent enzymes in dense core vesicles within presynaptic neurons and expressing optogenetic channels on their postsynaptic targets. When the bioluminescent substrate coelenterazine (CTZ) is introduced, bioluminescent light is generated at synaptic clefts that recently released enzyme, activating the optogenetic channels in neurons postsynaptic to a presynaptically-active input. Our group has tested this molecular tool extensively in vitro. Here we present data employing this molecule in vivo in the anesthetized mouse.
We targeted thalamocortical synaptic projections of the mouse vibrissal system from the posterior medial and ventral posteromedial (VPM) thalamic nuclei onto parvalbumin positive (PV) neurons in primary somatosensory cortex (SI). Thalamic neurons were virally targeted to express bioluminescent enzymes in dense core vesicles. In mice receiving vibrissal stimulation, application of CTZ directly onto the cortical surface of SI elicited strong bioluminescent light output, indicating that thalamic neurons were indeed releasing bioluminescent enzymes at their axonal terminals in SI. Next, we recorded laminar multi-unit activity in SI before and after application of CTZ to the SI surface. Upon CTZ administration and emission of bioluminescent light, a marked increase in multiunit firing was observed spanning a wide swath of SI laminae. In a second cohort of animals we virally targeted only VPM, which projects densely to PV cells in deeper layers while avoiding those in superficial layers. In this cohort of animals we observed a laminar shift to the middle layers of bioluminescence driven MUA activity in agreement with VPM termination patterns.
These data provide strong preliminary evidence that a synapse- and activity-dependent optogenetic construct driven by bioluminescent light is a viable and potentially powerful tool for dynamic neural circuit dissection.

Abstract: Experimental manipulation of neural activity in genetically defined populations is currently largely centered around optogenetic or chemogenetic techniques, each featuring unique strengths and limitations. To increase user flexibility, and facilitate designs where advantages of each above approach can be leveraged at distinct experimental stages, we have developed bioluminescent optogenetics (BL-OG) which provides combined opto- and chemogenetic control in a single molecule (a luminopsin, or LMO). The LMO features a bioluminescent light emitter fused to an optogenetic actuator, enabling both direct activation of the opsin using an LED (for temporally precise control) and chemogenetic manipulation of neuronal populations distributed throughout the brain via systemic administration of the bioluminescent substrate coelenterazine (CTZ). To expand the utility of BL-OG, we here sought to further increase the efficacy of chemogenetic (bioluminescent) activation of LMOs. Through engineering of novel Förster resonance energy transfer (FRET)-based bioluminescent emitters featuring superior brightness and emission spectra matched to *Volvox* channelrhodopsin 1 (VChR1), we develop and thoroughly benchmark a new excitatory LMO (LMO7) that will improve the efficacy of chemogenetic activation in targeted neuronal populations.

Abstract: BioLuminescent-OptoGenetics (BL-OG) is a combined strategy that allows chemogenetic and/or optogenetic cellular manipulation and regulation. Luminopsins are BL-OG fusion proteins, connecting bioluminescent luciferases with optogenetic actuators that can stimulate or inhibit neural circuits through administration of a small-molecule luciferin. Luminopsins drive robust fluctuations in MUA activity in neocortex with a response that is sensitive and proportional to luciferin availability [Gomez-Ramirez, et al., 2019].
Because they will provide several distinct benefits, we are creating an array of photoswitchable (PS) Luminopsins that enable brighter and color-shifted luciferase light production after activation. First, this strategy allows selection of specific cells (e.g., members of a neural ensemble sharing similar tuning) to achieve sustained chemogenetic control lasting up to several hours. To our knowledge, this construct is the first to provide such selectivity in chemogenetics. Second, because BL-OG cellular control is directly proportional to BL light production, photon emission allows real-time tracking of the duration and magnitude of PS-activated chemogenetic control: Relating the strength of ensemble manipulation to behavioral variables, re-energizing ensemble control, or choosing alternative ensembles can therefore be conducted optimally. Third, in contrast to holographic optogenetics, PS does not require maximal light delivery in a discrete millisecond-specific window, and can therefore be applied to deeper targets and a much larger array of cells, providing a more robust option for many experimental goals.
To date, we have developed multiple Luminopsin constructs that are effectively photo-switched ‘on’ through activated availability for bioluminescent FRET (BRET). We have now confirmed robust PS BL-OG activation can be achieved in mouse neocortical neurons in vivo, showing substantially brighter and color-shifted output when activated. Further, these constructs show robust two-photon (2P)-driven PS, providing a high degree of precision in choosing cells or processes to modulate. We are currently testing the magnitude of electrophysiological effects following PS BL-OG activation in neurons and the impact this molecule has on well-controlled psychophysical behavior.

Title: Bl-og related perceptual modulations in awake-behaving animals

Authors: *L. GRUEL BUDET, E. F. MURPHY, H. BAEZ, M. GOMEZ-RAMIREZ;
Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Optogenetics enable selective control of genetically-tagged cell ensembles with high temporal precision and single-cell resolution. A major limitation of optogenetics is the use of invasive external light devices to drive cell activity. A recent method, termed Bioluminescent OptoGenetics (BL-OG), circumvents this limitation by fusing a photo-enzyme to an optogenetic element. The optogenetic element is driven by bioluminescent light emitted by injecting a chemical substrate (e.g., Coelenterazine; *CTZ*)that is catalyzed by the photo-enzyme (e.g., slow-burn Gaussia Luciferase; *sb-GLuc)*. An unresolved question is whether the BL-OG technique is a reliable and viable method to modulate sensory processing and perception in behaving animals. Here, we trained mice to perform a speed-reaction time task with auditory and/or visual stimuli. Treatment mice were injected with the novel luminopsin-7 (LMO7)construct, a BRET-based BL-OG molecule, in the antero-lateral secondary visual cortex (AL-Vis). A control group underwent the same surgical procedure as the LMO7 mice, but were not injected with the virus. Preliminary data show that mice were able to detect unisensory and multisensory stimuli, with multisensory stimuli detected much faster and at a lower threshold level than unisensory stimuli. We expect to find that injection of h-CTZ will lead to enhanced detection in the LMO7 mice but not the control group. We further expect that BL-OG effects will lead to enhanced perception of multisensory stimuli as compared to unisensory stimuli. Our study will further our understanding of the BL-OG technique by providing an estimate of its effects on sensory processing and behavior.

Title: Non-invasive injections of h-Coelenterazine elicit proportional responses in mouse cortex

Authors: *E. F. MURPHY, H. BAEZ, L. GRUEL BUDET, M. GOMEZ-RAMIREZ;
Univ. of Rochester, Rochester, NY

Abstract: BioLuminescent OptoGenetics (“BL-OG”) is a chemogenetic method that enables optogenetic reactions without the use of an external light device. In BL-OG, a photo-enzyme (e.g., slow-burn Gaussia Luciferase; *sbGLuc*) is tethered to an optogenetic element (e.g., Volvox-Channelrhodopsin-1; *VCHR1*) that is activated via bioluminescent light. Bioluminescence is generated by injecting a chemical substrate (*luciferin*, e.g., Coelenterazine; *CTZ*) that is catalyzed by the photo-enzyme neighboring the opsin. In a

previous study, we showed proportional increases in neural firing and bioluminescence in response to higher doses of CTZ. However, these BL-OG effects were observed during invasive injections of the luciferin directly into the brain. Thus, to demonstrate that BL-OG is a viable method for modulating neural activity non-invasively, it is key to determine dose response curves when the substrate is injected systemically. Here, we injected different dosages of h-CTZ via the tail vein of mice expressing the BL-OG construct LMO7, a novel and more photo-efficient BRET-based molecule that tethers the bioluminescent and fluorescent protein NCS2 to VCHR1. Bioluminescence was imaged using an EMCCD camera while animals ran on a wheel, and different concentration dosages of h-CTZ were injected. Pilot data reveal proportional increases in bioluminescence in response to increasing dosages of h-CTZ. Our study furthers our understanding of the BL-OG technique by providing a map between BL-OG effects and systemic injections of h-CTZ via the tail vein.

Abstract: BioLuminescent-OptoGenetics (BL-OG) is a bimodal approach for controlling the activity of optogenetic elements. Opsins can be activated by light from a physical source or by applying a small chemical, a luciferin, that is oxidized by a luciferase enzyme thereby emitting bioluminescent light. Various luciferases have been tethered to opsins in blue light utilizing luminopsins (LMOs), and these have been applied for excitation and inhibition of targeted neuronal populations in vivo[1-4]. To expand the utility of BL-OG we generated red-shifted LMOs by combining a Renilla luciferase variant that emits light above 500 nm with red fluorescent proteins based on mCherry, mOrange, and mScarlet to leverage Förster resonance energy transfer (FRET) for bright and red light emitters. We used structure-guided design and directed evolution to optimize FRET efficiency between luciferase and fluorescent proteins, resulting in three LMOs with emission peaks between 560 - 592 nm. We tethered these red light emitters to excitatory (VChR1, ChrimsonR) and inhibitory (Halo, hGtACR1) red-shifted opsins and tested their efficacy in neurons in vitro and in vivo. This set of red LMOs expands the toolset for recording and controlling neural activities in the brain by allowing multiplexing with blue-shifted LMOs, opsins, and sensors.

Abstract: Optical imaging is a transformative tool for neuroscience, enabling the elucidation of biological circuits that generate behavior. State-of-the-art imaging tools rely on a restrained preparation, limiting natural behavior while measuring cellular activity via fluorescence (FL). Recently, advances in wearable miniature microscopy expanded the range of accessible behaviors by allowing imaging in freely behaving animals. However, miniature microscopes (miniscopes) are currently used for brain imaging using FL. Miniscopes have not been adopted for imaging bioluminescence (BL) and/or other parts of the body. However, unfavorable attributes of FL indicators constrain the extent of imaging experiments. These attributes include photobleaching, autofluorescence and excitation light scattering noise, especially in the parts of the body like the spinal cord due to myelination. All 3 issues can be eliminated, and an increase in imaging depth achieved, by using BL instead of the FL. BL does not require an external light source and offers a lower biological noise floor, often creating higher signal-to-noise ratio. However, the overall lower BL light intensity presents a challenge for imaging using low-cost low-sensitivity miniscopes.
The objective of our work is to improve the quality of cortical and spinal imaging using BL and miniature microscopy tools. To this end, we (i) present an expansion of the miniscope use towards neurovascular imaging in the spinal cord. Spinal neurovascular imaging is accomplished by integrating a custom 3D-

printed vertebral implant with miniscope hardware that ensures mechanical and optical stability over time up to 5 months post-implantation. Such implants allow interchangeable imaging of the brain or spinal cord in free or restrained mice. (ii) We demonstrate our ability of imaging BL calcium indicators using EM-CCD camera at rates up to 2 frames-per-second (FPS) through a cranial window in behaving animals following the systemic administration of BL substrate (luciferase), and as fast as 10 FPS with the topical administration of luciferase. With intracortical administration of luciferase BL calcium signals can be imaged using redesigned FL miniscopes (the 'BLmini') at rates as fast as 5 FPS (Celinskis et al., 2020). Altogether, our work presents significant progress towards BL calcium imaging with experimenter-friendly peripheral routes of substrate administration using low-cost wearable miniature microscopes across multiple sites throughout the nervous system.

Abstract: Genetically encoded optical sensors and advancements in microscopy instrumentation and techniques have revolutionized the scientific toolbox available for probing complex biological processes such as release of specific neurotransmitters. Most genetically encoded optical sensors currently used are based on fluorescence and have been highly successful tools for single-cell imaging in superficial brain regions. However, there remains a need to develop new tools for reporting neuronal activity *in vivo* within deeper structures without the need for hardware such as lenses or fibers to be implanted within the brain. Our approach to this problem is to replace the fluorescent elements of the existing biosensors with bioluminescent elements. This eliminates the need of external light sources to illuminate the sensor and overcomes several drawbacks of fluorescence imaging such as limited light penetration depth, excitation scattering, and tissue heating that are all associated with the external light needed for fluorescence imaging.We have bioengineered the first genetically encoded bioluminescent neurotransmitter indicators using a multistep screening approach. First rational design using a variety of split luciferases and linker

variants to fuse the luciferases to a sensing protein. Then an automated workflow to screen for improved variants in mammalian cells, using automation for mini preps and transfection of mammalian cell cultures. As a result, we created a BioLuminescent Indicator of the Neurotransmitter Glutamate (BLING). Using our protein evolution approach in mammalian cells, we were able to improve our BLINGs response by 2.5x. Our improved glutamate indicator demonstrated a 255% +/-50 increase in response to neurotransmitter presentation when expressed in mammalian cells, can report changes in extracellular glutamate when used in a plate reader and outperforms various fluorescent sensors in plate reader assays. Finally, to test the feasibility of imaging BLING we used real-time microscopy which demonstrated up to a 310% increase in light emission detectable at the single cell level. We expect this new approach to neurotransmitter indicator design to enable the engineering of bioluminescent probes for multiple additional neurotransmitters, ultimately allowing neuroscientists to monitor activity associated with a specific neurotransmitter as it relates to behavior in a variety of psychiatric disorders, among many other applications.

Abstract: Calcium is the ubiquitous cellular second messenger and calcium signals are proxy for biologically significant events including neuronal action potentials. Genetically encoded fluorescent calcium sensors are well established tools in neuroscience, but they have a number of limitations for use in biological tissue, such as tissue heating from illumination, other off-target biological effects of high-intensity excitation, and scattering of excitation light that confines imaging to small volumes of the brain. Previous generations of bioluminescent calcium indicators have insufficient brightness and relatively small calcium-dependent changes in signal magnitudes, and these properties have limited their widespread adoption in the neuroscience research community. Here, we present “Calcium

BioLuminescence-Activity Meters" (CaBLAMs), a family of bioluminescent calcium indicators engineered from a novel luciferase and calcium sensor domain topology. By optimizing each component of these indicators, including the luciferase domain, split site, calmodulin and RS20 peptide, and linker length and composition, we have achieved extremely low baseline emission at cytosolic resting calcium concentrations, a high Hill coefficient, and a very high signal change (delta-L/L) at physiologically relevant elevated cytosolic calcium concentrations. Further optimization of the luciferin (substrate) used for imaging the CaBLAMs generates signals large enough to observe glutamate-induced calcium events originating in dendrites and propagating to the soma in individual neurons ex vivo. These new sensors have the potential to enable imaging of calcium activity in deep brain regions in behaving mice for the first time without the need for an excitation light source.

Title: Effects of forebrain expression of chimeric GluN2 subunits on NMDAR synaptic pool at hippocampal excitatory synapses

Authors: *R. E. KEITH[1], T. C. DUMAS[2];
[2]Psychology, [1]George Mason Univ., Fairfax, VA

Abstract: N-methyl-D-aspartate receptors (NMDARs) are voltage-gated glutamatergic receptors which engage in both ionotropic and non-ionotropic signaling. In the hippocampus, NMDARs consist of two obligatory GluN1 subunits and two auxiliary GluN2 subunits (predominantly GluN2A and GluN2B) (Wyllie et al., 2011). During postnatal development, NMDARs undergo a GluN2 subunit switch from predominantly GluN2B prior to the third postnatal week to mostly GluN2A and triheteromeric NMDARs following the third postnatal week. However, this subunit switch is not accompanied by a change in the total NMDAR pool, despite the fact that GluN2 subunit composition of the NMDAR influences the trafficking of the receptor to the synapse. Indeed, it remains unknown how GluN2 functional domains (the N-terminus, transmembrane domains and C-terminus) may separately and independently affect the available pool of synaptic NMDARs. As the channel kinetics and protein-binding partners conferred by GluN2 subunits are unique, it is possible to separate the effects of GluN2 functional domains by determining the GluN2 expression of the NMDARs present at the synapse. The developmentally regulated expression of these subunits also permits dissociation of the influence of GluN2A and GluN2B functional domains at different stages of postnatal development. Thus, using transgenic mice which express the N-terminus and TM regions of GluN2A (ABc) or GluN2B (BAc) fused to the opposite

subunit type C-terminus, we examined the GluN1 content of hippocampal and neocortical postsynaptic density fractions prior to (P17-P19) and after (P22-P24) forebrain maturation, and in young adulthood (P30-P60). As GluN1 subunits are required for NMDAR assembly and the formation of functional channels, expression of GluN1 acts as a proxy for measuring NMDAR expression. Our findings demonstrate no differences in total NMDARs at the synapse between transgenic mice and wildtypes, suggesting that the expression of the ABc or BAc subunits alone does not increase the size of the NMDAR synaptic pool. Results from immunoprecipitation experiments demonstrate an approximate 30% transformation of NMDARs from native to transgenic. These results suggest that total NMDAR synaptic content is not affected by the functional domains of GluN2 subunits. Thus, it is likely the synaptic pool of NMDARs is more strongly regulated by patterned synaptic activity of NMDARs, rather than purely the structural composition of GluN2 subunit functional domains.

Title: RNA-binding FMRP and Staufen sequentially regulate the Coracle scaffold to control synaptic glutamate receptor and bouton development

Authors: *C. SONG[1], S. N. LEAHY[1], K. BROADIE[1,2,3];
[1]Biol. Sci., [2]Kennedy Ctr. for Res. on Human Develop., [3]Brain Inst., Vanderbilt Univ., Nashville, TN

Abstract: Fragile X Syndrome (FXS) caused by loss of the Fragile X Mental Retardation Protein (FMRP) is the leading heritable cause of both intellectual disability and autism spectrum disorders. Previously, we have established that FMRP plays important roles in modulating synaptic bouton formation and glutamate receptor (GluR) levels at the *Drosophila* neuromuscular junction (NMJ). However, the underlying molecular mechanism was entirely unknown. FMRP is primarily shown to act as an mRNA-binding translational regulator, with a number of known transcript targets. Here, we focus on FMRP-interacting mRNA-binding protein (RBP) Staufen and its downstream mRNA target, the actin-binding GluRIIA anchor Coracle. We tested FMRP, Staufen and Coracle interactions at the third instar NMJ, measuring synaptic bouton numbers and protein levels based on antibody labeling with fluorescent confocal imaging. Bouton numbers were counted blind to genotypes, and protein levels were quantified in sum-slice-projected images without including background fluorescent signals. We discovered that both *dfmr1* and *staufen* mutants, as well as trans-heterozygous double mutants, display increased synaptic bouton formation and GluRIIA levels, suggesting a common mechanism. To test protein-mRNA interactions, tagged FMRP and Staufen were transgenically expressed, followed by immunoprecipitation (IP) with anti-tag antibody-coated beads. By assaying IP'd RNAs, we found FMRP binds *staufen* mRNA and Staufen binds *coracle* mRNA, suggesting a FMRP-Staufen-Coracle pathway. With antibody labeling,

we found FMRP and Staufen both limit postsynaptic Coracle expression at the NMJ. We found that coracle mutants, as well as muscle-targeted coracle RNAi and overexpression, increase synaptic bouton formation and GluRIIA expression. Loss-of-function/gain-of-function phenotype convergence is consistent with Coracle functions in other contexts. Consistent with GluRIIA accumulation from disruption of the FMRP-Staufen-Coracle pathway, *dfmr1*, *staufen* and *coracle* mutants all elevate neurotransmission strength. FMRP, Staufen and Coracle also all suppress bone morphogenetic protein (BMP) trans-synaptic signaling mediating postsynaptic GluRIIA control of presynaptic bouton formation. These findings suggest that FMRP regulates Staufen to inhibit Coracle control of GluRIIA in the postsynaptic domain, and that postsynaptic GluRIIA in turn signals presynaptic bouton development. This work provides insights into the molecular mechanism of FMRP regulation of synaptic development, identifying potential new FXS treatment targets.

Title: Maturation of glutamatergic transmission onto dorsal raphe serotonergic neurons

Authors: *A. KISNER, A. POLTER;
The George Washington Univ., Washington, DC

Abstract: Serotonin (5-HT) is a developmentally regulated neuromodulator/neurotransmitter that plays a critical role in brain development and influences a wide range of physiological processes as well as susceptibility to psychiatric illnesses. Over the course of development, ongoing maturation of synaptic inputs from upstream brain areas critically regulate serotonergic circuit function. Previous studies demonstrated that in early postnatal development functional excitatory synaptic activity onto dorsal raphe (DR) 5-HT neurons progressively increases and undergoes significant changes during the first 21 days of life (Rood et al.). However, little is known about developmental adaptations of convergent glutamatergic and GABAergic synapses onto DR 5-HTergic neurons or expression and function of postsynaptic receptors that regulate synaptic strength of these cells. Here, we used acute slice electrophysiology to systematically study the maturation of synaptic function onto DR 5-HT neurons from the neonatal period through adulthood. We found that during early postnatal day (PND) 6 the ratio of excitatory:inhibitory synaptic transmission onto 5-HT neurons is nearly proportional (mean excitation-inhibition ratio of spontaneous synaptic current amplitude 0.87 ± 0.13 and frequency 0.92 ± 0.22). While inhibition remained relatively stable over development, the strength of glutamatergic transmission increased

throughout adolescence and adulthood (one-way ANOVA, $F_{(5,55)} = 4.975$, $p = 0.0057$). We next examined the developmental adaptation of glutamatergic receptors by measuring the AMPAR/NMDAR ratio. We found that the AMPAR/NMDAR ratio also gradually increases and peaks during adolescence (one-way ANOVA, $F_{(5,46)} = 3.245$, $p = 0.0047$) and remains relatively stable throughout adulthood. The contribution of the AMPAR-mediated component to the evoked-synaptic currents in 5-HT neurons was significantly higher than the NMDAR-mediated component and was stable across the entire developmental period. Lastly, we examined whether there are shifts in the composition of AMPARs in these synapses along development. The peak of current-voltage relationship of the AMPAR-component over the course of development showed that in a subset of 5-HT neurons these receptors are inwardly rectifying, indicating that they are permeable to calcium even into adulthood. We anticipate that our findings will be a starting point to understand how the maturation of synapses on 5-HT neurons contributes to the integration of information from upstream brain areas and reciprocal modulation of forebrain circuits by 5-HTergic neurons.

Title: Developmental regulation of H3K27me3 drives synapse maturation and social behavior

Authors: *U. CHAN[1], V. RAMESH[1], R. LI[1], M. MINTO[1], K. GE[2], A. E. WEST[1];
[1]Neurobio., Duke Univ. Sch. of Med., Durham, NC; [2]Natl. Inst. of Diabetes and Digestive and Kidney Dis., NIH, Bethesda, MD

Abstract: The deposition and removal of H3K27me3 by methyltransferases EZH1 and -2 and demethylases KDM6A and -B are tightly regulated throughout development to control transcription. This repressive mark is lost at specific loci during differentiation to mediate specific gene activation necessary for each developmental stage, thereby providing a mechanism underlying the induction of cell-specific and temporally specific gene expression programming. However, this raises the question as to what the role of H3K27me3 in non-dividing cells like neurons may be and whether there are mechanisms governing its dynamicity throughout neuronal development. We have previously identified a novel role for KDM6B in post-mitotic cerebellar granule neurons (CGNs) in mediating the induction of a mature gene expression program that includes many synaptic genes. Consistent with this, there is a gradual loss of H3K27me3 along specific loci of KDM6B target genes like *Grin2c* at different time points post-differentiation. Therefore, we hypothesize that dynamic regulation of H3K27me3 by KDM6B is required during CGN maturation for proper synaptic development. To do this, we conditionally knock out *Kdm6b* by electroporating CRE recombinase into the developing cerebellum of $Kdm6b^{fl/fl}$ mice. Neurons without

Kdm6b have smaller and less complex dendritic claws, which are the sites that contain a majority of the synaptic inputs onto CGNs. Furthermore, we have shown that proper claw formation is dependent on KDM6B's enzymatic activity. KO CGNs also have an increased distribution of VGLUT2-positive synapses on their smaller claws, suggesting that under normal conditions, KDM6B works to develop these claws in order for the cells to properly distribute synapses. Interestingly, mice lacking KDM6B's demethylase activity show deficits in social novelty and discrimination, highlighting a possible behavioral consequence linked to chromatin misregulation. Whether this aberrant phenotype is specifically due to synaptic defects associated with loss of KDM6B's enzymatic activity remains to be resolved. That being said, these experiments elucidated a novel role for KDM6B in regulating synapse development and expanded our knowledge on how chromatin regulation contributes to neuronal maturation and ultimately, social behavior.

Abstract: Protein Quality Control Machinery in the PostsynapticCompartment
Arun Upadhyay, Jeffrey N. Savas
Department of Neurology, Northwestern University Feinberg School of Medicine Chicago 60611
Background: Synapse formation is a tightly regulated developmental process controlled by multiple transcriptional factors, axon guidance cues, signaling pathways, and synaptic adhesion proteins. To maintain the synaptic structures, cells continuously replace old proteins with newly synthesized copies. However, the mechanisms involved in regulating the turnover of synaptic proteins are unknown.**Objective:** Identify the synaptic protein quality control (PQC) machinery. Determine if presynaptic or postsynaptic compartments selectively harbor different PQC factors.**Methods:** We isolated the synaptic membranes from P21 rat brains using classical sucrose-density gradient methods and purified the PSD fraction. We analyzed different fractions isolated from the brain and compared the proteomic profiles using sample multiplexing by isobaric TMTlabeling of peptides followed by MS3 mass spectrometry. Further bioinformatic analysis was performed to identify crucial PQC players in presynaptic and postsynaptic fractions. Immunoblots and other biochemical assays verified the results obtained.**Results:** Gene ontology (GO) enrichment analysis of the TMT experiment data sets revealed the abundance of numerous chaperones and components of the protein degradation machinery. While

chaperones were abundant in the synaptosome fraction, postsynaptic density (PSD)fractions were selectively enriched with UPS components, including ubiquitin-activating (E1), conjugating (E2), E3 ligase, and deubiquitinase enzymes. Among all these proteins, WW domain-containing HECT E3 ubiquitin ligases are most significantly enriched at postsynaptic locations. Notably, our results indicate that proteasome-mediated protein degradation actively regulates the turnover of proteins in postsynaptic compartments.**Conclusions.** Ubiquitin proteasomal system (UPS) synchronizes cellular processes in the postsynaptic compartment by regulating the turnover of critical protein components involved in signaling and metabolic processes. Our results suggest that HECT domain E3 ubiquitin ligases are essential components of postsynaptic proteostasis machinery required for neuronal development and protection from neurodegeneration.

Title: Latrophilin-2 controls topographic synaptic assembly of entorhinal inputs

Authors: *J. D. DONOHUE, T. R. MURPHY, G. R. ANDERSON;
Neurosci., Univ. of California, Riverside, RIVERSIDE, CA

Abstract: Brain circuits are comprised of distinct interconnected neurons that are assembled according to synaptic recognition molecules presented on defined pre- and post-synaptic sites. This cell-cell recognition process is mediated by varying cellular adhesion molecules, including the latrophilin family of adhesion G-protein coupled receptors (Lphn1-3; gene symbols *ADGRL1-3*). Recently, latrophilins have been shown to mediate excitatory synaptogenesis through trans-synaptic interactions with extracellular binding partners teneurins and FLRTs. Of the three latrophilin genes, Lphn2 demonstrates the most stringent expression patterning, and is the focus of this study. Here we sought to define cell type specific expression and Lphn2 protein localization within the parahippocampal circuit of interconnected subregions of the medial entorhinal cortex (MEC), presubiculum (PrS), and parasubiculum (PaS). In doing so, we find notable topographical expression patterning at both the protein and RNA level in all three of these interconnected regions. To study the role of Lphn2 in controlling the connectivity between these regions, we utilized a retrograde labeling approach. Performing dual-retrograde viral tracing from the Lphn2 deficient versus enriched compartments of the MEC reveals unique topographical patterning of inputs arising from the PrS and PaS which mirrors Lphn2 expression. We find that Lphn2 enriched compartments of these regions show strong connectivity, whereas Lphn2 deficient compartments of these

regions show similarly enriched connectivity. Using this retrograde viral labeling method coupled with a Lphn2 conditional knock-out mouse model, we find that deletion of Lphn2 expression in the MEC selectively impairs labeling of inputs arising from the ipsilateral PrS. Combined with analysis of Lphn2 expression within the MEC, these data reveal Lphn2 as a molecule that is expressed by defined cell types, and selectively controls circuit development between interconnected regions.

Title: Mechanism of Self-Avoidance in Synaptic Neurexin Complexes

Authors: *C. WANG[1], J. H. TROTTER[1], K. LIAKATH-ALI[1], S. LEE[1], X. LIU[2], T. C. SUDHOF[1,3]; [1]Mol. and Cell. Physiol., Stanford Univ., Stanford, CA; [2]Cell Biol., Yale Univ., New Haven, CT; [3]Howard Hughs Med. Inst., Stanford, CA

Abstract: Synapses are thought to be organized by interactions of presynaptic neurexins with postsynaptic ligands, such as neuroligins and cerebellins. However, when a neuron forms adjacent pre- and postsynaptic specializations, such as observed in dendro-dendritic or axo-axonic synapses, *cis*-neurexin/ligand interactions would be energetically favored but functionally inactive. Here, we reveal an organizational principle for preventing synaptic *cis*-interactions ('self-avoidance'). Using dendro-dendritic synapses between mitral and granule cells in the olfactory bulb as a paradigm, we show that, owing to its higher binding affinity, cerebellin-1 blocks the *cis*-interaction of neurexins with neuroligins, thereby enabling *trans*-interaction of neurexins with their ligands. In mitral cells, ablating either cerebellin-1 or neuroligins severely impaired granule cell->mitral cell synapses, as did overexpression of wild-type neurexins but not of mutant neurexins unable to bind to neuroligins. Our data uncover a

molecular interaction network that organizes the self-avoidance of non-functional neurexin *cis*-complexes, thus allowing assembly of functional *trans*-synaptic neurexin complexes.

Title: Exploring the mechanisms of Semaphorin/Plexin-mediated synapse formation in the intact hippocampus

Authors: *S. ADEL[1], T. KOWALSKI[2], M. BUCK[4], S. PARADIS[3];
[1]Brandeis Univ. Grad. Neurosci. Program, Waltham, MA; [3]Biol., [2]Brandeis Univ., Waltham, MA; [4]Case Western Reserve Univ., Cleveland, OH

Abstract: In the mammalian brain, two main types of chemical synapses - glutamatergic and GABAergic - play opposing roles in exciting or inhibiting the postsynaptic cell. While it is critical that upon cell-cell contact, new synapses form the correct postsynaptic specialization (excitatory or inhibitory), it remains a fundamental mystery in developmental neurobiology which molecular pathways specify this identity. We previously reported that in mammalian hippocampus, semaphorin-4D (Sema4D) and sempahorin-4A (Sema4A) promote formation of inhibitory synapses by signaling to their receptor Plexin-B1, while Sema4A also promotes formation of excitatory synapses by signaling to another Plexin-B family member, Plexin-B2. We sought to identify specific cellular signaling mechanisms downstream of Plexin-Bs that differentially specify formation of inhibitory or excitatory synapses. To accomplish this goal, we developed four chimeric versions of Plexin-B receptors with domain swaps between Plexin-B1 and Plexin-B2. We verified their expression and surface localization in COS7 cells. Currently, we are expressing the chimeric Plexin-B receptors in hippocampal slices from *Plxnb1; Plxnb2* double knockout mice to assay which domains are necessary and/or sufficient to promote excitatory or inhibitory synapse formation upon treatment with Sema4D or Sema4A. The results of these experiments will elucidate how different class 4 Semaphorins initiate distinct, Plexin-B signaling mechanisms to promote excitatory or inhibitory synapse formation.

Title: Role of p75 neurotrophin receptor in cortical parvalbumin-positive GABAergic interneurons plasticity and cognitive flexibility

Authors: *P. CHEHRAZI[1,2], B. CHATTOPADHYAYA[2], M. LAVERTUJOLIN[2], G. DI CRISTO[2]; [1]universite de montreal, Montreal, QC, Canada; [2]CHU St. Justine, Montreal, QC, Canada

Abstract: Parvalbumin (PV)-positive GABAergic interneurons constitute the majority of interneurons in the cortex and play a key role in the function and synchronization of cortical networks. Alterations in PV-interneuron connectivity, especially in the medial prefrontal cortex (mPFC), has been found in different psychiatric disorders. We have previously shown that the expression of the p75 neurotrophin receptor (p75NTR) regulates the time course of PV cell synapse maturation in a cell-autonomous fashion. Here, we show that p75NTR removal in postnatal PV cells affects the connectivity and plasticity of PV interneurons and mPFC function in adult PvCre dependent conditional knockout (cKO) mice. We first analyze the effect of p75NTR removal on the efferent and afferent connectivity of PV cells in the perisomatic region. We quantified putative synapses formed by PV cells, identified by the juxtaposition of PV and gephyrin, a post synaptic scaffolding protein of GABAergic synapses. We further used Synaptotagmin 2 immunolabeling to identify PV cell pre-synaptic sites Both the density of PV+gephyrin+ puncta and the percentage of perisomatic PV puncta showing juxtaposed gephyrin were significantly increased in mPFC but not in visual cortex (VC) of cKO mice. Similarly, Synaptotagmin+ puncta were significantly increased around pyramidal cell somata in mPFC of cKO mice. Further analysis of prefrontal PV cells showed higher density of putative excitatory synapse density on PV cell somata. An important indication of PV cell maturation is the appearance of specialized extracellular matrix structures called perineural nets (PNNs) around the soma and primary dendrites of mature cortical PV cells. p75 cKO mouse showed a significant increase in the number of PV cells encircled by PNN, as revealed by WFA staining, in mPFC but not VC. These mice also showed deficits in attentional set-shifting task, a measure of attention and cognitive flexibility, and in extinction of fear memories, both of which rely on mPFC function.We are currently investigating whether the observed structural remodeling lead to PV cell activity alterations as revealed by measuring expression levels of the neuronal activity marker c-Fos in PV cells following tail-pinch stimulation. In addition, we are investigating whether AAV-mediated reintroduction of P75NTR in PV cells can rescue their structural alteration in cKO mice. These findings suggest that P75NTR is a critical regulator of PV cell plasticity, thus modulating cognitive functions, in adult mPFC.

Title: Hormonally-regulated maturation of spontaneous neural activity and associative learning

Authors: *S. G. LEINWAND[1], K. SCOTT[2];
[1]Dept. of Mol. and Cell Biol., Univ. of California Berkeley, Berkeley, CA; [2]Univ. California -Berkeley, Berkeley, CA

Abstract: Adult behavior is the product of neural circuits that have been sculpted during development by genetic programs and experience in the form of neural activity. Despite the fundamental role of spontaneous neural activity in circuit refinement, the mechanisms underlying neural activity state transitions and their behavioral function remain poorly understood. The *Drosophila* mushroom body, with its well characterized anatomy, powerful genetic tools and well-established role in learned behaviors, is an ideal system for investigating the developmental maturation of higher order neural circuits and behavior. Here, we identify and characterize a hormonally-triggered age-dependent reduction of spontaneous activity in Kenyon cells, the principal neurons of the mushroom body, which is required for enhanced associative learning, thereby gaining insight into fundamental neurodevelopmental processes. By monitoring neural activity *in vivo*, we identified spontaneous, asynchronous activity in the mushroom body learning center of very young adult flies. This activity declines significantly over the first week of adulthood. Moreover, this activity is generated cell-autonomously via Cacophony voltage-gated calcium channels in a single cell-type, α'/β' Kenyon cells. We identified juvenile hormone, a crucial regulator of developmental timing similar to mammalian thyroid hormones, as the trigger for the transition from the young high activity state to the mature low activity state. Animals with juvenile hormone signaling transiently inhibited specifically in α'/β' Kenyon cells in a young sensitive period failed to transition to the mature low activity state. Our findings suggest that JH signaling directly orchestrates changes in ion channel and transcriptional activator gene expression that modify the output of Kenyon cell circuits. Fascinatingly, we observed a significant enhancement in aversive associative learning performance over the first week of adulthood, the same time course as the decrease in spontaneous activity. α'/β' activity in a young animal sensitive period was required for subsequent robust learned behavior in mature animals. Transient hormonal signaling in young animals was also required to enhance subsequent learned behavior. Thus, we identified a hormone-triggered neural activity state transition in young animals required for the maturation of associative learning. Taken together, these studies improve our understanding of fundamental mechanisms for brain development and suggest that hormone signaling in young animals coordinates the maturation of neural activity, enabling the emergence of mature adult behaviors.

Abstract: Cortical astrocytes can be reprogrammed into glutamatergic forebrain neurons through overexpression of the basic-helix-loop-helix transcription factor Neurog2 (Berninger et al., 2007). Over a period of 2-6 weeks *in vitro*, the reprogramming process stably induces properties such as acquisition of complex neuronal morphology, expression of neuron-specific proteins and the gain of functional neuronal properties such as action potential firing and establishment of synaptic connections. However, little is known regarding the extent to which induced neurons (iNs) can undergo lasting and hence functional transcriptional adaptations in response to changing network activity. Here, we assessed the transcriptional response of iNs to global network activity modulation and compared it to the response elicited in endogenous cortical neurons (eNs). To this end, we co-cultured iNs with eNs and pharmacologically inhibited network activity for 2 days. By performing single-nucleus RNA-seq analysis we demonstrate that iNs can undergo changes in known activity-dependent, synapse-related gene expression. Interestingly, however, iNs and eNs modulate mostly distinct sets of genes that possibly reflect differences in cell identity as well as maturation level. By inferring gene regulatory network dynamics, we are beginning to identify shared and unique transcriptional programs underlying responses to changes in neuronal network activity in endogenous and reprogrammed neurons.

Title: Mature parvalbumin interneuron function in prefrontal cortex requires activity during a postnatal sensitive period

Authors: *S. CANETTA[1], E. S. HOLT[2], L. J. BENOIT[1], E. TEBOUL[2], R. T. OGDEN[1], A. HARRIS[1], C. KELLENDONK[1];

Abstract: In their seminal findings, Hubel and Wiesel identified sensitive periods in which experience can exert lasting effects on adult visual cortical functioning and behavior via transient changes in neuronal activity during development. Whether comparable sensitive periods exist for non-sensory cortices, such as the prefrontal cortex (PFC), in which decreased activity can lead to persistent changes in adult circuit function and behavior, remains unknown.
In sensory cortices, experimental manipulations of activity are elicited by directly manipulating the primary sensory organ. This approach is not feasible in the PFC as it receives no direct sensory information. To overcome this challenge, we have developed a system that allows modulation of prefrontal activity during distinct developmental windows using viral expression of the DREADD receptor, hM4DG$_i$. Here, we specifically modulated the activity of prefrontal parvalbumin-expressing (PV) interneurons, as this cell population is known to sculpt the output of excitatory cortical pyramidal neurons and to undergo a protracted period of physiological maturation and integration into cortical circuitry during peripuberty and adolescence.
Using this system, we investigated whether peripuberty and adolescence is a sensitive period in which transiently altering the activity of PV interneurons can persistently impact adult PFC function and behavior. We expressed hM4DG$_i$, or the control protein mCherry, in developing PV interneurons, administered the agonist for hM4DG$_i$, clozapine-N-oxide, from postnatal day P14 to P50, and examined attentional set-shifting behavior and underlying prefrontal cortical activity using stereotrodes in adulthood (P90). We also assessed the connectivity of PFC PV cells onto pyramidal neurons in adulthood using optogenetics combined with slice electrophysiology. Sample sizes range from 4 to 17 and both sexes were included.
We now demonstrate that inhibition of prefrontal PV interneurons during peripuberty and adolescence results in *persistent* impairments in adult prefrontal circuit connectivity, *in vivo* network function and behavioral flexibility that can be ameliorated by targeted activation of PV interneurons using a stabilized step function opsin in the adult animal. In contrast, transient suppression of PV interneuron activity in adulthood produces no lasting effects. These findings identify an activity-dependent sensitive period for prefrontal circuit maturation and highlight how abnormal PV interneuron activity during development can persistently alter adult prefrontal circuit function and cognitive behavior.

Title: Role of GABAergic synaptic maturation in the anterior piriform cortex in the home-nest odor discrimination of infant rats. A behavioral and computational study

Authors: G. E. PARDO[1], C. MEDINA-SALDIVAR[1], C. BECERRA[1], L. F. PACHECO-OTALORA[1], *E. M. ORURO[2];
[1]Lab. de Investigación en Neurociencias, [2]Lab. de Neurocomputación y Simulación Social, Univ. Andina del Cusco, Cuzco, Peru

Abstract: Background: During the first two weeks of postnatal life, infant rodents exhibit social preferences guided by odors of the mother, other conspecifics, or other nest-typical scents. In mice pups, home odor preference is present as early as five days of age; however, the ability to discriminate home nest odors from other, closely related nests appears on the postnatal day (PND) 10. In the present work, we also report this phenomenon in infant rats. One possible explanation at the neuronal level for why PND 10 pups discriminate their nest odor from another very similar nest odor but not younger pups is the differential rewarding action of the maternal care profile (nest entries/exists) in the olfactory circuit involved in this behavior. Another possible explanation is the developmental change of GABAergic synaptic transmission in the olfactory cortex. **Methods**: To test the first hypothesis, we use our previous olfactory bulb (OB)- anterior piriform cortex (aPC) computational circuit model for PND 5-8 rat pups built with our own experimental data and conditioned to home odor as the conditioned stimulus (CS) paired with norepinephrine (NE) release. The CS-NE pairing was simulated according to the maternal care profile experimental data corresponding for PND 5 and PND 10 and then evaluated for the response of the OB-aPC circuit to the CS and other nest odor, 60% similar to the home odor. To test the second hypothesis, we included experimental data from PND 5 and PND 10 aPC GABA synaptic input profile to OB-aPC computational circuits and then simulated the home-odor processing in the presence of NE release. This configuration attempts to represent active odor processing of the pups inside the nest while receiving maternal care. The response of the OB-aPC circuit to the home odor and other nest odor, 60% similar to the home odor, was evaluated before and after the odor-NE exposition. **Results**: The results show that the number of active neurons and evoked spikes for the home-odor and other nest odor were similar for both ages in the maternal profile conditioning simulation. On the other hand, the number of active neurons and evoked spikes in response to home odor were higher than for the other nest in the PND 10 circuit, but this comparison was similar in the PND 5 circuit. **Conclusions**: Our results support the idea that the ability to discriminate between closely associated nest odors in PND 10 rat pups can be, at least partially, attributed to the developmental changes of GABA synaptic transmission in the odor processing circuits of the rats rather than to a change in rewarding stimulation of the maternal care profile.

Title: Spontaneous neuronal activity is reduced during the 'vulnerable' period of nascent neural circuit formation in the hippocampus of Ts65Dn mice, a genetic model of Down syndrome

Authors: F. MADAMBA, B. K. LE, ***A. M. KLESCHEVNIKOV**;
Univ. of California San Diego, La Jolla, CA

Abstract: Down syndrome (DS), a developmental disorder due to triplication of chromosome 21, is characterized by developmental delays and profound cognitive impairment. Most of the changes leading to the abnormalities become apparent during the "vulnerable" early period of brain development when neonatal neural circuits are formed and developed. Spontaneous neuronal activity plays a pivotal role in the establishment of appropriate synaptic connections and the maturation of the neural circuits. Here we compared spontaneous neuronal activity in the CA3 region of littermate Ts65Dn and normosomic control (2N) pups during the first three weeks of postnatal development. The measurements were performed using microelectrode recordings of spontaneous multi-unit activity (MUA) in acute hippocampal slices. We observed that, on average, the MUA frequency was significantly reduced in slices of Ts65Dn *vs*. 2N pups at the age of p8 - p12 (2N: 100 ± 12.6%, Ts65Dn: 66.1 ± 6.9%, $p = 0.011$). In older animals (p14 - p25), the averaged MUA frequency was not different in Ts65Dn *vs*. 2N pups (2N: 100 ± 8.8%, Ts65Dn: 103.9 ± 8.8%, $p = 0.37$). One of the factors contributing to the decrease in spontaneous neuronal activity is the increased expression of Kir3.2 subunits of G-protein-coupled inwardly rectifying potassium channels, which gene (*Kcnj6*) is triplicated in DS and Ts65Dn DS model. The decrease in spontaneous neuronal activity likely affects synaptogenesis and contributes to the formation of malfunctioning neural circuits, which serve as the neural basis for cognitive abnormalities in DS. Correcting spontaneous neuronal activity during this 'vulnerable' period of brain development by genetic or pharmacological means might correct the formation of neural circuits and improve cognition in DS models.

Title: Emergence of complex network topology from the self-organization of cultured neural circuits

Authors: *P. CORREIA ANTONELI[1], T. F. VARLEY[3], M. PORCIONATTO[1], O. SPORNS[3], J. FABER[2];

Abstract: In the last two decades the study of neural elements, such as neurons and brain areas, and their interactions in a network perspective has been an area of active research. The discovery of the small-world and scale-free properties in these networks has been helping to uncover their complex dynamics. However, little is known about how these complex frameworks emerge during neurodevelopment and how they are changed by sensory stimuli. Regarding small-world architecture, some hypotheses were raised in the computation models research field. Watts and Strogatz (1998) proposed a random rewiring scenario of a lattice network for generating small-world networks, while Kwok et al. (2007) suggested a Hebbian-like rewiring scenario of random neuronal networks. Nonetheless, the biological rewiring process is not efficient, especially when considering structural networks. To investigate how the self-organization of *in vitro* neural circuits drives to complex neuronal network topology we applied effective connectivity techniques to electrophysiological signals from rat dissociated hippocampal neuron cultures during their maturation process (29 days *in vitro*, freely available data set: 10.6080/K0PC308P). Bivariate Transfer Entropy, an information-theoretic quantity used to measure time-dependent interactions, was computed using binarized spike rasters derived from the neural recordings to construct weighted and directed networks. Topological properties were measured using graph-theoretic metrics and compared during different stages of network development (min: 9, max: 18, mean: 15 per day *in vitro*). As the number of edges in the network increased over time neurons formed clusters and the small-world topology emerged. Further, we detected the subdivision of the networks into communities where modules of few highly connected neurons were integrated mostly by high firing rate neurons. These findings suggest an important role of silent synapses activation during neurodevelopment. We hypothesized that the organization of the developing network topology in these complex frameworks is due to plasticity and homeostatic mechanisms that reinforce synchronized spontaneous activity by activating silent synapses and scaling active ones. Once such a mechanism might establish effective connections, clustering together and linking within modules synchronized neurons as well as favoring connections between high firing rate neurons. This empirical study allowed the formulation of a new hypothesis regarding small-world architecture and other complex network properties, instead of considering a rewiring of connections we suggest a selection of silent ones.

Ctr. on Aging, Boston, MA; [8]Dept. of Neurol., Yale Sch. of Med., New Haven, CT

Abstract: Rationale: Brain development is guided by an interplay of genetic and environmental factors. Dietary contributions, including bioactive compounds in human milk, are incompletely understood. We investigated human milk samples collected across global populations and found that the sugar alcohol *myo*-inositol is most abundant in the first postnatal weeks when synapses form rapidly in the infant brain. We analyzed effects of *myo*-inositol on brain development in the visual system due to its well-defined postnatal maturation. Methods: We supplemented the diet of male and female C57B6J mice with 50 mg/kg body weight *myo*-inositol or vehicle control daily from the day after birth to postnatal day 8 to 35 (P8-P35). We measured visual acuity by recording visually evoked potentials from the visual cortex (V1) of adult animals. Furthermore, we measured thalamic eye input segregation by labeling of retinal ganglion cells using cholera toxin (CTB) bound fluorescent dyes. Microglial pruning of retinogeniculate synapses was measured with immunohistochemistry (IHC) staining for a marker of microglia. Reconstructions of cells were then used as 3D masks and internalized CTB-conjugated dyes were quantified. IHC was used to characterize synapse size and density in V1. Investigators were blinded to treatment allocation during image acquisition and data analysis. Results: *Myo*-inositol supplementation increased adult visual acuity from 0.38 ± 0.17 to 0.66 ± 0.30 cycles per degree (unpaired t-test; N=5/8, t=4.49, p=0.0009). At P14, *myo*-inositol significantly augmented eye input segregation in the thalamus. There was no difference in segregation at the earlier P11 timepoint. In the same region, microglia from *myo*-inositol treated P8 mice contained 28 ± 15% more CTB-labeled boutons, occupying 4.3 ± 0.42% of the cell volume compared to 3.4 ± 0.24% for control animals (unpaired t-test; N=5/6, t=1.88, p=0.046). In V1b at P35 we found a selective increase in the size but not density of Homer positive puncta, a marker of postsynaptic excitatory synapses. Size was increased from 0.129 ± 0.02 μm^2 in control animals to 0.192 ± 0.02 μm^2 for *myo*-inositol supplementation (unpaired t-test; N=5/4, t=2.764, p=0.028). Conclusions: Dietary complementation with *myo*-inositol from birth substantially increased visual acuity. This was accompanied by improved formation of neuronal connectivity, with *myo*-inositol promoting retinotopic input refinement and synaptic pruning in the visual thalamus and synapse maturation in the visual cortex. These results reveal significant effects of the human milk component *myo*-inositol on neuronal connectivity and input processing in the developing brain.

Title: Dexmedetomidine: how safe is this anesthetic?

Authors: *N. JIMENEZ-TELLEZ[1], F. IQBAL[2], M. PEHAR[2], A. CASAS-ORTIZ[1], T. K. RICE[3], N. I. SYED[4];
[1]Biochem. and Mol. Biol., [2]Hotchkiss Brain Inst., [3]Anesthesiology, Perioperative and Pain Med., [4]Cell Biol. and Anat., Univ. of Calgary, Calgary, AB, Canada

Abstract: Anesthetics are an essential part of most - if not all - major clinical procedures. However, the precise mechanisms of how anesthetics exert their actions remain poorly defined. Moreover, notwithstanding their essential requirements for all surgical procedures, recent animal studies have raised alarm bells regarding anesthetic's long-term cytotoxic effects - especially on the brain. In this study, we tested dexmedetomidine (DEX), an anesthetic agent with distinctive molecular targets, to evaluate its effects on neuronal development and cognition both *in vitro* and *in vivo*. For the *in vitro* model, rat cortical neurons extracted from postnatal day 0 pups (P0) were exposed to different DEX concentrations (0.05 µM to 10 µM) and different cellular parameters were assessed, such as cellular viability, neurite outgrowth, synaptic formation, mitochondrial morphology and reactive oxygen species (ROS) production. For the *in* vivo model, rat pups were injected subcutaneously with DEX 25 µg/kg on P7 and again on P8. Open field testing was used to assess locomotor skills, anxiety and willingness to explore a new environment and hippocampal-dependent memory was evaluated on P60 using Morris Water Maze (MWM) and Novel Object Recognition tests (NORT). We show here that DEX does not cause neuronal cell death when used below 10 µM. Interestingly, DEX-exposed neurons showed an increased neuronal outgrowth, albeit with no differences in corresponding synaptic puncta formation. Furthermore, DEX resulted in a hyperfused mitochondrial network, occurring in a time-dependent manner, which also caused reduced ROS production. Subcutaneous DEX injections in rat pups did not alter the respiratory rate or oxygen saturation (SpO2). DEX did not impact locomotor skills, anxiety, or willingness to explore. Finally, DEX also did not affect spatial recognition and hippocampal-dependent memory. This study demonstrates the non-neurotoxic nature of DEX both *in vitro* and *in vivo* in an animal model providing support for its utility as a safer anesthetic agent.

Title: The timing of the GABA shift affects the postnatal development of inhibitory and excitatory synapses

Authors: *C. N. E. PEERBOOM, T. B. WIJNE, M. P. J. M. RIETER, N. L. JONKER, C. J. WIERENGA;
Utrecht Univ., Utrecht, Netherlands

Abstract: GABA signaling shifts from depolarizing to hyperpolarizing during the second postnatal week in rodents. The GABA shift results from a reduction in intracellular chloride concentration mediated by increased activity of the chloride exporter KCC2 relative to the chloride importer NKCC1. A delayed GABA shift has been observed in patients with autism spectrum disorder and in several mouse models for neurodevelopmental disorders. It is currently unclear whether a delayed GABA shift is cause or consequence for alterations in synaptic transmission observed in these mouse models.
Here we assessed the consequences of mistimed GABA shift on synapse development in hippocampal slice cultures. We first verified that in our slices GABA shifts between day in vitro (DIV) 2 and 22. We then set out to delay the GABA shift by blockingKCC2 with VU 0463271 or furosemide during DIV2-8 and assessed the consequences for inhibitory and excitatory postsynaptic currents (IPSCs and EPSCs) at DIV9 and DIV21. We used perforated patch clamp and the chloride indicator SuperClomeleon to assess GABA function and intracellular chloride levels. Blocking KCC2 with VU 0463271 resulted in a depolarizing GABA reversal potential at DIV8, which normalized at DIV20. Inhibitory signaling was not affected at DIV9. However, at DIV21, when chloride levels were restored, the frequency of spontaneous IPSCs was increased, while amplitudes were unaffected.
Unexpectedly, GABA became strongly hyperpolarizing at DIV 8 after DIV2-8 furosemide treatment. We observed a decrease in the frequency of spontaneous IPSCs at DIV9, which appears due to an activity dependent suppression of inhibitory transmission. We found that this was independent of BDNF or endocannabinoids. When chloride levels were restored at DIV 21, the frequency of spontaneous IPSCs and the amplitude of miniature IPSCs were increased. We are currently examining the effects of inhibiting KCC2 on excitatory transmission and spine development. Our results indicate that the timing of the GABA shift affects postnatal development and maturation of inhibitory synapses.

Title: Evidence for cell type specific local neuropeptide signaling from single-cell transcriptomes of forebrain neurons from four divergent tetrapods

Authors: *S. J. SMITH;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The primary function common to all neurons is communication with other neurons. This communication can take many forms, including synaptic transmission and slow neuromodulation via secreted neuropeptides (NPs). Because neurons are very diverse in the particulars of such communication, neuron type classification schemes have proven very useful in exploring the emergence of network function, behavior and cognition from individual neuronal communication links.
To shed light on the evolution and functional relevance of peptidergic modulatory signaling within local brain regions, I have analyzed published genome-wide single cell RNA-Seq transcriptomic datasets acquired from turtle pallium (Tosches MA Science 2018 10.1126/science.aar4237), songbird HVC and RA nuclei (Colquitt B Science 2021 10.1126/science.abd9704), mouse motor cortex (Yao Z Cell 2021 10.1016/j.cell.2021.04.021) and human motor cortex (Bakken T E bioRxiv 2020 10.1101/2020.03.31.016972). Samples in each dataset were similarly annotated by hierarchical neuron-type classification.
Quantitative analysis of these single-cell transcriptomes reveals that the vast majority of neurons sampled from each tetrapod express one or more genes encoding neuropeptide precursor proteins (NPPs) at exceptionally high levels and in highly cell-type-specific combinations. Virtually all cells sampled also showed diverse cell-type-specific expression of multiple neuropeptide-selective G protein-coupled receptor (NP-GPCR) genes at high levels.
Many of the NP-GPCR genes expressed with a given brain region are cognate in their neuropeptide selectivity to NPPs expressed within that same brain region, suggesting the likelihood of local, strictly paracrine neuropeptide signaling. This prospect is particularly compelling for the GABAergic neuron types, since most such neurons are relatively sparse and lack distant axonal projections, making distant actions of GABAergic-neuron peptide release unlikely. The extraordinarily high-levels of NPP gene transcription by GABAergic neurons nonetheless argue that the NP products must be secreted and play major significant adaptive roles in local neuronal neuromodulatory communication.
This poster illustrates all findings noted above and documents both similarities and differences in NP gene expression patterns amongst the varied forebrain regions studied. The many similarities, regardless of whether they result from evolutionary conservation or convergence, add to evidence that NP signaling has long been and remains of fundamental importance to all adaptive nervous system function (Jekely G Proc Roy Soc B 2021 10.1098/rstb.2019.0761)

Title: Peptidergic modulation of fear responses by the Edinger-Westphal nucleus

Authors: *M. F. PRIEST, S. N. FREDA, D. BADONG, V. DUMRONGPRECHACHAN, Y. KOZOROVITSKIY;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Many neuronal populations that release fast-acting excitatory and inhibitory neurotransmitters in the brain also contain slower acting neuropeptides. These facultative peptidergic cell types are common, but it remains uncertain whether obligate peptidergic neurons, which do not release canonical fast-acting neurotransmitters, exist. Our fluorescence in situ hybridization, genetically-targeted electron microscopy, and electrophysiological characterization data strongly suggest that neurons of the non-cholinergic, centrally-projecting Edinger-Westphal nucleus in mice are fundamentally obligately peptidergic. We further show, using fiber photometry, monosynaptic retrograde tracing, anterograde projection mapping, and a battery of behavioral assays, that the peptidergic Edinger-Westphal activates in response to threatening stimuli including loss of motor control, and that it promotes fear responses and analgesia. Together, these findings elucidate an integrative, ethologically relevant function for the Edinger-Westphal nucleus and functionally align the nucleus with the periaqueductal gray, where it resides. This work advances our understanding of the peptidergic modulation of fear and provides a framework for future investigations of putative obligate peptidergic systems.

Title: Human central cervical nucleus - chemoarchitecture and involvement in pain processing

Authors: *E. CANDAR[1], I. DEMIRCUBUK[2], G. SENGUL[3];
[1]Dept. of Neurosci., [2]Dept. of Anat., Ege Univ. Inst. of Hlth. Sci., Izmir, Turkey; [3]Ege Univ. Sch. Med., Izmir, Turkey

Abstract: Central cervical nucleus (CeCv), one of the precerebellar nuclei of the spinal cord, is located in upper cervical segments (C1-C4) and forms a column within the limits of lamina 7, adjacent to lamina 10. CeCv neurons receive afferents from neck muscles, joints of the neck, labyrinth, and project to the contralateral cerebellum via the superior cerebellar peduncle. CeCv has been shown in the cat, rat, mouse, rhesus monkey, marmoset and human. In this study, we performed an immunohistochemical analysis of neural markers for pain in the CeCv to investigate the role of this nucleus in pain processing. 10% formalin-fixed C1-C4 segments of the human spinal cord were cut on a cryostat at a thickness of 30 micrometers and stained using glutamate, GABA, substance P, calcitonin gene-related peptide, enkephalin, glycine, serotonin, acetylcholine and noradrenaline immunohistochemistry. We observed that all of these markers were found in CeCv neurons, indicating the involvement of this precerebellar nucleus in pain, in consonence with recent data building a general consensus that the cerebellum is involved in pain processing, although its specific role still remains unclear.

Title: Mu opioid receptor occupancy by intravenous naloxone in rat brain

Authors: *K. A. O'CONOR[1], Y. KANG[2], A. C. KELLEHER[1], A. BAKHODA[1], S. EISENBERG[1], J. RAMSEY[1], W. ZHAO[3], S. KIM[1], N. D. VOLKOW[3];
[1]Natl. Inst. on Alcoholism and Alcohol Abuse, Bethesda, MD; [2]Howard Univ., Washington, DC; [3]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: In recent years, the United States has seen a drastic rise in opioid overdose deaths that has been fueled by synthetic opioids (e.g. fentanyl, carfentanil) flooding the illicit drug market. These synthetic opioids pose a greater risk for overdose than heroin, and their reversal by naloxone (NLX) is much more challenging. Therefore, there is an urgent need to establish a reliable method for reversing opioid-induced respiratory depression. Though NLX has a high affinity for the mu opioid receptor (MOR), there have been concerns that it may be insufficient for displacing synthetic opioids or that its short half-life may result in renarcotization after a single dose administration. In this study, we assess [^{11}C]Carfentanil ([^{11}C]CFN) displacement by NLX and estimate MOR occupancy by NLX over time at clinically relevant doses using PET in rats. We show that NLX rapidly displaces [^{11}C]CFN from the brain and that MOR occupancy by NLX after 5 minutes is greater than 85% for 0.4 mg and 2.0 mg human equivalent doses (HED)). MOR occupancy by NLX decreased over time in a dose-dependent manner, with 50% occupancy

at 40 minutes for 0.4 mg HED and 80 minutes for 2.0 mg HED. Together, these results suggest that clinically relevant doses of intravenous NLX are effective for acute reversal of opioid overdose but may be insufficient in preventing renarcotization due to the abolishment of their MOR antagonism 60 minutes post-treatment which was faster at the lower 0.4 mg HED dose. Moving forward, it is necessary to establish a more reliable, long-lasting method for opioid overdose reversal.

Title: A novel role for the hypothalamic paraventricular nucleus in resuscitation from opioid-induced respiratory depression by fentanyl in the rat

Authors: *A. D. BRACKLEY, T. TRUONG, J. CONTRERAS, M. ANDRADE, G. M. TONEY; Cell. & Integrative Physiol., UT Hlth., San Antonio, TX

Abstract: Opioid receptor antagonists, like naloxone, are the gold standard for reversal of opioid-induced respiratory depression (OIRD). We recently found that systemic oxytocin reverses fentanyl OIRD in rats. Naloxone triggers a surge in oxytocin release from the hypothalamic paraventricular nucleus (PVN) in anesthetized rats. Given that naloxone induces PVN oxytocin release, we hypothesized that the PVN, an unrecognized brain region for opioid overdose reversal, is capable of respiratory resuscitation following fentanyl OIRD. Naloxone (5 mg/kg, i.v.) was given to conscious rats with indwelling venous catheters. Blood samples were extracted at 5 min post-naloxone to measure plasma oxytocin by ELISA. Systemic naloxone resulted in a surge in plasma oxytocin compared to vehicle in the conscious rat. Under anesthesia, phrenic nerve activity was recorded in vagotomized, paralyzed, and artificially ventilated rats to quantify inspiratory drive following fentanyl (60 nmol/kg, i.v.) and assess OIRD reversal potential following unilateral PVN nanoinjection of naloxone (3 nmol/kg, 50 nL) or vehicle (50 nL). Naloxone administration directly into the PVN both reversed and prevented OIRD by systemic fentanyl in the rat. To determine if stimulation of PVN oxytocin neurons is sufficient to counteract OIRD expired CO_2 was used to monitor rhythmic ventilation and to quantify bradypnea during OIRD in spontaneously breathing mice with channelrhodopsin expressed exclusively in oxytocin neurons. Following fentanyl OIRD, blue light (473 nm, 3.9 mW) pulses (10 ms, 20 Hz) or dummy pulses were delivered to the PVN using a 5 s On/1 s Off pattern for 3 min. Photostimulation of PVN oxytocin neurons prevented lethal effects of fentanyl OIRD, whereas dummy pulses failed to prevent lethal respiratory arrest in the mouse. Here, we

confirm that naloxone stimulates oxytocin neurons of the PVN and results in a surge of plasma oxytocin. PVN opioid receptor antagonism and photoactivation of PVN oxytocin neurons are individually capable of reversing OIRD. Findings also indicate that PVN oxytocin neurons, previously unrecognized in reversal of OIRD, are a novel target for resuscitation agents.

Title: Unique properties define subpopulations of dynorphin-containing neurons within the medial prefrontal cortex

Authors: *S. M. CASELLO, H. E. YARUR, H. WANG, Q. WANG, N. LOOMBA, H. A. TEJEDA; Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The medial prefrontal cortex (mPFC) plays an essential role in cognitive processing and regulation of emotion, sociability, and motivation. Dysfunction of the mPFC is associated with numerous neurological and psychiatric disorders including depression, anxiety disorder, schizophrenia, and addiction. These psychiatric disorders are characterized by overlapping symptom clusters, including anhedonia, cognitive deficits, and anxiety, which suggests common neurological circuitry is involved. The dynorphin (Dyn)/KOR system is highly expressed in the mPFC and is a prominent modulator of motivated behavior as well as highly implicated in stress-induced dysphoria and vulnerability to drug abuse. Although the Dyn/KOR system has been investigated in subcortical regions, our understanding of how it is embedded in mPFC networks is limited. Intricate organization of mPFC networks is crucial for proper function of these circuits, and characterizing dynorphin-containing neuron morphology and organization within in the mPFC is a necessary step to uncovering how the Dyn/KOR system shapes cortical circuits that underlie neuropsychiatric disorders. In this study, we used a combination of transgenic mice, viral tracing approaches, and ex-vivo electrophysiology to both anatomically and electrophysiologically characterize the neuronal populations that express dynorphin in the mPFC as well as elucidate their connectivity within cortical circuits. *In-situ* hybridization revealed dynorphin is predominately expressed in glutamatergic neurons and a subpopulation of GABAergic interneurons. Ex-vivo patch clamp recording confirmed that dynorphin neurons make excitatory and inhibitory

monosynaptic connections within mPFC circuitry. Investigation of excitatory dynorphin-containing neuronal long-range projections through use of both anterograde- and retrograde- viral tracing revealed outputs to the nucleus accumbens, basolateral amygdala, paraventricular nucleus of the thalamus, lateral hypothalamus, and ventral tegmental area. Further, neuronal arborization and branching patterns were investigated to identify morphological features of dynorphin-containing mPFC cell types. Uncovering the identity of mPFC dynorphin-containing neurons and the anatomical architecture of the Dyn/KOR system within the mPFC is a critical step in elucidating how dynorphin peptides shape cortical circuits that underlie neuropsychiatric disorders. Understanding this system within the mPFC may reveal therapeutic targets to treat symptoms associated with various neuropsychiatric disorders including depression, anxiety disorder, and schizophrenia.

Title: Ace-2-interacting domain of sars-cov-2 (aids) peptide attenuates spike s1 associated behavioral and neuronal implications in mice

Authors: *R. PAIDI, K. PAHAN;
Rush Univ. Med. Ctr., Chicago, IL

Abstract: Background Coronavirus disease 2019 (COVID-19) is a serious infectious illness caused by the virus strain severe acute respiratory syndrome coronavirus-2 (SARS CoV-2). Covid-19 patients are suffered from several brain difficulties, but the underlying mechanism is not clear. So far, there is no proper therapeutic strategy against Covid-19 and its complications on the brain. **Methods** Since SARS-CoV-2 binds to angiotensin-converting enzyme 2 (ACE2) for entering into host cells, to target COVID-19 from a therapeutic angle, we designed a hexapeptide corresponding to the ACE2-interacting domain of SARS-CoV-2 (AIDS) that inhibits the association between receptor-binding domain-containing spike S1 and ACE-2. Recombinant spike S1 was administered Intranasally for 14 days. Wild type and mutant AIDS peptide were administered post 5 days treatment of spike S1. Post two weeks treatment, we performed several behavioral assessment and biochemical evaluation **Results** Intranasal intoxication of C57/BL6 mice with recombinant SARS-CoV-2 spike S1 led to fever, increase in IL-6 in lungs as well as in the brain, and impairment in spatial learning memory functions and motor disabilities, mimicking some of the important symptoms of COVID-19. Intranasal treatment with wtAIDS, but not mAIDS, peptide reduced fever, enhanced locomotor functions, and cognitive and memory functions in SARS-CoV-2 spike S1-intoxicated mice. Our studies show wtAIDS peptide attenuates Spike S1 inducted cytokine levels in

the brain. **Conclusion** Our results illustrated that, selective targeting of ACE2-to-SARS-CoV-2 interaction by wtAIDS may be beneficial for COVID-19 associated memory and learning deficits via maintaining the cytokine levels

Title: Behavioural characterization of GRIN1 Y647S$^{+/-}$ patient variant mouse model

Authors: *M. T. SULLIVAN[1], K. INTSON[1], P. YAN[1], D. E. WATKINS-CHOW[2], S. Y. YUAN[1], D. J. STEVENS[1], V. C. RADBURN[1], W. J. PAVAN[2], A. J. RAMSEY[1];
[1]Pharmacol. & Toxicology, Univ. of Toronto, Toronto, ON, Canada; [2]Natl. Human Genome Res. Inst., Bethesda, MD

Abstract: Rationale: GRIN1 disorder is a neurodevelopmental disorder characterized by mutation to the GRIN1 gene; responsible for the genetic programming of the indispensable GluN1 subunit of NMDA receptors. Patients carrying a mutation in GRIN1 present with a large range of phenotypes of varying severity including developmental delay, intellectual disability, motor dysfunction and seizure. Cell-based assays give only partial information on the functional consequences of specific mutations and how they contribute to the individual's phenotype. Therefore, the study of mouse models carrying patient variants is necessary to fully understand the mechanisms disturbing the NMDA receptor in each mutation and to determine effective treatments for GRIN1 patients. Objectives: We aimed to characterize the behavioural profile of male and female adult mice heterozygous for the GRIN1 patient variant Y647S in domains of seizure, locomotor activity, stereotypy, social behavior, working memory and anxiety-like behaviour. Ultrasonic communication was characterized in Y647S$^{+/-}$ mice during early development.Results: Y647S$^{+/-}$ mice (n=10) displayed seizures and travelled increased distance in the open field test compared to wildtype mice (n=9). In the social interaction test, Y647S$^{+/-}$ mice spent significantly longer visiting the novel mouse compared to wildtype and while in the elevated plus maze, Y647S$^{+/-}$ mice spent a significantly larger percentage of time in the open arms. In the domains of stereotypy and working memory, Y647S$^{+/-}$ mice did not differ significantly from wildtype. Y647S$^{+/-}$ pups (post-natal day 6) displayed reduced latency to first USV call and made a greater overall number of calls compared to the wildtype pups. Conclusion: The present study demonstrates that Y647S$^{+/-}$ GRIN1 patient variant mice display a phenotype characterized by seizure, hyperlocomotion, increased sociability and reduced anxiety. These behaviours appear to closely align with the clinical symptoms of patients carrying the Y647S

variant. Ultimately, these results will provide the behavioural baseline for the investigation of treatments for GRIN1 patients harboring the Y647S variant and other individuals with GRIN1 disorder.

Title: Characterizing the impact of patient derived GRIN1 Y647S+/- mutation on cortical neurophysiology in a mouse model

Authors: *S. VENKATESAN[1], A. J. RAMSEY[2], E. K. LAMBE[1];
[1]Dept. of Physiol., [2]Dept. of Pharmacol. and Toxicology, Univ. of Toronto, Toronto, ON, Canada

Abstract: NMDA receptors (NMDARs) are essential for synaptic function, plasticity and enable supralinear integration of glutamatergic inputs to generate dendritic plateau potentials. *GRIN1* neurodevelopmental disorder is a rare genetic condition caused by *de novo* mutations in the *GRIN1* gene encoding the obligate GluN1 NMDAR subunit and is characterized by profound neurological deficits. The mechanisms underlying these deficits are unclear, as the consequences of various human *GRIN1* mutations on NMDAR function, dendritic integration and plasticity are unknown. Identifying the exact nature of NMDAR dysfunction can help determine the course of treatment for patients carrying the mutation. Here, we characterized the neurophysiological consequences of the patient derived *GRIN1* Y647S$^{+/-}$ mutation using transgenic mutant mice (*Grin1* Y647S$^{+/-}$) and wildtype littermate mice of both sexes. Patch clamp electrophysiology of layer 5 pyramidal neurons in the prefrontal cortex was used to examine different aspects of NMDA receptor functionality. We measured whole-cell currents evoked by bath application of NMDA as a gross measure of NMDAR activity and found them to be dramatically enhanced in the Y647S$^{+/-}$ mice. Ongoing work is examining synaptically-evoked NMDA EPSCs and NMDA dependent supralinear dendritic integration to identify synaptic and dendritic dysfunctions caused by Y647S$^{+/-}$. We are interested in how the Y647S$^{+/-}$ mutation affects integrated functioning of the NMDA receptor in close association with other synaptic ion channels and its consequences for synaptic integration and plasticity. Future work will test targeted drugs to rescue NMDAR signaling in these mice.

Title: Functional analysis of genetic variations in the cytosolic domain of NMDA receptors

Authors: *V. KUCHTIAK, E. TOMOVIC, L. VYKLICKY JR, A. BALIK;
Dept. of Cell. Neurophysiol., Inst. of Physiol. CAS, Prague, Czech Republic

Abstract: The function of the excitatory synapses depends on the expression and activity of ionotropic glutamate receptors, which include calcium-permeable NMDA receptors (NMDARs). NMDAR family is represented by three subunits, GluN1 (eight splice variants), GluN2 (isoforms A-D), and GluN3 (isoforms A-B). The receptor is composed of two obligatory GluN1 subunits and two subunits in different combinations of GluN2A-D and GluN3A-B. Each subunit consists of four domains: the extracellular amino-terminal, ligand-binding domains, the transmembrane domain, and the intracellular C-terminal domain (CTD). CTD has the lowest homology between NMDAR subunits and represents up to half of the entire NMDAR subunit (GluN2A/B), which indicates the functional consequences for the receptor. Indeed, CTD of the NMDAR is essential for many of its properties such as trafficking of receptor to synapses, endocytosis, and subsequent degradation of the receptor. The direct effect of CTD on the functional properties of the NMDAR ion channel has been also shown. CTD interacts with several intracellular proteins such as cytoskeletal proteins, scaffold proteins, or proteins involved in intracellular signalling. In addition to protein binding, CTD is a target of numerous post-translational modifications regulating the functional properties of the receptor. Amino acid mutations in the cytosolic part of NMDAR subunits have been found in individuals with various neurological impairments. These mutations could then contribute to the emergence and development of the disorder. We employed electrophysiological measurements and microscopy analysis to study the impact of 6 diseases associated mutations (schizophrenia, epilepsy) found in the CTD of GluN2A/B subunits. We analysed the ion channel properties, changes in the surface expression, and trafficking to synapses. Our results suggest that mutations in CTD affect ion channel properties, such as glutamate potentiation and open channel probability. The majority of the mutations we studied have decreased surface expression and receptor trafficking to the synapses. Among the mutations studied, the mutation V967L in the CTD of the GluN2A subunit led to the most significant changes, such as a 30% reduction in surface expression and synaptic localization. In summary, we showed that genetic changes in the intracellular domain of the NMDA receptor altered the functions of the receptor especially impairing its delivery to the cell surface and synaptic localization that might induce hypofunction of NMDAR signalling and thus contribute to the emergence of neurological disorders.

Title: Lupus auto-antibodies relieve zinc inhibition to positive modulate NMDA receptor currents

Authors: *J. GUPTA[1], L. P. WOLLMUTH[2];
[1]Stony Brook University, Stony Brook, NY, United States, Stony Brook, NY; [2]Neurobiol & Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Systemic Lupus Erythematosus (SLE) is an autoimmune disease that affects nearly 1.6 million Americans, primarily women and minorities. Up to 50% of patients with SLE experience neuropsychiatric symptoms such as amnesia, cognitive fatigue, and impaired concentration clinically referred to as Neuropsychiatric Lupus (NPSLE) and colloquially referred to as “brain fog”. In SLE, a subset of double stranded DNA reactive autoantibodies (DNRAbs) cross reacts with the amino terminal domain (ATD) of NMDA receptors (NMDARs), directly implicating this excitatory ion channel in SLE neuropathology. Specifically, DNRAbs interact with the DWEYS structural motif within the hinge region of the bilobed ATD. DNRAbs bind to NMDARs containing GluN2A and GluN2B subunits, but we recently demonstrated that G11, a patient derived monoclonal DNRAb, preferentially acts on GluN2A-containing NMDARs as a positive allosteric modulator (PAM). The PAM action of G11 increases NMDAR response to agonist and may impair spatial memory. However, a mechanistic understanding of the interaction between DNRAbs and GluN2A-containing NMDARs that mediates this positive allostery is unknown. We propose that the DNRAb-NMDAR interaction facilitates greater NMDAR currents by opposing the action of zinc, a negative allosteric modulator (NAM) of NMDARs that also acts at the ATD. Consistent with this idea, preliminary data indicates that positive allostery induced by DNRAbs is strongly reduced in the absence of Zn2+. We are quantitatively determining the reduction of positive allostery by DNRAbs by (i) assaying zinc response curves of GluN2A and GluN2B containing NMDARs using whole-cell electrophysiology and (ii) determining how the open or closed conformation of the ATD impacts the extent of allostery. With this data we can begin to understand the interaction between DNRAbs and zinc at the ATD binding site.

Title: The GluN2A Subunit of the NMDA Receptor Modulates the Rate of Functional Maturation in Parvalbumin-positive Interneurons

Authors: *C. CAMP[1], L. SHAPIRO[1], A. HANCOCK[3], A. VLACHOS[3], R. E. PERSZYK[1], N. SHARIATZADEH[1], A. ESCAYG[2], S. KOH[4], C. MCBAIN[3], K. A. PELKEY[3], S. F. TRAYNELIS[1]; [1]Pharmacol. and Chem. Biol., [2]Human Genet., Emory Univ., Atlanta, GA; [3]Section on Cell. and Synaptic Physiol., NIH, Bethesda, MD; [4]Ohama Children's Ctr., Univ. of Nebraska Med. Ctr., Ohama, NE

Abstract: N-methyl-D-aspartate receptors are glutamate-gated, calcium-permeable ion channels involved in a host of normal brain functions, including neuronal development. Traditionally, the GluN2A subunit, encoded by the *GRIN2A* gene, is thought to signal brain and circuit maturation, given its unique expression pattern where transcripts are low embryonically and then significantly increase during preadolescence. Advances in whole exome sequencing have identified mutations in the *GRIN2A* gene to be causal to several neuropathological diseases, including epilepsy and intellectual delay. More specifically, 56% of *GRIN2A* mutations are loss-of-function (LoF) , displaying diminished receptor function and/or surface expression, with *Grin2a*$^{-/-}$ mice have been reported as having signatures of epileptiform activity. However, little is understood regarding GluN2A's impact on neurodevelopmental and how its absence may impact the GABAergic interneuron network. Our data show that *Grin2a* $^{-/-}$ mice contain 33% more parvalbumin^{+} interneurons in the hippocampal CA1 region during preadolescence and adulthood. This increase in GABAergic interneuron cell density appears to be unique to parvalbumin^{+} cells, as cholecystokinin^{+} and somatostatin^{+} interneurons are unchanged across *Grin2a*$^{-/-}$ and wildtype mice. Despite an increased cell count, colocalization staining for parvalbumin^{+} synaptic densities and measures of parvalbumin cell-specific tonic inhibition remains unchanged in preadolescence and increases as the animal ages, suggesting delayed maturation. In addition, parvalbumin^{+} cells from preadolescent *Grin2a*$^{-/-}$ mice exhibit immature intrinsic and firing properties, such as an increased membrane time constant and input resistance, lower threshold for depolarization-induced block, and longer action potential half-widths than age-matched WT controls, all of which become corrected in adulthood. The sum of these data suggest that the GluN2A subunit is involved in promoting cues for interneuron apoptosis during development, as well as influencing the rate of parvalbumin^{+} cell functional maturation. The ramifications of these abnormalities are still underexplored, but likely generate a vulnerability time window during preadolescence in which an epileptiform network can manifest. Viral strategies aimed at reintroduction of the *GRIN2A* gene during this critical time window could represent a viable gene therapy option for LoF *GRIN2A* patients.

Title: Hidden intermediate states of NMDAR in synapse dynamics

Authors: *M. HE[1], L. P. WOLLMUTH[2];
[1]Biochem. and Cell Biol., [2]Neurobiol & Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: NMDA receptors (NMDARs) are ionotropic glutamate receptors that mediate fast synaptic transmission and the synaptic plasticity underlying learning and memory. Dysfunction of NMDARs contributes to numerous neurological diseases including Alzheimer's disease, intellectual disability, epilepsy, autism spectrum disorder, and schizophrenia. NMDARs are obligate hetero-tetramers, formed by two glycine-binding GluN1 subunits and typically two glutamate-binding GluN2(A-D) subunits. A key function of NMDARs at synapses is to efficiently convert transient presynaptically released glutamate into opening of the ion channel pore, a process referred to as gating. Previously, we applied glutamate to outside-out patches containing single NMDARs. This approach is revealing since it shows underlying gating details that are not seen either with whole-cell or steady-state single channel patches. We found that glutamate applications to GluN1/GluN2A channels, which were fully saturated with agonist, resulted in either failures (no current) or successes (single channel currents) with successes occurring through two distinct intermediate pathways : rapidly after agonist binding (fast component) or with a considerable delay (slow component). These various pathways are important for synaptic transmission since they will determine how strongly the channel contributes to fast synaptic signaling. The mechanistic basis of failures and how physiological factors such as pH and Zn^{2+} affect these components is unknown. In terms of failures, one possibility is that they reflect that the channel did not recover from desensitization that arose with the prior glutamate application. However, as we increase the wait time between applications (from 4 to 10 seconds), failure rates are not decreased or eliminated. In contrast to GluN2A-containing NMDARs, which have a high open probability, diheteromeric NMDARs containing GluN2B, GluN2C, or GluN2D have a much lower open probability yet the pathways these receptors take to reach channel activation are unknown. We propose that GluN2(A-D) use the same conformational intermediates as GluN2A-containing receptors but differ in their ability to enter into the intermediate pathways. We will therefore address subunit-specificity of the failures and pathways, as well as physiological factors, such as pH and Zn^{2+}. These experiments will allow us to understand the functional diversity of NMDAR subtypes, which is also critical to unraveling the basis for neurological diseases.

Title: Direct visualization of triheteromeric NMDA receptors

Authors: *M. ANDERSON[1], A. NIGAM[2], J. W. JOHNSON[2], T. A. BLANPIED[1];
[1]Dept. of Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Glutamatergic signaling via NMDA receptors (NMDARs) is critical in synaptic plasticity, brain development, excitotoxicity, and numerous degenerative and cognitive disorders. Each functional NMDAR comprises four subunits: two obligatory GluN1 subunits and two GluN2A-D or GluN3A-B subunits. Importantly, NMDARs with different GluN2 subunit compositions display strikingly different biophysical characteristics, and the GluN2 subunits also control unique protein interactions and signaling. Accordingly, the physiological characteristics of excitatory synaptic transmission and plasticity, as well as synaptic pathology, depend on the NMDAR subtypes expressed and trafficked to synapses. Thus, identifying how neurons control abundance of specific NMDAR subtypes has been a longstanding goal in neuroscience. Unfortunately, our understanding of these mechanisms has been crucially restricted by inability to visualize one of the key classes of NMDARs in neurons, triheteromeric receptors that contain GluN1 and two different GluN2 subunits. Indeed, in many parts of the brain including the hippocampus, triheteromeric NMDARs containing both GluN2A and GluN2B subunits are the most common NMDAR subtype. However, the subcellular distribution of triheteromeric NMDARs remains mysterious and the mechanisms controlling their trafficking to and from synapses remain almost totally unknown. Here, we introduce a new method for direct visualization of triheteromeric NMDARs in neurons using biomolecular complementation. We tagged the N-termini of GluN2A and GluN2B subunits with two components of split fluorescent proteins or of a split HaloTag enzyme that is catalytically active only when the two parts are brought within close proximity. Thus, after transfection of these tagged subunits, standard fluorescent imaging can be used to detect specifically NMDARs containing both GluN2A and GluN2B subunits in a single receptor complex. Whole-cell recordings demonstrate that activation of split-tagged NMDARs by glutamate is unaltered by the presence of the tags. Further, the split-tagged subunits do not undergo detectable interreceptor complementation, and neurons expressing the complementing receptor subunits displayed no morphological abnormalities. Using this tool, we find that triheteromeric receptors traffic avidly to synapses and display unique subcellular trafficking characteristics. These probes will fill longstanding gaps in our knowledge of NMDARs and lay necessary groundwork for investigation of other aspects of triheteromeric NMDAR trafficking in healthy neurons and disease models.

Title: Regulation of NMDA receptor channel block by intracellular calcium

Authors: *M. B. PHILLIPS[1,2], N. V. POVYSHEVA[1], J. W. JOHNSON[1];
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Neurosci. Inst., New York Univ. Langone Hlth., New York, NY

Abstract: N-methyl-D-aspartate receptors (NMDARs) are key mediators of neuronal Ca^{2+} influx. NMDAR-mediated Ca^{2+} influx plays a central role in synaptogenesis, synaptic plasticity, dendritic integration, and neuronal survival. However, excessive NMDAR activity can lead to buildup of pathological levels of Ca^{2+} inside neurons, which initiates cellular signaling pathways that result in neuronal death. Thus, NMDAR antagonists, particularly NMDAR channel blockers, remain a subject of great clinical interest. The NMDAR channel blocker memantine is a well-tolerated Alzheimer's disease medication that also shows promise in treatment of other neurological disorders. Interestingly, memantine enhances desensitization of NMDARs by stabilizing a Ca^{2+}-dependent desensitized receptor state. Consequently, memantine inhibits NMDARs more effectively in conditions that allow for increased influx and intracellular accumulation of Ca^{2+}. These features could allow memantine to preferentially target overactive NMDAR subpopulations, i.e., NMDARs in cells subjected to pathological Ca^{2+} influx. Here we systematically examine the effect of intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) on NMDAR inhibition by memantine. Utilizing specially designed Ca^{2+}-buffering solutions and whole-cell patch-clamp recordings, we demonstrated that NMDAR channel block by memantine is directly related to $[Ca^{2+}]_i$, with memantine IC_{50} decreasing as $[Ca^{2+}]_i$ increases. IC_{50}s for the prototypical NMDAR channel blocker Mg^{2+} and another clinically important organic channel blocker, ketamine, were found to be unaffected by changes in $[Ca^{2+}]_i$. Interestingly, although we show that $[Ca^{2+}]_i$ increases desensitization of both GluN1/2A and GluN1/2B receptors, $[Ca^{2+}]_i$ only affects memantine inhibition of NMDARs containing the GluN2A subunit. Memantine IC_{50} measurements in cultured primary cortical neurons revealed that memantine inhibition of native NMDARs also depends on $[Ca^{2+}]_i$. Our experiments show that memantine inhibition of GluN1/2A receptors is dynamically regulated by fluctuations of $[Ca^{2+}]_i$ across both physiological and pathological ranges, and that memantine inhibition of a mixed population of native NMDARs containing both GluN2A- and GluN2B-containing receptors is $[Ca^{2+}]_i$ dependent. Thus, the $[Ca^{2+}]_i$ dependence of NMDAR inhibition by memantine has the potential to profoundly impact the effects of memantine on neuronal function.

Title: Characterization of light-sensitive NMDA receptor positive allosteric modulators

Authors: *Y. GE[1], Z. ZHANG[2,3], Y. WANG[1], A. WOOLLEY[2], M. DONG[2,4];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Univ. of Toronto, Toronto, ON, Canada; [3]East China Univ. of Sci. and Technol., Shanghai, China; [4]Qingdao Univ., Qingdao, China

Abstract: Light-switchable compounds are critical research tools for regulating receptor activity with a high degree of temporal and spatial specificity. Currently, there is no light-switchable modulator for N-methyl-d-aspartate glutamate receptors (NMDAR) ion channels, which are important drug targets for many central nervous system disorders. Our previous virtual screening approach identified several NMDAR positive allosteric modulators (PAMs), some of which contained an arylhydrazone backbone that can undergo E/Z isomerization under appropriate conditions. In this study, we investigated and optimized the photo-isomerization properties of several NMDAR PAMs as reversible photo switches. Combining analytical chemistry approaches and electrophysiology recordings of the HEK293 cells transiently expressing rat NMDARs containing GluN1/GluN2A or GluN1/GluN2B subunits, we found that two of the arylhydrazones compounds readily undergo *E*-to-*Z* isomerization under blue light, resulting in over 50-fold less potency in modulating the currents gated through two prominent NMDAR subtypes. To further optimize their photoswitchability, we characterized another compound HILKOD that undergoes both *E*-to-*Z* and the reversible *Z*-to-*E* isomerization using blue light and UV light, respectively. The two isomers also have substantially different bioactivities on NMDARs. We concluded that arylhydrazone compounds can be effective photo switches for NMDARs, and further optimizing these compounds may result in highly effective research tools for manipulating the physiological activities of NMDARs.

Title: NMDA receptor subtype dependence and kinetics of membrane to channel inhibition by (+)-MK-801

Authors: *A. NIGAM[1], M. WILCOX[2], J. W. JOHNSON[1];
[1]Dept. of Neurosci. and Ctr. for Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Jakob and Partners Consulting, Miami, FL

Abstract: MK-801 is a high-affinity NMDAR channel blocking antagonist. It is now widely used as a crucial research tool to investigate NMDAR properties and their contributions to synaptic transmission. Investigation of NMDAR channel blocking drugs such as MK-801 and memantine (approved by the FDA for treatment of Alzheimer's disease) also has broad therapeutic implications. NMDARs are highly calcium permeable tetrameric ionotropic glutamate receptors that are formed by pairing two GluN1 subunits with two GluN2 (A-D) and/or GluN3 (A-B) subunits. NMDAR channel blockers act by blocking ion flow at a site in the ion channel (the "deep site"). Glasgow et.al. (2018, Neuropharm 137, 344) showed that memantine can access the deep site via two paths: the traditional channel blocking path from the extracellular solution, or by associating with a "second site" from which memantine can transit to the deep site following NMDAR activation. We recently found that the second site is actually a reservoir of drug molecules located in the cell membrane; we thus renamed the phenomenon "membrane to channel inhibition" (MCI). Here we investigate MCI by MK-801 using tsA201 cells transfected to express NMDARs. We measured MCI concentration-inhibition curves for the GluN1/2A - GluN1/2D NMDAR subtypes. To ensure that MK-801 could not block NMDARs from the extracellular solution, we applied MK-801 in the absence of glutamate; removed MK-801 from the extracellular solution; applied 1 mM glutamate (all solutions contained 100 µM glycine); measured the minimum NMDAR-mediated current relative to control current (I_{MCI}/I_{Con}). We found that at -65 mV, the MK-801 MCI IC_{50} of GluN1/2A receptors (0.85 ± 0.04 µM) was not significantly different from the MCI IC_{50} of GluN1/2B receptors (0.67± 0.16 µM). Interestingly, we did not observe MCI following application of MK-801 at concentrations up to 10 µM to GluN1/2C or GluN1/2D receptors. We also examined the time course of MCI onset (τ_M) following application of 1 µM MK-801 and found that τ_M for GluN1/2A receptors (0.93 ± 0.03 s) was significantly different from τ_M for GluN1/2B receptors (1.20 ± 0.05 s). To determine the time course of MK-801 exit from the membrane we varied the time between termination of MK-801 application and glutamate application. Using GluN1/2A receptors and 10 µM MK-801, we found that MK-801 exits the membrane with a time constant of 7.06 ± 1.1 s, reflecting much slower kinetics than memantine. Overall, MK-801 MCI exhibits NMDAR subtype dependence and kinetic properties that shed light on the wide range of MCI characteristics that can be exhibited by NMDAR channel blockers.

Title: Controlling excitotoxicity and stabilizing serial activation of ionotropic glutamate receptors for a robust automated patch clamp assay

Authors: *A. YEHIA;
Fluxion Biosci., Alameda, CA

Abstract: A robust ligand gated assay depends on the serial activation of the receptor forming a repeating, consistent and stable response. This is a major requirement for all manual and automated patch clamp studies of said receptors. Considering the effects of lingering agonists and activators on ligand-gated receptors, a complete and continuous extracellular solution replacement is key in the success of these assays. Ionotropic glutamate receptors such as NMDA receptors, when expressed in HEK293 cells, can lead to excitotoxicity of the host cells due to circulating natural agonists from neighboring cells. Hence, when expressed and activated, channel blockers are added to prevent excessive cell death. Although possible with manual patch clamp, effective in-assay removal of these blockers and natural agonists can pose a challenge to most automated system with high dependencies on external liquid handlers. Here we demonstrate how a unique in-assay solution exchange can alleviate most of these assay challenges with a continuous flow of wash solutions, providing a foundation for a consistent high throughput drug screening of ionotropic glutamate receptors. Data from glutamate receptors such as NMDA Receptors (NR2A/B/D) under various conditions of protective block will be presented.

Title: Molecular Mechanisms of intrinsic excitability and axon initial segment plasticity

Authors: G. D. VITELLI[1], A. ISHAQ[1], W. BREW[2], **A. R. MOORE**[1];
[1]Biol., [2]Temple Univ., Philadelphia, PA

Abstract: Proper neuronal function is dependent on the brain's ability to produce stable high-quality output yet remain flexible in an ever-changing environment, a phenomenon commonly referred to as neural plasticity. At the cellular level, changes in external cues, such as experience or perturbation, lead to homeostatic adjustments of either the synaptic connectivity between neurons, the intrinsic electrical properties of individual neurons, or both in order to maintain balanced network activity. When these processes are disrupted stability cannot be maintained and long-term undesirable neurological consequences. An emerging feature in mental health disorders is a change in axon initial segment morphology and neuron excitability. Once thought to be a static structure, the axon initial segment has now been observed to be highly dynamic during development, in response to activity-dependent changes, and in disease. More specifically, an increase in neuronal activity can lead to a decrease in AIS length, whereas a decrease in activity can lead to an increase in AIS length. These structural changes allow the

neuron to maintain its activity within a given range, or setpoint, and can occur on a time scale of hours to days. However, despite the importance of AIS plasticity on neuronal excitability, the underlying molecular mechanisms regulating AIS length in response to neuronal activity remain largely unexplored. Recently, we identified the small Ras-like GTPase, Rem2, as an activity-dependent negative regulator of intrinsic excitability. More specifically, acute deletion of Rem2 leads to a significant increase in neuronal firing rate, independent of synaptic changes. In an effort to understand the contribution of intrinsic excitability changes in the context of Rem2, we examined the axon initial segment length following Rem2 knockdown in primary neuron cultures. We found that knockdown of Rem2 leads to a significant reduction in axon initial segment length and a proximal shift of the axon initial segment from the soma compared to control neurons. This data suggests, that Rem2 may play a role in regulating axon initial segment morphology and plasticity.

Title: Thalamocortical neuron firing & circuit maturity is dependent on the expression of the transcription factor, Shox2

Authors: *I. FEBBO[1], V. WARKINS[1], A. J. SULLIVAN[1], N. VARGAS[1], L. A. SCHRADER[2];
[2]Cell & Mol. Biol., [1]Tulane Univ., New Orleans, LA

Abstract: Thalamocortical circuitry is central to the generation of sensory perception, disruptions of which have been linked to sensory perception disorders, such as autism, schizophrenia, and specific epilepsies. Thalamocortical neurons (TCNs) integrally support proper function of this circuit through tightly regulated firing activity and connectivity. While it is understood that TCNs send primary relay processes from the thalamus to sensory cortex and possess pacemaker capabilities, which are generated primarily by T-type and HCN current interplay, the transcriptional and epigenetic factors that are important for generation of these properties are unknown. Our lab has discovered that the transcription factor, Shox2, is highly expressed in the thalamus and important for expression of multiple ion channels in TCNs. Global Shox2 KO mice present with somatosensory deficits, their TCNs have reduced T-type and HCN currents, and the mRNA and proteins that mediate the expression of the channels that generate these currents are significantly reduced within the thalamus. To further characterize Shox2-expressing neurons and determine whether expression of Shox2 plays an integral role in their capacity to function properly within the thalamocortical circuit, we performed stereotaxic injections of GFP-cre virus into the somatosensory nucleus of the thalamus—ventrobasal (VB)—of Shox2fl/fl mice, creating a VB-targeted KO in GFP labeled Shox2 TCNs. Patch clamp electrophysiology analysis of Shox2 KO TCNs revealed an immature firing phenotype, increased input resistance and reduced T-type current compared to control

neurons. Further, whisker somatomotor function was impaired, and VB-specific Shox2 KO at PND6 disrupted cortical barrel formation. Altogether, these data show that Shox2 mediates TCN capacity to generate burst firing activity and integrate into the thalamocortical circuit, and presents as a target to further investigate for TCN maturation and function within TC circuitry.

Frankfurt, Frankfurt, Germany

Abstract: We have recently shown that 1-(2,4-xylyl)guanidinium (XG), previously reported to be a blocker of gating pore currents, also inhibits the slow pacemaking of midbrain dopaminergic (DA) neurons (Jehasse *et al*., SFN abstract, 2019 ; Jehasse *et al*., Neuropharmacology, in the press). Further work was carried out to characterize this effect and try to determine the molecular target of XG. The inhibitory effect of XG was very reproducible throughout the midbrain: all slowly pacemaking DA neurons were inhibited by the drug at similar concentrations (IC_{50} around 400 µM). Since the carbonate salt of XG is not very water-soluble, we developed another salt (a mesylate) of XG, which is much easier to use, and which produced the same effect. Interestingly, XG was equieffective when applied inside DA neurons. A closely related molecule, 2-guanidinobenzimidazole, which had been shown to block the Hv1 proton channel, was much less effective, suggesting that the steric constraints for binding to the target of XG are rather strict. In voltage clamp, using the so-called pacemaker clamp technique, we could isolate a small inward XG-sensitive current operating near the threshold of the action potential. This current did not have the properties of a typical gating pore current. Using ion-substitution experiments, we found that the XG-sensitive conductance is carried both by Na^+ and Cl^-, with some competition between these two ion species. The dopamine transporter could be excluded as a target for XG. In addition, XG had no effect

on the biophysical properties of I_A and I_h. We finally asked whether the current could be due to editing of a transmembrane domain of an ion channel species. We found no molecular evidence for such editing in rat substantia nigra. Moreover, the pacemaking of these neurons was identical in WT mice and in Adar2(-/-) Gria2(R/R) mice, ADAR-2 being the main source of RNA editing in mammalian cells. In summary, our data shows that XG inhibits slow pacemaking of DA neurons by blocking a yet to discover membrane protein target which does not need RNA editing to be functional.

Title: Activation of vasopressin 1A receptors excites Type III/CRF neurons of the bed nucleus of the stria terminalis (BNST)

Authors: *W. FRANCESCONI, F. BERTON, S. H. OLSON, J. DABROWSKA;
Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

Abstract: The bed nucleus of the stria terminalis (BNST) has emerged as a key brain region translating an exposure to unpredictable threats into sustained fear. In rats, dorsolateral BNST ($BNST_{DL}$) contains three types of neurons functionally classified as Type I, II, and III. The $BNST_{DL}$ is innervated by oxytocin (OT) and vasopressin (AVP) fibers and has high expression of OT (OTR) and AVP receptors (V1aR), but the roles of OTR and V1aR in the modulation of $BNST_{DL}$ activity remains elusive. Hence, we used *in vitro* patch clamp electrophysiology to determine if OTR or V1aR activation affects $BNST_{DL}$ activity in a cell-type specific manner. We recently demonstrated that OT directly increases the excitability and spontaneous firing of Type I neurons, indirectly inhibits the spontaneous firing of Type II neurons, whereas it reduces GABA-ergic inhibition in Type III $BNST_{DL}$ neurons, all in the OTR-dependent manner (Francesconi et al., 2021). Here, we demonstrate that application of AVP (0.2 μM) directly excites two types of $BNST_{DL}$ neurons, Type I neurons via OTR-dependent mechanism and Type III $BNST_{DL}$ neurons via V1aR-dependent fashion. In Type I neurons, AVP induced a leftward shift of input/output relationship, demonstrating a significant increment of steady state frequency of firing (SSF, $F(5, 42) = 9.471$, $P<0.0001$, n=9), which was blocked by OTR antagonist (d(CH2)5(1), D-Tyr(2), Thr(4), Orn(8), des-Gly-NH2(9)]-Vasotocin). In Type III neurons, AVP also induced a leftward shift of input/output relationship ($F(1, 23) = 95.14$, $P<0.0001$, n=6), which was blocked by selective and potent V1aR antagonist ($d(CH_2)_5^1$,$Tyr(Me)^2$,Arg^8)-Vasopressin). Notably, in the presence of the V1aR antagonist, Type III neurons remained silent and did not fire unless injected with current of 110 pA or more. Lastly, since Type III $BNST_{DL}$ neurons are putative corticotropin-releasing factor (CRF) neurons of the $BNST_{DL}$, we recorded the effects of AVP from CRF-$BNST_{DL}$ neurons of Cre-CRF transgenic rats (Cre-recombinase

under CRF promoter) injected with Cre-dependent AAV-mCherry into the $BNST_{DL}$. We identified the CRF-mCherry neurons as Type III and we show that AVP has a trend in exciting these Type III/CRF neurons. Our results demonstrate that whereas OTR activation reduces GABA-ergic inhibition in Type III neurons, V1aR activation directly excites Type III/CRF neurons of the $BNST_{DL}$. As CRF-$BNST_{DL}$ neurons were shown to mediate sustained fear, our results imply that V1aR activation in the $BNST_{DL}$ plays an important role in mediating this behavior.

Title: Histamine H_2 receptor activation enhances excitability of medium spiny neurons in the nucleus accumbens

Authors: G. ACETO[1], L. NARDELLA[2], C. COLUSSI[3], V. PECCI[2], S. NANNI[2,1], C. GRASSI[2,1], ***M. D'ASCENZO**[2,1];
[1]Fondazione Policlinico Universitario A. Gemelli IRCCS, Rome, Italy; [2]Univ. Cattolica del Sacro Cuore, Rome, Italy; [3]Natl. Res. Council, Rome, Italy

Abstract: Histaminergic neurons are exclusively located in the hypothalamic tuberomammillary nucleus, from where they project to many brain areas including the nucleus accumbens (NAc). The NAc integrates diverse monoaminergic inputs to coordinate motivated behavior. While the NAc express various histamine (HA) receptor subtypes, mechanisms by which HA modulates intrinsic excitability of medium spiny neurons (MSNs) in the NAc are still poorly understood. Using whole-cell patch-clamp recordings we found that pharmacological activation of postsynaptic H_2 receptors elevates the excitability of MSNs. The evoked firing of MSNs increased after seconds of local H2 agonist administration and remained elevated for minutes. Consistent with the negative modulation of A-type K^+ currents, H_2 receptor activation accelerated subthreshold depolarization in response to current injection, reduced the latency to fire, and diminished action potential afterhyperpolarization. The increased excitability was protein kinase A-dependent and associated with decreased A-type K^+ currents measured in voltage-clamp configuration. Furthermore, selective pharmacological inhibition of the Kv4.2 channel, the main molecular determinant of A-type K^+ currents in MSNs, mimicked the increased excitability induced by H2R activation. Together, our findings indicate that histaminergic transmission in the NAc increases MSN intrinsic excitability through H_2 receptor-dependent modulation of Kv4.2 channels.

Title: Mitochondrial Ca^{2+} uptake by the MCU controls activity-evoked changes in Ca^{2+}-dependent excitability and energy metabolism in pyramidal neurons.

Authors: *C. GROTEN[1], B. A. MACVICAR[2];
[2]Ctr. for Brain Health/Psychiatry, [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Mitochondrial Ca^{2+} uptake via mitochondrial Ca^{2+} uniporter (MCU) is implicated in the regulation of mitochondrial functions and brain activity by its control of energy metabolism, Ca^{2+} signaling, ROS generation, and apoptotic signaling. Despite this, the involvement of this process in pyramidal neurons during action potential firing has not been clearly defined. To address this, we determined the relationship between spiking frequency and mitochondrial Ca^{2+} uptake in cortical and hippocampal pyramidal neurons ex vivo using simultaneous electrophysiology and two-photon microscopy. We then examined how mitochondrial Ca^{2+} uptake was linked to activity-evoked changes in metabolism, cytoplasmic Ca^{2+} signaling, and excitability. Current-clamp recordings from single cortical pyramidal neurons expressing the genetically-encoded mitochondrial Ca^{2+} reporter, mitoRGECO1.0, revealed a firing frequency threshold (5 Hz) above which a long-lasting change in the Ca^{2+} content of somato-dendritic mitochondria was observed. Such responses were also noted during stimuli which mimic endogenous firing patterns and were blocked by inhibiting the MCU using Ru360. The coupling between spike firing and mitochondrial Ca^{2+} uptake also varied between brain regions, with hippocampal neurons being more responsive than cortical neurons. Examination of neuronal metabolism with NAD(P)H autofluorescence demonstrated that changes in NADH consumption and generation associated with high frequency firing were strongly governed by the MCU. Additionally, blocking the MCU with Ru360 substantially enhanced the magnitude and duration of cytosolic Ca^{2+} signals, but only at firing frequencies above 5 Hz. This increase in cytosolic Ca^{2+} in the absence of MCU function resulted in an enlargement of the spike-evoked afterhyperpolarization and its associated membrane current, indicating that mitochondrial Ca^{2+} uptake reduces the Ca^{2+}-dependent activation of K^+ channels. Collectively, our results reveal that MCU-dependent mitochondrial Ca^{2+} uptake occurs in response to high frequency action potential firing to facilitate energy metabolism and reduce the negative feedback control of excitability in pyramidal neurons. We propose that MCU-dependent mitochondrial Ca^{2+} uptake can act through these mechanisms to facilitate pyramidal neuron function during the critical brain processes associated with high frequency signaling.

Abstract: Mitochondrial Ca2+ uptake through the mitochondrial calcium uniporter (MCU) facilitate synaptic energy homeostasis and shape synaptic transmission. As MCU plays a vital role in bioenergetics, signal transduction, its dysfunction is related to many neurodegenerative diseases. Inhibition of MCU is a novel therapeutic strategy for neurodegenerative disorders. Ru265 is a new, selective, cell-permeable ruthenium complex and highly potent with respect to MCU inhibition. Treatment with RU265 reduces Hypoxic/Ischemic-induced sensorimotor deficits and brain injury. However, higher doses of Ru265 can increase the frequency and duration of seizure-like behaviors, which result in undesirable side effects. In this study, we report an asynchronous neurotransmitter release at synapses caused by Ru265. Whole-cell patch-clamp voltage recordings from postsynaptic MNTB principal neurons, which receive excitatory inputs from the calyx of Held, show that treatment with Ru265 elicits high-frequency of big events on synaptic spontaneous activity, and increased asynchronous release following a high-frequency (300 Hz) stimulus train. While increased asynchronous transmission following high frequency activity is suggestive of increased Ca2+ load in the terminal and impaired mitochondrial Ca2+ uptake, spontaneous synchronized synaptic transmission may be due to a second, independent mechanism. Acute viral perturbation was used to eliminate MCU expression at calyx terminal to determine the extent to which the MCU contributes to asynchronous release, and to test for off-target effects of Ru265. Similar experiments to test for spontaneous activity due to Ru265 are being conducted in primary neuronal cultures, where MCU has been deleted. Our study provides mechanistic insight into the off-target effect of Ru265 by determining other potential cellular targets in addition to MCU in electrically excitable cells. Result from this study will also support the therapeutic potential of MCU inhibition in the treatment of ischemic/reperfusion brain injury, and assist in design and validation of future compounds to engage MCU in neurons.

Title: A Mechanism for Delirium: the impact of neuro-virulent cytokines on neuronal signaling

Authors: *S. R. RAJAYER[1], S. M. SMITH[1,2];
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]VA Portland Healthcare Syst., Portland, OR

Abstract: Delirium is a common disturbance in attention and awareness that develops over hours-days, is a direct consequence of other medical conditions such as trauma, sepsis and other critical illness, and worsens long-term cognitive impairment. Neuro-inflammation represents a common pathway through which delirium-triggering diseases act. An absence of effective therapies emphasize the need for greater understanding of the pathophysiology of delirium. Glial cells sense systemic inflammation across the blood-brain barrier and become activated, releasing cytokines within the brain. In one disease model, systemic infection with neuro-virulent coronaviruses caused delirium and specifically increased levels of TNF-α, IL-1β, IL-6, IL-12 and IL-15 in the mouse brain. We tested how the panel of neuro-virulent cytokines (NVC) elicited by coronaviruses changed neuronal function. We incubated mouse neocortical cultures for 22-28 h with NVC as a model of delirium. Using whole cell patch clamp methods, we found that NVC treatment depolarized the resting membrane potential compared to control (-68 ± 1 mV versus -75 ± 1 mV; $P < 0.0001$, n = 28 and 21 respectively) without affecting the action potential characteristics. Delirium is often diagnosed due to altered responses to stimuli. We tested how NVC exposure altered the responses of neocortical neurons to changes in the microenvironment. The sensitivity to changes in external Ca^{2+} and Mg^{2+} concentrations from physiological (1.1 mM, $T_{1.1}$) to low (0.2 mM, $T_{0.2}$) levels increased the spontaneous activity in controls but not NVC-treated cells. ($P = 0.026$, ANOVA). In the control neurons, spontaneous firing rates of neurons were substantially increased from 0.02 ± 0.01 Hz to 2.1 ± 1.2 Hz ($P = 0.046$), while in NVC-treated neurons the change in frequency of spontaneous firing was absent with the divalent change (0.5 ± 0.4 Hz to 0.9 ± 0.3 Hz, n = 15, $P = 0.16$). Similarly, increases in evoked spiking (20-40 pA current injections) were present in control neurons but not in the NVC-treated cells following the decrease in external divalent concentrations ($P = 0.003$, 2WRM ANOVA, Control: 3.4 ± 1.6 Hz in $T_{1.1}$ vs. 11.4 ± 1.6 Hz in $T_{0.2,}$ n=28, $P < 0.0001$; N VC: 6.1 ± 2.0 Hz in $T_{1.1}$ vs. 6.2 ± 1.6 Hz in $T_{0.2,}$ n=21 p=0.99). The depolarization caused by $T_{0.2}$ application was unchanged by NVC treatment. Taken together, these findings point to a substantial and surprising reduction in the sensitivity of neurons to changes in the microenvironment following exposure to NVCs. Uncovering the mechanism by which this loss of adaptability occurs will enhance our understanding of the pathogenesis of delirium.

Title: Investigating the role of a neuronal tRNA methyltransferase in oxidative stress and brain development

Authors: *J. L. DUMOUCHEL[1], K. R. MADHWANI[2], C. HOGAN[4], K. M. O'CONNOR-GILES[3,5]; [1]Mol. Pharmacol. & Physiol. Grad. Training Program, [2]Neurosci. Grad. Training Program, [3]Dept. of Neurosci., Brown Univ., Providence, RI; [4]Lab. of Genet., Univ. of Wisconsin- Madison, Madison, WI; [5]Carney Inst. for Brain Sci., Providence, RI

Abstract: Proper development and function of the nervous system relies on dynamic regulation of neuronal genes during transcription and translation. Studies of transfer RNA (tRNA) modifying enzymes, mostly in yeast, have highlighted the importance of chemical modifications for tRNA stability and protein synthesis. In humans, mutations in tRNA modifying enzymes have been found to disproportionately affect the nervous system resulting in neurodevelopmental disorders as well as aberrant oxidative stress response. Yeast tRNA methyltransferase 9 (TRM9) methylates wobble uridine of the anticodon loop to reinforce cognate codon-anticodon pairings. Notably, TRM9 modulates the translation of specific mRNAs in response to DNA damage and oxidative stress. In animals, two TRM9 paralogs, ALKBH8 and TRMT9B have been identified. ALKBH8 has been shown to carry out the canonical wobble uridine methylation observed in yeast. While TRMT9B acts as a tumor suppressor, the mechanism is unknown. Using CRISPR-gene editing in *Drosophila*, we generated the first *in vivo* loss-of-function TRMT9B model. Consistent with its role in oxidative stress response in yeast, *TRMT9B* null mutants exhibit increased sensitivity to paraquat, a herbicide that induces reactive oxygen species. Following a single paraquat dose, 80% of *TRMT9B* null flies died within one day compared to 50% of wild-type flies and genetic rescue. Intriguingly, we initially identified TRMT9B from a RNAi screen for regulators of synaptic growth and function and found that loss of TRMT9B induces synaptic overgrowth and significantly diminishes neurotransmitter release. Previous studies have shown that oxidative stress can result in synaptic overgrowth. To understand whether TRMT9B's role in synaptic growth is linked to its role in regulating oxidative stress response and define the mechanism of TRMT9B function, we are assessing reactive oxygen species (ROS) levels at synapses using fluorogenic dyes specific for ROS, investigating a potential role for antioxidants in rescuing neurodevelopmental phenotypes, and conducting transcriptomic and proteomic studies. We will present our latest findings on TRMT9B's role in regulating oxidative stress during neurodevelopment.

Title: Age-related neuroinflammation and pathology in the locus coeruleus and hippocampus: beta-adrenergic antagonists exacerbate impairment of learning and memory in aged mice

Authors: *A. K. EVANS[1], H. PARK[1], N. SAW[2], K. SINGHAL[3], G. OGAWA[2], R. D. LEIB[3], M. SHAMLOO[1];
[1]Stanford Univ. Sch. of Med., Palo Alto, CA; [2]Stanford Behavioral and Functional Neurosci. Lab., [3]Vincent Coates Fndn. Mass Spectrometry Lab., Stanford Univ., Palo Alto, CA

Abstract: The locus coeruleus (LC) is the main source of noradrenergic input to the forebrain and hippocampus, and may be vulnerable to degeneration and contribute to age-related cognitive decline and neuroinflammation. Additionally, inhibition of noradrenergic transmission by brain-permeable beta-blockers, commonly prescribed for hypertension, could exacerbate age-related cognitive impairment. This study was designed to test the effects of age and the acute effects of a brain-permeable beta-adrenergic agonist and antagonist on 1) learning and memory, 2) inflammation in plasma and the brain and 3) pathology in the LC and hippocampus. Young (3 months) and aged (18 months) male mice were administered propranolol (beta-blocker) or mabuterol (beta-adrenergic agonist) acutely around behavioral assessment in multiple learning and memory platforms. Inflammatory markers were evaluated in plasma and in the brain and evidence for microgliosis, pathology, and changes in the proteome were evaluated in the LC and hippocampus. An increase in hippocampal and LC microgliosis and inflammatory proteins in the hippocampus was detected in aged mice. We report pathological hyperphosphorylation of the postsynaptic NMDA receptor subunit 2B (NR2B) in the hippocampus, suggesting neuronal hyperexcitability. Furthermore, the aged proteome revealed an induction in proteins related to energy metabolism, and mitochondria dysfunction in the LC and hippocampus. In a series of hippocampal dependent behavioral assessment tasks, acute beta-adrenergic agonist or beta blocker administration altered learning and memory behavior in both aged and young mice. In Y-maze, propranolol and mabuterol differentially altered time spent in novel versus familiar arms in young and aged mice. Propranolol impaired Novel Object Recognition in both young and aged mice. Mabuterol enhanced trace learning in fear conditioning. Aged mice froze more to context and less to cue. Propranolol impaired contextual recall in aged mice. In conclusion, our data provide evidence for neuroinflammation in the locus coeruleus and hippocampus in aged mice alongside evidence for metabolic challenge in the locus coeruleus and extrasynaptic deficiency of NMDA receptor signaling in the hippocampus. These age-related changes in neurobiology were accompanied with heightened effects of beta-adrenergic pharmacology on learning and memory. Future studies will examine consequences of *chronic* beta-blocker administration for cognitive deficits, pathological progression, and enhanced neuroinflammation in the LC as well as other key regions in the aged brain.

Title: Additive effect of age and chronic intermittent hypoxia on mouse behavior

Authors: L. FRASSON DOS REIS, R. KELLY, V. B. FENIK, K. ZULOAGA, *I. RUKHADZE; Neurosci. and Exptl. Therapeut., Albany Med. Col., Albany, NY

Abstract: Introduction: Obstructive sleep apnea (OSA) is a growing sleep-related breathing disorder that has morbid metabolic, cardiovascular, and neurocognitive sequeale. Due to recurrent apneic events during sleep, OSA patients chronically experience intermittent hypoxia and sleep fragmentation leading to cognitive impairment and neurodegenerative changes in several brain regions. The prevalence of obstructive sleep apnea is dramatically increased with age. While intermittent hypoxia may further exacerbate neurocognitive deficits in elderly OSA patients, we sought to investigate the effect of chronic intermittent hypoxia (CIH), an animal model of OSA, on cognitive function in aged mice using the open field and object place behavioral tests. **Methods:** Twenty young (3-4 months-old) and old (16-20 months-old) wild type C57BL/6 male mice were subjected to CIH (5 young and 5 old mice) and sham-treatment (5 young and 5 old mice). The CIH groups were exposed periodically to the room oxygen levels (21% O2 for 3 min) and a nadir (10% O2 for 4 min) applied from 7:00 AM to 5:00 PM daily for 35 days. The sham-treated groups were exposed to identically timed room air exchanges. After CIH exposure, all mice were subjected to behavioral testing. Anxiety-like behavior and general locomotor activity were tested with the open field and the spatial memory, with the object-location memory test. **Results:**In the open field test, old sham mice spent more time at the center of the field compared to young sham mice (10.5% $\pm$ 7.6 (SD) vs. 7.70% $\pm$ 3.9; $p<0.05$) whereas the CIH treatment increased the time spent in center in both young (16.7% $\pm$ 4.7) and old mice (23.7% $\pm$ 2.4; $p<0.001$), by two-way ANOVA. However, there was no difference in the level of activity or traveled distance between the groups. In the object-location memory test, the relative times for exploring the new location of an object were approximately 60% in all groups, except for the CIH-treated old mice, which tended to spend less than 50% of the time.**Conclusions:** The results obtained in the open field test suggest that aging and CIH have negative additive effect on the level of anxiety, rather than on the general locomotor activity in mice. **Support:** NIH Grants R01AG065233 (IR&VBF) and R01NS110749 (KZ)

Title: Diabetes-related Cerebral Amylin Vasculopathy Induces Brain Hypometabolism

Authors: *E. WINFORD[1], N. VERMA[2], A. KUMAR[2], S. DESPA[2], F. DESPA[2];
[1]Neurosci., [2]Pharmacol. and Nutritional Sci., Univ. of Kentucky, Lexington, KY

Abstract: Background: Type-2 diabetes is a metabolic disorder that increases the risk for cerebrovascular diseases and dementia. We and others reported previously that this risk is associated with elevated blood levels of amylin (an amyloidogenic hormone synthesized and co-secreted with insulin), which promotes amylin amyloid deposition in the brain microvasculature (cerebral amylin vasculopathy). We also showed that inducing amylin dyshomeostasis in rats by pancreatic-specific expression of human amylin (amylin from rodents is non-amyloidogenic) leads to cerebral amylin vasculopathy and neurological deficits. Here we tested the hypothesis that cerebral amylin vasculopathy is a contributing factor to diabetes-associated brain hypometabolism. **Methods:** We conducted brain RNAseq analysis and proteomics in 16-month old rats expressing human amylin in the pancreas (HIP rats), amylin knockout (AKO) rats, and normal rats expressing wild-type (WT) rat amylin (n =10 males/group). Library and construction, and sequencing was performed using commercial service (Omega Bioservices). Briefly, sequence reads were aligned to the Rattus norvegicus genome (rn5) using STAR. Individual sample reads were quantified using HTseq and normalized via Relative Log Expression (RLE) using DESeq2 R Library. Isolated brain homogenates from WT and HIP (n =7/group) rats were used for western blot analysis for enzymes significantly changed in RNA seq analysis that is important in the glycolytic pathway. **Results:** In the brains of rats with amylin vasculopathy (HIP rats), RNA seq analysis shows a significantly altered pathway important for metabolism compared to WT littermates. The genes in these pathways were associated with glycolysis and revealed that amylin significantly decreases the expression of these proteins. Many of these pathways were inversely regulated in AKO vs. WT rats. **Conclusion:** Increased amylin levels in the circulation provokes cerebral amylin vasculopathy causing significant alteration of the brain gene expression. Cerebral amylin vasculopathy is a contributing factor to diabetes-related brain hypometabolism through the dysregulation of enzymes important in the glycolytic pathway.

Title: Oxidative Stress Reduces proNGF Transport and Causes Neurodegeneration in Basal Forebrain Cholinergic Neurons

Authors: *M. FAHNESTOCK[1], A. SHEKARI[1], C. WU[2];
[1]McMaster Univ., Hamilton, ON, Canada; [2]UCSD Sch. of Med., La Jolla, CA

Abstract: Profound and early basal forebrain cholinergic neuron (BFCN) degeneration is a hallmark of Alzheimer's disease (AD). We sought to determine whether mechanisms related to oxidative stress, a longstanding hypothesized contributor to aging and AD, account for this neurodegeneration. BFCNs depend for survival and function on neurotrophins like nerve growth factor (NGF) which are retrogradely transported from BFCN target tissue. We have recently shown that the retrograde transport of proNGF, the only detectable form of NGF in the brain, is reduced with age in cultured BFCNs and coincides with the loss of proNGF receptor tropomyosin-related kinase A (TrkA). We found that elevation of intracellular oxidative stress via antioxidant deprivation significantly reduced both TrkA immunoreactivity and proNGF retrograde transport in rat BFCNs cultured in microfluidic chambers. TrkA levels are partially regulated by protein tyrosine phosphatase 1B (PTP1B), an enzyme whose activity is reduced by the oxidation of a cysteine residue within its active site. siRNA knockdown of PTP1B and pharmacological PTP1B antagonism via selective inhibitor TCS401 significantly reduced TrkA levels in BFCNs. Furthermore, TCS401 treatment reduced proNGF retrograde transport in BFCNs and reduced axonal uptake of proNGF-KKE, a mutant form of proNGF that only binds TrkA. Treatment of BFCNs with thioredoxin-1 and thioredoxin reductase, antioxidants responsible for the reactivation of oxidized PTP1B, significantly increased TrkA levels and rescued proNGF uptake and transport in BFCNs following antioxidant deprivation. Lastly, oxidative stress resulted in axonal degeneration in the presence of either proNGF or proNGF-9/13, a mutant proNGF that binds only to $p75^{NTR}$. Degeneration did not occur in the presence of either proNGF and thioredoxin-1 or proNGF-KKE. Our results suggest that, during aging and in AD, increased oxidative stress reduces TrkA levels and proNGF transport through a PTP1B-dependent mechanism. TrkA loss and impaired proNGF retrograde transport result in BFCN degeneration and may contribute to memory loss in aging and AD.

Title: Apolipoprotein E regulates ferroptosis vulnerability in astrocytes

Authors: *S. E. V. RICHARDS[1], E. L. RICQ[1], M. L. YANG[1], S. L. SCHREIBER[2];
[1]Broad Inst. of MIT and Harvard, Cambridge, MA; [2]Harvard Univ., Cambridge, MA

Abstract: Recent studies suggest that cell loss by ferroptosis is of interest in neurodegenerative disease, including late onset Alzheimer's disease (LOAD). While evidence suggests that both neurons and microglia are susceptible to ferroptosis, there is little direct evidence of ferroptosis susceptibility in other glial subtypes. Furthermore, the mechanisms which confer ferroptosis vulnerability in central nervous system (CNS) cell types are largely unexplored. Here, we present evidence that astrocytes are vulnerable to ferroptosis and that this vulnerability is regulated by apolipoprotein E (apoE), the primary lipid and cholesterol transport protein of the CNS. ApoE exists as three isoforms in humans: apoE2, apoE3, and apoE4, with apoE4 conferring significant risk for LOAD. Experiments in immortalized targeted replacement mouse astrocytes reveal that all apoE isoforms confer protection from ferroptosis, but that apoE4 is notably deficient in this capacity. Whole-cell lipidomics and downstream analyses reveal that broad dysregulation of lipid storage may underlie enhanced ferroptosis vulnerability in apoE4-expressing astrocytes. This work establishes apoE as a regulator of ferroptosis vulnerability in astrocytes and provides evidence of a novel mechanism by which apoE4 may confer risk for neurodegenerative disease.

Abstract: Glioblastoma multiforme (GBM) is the most frequent and lethal of the primary brain tumors, with median overall survival ranging from 10 to 18 months and a five-year survival of less than 5 %.

GBM remains an incurable disease. GBMs are highly heterogeneous tumors whose landscape is modeled by immunomodulatory and metabolic mechanisms elicited by malignant cells. Among these mechanisms, overexpression of the indoleamine-2, 3-dioxygenase (IDO), the rate-limiting enzyme of tryptophan catabolism through the kynurenine pathway (KP), has been associated with a poor prognosis in patients with GBM. However, the expression and activity of downstream enzymes of the KP, such as kynurenine monooxygenase (KMO), remains poorly understood in GBM pathophysiology. Thus, the aim of this work was to analyze KMO mRNA and protein expression as well as KMO activity inhuman GBM cells lines and in patient-derived GBM samples. KMO mRNA levels were quantified by RT-qPCR, KMO protein expression was determined by flow cytometry and immunofluorescence, KMO activity was evaluated by HPLC in A172, LN18, U87, and U373 cells, and in patient-derived GBM samples. Genomic analysis of KP enzymes expression was performed using TGCA gene expression data. KMO was expressed and active in GBM cells as well patient samples with a heterogeneous pattern. Furthermore, our results are in accordance with the bioinformatic analysis that showed that KMO is expressed in both low-grade gliomas and GBM, favoring the long arm of the KP. These results demonstrate the novel expression and activity of KMO in GBM which could have metabolic and immunomodulatory implications in the tumor microenvironment.

Title: Elevated neuropeptide (SST, BDNF) expression induces ER stress and altered proteostasis

Authors: *T. TOMODA[1], M. L. MACDONALD[2], M. CHIKINA[2], W.-H. YU[1], E. SIBILLE[3];
[1]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [2]Univ. of Pittsburgh, Pittsburgh, PA; [3]CAMH - Univ. of Toronto, Toronto, ON, Canada

Abstract: Neuropeptides are secretable polypeptides that are produced in response to intrinsic and extrinsic neural activities and play a range of neuromodulatory roles across brain circuitry. Combined transcriptomic and proteomic analyses demonstrated significantly altered expression of a group of neuropeptides in aging brains and brain disorders, as exemplified by downregulated BDNF, SST, CRH, CORT and NPY among others. In contrast, non-secreted intracellular peptides are seldom affected by the same conditions. Neuropeptides are initially produced as long precursor molecules and then processed through the endoplasmic reticulum (ER) and trafficking vesicles to become smaller bioactive mature

peptides. To understand the mechanisms for age- or disease-associated universal downregulation of neuropeptides, we hypothesized that excess demand for neuropeptide precursor processing may cause ER overload or maladaptive ER stress, leading to altered protein homeostasis or proteinopathies. To test this hypothesis, we chose preproBDNF and preproSST as prototypical neuropeptide precursors and show that forced expression of these neuropeptides, but not the processed mature form (for SST), in neurons induces ER stress and protein aggregation, two hallmarks of cellular aging or altered proteostasis. We next used quantitative mass-spectrometry to show changes in both soluble and insoluble proteome that highlight biological functions related to ER stress, chaperones, unfolded protein binding, protein quality controls and post-translational modifications (73 proteins enriched in the insoluble fraction upon preproBDNF expression, q-values from 10^{-3} to 10^{-9}). Together these preliminary results support the hypothesis that elevated production of neuropeptides can induce ER stress-related biological changes and that this cellular risk is mediated by processing of the precursor peptide.

Title: Cortical Iron Disrupts the Anatomical Connectivity of Working Memory Networks by Damaging Proximal White Matter Microstructure in Older Adults

Authors: *V. ZACHARIOU, C. E. BAUER, B. T. GOLD;
Neurosci., Univ. of Kentucky, Lexington, KY

Abstract: Aging is associated with accumulation of non-heme brain iron, which has been linked with oxidative stress, demyelination and cognitive decline. For instance, several previous studies have reported negative associations between iron concentration in the brain and working memory performance. However, the mechanisms by which excess brain iron interferes with working memory are not well understood. One possibility could be that increased non-heme iron concentrations in brain regions that support working memory, increase oxidative-stress-related injury to proximal white matter (WM) which can disrupt the anatomical connections between them. Here, we explored this possibility using quantitative susceptibility mapping (QSM), an in-vivo MRI technique for measuring iron concentration in brain tissue, in conjunction with fMRI, diffusion tensor imaging (DTI) and neurite orientation dispersion and density imaging (NODDI). A cohort of 113 cognitively normal older adults (69 women; age range: 60-86) performed an N-Back visual working memory task inside a 3T Siemens Prisma MRI scanner (64-

channel head coil). Using whole-brain fMRI activity from this task, we identified a network of bilateral brain regions in which the magnitude of activity in response to the N-Back task was significantly stronger than a control task. These regions included the anterior and posterior cingulate cortex, the dorsolateral prefrontal cortex, the middle frontal gyrus and the inferior parietal lobules. Then, using each of these regions as a seed, probabilistic tractography was conducted to map the WM connectivity between the seeds. In addition, QSM values were extracted from each of the seed ROIs as a measure of iron concentration. Voxelwise, linear regressions were then conducted between QSM values and (1) neurite density (ND), (2) radial diffusivity (DR), both of which are measures of WM microstructure integrity. All voxelwise regressions were constrained within a mask of the WM network we identified using probabilistic tractography and controlled for participant age. We found that iron concentration extracted from frontal-lobe seed ROIs predicted lower ND and higher DR in frontal but not parietal lobe regions of the WM network. Conversely, iron concentration extracted from parietal-lobe seed ROIs predicted lower ND and higher DR in parietal but not frontal lobe regions of the WM network. Based on these findings, we conclude that in older adults, non-heme iron in brain regions supporting working memory can disrupt their anatomical connectivity by damaging proximal WM microstructure.

Abstract: Defective proteostasis is one of the hallmarks of aging cells and tissues. Out of the different components of the proteostasis network, we are interested in autophagy and its changes with age in retina. In this study we focus on a selective form of autophagy known as chaperone-mediated autophagy (CMA).

We have previously shown that regulation of CMA in the retina is unique, since contrary to other organs that respond to a blockage in CMA with upregulation of macroautophagy, loss of CMA in retina is not compensated for. In this work, we set to understand the physiological role of CMA in the retina and the potential beneficial effects of upregulating this selective form of autophagy as an effective intervention to delay consequences of aging in the retina and to ameliorate degeneration in age-related retinal pathologies. To that effect, we have used genetic approaches to modulate CMA in vivo. Using a mouse model deficient for LAMP-2A, the lysosomal membrane protein essential for CMA, we have found that CMA blockade leads to impaired visual function. Conversely, mice that overexpress LAMP-2A show higher resistance to chemically-induced photoreceptor damage and are more protected against the visual function decline associated with normal aging. Overall, our results support a cytoprotective role for CMA in retina, which becomes essential under conditions, such as aging, and also highlight the feasibility of upregulating CMA against retinal degeneration.

Title: Assessing behavioral impairment after Doxorubicin Chemotherapy in Rats

Authors: *B. POUDEL[1], T. KEENE[1], J. L. CHEATWOOD[2];
[1]Southern Illinois Univ., Carbondale, IL; [2]SIU Sch. of Med., Carbondale, IL

Abstract: Chemotherapy can notably lengthen the survival of cancer patients. Nevertheless, it has been associated with deficits in cognition and memory, delayed processing speed, and executive function which is widely recognized as chemotherapy-induced cognitive impairment or Chemo brain. In addition, it also causes the disruption of hippocampal cell proliferation and neurogenesis, increased oxidative stress, and disruption in white matter. Doxorubicin is a reactive oxygen species producing antineoplastic Anthracycline agent that adversely affects hippocampal neurogenesis and induces apoptosis. Twelve young adult female Long Evans hooded rats were assigned to either the Control(0.9% saline) or Dox groups (6mg/kg IP injection; once weekly for 4weeks). Rats were assessed on several behavioral tests including the string-pulling task, bar walk test, and open field test. Afterward, two individuals blind to the treatment group calculated the average time duration, number of attempts to pull the string, number of misses, total number of mouth contacts before and after treatment for the string-pulling task, number of deep slips, slight slips, and the total number of slips for bar walk test. Similarly, the number of entries to the center, number of entries to the corners, time spent at the center vs corner, and latency to first enter and exit the center was calculated for the Open field test and compared between two groups. Students t-test was performed across the groups. No significant differences were detected between Dox-treated and

Control rats which suggests that the Dox-treatment produced little or no significant peripheral neuropathy that disrupted performance on the motor task we used.

Title: Hdac3 regulates gene expression within the auditory cortex during the formation of discriminative auditory memories.

Authors: *G.-E. GRAHAM[1], M. S. CHIMENTI[2], K. L. KNUDTSON[2], D. N. GRENARD[1], L. CO[1], M. VELEZ[3], T. TCHOU[1], K. M. BIESZCZAD[1];

Abstract: The ability to form lasting memory for sensory experiences over a lifetime requires the induction of experience-dependent sensory system plasticity. Memories for sound meaning require experience-dependent changes within the auditory system for comprehension of sound and sound-guided action. Epigenetic mechanisms are powerful controllers underlying experience-dependent changes that can have lasting effects on neuronal function that lead to robust changes in behavior. Inhibition of the epigenetic histone deacetylase 3, HDAC3, enables *de novo* DNA transcription, which is necessary for neural plasticity and long-term memory that guides behavior. HDAC3 has been shown to regulate the precision of auditory memories by facilitating auditory cortical (ACx) plasticity when its function is blocked (Bieszczad et al., 2015; Shang et al., 2020; Rotondo & Bieszczad, 2020). However, it is largely unknown which genes HDAC3 controls for its effects on auditory memory and learning-induced ACx plasticity. RNA-sequencing on ACx samples was performed to determine genome-wide effects of blocking HDAC3 during auditory discrimination training. Our results suggest that the inhibition of HDAC3 amplifies the magnitude of learning-induced gene expression compared to vehicle and naïve groups. In addition and interestingly, there are only a handful of unique genes that are *differentially* expressed between HDAC3 inhibited animals compared to animals with uninhibited HDAC3. Identified DEGs were: *Adamts13, U6, Cabin1, Rexo4, Snhg11, Zfhx2, Celf5,* and *Ms4a6e*. We have further utilized single molecule fluorescent *in situ* hybridization (smFISH) technologies to target specific genes of interest *c-fos, egr1,* and *nr4a2,* which are under the control of HDAC3 in other systems. Combining bulk RNA-seq with more sensitive and cell-type specific smFISH techniques has allowed determination of both broad and more subtle quantitative changes in HDAC3-mediated learning-induced gene expression in the auditory system. Together, these results define the role of HDAC3 by its action on genetic targets

within the auditory cortex that may be key for neuroplasticity events that support the consolidation of highly precise and lasting auditory memories.

Title: Subtle changes to task demands engage categorically different forms of learning-induced cortical neural plasticity that underlie memory enhancements mediated by HDAC3-inhibition

Authors: *A. SHANG[1], K. M. BIESZCZAD[2];
[1]Rutgers Univ., Piscataway, NJ; [2]Psychology, Behavioral and Systems Neurosci., Rutgers The State Univ. of New Jersey, Piscataway, NJ

Abstract: Epigenetic mechanisms that regulate transcription are powerful modulators of learning-induced neuroplasticity and long-term memory (LTM) formation. Inhibition of histone deacetylase 3 (HDAC3i) has been shown to facilitate LTM formation in the adult brain (McQuown & Wood, 2011). Previous work has demonstrated a role for HDAC3-i to promote the formation of highly precise memory for learned sound-cues with substrates in the auditory cortex (AudCtx). In rats trained on either single-tone detection, two-tone discrimination, or tone-cued extinction tasks, pharmacological HDAC3i during post-training consolidation promoted the formation of highly sound-specific memory, assessed behaviorally on a cued memory test (Bieszczad et al., 2015; Shang et al., 2019; Rotondo & Bieszczad, 2020, 2021). The increases in LTM specificity occurred with concomitant decreases in AudCtx tuning bandwidth (thereby increasing neural selectivity for the specific sound feature) only in sites tuned to the learned tone-frequency. This led to the hypothesis that HDAC3 has a role to modify AudCtx tuning bandwidth (BW) in the service of making memories more specific to behaviorally relevant sound features. We tested this hypothesis by training adult male Sprague-Dawley rats (n = 12) on a more perceptually challenging version of a frequency discrimination task. There were no group differences in the ability to perform the more difficult task. Consistent with prior work, memory testing revealed highly frequency-specific cued behavior in HDAC3i-treated animals (vs. vehicle). Surprisingly, multiunit recordings did not find narrower tuning BW for AudCtx sites tuned to either of the tones in HDAC3i-treated animals. Instead, we identified effects of HDAC3i on the magnitude and variability of sound-evoked responses across a range of frequencies. These results imply that HDAC3 does not simply control cortical tuning BW to promote the formation of precise sensory LTM, but instead likely acts on natural activity-dependent processes that are dictated by task demands. The more perceptually difficult task likely engaged activity-dependent processes that promoted encoding strategies better suited to the increased task difficulty. More broadly, these findings indicate that different forms of learning-induced plasticity in AudCtx may be redundantly

and non-linearly linked to select forms of behavioral change. These results highlight the importance of design in behavioral tasks to engage desired activity-dependent processes that can be harnessed and reinforced using pharmacological intervention like HDAC3i to promote cortical and behavioral function for individualized remediation.

Title: Cellular mechanisms underlying intrinsic plasticity in the zebra finch auditory cortex

Authors: *Y. LU, C. D. MELIZA;
Dept. of Psychology, Univ. of Virginia, Charlottesville, VA

Abstract: In zebra finches and other songbirds, the auditory system undergoes a sensitive period where the acoustic environment shapes auditory processing that supports auditory perception of vocalizations. In the caudal mesopallium (CM), a cortical-level auditory area implicated in discriminating and learning species-specific vocalizations, there is subset of neurons that only fire transiently at the onset of current injections (i.e., phasic firing). Phasic firing can enhance the reliability and selectivity of neural responses to complex acoustic stimuli. Previous work shows phasic excitability increases during the sensitive period for song memorization. Phasic excitability increases in parallel with the proportion of CM neurons that express Kv1.1, a low-threshold potassium channel that facilitates phasic firing. These correlated changes in intrinsic plasticity (IP) and Kv1.1 expression only occur in a noisy acoustic environment, suggesting that an experience-dependent mechanism regulates expression of Kv1.1 and its localization to the plasma membrane. Here, we first investigated the cellular mechanisms underlying this IP. We stimulated CM neurons in brain slices under current clamp to determine the intrinsic dynamics, followed by post-hoc Kv1.1 expression analysis. We found that Kv1.1-positive neurons were significantly more phasic than Kv1.1-negative neurons (n=39). However there were Kv1.1-positive neurons with tonic excitability. This suggests Kv1.1 expression is necessary but not sufficient for phasic excitability. During the recording, we observed a subset of tonic neurons become phasic over the course of several minutes of currents injection (n=26). Thus, we hypothesized IP could be induced through a mechanism of activity-dependent membrane expression of Kv1.1. To test this, we first compared the change of intrinsic excitability of tonic neurons under 25 minutes of current injection to that where the neurons were held around the resting potential. Then to test the dependence of intrinsic plasticity on Kv1.1, we applied 4AP, a blocker of voltage-gated potassium ion channels, to the neurons that showed IP after the currents injection. We found that CM neurons showed activity-independent IP (n=38), and that the IP was reversed by 4AP (n=7). This suggests Kv1.1 may drive IP in an activity-independent manner. Currently, we are performing perforated patch to control for cell dialysis, the artifacts of *in vitro* whole-cell recording, that might

emerge in the IP of the recorded neurons. Next, we will test the dependence of IP on calcium influx by loading the internal solution with BAPTA.

Title: Voltage- and calcium-activated potassium (BK) channel disrupts short-term startle habituation

Authors: *Y. WIESENFELD[1,2], J. C. NELSON[1,3], M. GRANATO[1];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]The Rockefeller Univ., New York, NY; [3]Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Habituation is an evolutionarily conserved learning process involving repression of a response to repeated stimuli. Enabling animals to selectively focus on pertinent stimuli, it is thought to be a basis for more complex types of learning. Studies in vertebrates and invertebrates identified genetic and circuit processes regulating habituation, though its molecular basis remains unclear. Recent evidence suggests that dynamic changes in the calcium- and voltage-gated K^+ (BK) channel regulate short-term habituation of startle responses. Also, mutations of the channel are linked to human disorders involving habituation deficits, including ADHD and schizophrenia. Yet studies show conflicting effects of BK channel activation on habituation learning. We first employed pharmacological manipulations of channel activity to evaluate its role in acoustic and visual startle habituation in zebrafish. We found that BK channel opening using meclofenamic acid weakened habituation learning in both systems, while channel closing using paxilline enhanced habituation. Next, we generated loss-of-function BK channel mutants using CRISPR-Cas9 genome editing to validate the antagonistic role of BK channel activity on habituation learning. Animals with a 305 kb deletion in the *kcnma1a* gene, one of two paralogs encoding for the pore-forming α-subunit of BK channels in zebrafish, demonstrated enhanced acoustic habituation and a longer startle latency to dark flashes compared to siblings, supporting the results of our pharmacological experiments. Our findings paradoxically suggest that promoting neurotransmitter release by decreasing potassium conductance *suppresses* startle responses. We propose that the predominant role of the BK channel in startle habituation is at the level of inhibitory neurons. In the future, *in vivo* calcium imaging of individual neurons may help pinpoint where in the startle circuitry BK channels influence habituation learning. Understanding how the channel disrupts habituation will provide insight into the mechanisms most critical for this adaptive process.

Title: Processing of valence in the mouse auditory cortex

Authors: *J. D. JOHNSON, Z. LI;
Natl. Institue of Mental Hlth., Bethesda, MD

Abstract: The auditory cortex is the primary site of sound processing within the brain, however processing of non-auditory information within this region is being increasingly discovered. Learning to associate stimuli emotional or motivational valence is a critical skill in survival, and disturbances in these associations are found in a range of diseases such as PTSD or schizophrenia. While alterations to tone frequency processing have been seen to be affected by associations with rewarding or aversive stimuli, it is unclear how these factors intersect at the neuronal level, and whether neurons within the auditory cortex have innate, conditional or long-term valence responsiveness independent of sound. Longitudinal two-photon calcium imaging was used to assay neurons in the auditory cortex during the conditioning, recall and pair switching of pure tones with both rewarding and aversive stimuli. Following conditioning, a subset of neurons in the auditory cortex were shown to respond to valence coded stimuli when either rewarding or aversive stimuli were presented alone, these neurons were composed of cells with and without tone responses. These valence responsive cells were predominantly active when either rewarding or aversive stimuli were presented but could also show responses to both valences. Once the initial conditioning pairs were reversed, subsets of neurons could undergo a switching of their stimuli response to the opposing valence, as well as gaining a new or losing the initial conditioned response. The valence responsive cells appear to form ensembles with tone responsive cells and potentially indicate a local mechanism to influence emotionally linked auditory information within the auditory cortex.

Title: Activity in mouse motor cortex reflects action and its expected sensory consequences

Authors: *B. E. HOLEY, D. M. SCHNEIDER;
NYU, New York, NY

Abstract: Throughout sensory cortices, neural activity is influenced by behavior. While behavior-related modulation can be generic (e.g. gain control), it can also be precise, such as suppression in the auditory cortex of neural responses to sounds that are predictable consequences of an animal's movements. Suppression of neural responses to self-generated sounds has been observed in humans, monkeys, and mice, and likely involves motor cortical projections to auditory cortex. In the mouse, projections from the secondary motor cortex (M2) are active during behavior and target inhibitory networks in the auditory cortex (AC), consistent with a role for M2 in mediating predictive suppression. However, it remains unknown what information M2 sends to AC during sound-generating movements. We ask whether M2

activity reflects purely movement-related information, or also reflects expectations about the sensory consequences of a movement. To answer these questions, we trained mice to push a lever with their right forelimb to achieve a water reward. At a fixed position, the lever produces a predictable and experimentally controlled sound, which the mice perceive as being self-generated. After training with a single predictable sound, we record the activity of M2 cell populations during the lever behavior. During electrophysiology, the lever first produces the tone that mice had learned to expect during training. We find that a majority of the recorded M2 population is active during the lever behavior, including preparatory activity before movement initiation and a large fraction of cells with peak firing rates just before and after the self-generated tone. We used optogenetic stimulation of ChR2+ M2 terminals in A1 to antidromically identify the subset of recorded cells that project to A1. A1-projecting M2 cells have activity patterns similar to the broader M2 population, but they are more likely to be active around the time of the tone. After producing 50-100 trained tones, the sound produced by the lever movement was unexpectedly and permanently switched to a novel tone. Interestingly, while mice lever behavior remains stable, we find a sub-population of M2 cells, including A1 projectors, that significantly change their firing rates after the tone change. Some of these neurons change their activity prior to the tone, indicating that these changes cannot only be accounted for by the occurrence of the novel tone. The timescale of changes varies from rapid (i.e. upon the first novel sound) to gradual (accumulating over trials). Together, these findings suggest that M2 not only represents motor-related aspects of a forelimb movement, but also the acoustic consequences of the movement.

Title: Neural and behavioral variability in auditory perceptual learning

Authors: *K. A. MARTIN[1], C. J. BREDENBERG[1], E. P. SIMONCELLI[1,2], C. SAVIN[1], R. C. FROEMKE[3,4,5,6];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Flatiron Inst., Simons Fndn., New York, NY; [3]Dept. of Neurosci. and Physiol., [4]Skirball Inst. for Biomolecular Med., [5]Dept. of Otolaryngology, [6]Neurosci. Inst., New York Univ. Med. Ctr., New York, NY

Abstract: Perceptual learning is associated with altered cortical representations of task-relevant stimuli in trained animals relative to naive ones. Despite their association with perceptual improvement, such changes in neural tuning are typically not measured throughout learning. Additionally, there is a large degree of variability in perceptual learning rates across animals, which is largely ignored when recording and interpreting neural activity. To address these limitations, we developed an experimental and

computational framework for describing how sensory representations change during auditory perceptual learning.
We recorded from a population of neurons throughout auditory conditioning using two-photon imaging of layer 2/3 excitatory neurons in the auditory cortex of mice. To obtain water reward, mice learned to to distinguish a single, center frequency (11-16 kHz) from non-center frequencies by licking left and right, respectively. Discrimination performance improved over 10-45 days through multiple phases of learning (N=52 animals).
Across trained animals, despite similar trained behavioral performance, we observed two distinct tuning profiles of excitatory neurons. Specifically, individuals exhibited either a relative enhancement or suppression of the frequencies reported as center. Despite the variability in neural responses, there was a consistent increase in number of neurons with a maximum response a quarter octave away from the behavior discrimination threshold (N=10 animals). Additionally, we found these neurons had the steepest slope at the behavior discrimination threshold (N=10 animals). Thus, we found a relative increase of neurons that are most sensitive to detecting minor differences in frequency around the behavior discrimination threshold, potentially facilitating improvement in the discrimination between frequencies that are similar but are classified differently behaviorally.
To make sense of the across animal variability in tuning, we trained a network model by reward-modulated Hebbian synaptic learning (Williams, 1992) to learn the same task. We found that the simulated network learns at similar rates as real animals. The model captures the across-animal variability in tuning, specifically capturing the suppression or enhancement of center frequency representations. Overall, both data and model reveal nontrivial learning dynamics associated with perceptual learning in auditory cortex, with initial tuning driving across-animal variability in the emerging representations.

Title: Plasticity in layer 1 of auditory cortex during auditory perceptual learning

Authors: *A. M. LEMESSURIER[1], K. A. MARTIN[1], C. E. OLIVER[1], R. C. FROEMKE[2];
[2]Otolaryngology, [1]NYU Med., New York, NY

Abstract: Auditory perceptual learning, in which subjects learn to recognize and discriminate acoustic stimuli, is associated with changes in the tonotopic organization of responses to sound in auditory cortex [1]. Frequency tuning in auditory cortex neurons can change depending on behavioral relevance and context, and this contextual modulation as well as behavioral performance depends on activity in

inhibitory circuits [2]. Stimulation of neuromodulatory centers projecting to cortex can speed perceptual learning and induce tonotopic map plasticity [3,4]. The circuit mechanisms mediating the influence of neuromodulators on inhibitory networks are under investigation. Interneurons in layer 1 (L1) receive input from long-range neuromodulatory and intracortical inputs, and target the dendrites of pyramidal cells as well as layer 2/3 (L2/3) interneurons, positioning them to gate integration of neuromodulatory and sensory input [5]. We hypothesize that plasticity in L1 is a crucial component of auditory perceptual learning. We trained 5 mice on an appetitive, 2-alternative forced-choice tone recognition task [6] while measuring activity in NDNF interneurons on each day of training using chronic 2-photon calcium imaging. Each mouse initially achieved <80% correct discriminating a center tone and a foil spaced 1.5 octaves apart before the introduction of additional foils spaced 0.25, 0.5, 1, and 1.5 octaves surrounding the target. After 28 +/- 7 days of training each mouse correctly identified tones on 76 +/- 4% of trials. Within each mouse, NDNF neurons displayed a variety of tuning profiles for tones used in the task at the end of training, including a relative suppression of responses to the target tone in some neurons, as well as enhanced responses in others. Additionally, tuning in NDNF neurons was task modulated - tuning curves differed within most cells between the task context and passive tone presentation outside of the task context. These results suggest that tuning in NDNF interneurons may be plastic over the course of training, and that activity in these neurons may shape the context-dependent activity in downstream neurons.

Abstract: Cochlear implants (CIs) are auditory neuroprostheses that restore hearing to over 500,000 humans world-wide, including over 3,000 at our clinic at NYU since 1984. The CI restores hearing by bypassing damaged parts of the sensory transduction epithelium of the inner ear and directly stimulates primary afferent neurons via pulses of electrical current. Despite significant distortion in the encoding of sound, human cochlear implant users can fully identify spoken words without the aid of other sensory cues. Significant variability, however, exists in peak speech comprehension outcomes; our hypothesis is that central plasticity underlies variability in CI outcomes. To test this hypothesis, we have developed a behaviorally and physiologically-validated system for studying cochlear implants in rats (King et al. 2016, Glennon et al. 2021). Moreover, we have previously developed micro-electrocorticography (µ-ECoG) arrays for chronic tracking of sound evoked responses over rat auditory cortex in freely moving rodents (Insanally et al. 2016).
Here, we trained rats on a self-initiated two-alternative forced-choice (2AFC) task to examine perceptual learning in a more complex version of our previous go/no-go task. Normal hearing rats were first trained to nosepoke-left for 4 kHz center tones and nosepoke-right for all other presented frequencies. Next, trained rats were bilaterally deafened and unilaterally fitted with an 8-channel cochlear implant. CI implanted rats were retrained with the center 4 kHz tone replaced by a single intracochlear stimulating electrode. All rats trained on the acoustic version of the task eventually reached high discrimination performance (n=12, overall hit rate > 80%) and CI implanted rats reached high discrimination performance within 2-3 weeks (n=4, overall hit rate >75%). We also implanted µ-ECoG arrays over the primary auditory cortex to compare and track the reliability of sound and CI-evoked responses, both acutely (n=4) and chronically (n=2). Single-trial acoustic-evoked measurements indicated reliable evoked activity and the spatial distribution of activity enabled the detection of network topography. Single-trial measurements during CI-stimulation revealed reliable evoked responses to intracochlear electrode stimulation (d-prime >1, evoked vs baseline activity). Network topography was not obvious for activity evoked by stimuli across the electrode array. These results demonstrate the efficacy of the CIs in restoring behaviorally relevant auditory cues in bilaterally deafened rats. Our next step is to relate this adaptation period to network-level evoked activity across the primary auditory cortex.

Title: Monosynaptic activation of inhibitory neurons in mouse superior colliculus by retinal ganglion cells in vivo

Authors: *C. GEHR[1], J. SIBILLE[2], J. KREMKOW[3];
[1]Neurosci. Res. Ctr., Charité - Universtätsmedizin Berlin, Berlin, Germany; [2]Neurosci. Res. Ctr., Charité - Universitätsmedizin Berlin, Berlin, Germany; [3]Neurosci. Res. Ctr., Charité-Universitätsmedizin Berlin, Berlin, Germany

Abstract: The superior colliculus (SC) is a midbrain structure that receives direct inputs from retinal ganglion cells (RGCs) but whether excitatory (ExN) and inhibitory (IN) SC neurons differentially integrate retinal activity *in vivo* is unknown. We have recently developed an innovative approach to measure large populations of RGCs simultaneously with their postsynaptic SC targets *in vivo* using Neuropixels probes (Sibille et al., SfN 2021). This study revealed that RGCs strongly drive synaptically connected SC neurons among some weaker connections. However, this study lacks the distinction between cell-types of the postsynaptic SC neuron and it remains an open question whether these strong connections are cell-type specific. Here we examine whether there are differences in the connection strength of monosynaptic retinal activation onto SC ExNs and INs by studying retinal inputs onto SC INs and ExNs. It could be that the strong retinal afferent inputs are preferentially found onto SC INs whereas the weak inputs project onto SC ExNs. This would be similar to thalamo-cortical circuits (TC) where cortical INs receive strong thalamic input (Swadlow 2002, 2003) while the afferent drive onto ExNs is usually weak (Kremkow et al. 2016; Bereshpolova et al. 2020). Alternatively, the wiring in retino-collicular circuits could follow a different principle where the afferent input onto SC INs and SC ExNs is similar in strength. To address these two possibilities, we combined our novel approach of recording RGC inputs onto SC neurons (Sibille et al. 2021 SFN) with optotagging of SC INs in the VGAT-ChR2 mouse line. Connected RGC-SC pairs were identified using cross-correlation analysis and connection strength was estimated from the efficacy of RGC spikes driving postsynaptic spiking in SC neurons (Reid 1995; Bershpolova et al. 2020). Our preliminary results indicate that both SC INs and ExNs can be strongly driven by retinal inputs; furthermore, both populations also receive weak RGC inputs (number of connected pairs: RGC-SC IN = 59, RGC-SC ExN = 142), not showing a significant difference in synaptic efficacy between SC ExN and INs ($p > 0.05$, Wilcoxon rank-sum). Interestingly, monosynaptic activation of SC INs by RGCs appears to be similar in strength as compared to the afferent thalamic drive onto cortical INs. However, in contrast to the weak activation of cortical ExNs, putative SC ExNs also receive strong afferent inputs. In summary, our preliminary results suggest that ExNs and INs in the SC are strongly driven by their afferent retinal inputs which implicates that the wiring in the retino-collicular circuit follows different principles compared to thalamo-cortical circuits.

Title: Large-scale in vivo paired recordings with Neuropixels probes reveal strong and specific connections between retina and midbrain in mammals and birds

Authors: *J. SIBILLE[1], C. GEHR[1], J. BENICHOV[3], H. BALASUBRAMANIAN[1], K. TEH[1], T. LUPASHINA[1], D. VALLENTIN[4], J. KREMKOW[2];

Abstract: The output of the retina is carried by retinal ganglion cells (RGCs) along parallel functional pathways to multiple areas distributed across the vertebrate brain. The functional organization of the synaptic connections between RGCs and their postsynaptic target neurons is largely unknown. Here, we discovered that high-density Neuropixels probes allow the measurement of large populations of RGC axons where they form synaptic contacts, in vivo. The electrophysiological signature of RGC afferent inputs is made of a triphasic waveform composed of the axonal action potential, the axonal terminal response and, finally, the corresponding responses from the synaptically connected dendrites. The signal is spread across multiple recording sites, capturing the axonal synaptic contact field of individual RGCs in vivo. Consequently, midbrain neurons can be recorded simultaneously with their presynaptic RGC inputs, at large scales reaching up to 200 functionally connected pairs in individual recordings. Furthermore, we confirmed that these large-scale paired recording are possible in both the mammalian superior colliculus (mouse, Mus musculus) and the avian optic tectum (zebra finch, Taeniopygia guttata). Using our novel approach to study the spatial organization of retinal axons within the midbrain, we discovered that retinal mosaics are mapped onto the midbrain isomorphically with single cell precision. Functionally, we show that single RGC axons connect to their target neurons with strong and specific connections, i.e. a limited functional convergence and log-normally distributed connection strength. Overall, our results show that high-density electrodes can capture multiple neuronal compartments simultaneously in vivo, including afferent axons and their synaptically evoked dendritic responses as well as somatic activity of local neurons; permitting large-scale paired recordings between brain regions. In addition, we conclude that the retinotectal connectivity follows a common organizing principle in mammals and birds that provides a precise and reliable representation of the visual world to neurons in the midbrain.

Title: Separate populations with different response dynamics project to visual thalamus and periaqueductal gray in the superior colliculus of mouse

Authors: *T. WHEATCROFT, A. SALEEM, S. SOLOMON;
Univ. Col. London (UCL), London, United Kingdom

Abstract: The superior colliculus (SC) projects to other brain centres through multiple pathways, which are thought to be important in rapid, visually guided behaviours. Projections from the SC to the visual thalamus and the periaqueductal gray (PAG) may be important for behaviour, however the extent to which these projections are anatomically distinct remains poorly understood. Moreover, whether these projections are functionally distinct, in terms of visual tuning and dynamics, is not known. We assessed the anatomical and functional segregation of these pathways in adult male C57BL6/J mice.
To assess anatomical segregation we injected CTB conjugated to different fluorophores into the visual thalamus and periaqueductal gray. We found that thalamus-projectors were concentrated in the optic layer, whereas PAG-projectors were mainly in the intermediate and deep layers. At the interface between the optic and intermediate layers, thalamus and PAG-projectors formed intermingled but separate populations of neurons.
To assess functional segregation we injected retrogradely-transported Cre virus into an area, to gate expression of GCamp7s in the SC. We implanted a lens above the SC and measured the global, calcium-dependent fluorescent signal while presenting visual stimuli to head-fixed mice free to run on a treadmill. In both projection populations this global signal was responsive to approaching and translating objects, preferred slower visual speeds, and preferred novel visual stimuli. Thalamus-projectors showed more sustained responses, while PAG-projectors primarily responded to the onset of visual stimuli. Both populations showed increase in calcium signal around the onset of locomotion.
In summary, we found parallel projections from SC to visual thalamus and PAG. The tuning of visual responses in the two pathways was similar but the dynamics of response were not. The different dynamics may be adaptive, allowing possibility of rapid responses to visual objects via projections to PAG, and sustained analysis of the same objects via projections to visual thalamus.

Title: Trans-seq decodes a specific mammalian retinotectal synapse assembled by nephronectin

Authors: *F. WANG[1], N. Y. TSAI[1], K. TOMA[1], C. YIN[1], J. TAKATO[4], E. L. PAI[2], J. L. RUBENSTEIN[3], E. M. ULLIAN[1], X. DUAN[1];

Abstract: Precise neural circuit assembly is necessary for the brain to process complex sensory information and produce proper behaviors. While significant progress has been made on classifying mammalian neuronal types and understanding molecular mechanisms for local neural circuit assembly, there is a lack of systematic methods to map long-range synaptic connections and decode the underlying molecular determinants of such connectivity. Here, we developed Trans-Seq to fulfill this task, bypassing tedious anatomical and functional measurements. Trans-Seq efficiently maps connectivity across neuron types and reveals information of their corresponding transcriptional profiles, thereby uncovering candidate molecules that may confer wiring specificity. Trans-Seq uses a versatile and optimized fluorescent anterograde transsynaptic tracer, enabling isolation and transcriptional profiling of individual post-synaptic partners of genetically or regionally defined presynaptic cells. Using mouse retinotectal connections as a model system, we applied Trans-Seq to study how long-range synaptic specificity is achieved from the eye to the brain. By applying the anterograde tracer to all retinal ganglion cells (RGCs), the subsequent Trans-Seq allowed us to classify all retinorecipient neuron types in the superior colliculus (SC). Furthermore, we identified distinct input patterns onto these SC recipient neurons by conducting differential Trans-Seq from two distinct RGC subclasses. Through such characterizations and comparisons, we identified a unique and specific synaptic connection from αRGCs to Nephronectin-positive wide-field neurons (NPWFs) in the SC. This synaptic pair was subsequently validated using genetic labeling, electrophysiology, and retrograde tracing. Furthermore, we revealed, using Trans-seq transcriptomics data, that the synaptic pair is wired together via interactions between presynaptic Integrin-α8β1 and post-synaptic Nephronectin. To our knowledge, Nephronectin is the first cue discovered in mammalian SC to confer retinotectal synaptic specificity at neuronal type resolution. These results demonstrate how Trans-Seq efficiently maps long-range synaptic connections at neuron-type resolution and simultaneously captures molecular determinants for synaptic specificity. This new platform offers a new avenue to decode circuit assembly across brain regions. Using molecular and genetic tools gained from circuit mapping, we are pursuing new directions to link these genetically defined parallel retinotectal circuits to different visual evoked behaviors, such as looming responses or prey-capture behaviors.

Title: Characterization of visual response properties and connectivity of Wide-field vertical neurons in the mouse superior colliculus

Authors: *E. SAVIER, H. CHEN, K. MCHANEY, J. CANG;
Biol. and Psychology, Univ. of Virgina, Charlottesville, VA

Abstract: Vision is a sense that serves many different ethological functions across species. Visual information can be used to either detect preys or predators, and therefore generate orienting or escaping responses. The superior colliculus has been implicated in the orchestration of these behaviors. Within this structure, at the interface between the primary and the secondary visual pathway, lay the wide-field vertical neurons (WFV). WFV are a conserved morphologically defined cell-type found across many taxa from reptiles to highly visual mammals, independently of their visual ecology. These neurons display wide arborization and typical bottlebrush distal tips which form connections with retinal ganglion cells axonal terminals. In mammals, these neurons receive direct inputs from the retina and the primary visual cortex, and have the pulvinar as a known target, however, their brain-wide connectivity remains to be identified. These cells display peculiar response properties, but despite their ubiquity and unique morphology, their contribution to vision remains elusive.
In this study, we have characterized WFV morphology, connection, and visual response properties *in vivo* in the laboratory mouse. Sparse retrograde tracing using an intersectional approach revealed their exquisite morphology and projection patterns. Two-photon calcium imaging in awake mice using a transgenic Cre-line targeting specifically WFV (NTSR1-Cre) confirmed their unique response properties. WFV showed a strong preference for small moving stimuli and a slight bias for certain directions. Interestingly, visual responses to distinct visual stimuli showed variable degrees of adaptation upon repeated presentation. In addition, Cre-dependent rabies tracing unraveled a variety of sources of input which had not been described previously.
These results place WFV as a major integrator of visual information in the superior colliculus. Their adaptation to looming stimulus suggest a role in ethologically relevant function in avoiding inappropriate responses, while sustained responses to small moving stimulus might be linked to attentional processes and orienting behaviors. Taken together, this initial characterization paves the way to elucidate the role of these neurons in visual behavior.

Title: Efficiency of retrograde labeling by rAAV2-retro-hSyn viral vector in the rat retinocollicular pathway.

Authors: *R. NANJAPPA, M. D. DILBECK, J. R. ECONOMIDES, J. C. HORTON;
Ophthalmology, Univ. of California San Francisco, San Francisco, CA

Abstract: Viral vectors allow tracing of neural circuits and hold potential for pathway-specific manipulation. Efficiency of labeling depends upon the viral serotype, the promoter used to drive expression of the gene of interest, and the neural pathway being probed. In 7 rats we injected a 50:50 mixture of two tracers, rAAV2-retro-hSyn-EGFP and rAAV2-retro-hSyn-mCherry, using electrophysiological recordings to guide placement into the visually responsive layers of the superior colliculus. A single injection was made on either one side or both, concentration 1.9 - 2.2 x 10^{13} vg/ml, total volume 1-2 µl. In vivo fundus imaging was performed 3 - 20 days afterwards. No labeling was present at 3 days, but later, retrogradely labeled retinal ganglion cells (RGCs) became visible. Most cells were labeled by both EGFP and mCherry, but clear examples of single-labeled cells were present. In one animal, the fundus image was aligned with the post-mortem retinal flatmount to establish that the in-vivo labeling truly corresponded to RGCs. In all rats, it was evident that only a minority of RGCs was virus-labeled. At best, 20% of DAPI-stained cells in the ganglion cell layer exhibited EGFP or mCherry fluorescence. The concordance of labeling by the 2 fluorophores was surprisingly imperfect, confirming observations from fundus photography. For example, in one heavily labeled field 717 cells exhibited mCherry, 532 exhibited EGFP, but only 357 cells exhibited both. To determine the percent of cells comprising the retinocollicular pathway that were retrogradely labeled by the viruses, we mixed Fluorogold into the injection pipette. Unfortunately, this strategy severely reduced the amount of retinal EGFP and mCherry labeling. We therefore staggered the injections, first injecting a mixture of the two viruses, followed 4 weeks later by Fluorogold at the same site. In the injection case showing the most robust labeling, 32% of retinocollicular cells were labeled (517 mCherry/1588 Fluorogold). We conclude that: 1) In-vivo fundus photography can be used to image RGCs labeled by fluorophore-expressing viral vectors transported retrogradely from the superior colliculus, 2) Some RGCs exhibit only a single label, despite the same virus encoding either label being mixed together in the injection pipette, 3) Addition of Fluorogold to the injection pipette containing the viruses impairs fluorophore expression, and 4) rAAV2-retro-hSyn succeeds at labeling, at most, only a third of the RGCs that projects to the superior colliculus in the rat.

Title: Correlated variability across neurons in primate superior colliculus depends on functional class

Authors: *L. N. KATZ, G. YU, J. P. HERMAN, R. J. KRAUZLIS;
Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: Neuronal responses to repeated presentations of the same stimulus are variable, and often correlated between pairs of neurons in a population. Such correlated variability (spike count correlations, r_{SC}) can constrain how information is read out across the brain and is therefore a key property of the neural code that guides behavior. A large body of work has identified that the degree of r_{SC} is influenced by behavioral goals and by intrinsic properties of the neurons such as tuning. However, investigations of r_{SC} have tended to take place within a brain region, without taking local microcircuits into account. Such microcircuits can serve different functions, reflect different processing stages, and be associated with either feedforward or feedback signals, likely leading to distinct degrees of r_{SC} within the region.Here we report that r_{SC} depends on functional class, a neuronal property thought to reflect membership in a distinctive microcircuit. We recorded from populations of neurons (n = 672) in the macaque superior colliculus (SC), a structure that contains neurons with well-defined functional classes. During an oculomotor working memory task, different classes of SC neurons exhibited differing degrees of r_{SC}. Neurons functionally classified as “visual” or “movement” exhibited modest degrees of r_{SC}, while those classified as “delay” (which exhibit persistent activity in the absence of sensory input) displayed the highest degree of r_{SC}, especially during the delay epoch of the task. The higher degree of r_{SC} in delay neurons was more pronounced during memory guided saccades than visually guided, and was present only among pairs of neurons within SC on one side of the brain, not between SCs.The dependence of r_{SC} on functional class indicates that subpopulations of SC neurons occupy distinct circuit niches with different modulatory inputs. Overall, these findings highlight the importance of considering functional class when interpreting the significance of r_{SC} in the SC, and more broadly, in other regions of the primate brain.

Title: Visual response properties of VIP- and SST-positive neurons in the mouse superior colliculus

Authors: *V. J. DEPIERO[1], Y. LIU[1], J. N. CAMPBELL[1], J. CANG[1,2];
[1]Biol., Univ. of Virgina, Charlottesville, VA; [2]Psychology, Univ. of Virginia, Charlottesville, VA

Abstract: The superior colliculus (SC) and its non-mammalian homologue the optic tectum is a midbrain structure important for visual processing, multimodal integration, and sensorimotor transformation. In mice, more than 85% of retinal ganglion cells project to the superficial SC, making it the most prominent visual center in this species. Here, we investigate the function of superficial SC neurons from two readily available mouse lines, the vasoactive intestinal peptide-expressing (VIP)-IRES-Cre mice and the somatostatin-expressing (SST)-IRES-Cre mice. By crossing these mice with the Ai9 reporter line and virally expressing GCaMP6f, we recorded visually evoked neuronal responses in the SC of awake animals using two-photon fluorescence calcium imaging. Our suite of visual stimuli allows us to extract various feature-specific aspects of visual processing, including direction and orientation selectivity, response to a looming disk, and receptive field mapping. We also use RNAscope to validate the spatial distribution and reveal excitatory/inhibitory identity of these cells by co-staining for vesicular glutamate transporter 2 (VGluT2), vesicular GABA transporter (VGAT) and VIP or SST in wildtype animals. We find that VIP expressing neurons are sparsely labeled in the most superficial layer of the SC. Visual responses of VIP neurons show less selectivity to direction, orientation, and looming stimuli than neighboring VIP negative neurons. The receptive fields of VIP positive neurons show highly overlapping ON and OFF subfields. On the other hand, SST neurons are predominantly labeled throughout the lower visual layers of the superficial SC. SST positive neurons also have overlapping ON and OFF receptive fields and have a similarly low preference of direction selectivity as their neighboring SST negative neurons. Finally, unlike what is observed in the cortex, VIP-positive neurons in the SC actually express VGluT2, a marker of excitatory neurons; and SST-positive neurons in the SC express VGAT, confirming that they are in fact inhibitory cells. Together these findings show that VIP- and SST-positive neurons in the visual layers of the SC are likely distinct cell types of visually responsive neurons that respond to both ON and OFF stimuli but lack strong tuning toward a particular visual feature. These data will aid future studies to understand how excitatory and inhibitory neurons process visual information in the SC.

Title: Attention-related activity emerges in mouse superior colliculus through learning

Authors: *K. K. COVER, L. WANG, K. ELLIOTT, R. J. KRAUZLIS;
Lab. of Sensorimotor Res., NEI, Bethesda, MD

Abstract: Visual selective attention is not wired into the brain fully formed and immutable but is learned and refined as animals interact with their environment. Among the brain structures that could play a central role in this process, the superior colliculus (SC) stands out because of its highly conserved role in coordinating behavioral responses to visual events and its functional link to mechanisms of reinforcement learning in the basal ganglia. Here we investigated this process by studying neuronal activity in the mouse SC at different stages of learning of a covert visual selective attention task. In our visual attention task, mice learned to detect an orientation change in one of two Gabor patches with the location of the potential change indicated by a preceding spatial cue. We recorded neuronal spiking activity during this task in superficial and deeper SC layers in three cohorts of mice that possessed different levels of expertise: task-naïve (N=6 mice, n=417 units), intermediate learners (N=5, n=429), and experts (N=4, n=378). We found several markers of attention-related SC activity that differed by expertise and SC laminar location. Response habituation of SC neurons for task-relevant visual events was greatest in the deeper layers of naïve mice and was significantly less prominent in intermediate and expert mice. In contrast, response habituation was weaker in superficial SC layers and varied little across expertise levels. Attention-related modulation - defined as enhanced activity evoked by the visual stimulus at the cued location during the delay period prior to the orientation change - was absent in task-naïve mice, emerged with intermediate learners, and was largest in the expert mice. This attention-related modulation was also more pronounced in the deeper SC layers. Together, these results demonstrate that specific components of SC neuronal activity related to visual selective attention emerge over time in particular SC layers as mice learn the value of spatial cues and visual events.

Title: Interdigitation of Ocular Inputs to the Macaque Superior Colliculus

Authors: *M. D. DILBECK, Z. R. SPAHR, J. R. ECONOMIDES, R. NANJAPPA, J. C. HORTON;
Univ. of California San Francisco, San Francisco, CA

Abstract: Approximately 10% of retinal ganglion cells project to the superior colliculus in the macaque. Hubel, LeVay, and Wiesel (1975) injected a radioactive tracer into one eye in 4 macaques to label the ocular inputs to the superior colliculus. Axon terminals were present in the stratum griseum superficiale, aggregated into irregular clumps of silver grains separated by unlabeled gaps. By analogy with the ocular dominance columns in layer 4C of striate cortex, they concluded that the unlabeled holes corresponded to inputs from the other eye. An alternative interpretation is that inputs from the two eyes are largely overlapping, with the unlabeled gaps corresponding to zones within the superficial gray that receive no direct ocular input. Such an anatomical arrangement might explain why virtually all tectal cells are binocular, unlike cells in layer 4C of striate cortex, which are mostly monocular. To address this issue, we performed experiments in 2 macaques. In the first animal, tritiated proline was injected into the right eye and the pattern of radiolabeling was examined in serial 30 μm sections through the entire superior colliculus. The results confirmed the prior report of Hubel et al, by showing marked aggregation of silver grains with interspersed unlabeled zones. There were also regional differences in the density and laminar distribution of the proline label that depended on location within the visual field representation. In the second animal cholera toxin B - Alexa 488 was injected into the right eye and cholera toxin B - Alexa 594 was injected into the left eye. The superior colliculus was sectioned serially at 40 μm and the two fluorescent labels were compared in each section. The main finding was that the two labels tended to interdigitate: conspicuous gaps in one label were usually filled by a cluster of the other label. Rarely, gaps in both labels coincided. Throughout much of the superior colliculus, the labels from the two eyes showed extensive overlap. We conclude that ocular inputs to the macaque superior colliculus form a dovetailed mosaic, but unlike a fine piece of joinery, there is much intermingling in projections. There also exist laminar and regional differences in the density of label from each eye that are related to visual topography.

Title: Functional diversity of identified dopamine substantia nigra neurons in freely moving mice

Authors: *D. SCHENKEL, M. KUHN, S. BETZ, G. SCHNEIDER, J. ROEPER;
Johann Wolfgang Goethe-University Frankfurt, Frankfurt, Germany

Abstract: Dopamine substantia nigra (DA SN) neurons are a major target of Parkinson's disease (PD) and their degeneration is thought to contribute to the core motor impairments such as bradykinesia in PD. However, the functional relevance of electrical activity patterns of DA SN neurons for the control of voluntary movement is unclear. Also, there is considerable diversity among DA SN neurons. Alves da Silva and colleagues (2018) showed that about 50% of recorded DA SN neurons transiently increase and about 25% of recorded DA SN neurons decrease their firing rate shortly before the initiation of self-paced

movement in the open field. To study these neurons in awake behaving mice in detail, we performed extracellular single-unit recordings of DA SN neurons in awake freely moving mice, while simultaneously recording their head and body movements using an accelerometer and a video-tracking software. In our data set of n = 61 (N = 18) pharmacologically identified DA SN neurons, we confirmed the functional diversity with regards of transient responses in close associations to spontaneous movement initiation.To differentiate between DA SN neurons with distinct axonal projections, we currently establish retrograde tagging methods.

Abstract: Based on electrophysiological properties, dopamine (DA) midbrain neurons can be segregated into two main subpopulations: conventional DA neurons projecting to dorsal striatum or the lateral shell of nucleus accumbens and atypical DA neurons projecting - among others - to medial shell and core regions of nucleus accumbens or the medial prefrontal cortex. While some of their distinct biophysical properties (Lammel et al. 2008) and different firing pattern in vivo (Farassat et al. 2019) have already been described, their differences regarding maximal firing rates and their distinct onset of depolarization block have not yet been studied in detail. By systematically exploring the parameter space of a computational single-compartment model of DA neurons, we identified slow inactivation of voltage-gated sodium channels as a candidate mechanism that might differentiate between conventional and atypical DA neurons. In particular, the model suggested that conventional DA neurons enter depolarization at lower firing rates because of enhanced slow inactivation of voltage-gated channels and that depolarization block could be overcome by injection of additional depolarizing current. This prediction was tested with projection-specific in vitro patch-clamp experiments in identified and retrogradely labeled DA neurons. We confirmed that lateral shell-projecting, conventional DA neurons entered depolarization block at lower frequencies (17.0 ± 3.3 Hz; n = 7, N = 3) compared to the medial shell-projecting, atypical DA neurons (31.9 ± 4.6 Hz; n = 13, N = 3). In addition, only lateral shell-projecting, conventional DA neurons triggered an action potential (amplitude 37.5 ± 10.2 mV, peak slope 15.1 ± 4.8 V/s, threshold for spike generation = 5 V/s; n = 7, N = 3) induced by additional depolarizing current injection during depolarization block, while atypical DA neurons showed a significantly slower and smaller depolarizing

responses (amplitude 17.7 ± 3.8 mV, peak slope 4.5 ± 1.7 V/s, threshold for spike generation = 5 V/s; n = 13, N = 3). To further test the predictions of the computational models, we currently study gating properties of voltage-gated sodium channels in defined conventional and atypical DA neurons.

Title: Projection-specific hierarchical organisation of somato-dendritic dopamine 2 receptor inhibition among midbrain dopamine neurons

Authors: *N. HAMMER, B. FISCHER, S. STOJANOVIC, J. ROEPER;
Inst. of Neurophysiol., Frankfurt Am Main, Germany

Abstract: Most midbrain dopamine (DA) neurons are inhibited by activation of somato-dendritic D2-autoreceptors (D2R) (1). In their landmark paper, Beckstead et al. demonstrated the presence of synaptic D2R signalling between pre- and postsynaptic DA neurons in midbrain slices in vitro (2). In addition, spontaneous D2R mediated IPSCs were recorded in DA neurons showing functional dendro-dendritic vesicular DA release between midbrain DA neurons (3). Previous studies from our group reported different D2R and GIRK2 expression levels in midbrain DA neurons projecting to distinct target areas (4), but the functional contribution of synaptic and extrasynaptic D2R signaling within and across these DA subpopulations is currently unknown. Distinct somato-dendritic D2R-signaling might also contribute to the different functional in vivo properties we recently identified (5).Therefore, we recorded electrically evoked, D2R-mediated slow inhibitory postsynaptic currents (eIPSCs) in retrogradely identified DA neurons in vitro. These sulpiride-sensitive sIPSCs displayed kinetics and current peak amplitude ranges in agreement with previous studies (2). However, we observed significant differences in peak D2R-sIPSC amplitudes between DA neurons projecting to ventral (i.e. lateral shell of the nucleus accumbens (lNAcc), medial shell of the nucleus accumbens (mNAcc)) and dorsal striatum (e.g. dorsomedial striatum (DMS), dorsolateral striatum (DLS)). Mean eIPSC amplitudes of lNAcc-projecting DA neurons displayed at least two-fold larger currents compared to DA neurons projecting to other compartments of the striatum (lNAcc: 27.1 ± 2.5 pA (n = 21); mNAcc =12.2 ± 3.1 pA (n = 9); DMS = 16.3 ± 1.4 pA (n = 23); DLS =12.5 ± 1.3pA (n=18).To investigate the interaction between defined DA subpopulations, we developed a projection-specific viral approach to optogenetically excite a projection-selective pool of presynaptic DA neurons while recording a single postsynaptic DA neuron with retrogradely defined axonal projections. Optogenetically stimulating presynaptic DA neurons projecting to DLS while recording a DA neuron projecting to lNAcc, we recorded robust optically-evoked, sulpiride-sensitive D2-IPSC (oIPSC) ($lNAcc_{DLS}$: 14.9 ± 3.7 pA (n = 13). In contrast, when reversing pre- and postsynaptic DA neurons, little to no oIPSCs were recorded in DLS projecting DA neurons (DLS_{lNAcc}: 3.6 ± 1.4 pA (n = 9). These results suggest a lateral-to-medial hierarchical organisation of D2R-inhibition among distinct DA subpopulation

in the midbrain. (1) Lacey et al. 1987(2) Beckstaed et al. 2004(3) Gantz et al. 2013(4) Lammel et al. 2008(5) Farassat et al. 2019

Title: An in vivo patch-clamp study of K-ATP Channels in midbrain dopamine neurons

Authors: *R. EGGER, J. ROEPER;
Goethe-University Frankfurt, Frankfurt am Main, Germany

Abstract: We have recently established deep in vivo patch-clamp recordings of dopamine (DA) midbrain neurons in mice (Otomo et al. 2020). We now apply this approach to study the functional role of ATP-sensitive potassium (K-ATP) channels. We have previously demonstrated that the expression of K-ATP channels in DA neurons in the medial substantia nigra (SN) are required for in vivo burst firing and in turn for novelty-induced exploratory behavior (Schiemann et al. 2012). However, the moment-to-moment contribution of K-ATP channels to ongoing in vivo activity of DA neurons has not yet been explored. To address this question, we added 100 µM of the K-ATP channel blocker tolbutamide to the internal pipette solution to inhibit these channels selectively in the target cell in vivo. Previous control experiments comparing electrical in vivo activity in on-cell and whole-cell mode demonstrated stable firing pattern and gave no evidence that in vivo whole-cell patching *per se* altered intrinsic K-ATP channel activity (Otomo et al. 2020). When dialyzing tolbutamide into DA SN neurons, we observed distinct effects. In n = 11/22 cells, the firing frequency rapidly increased, which was accompanied by a net membrane depolarization. Some of these cells (n = 7 of 11) went into depolarization block, from which they were rescued by injection of negative currents. In contrast, DA neurons in the ventral tegmental area (VTA, n = 11) did not alter their in vivo firing activity in response to tolbutamide dialysis. This preliminary data set suggests that in a least a subset of DA SN neuron K-ATP channels are continuously open and shape ongoing electrical activity. Similar to previously reported for pancreatic alpha-cells (Göpel et al. 2020) open K-ATP channels in some DA neurons might be necessary for action potential firing. References:

Title: Bidirectional spike frequency adaptation in neurons of the external globus pallidus

Authors: *C. J. WILSON;
Univ. Texas San Antonio, San Antonio, TX

Abstract: In the external segment of globus pallidus (GPe), the neurons fire continuously even in the absence of synaptic input. The balance of afferent excitation and inhibition changes the net synaptic current and thereby the firing rates of each cell. An increase in striatal inhibition in GPe is associated with models of Parkinson's disease and is expected to reduce the average firing rate, but in most studies the change in firing rate is modest or even undetectable. This is unexpected because GPe neurons have long been known to be very sensitive to transmembrane currents, although the current steps used in those studies have been brief (0.5-1 s), disregarding possible adaptation. The sensitivity of two kinds of GPe neurons, identified by expression of either parvalbumin (PV) or Npas1, were studied in mouse slices using 20 s current pulses. As reported by others, both neuron types were usually spontaneously active. On average, PV neurons fired faster and were more regular, but there was overlap between the distributions of these for the two groups. Both adapted their firing rates as expected at the onset of a depolarizing current step. Increases in firing rate caused by depolarizing currents decayed on a similar time scale in both cell types. There was some recovery of firing rate during hyperpolarizing pulses in both cell types, with larger currents required to maintain silence for 20 seconds than was required to initially silence firing. However, PV and Npas1 cells differed in this escape of firing during hyperpolarization. Whereas Npas1 neurons could readily be silenced for the entire 20 s period by modest injected currents (<50 pA), PV neurons routinely resumed firing after a few seconds, despite currents 2-3 times larger. PV and Npas1 cells were readily differentiated from each other by this one measurement. The ability of PV cells to overcome hyperpolarizing current was also evident in their membrane potential trajectories during the hyperpolarizing pulse, consisting of a slow depolarizing ramp leading to firing at increasing rates throughout the pulse. The results suggest that PV neurons, which target the subthalamic nucleus and basal ganglia output neurons are less likely to be silenced by prolonged striatal inhibition than Npas1 neurons, which do not project to basal ganglia output neurons. PV neurons' firing has a much higher sensitivity to transient changes in the balance of synaptic excitation and inhibition than to its DC average.

Title: Local connectivity alter spike responses in network models of globus pallidus pars externa

Authors: *E. OLIVARES[1], M. H. HIGGS[2], C. J. WILSON[1];
[1]Univ. Texas San Antonio, San Antonio, TX; [2]Oklahoma Med. Res. Fndn., Oklahoma City, OK

Abstract: Globus pallidus pars externa (GPe) is traditionally considered a relay nucleus that inverts the signal arriving from striatum and passes it to the basal ganglia output neurons, but interconnections between the GPe neurons may alter those signals. GPe neurons are autonomous oscillators whose local axon collaterals create an active inhibitory network, but spike timing correlations among GPe neurons have been elusive. We constructed network models of GPe to investigate the effects of local connectivity on firing and responses to stimuli. Because GPe neurons are oscillators, we simulated them using phase models that predict the time of the next spike considering all the synaptic inputs arriving during the inter-spike interval (ISI). We experimentally measured the firing rates, and phase resetting curves of 19 GPe neurons in mouse brain slices. Using this dataset, we generated 1000 artificial neurons with diversity similar to that of the recorded neurons. As the connectivity pattern in GPe is not fully known, we tested the network in two different architectures: small-world and random. Each network was created using the same set of 1000 neurons and the same total number of connections (10/neuron). At steady state, the two networks produced similar distributions of firing rates and coefficient of variation of ISI. Pairwise correlations and cross-correlations were scarce and mostly limited to monosynaptically connected pairs. When stimulated by a shared inhibitory input, the post-stimulus time histogram (PSTH) of the networks showed a biphasic response that is rapidly damped by the network synaptic interaction. The network decreased the size and reduced cell-to-cell differences in the initial decrease in response probability by a differential balance in the effect of external inhibition and local disinhibition. The initial response perturbed the network stationary probability distribution of phases, increasing the density of neurons at late phases in their firing cycles. As the external inhibition decays, the neurons held by inhibition at late phases resumed their phase advance, generating a transient increase in firing probability, this secondary response was limited to the fastest neurons in the network. Our results were robust across the network architectures and show that in sparsely coupled networks of heterogeneous autonomous oscillator neurons like GPe, the local inhibitory activity does not generate a global synchrony. We also show that during the response to shared inputs, the local interactions reduces the temporal reverberation of the stimulus in the network, presumably allowing a more effective temporal discrimination of external stimuli.

Title: Local inhibition in the GPe controls the firing patterns of GPe neurons and shapes their responses to external input

Authors: *J. A. JONES[1], M. H. HIGGS[2], C. J. WILSON[2];
[1]Univ. of Texas at San Antonio, San Antonio, TX; [2]Biol., The Univ. of Texas at San Antonio, San Antonio, TX

Abstract: The external globus pallidus (GPe) is a network of autonomous oscillators that influence all basal ganglia nuclei through their widespread axonal projection patterns. Two neuronal superclasses with distinct projection patterns dominate the GPe, parvalbumin-positive (PV) and neuronal PAS domain protein 1-positive (Npas1) neurons. PV and Npas1 GPe neurons exhibit different ranges of autonomous firing activity and provide ongoing GABAergic input streams to one another through local axon collaterals. To determine the effect of local inhibition on the firing patterns of PV and Npas1 GPe neurons, we obtained perforated-patch, current-clamp recordings in coronal slices of the GPe from male and female mice before and during GABA-A receptor blockade. GABA-A blockade had variable effects on GPe neurons' firing rates and regularity. PV neurons with high spontaneous IPSP rates exhibited large increases in firing rate and regularity following blockade, whereas Npas1 neurons showed variable firing rate changes that were weakly correlated with blockade. These results suggest that local collaterals in the GPe exert stronger control of PV firing than Npas1 firing, although they receive a similar synaptic barrage. In addition to the local inhibition, PV neurons receive a powerful inhibition from GABAergic striato-pallidal neurons of the indirect pathway. To determine whether local collaterals propagate indirect pathway inputs through the GPe network, we recorded spontaneous IPSCs of GPe neurons while applying brief light pulses to indirect pathway striato-pallidal axons expressing channelrhodopsin. Evoked striato-pallidal synaptic input reset periodic IPSCs from local collaterals, showing that striato-pallidal inhibition is propagated through the GPe network. To determine whether local collaterals from PV neurons shape spiking responses to external inhibition, we recorded from single PV neurons while applying brief inhibitory pulses to all PV neurons in the GPe network using archaerhodopsin both before and after blocking synaptic inhibition from local collaterals with GABA-A receptor blockade. Brief optogenetic inhibition of PV neurons transiently reduced both their firing rates and IPSP rates. After GABA-A blockade, optogenetic inhibition produced greater reductions in firing rate and greater spiking reset. These results suggest that local collaterals in the GPe reduce the magnitude of PV neurons' responses to external inhibition but may increase the bandwidth of GPe signaling by removing prolonged oscillatory responses.

Title: Dynamic recruitment of cell-type specific inhibition in premotor cortex during motor learning

Authors: *S. E. ARROYO, S. BARATI, K. GANGULY;
UCSF, San Francisco, CA

Abstract: Motor learning depends on coordinated changes in neuronal population dynamics in both premotor (M2) and motor (M1) cortex. Prior work supports a model in which M2 relays contextual information to M1, thereby exerting a top-down modulatory influence on M1 activity. However, the synaptic mechanisms that mediate the evolution in M2 population dynamics over the course of motor learning are not well understood. To investigate how cell-type specific inhibition contributes to emergent neural dynamics in M2 during motor learning, we have recorded from vasointestinal peptide (VIP) and somatostatin (SST) expressing inhibitory interneurons across several days as mice learned a skilled reach-to-grasp task. Neuronal activity was recorded by selectively expressing a genetically encoded calcium indicator (GCaMP 7f) in SST or VIP neurons. Transfected neurons were then imaged using microendoscopic, single-photon techniques, allowing for simultaneous recording from large ensembles of genetically identified neurons in freely moving and behaving mice. Over the course of five behavioral sessions, mice learned to reach for a small food pellet reward (a skill that has been previously shown to depend on motor cortex), manifesting as a five-fold decrease in reaction time and 1.5-fold increase in reach success. In early behavioral sessions, both SST and VIP neurons were recruited around the time of reach onset. Over the course of learning, SST recruitment was shifted to the right (later in time with respect to reach onset), and as a population SST interneurons were increasingly co-activated in a narrow temporal window. In contrast, VIP recruitment was shifted to the left (earlier in time with respect to reach onset) and as a population VIP recruitment became less synchronous with learning. These data suggest that VIP neurons in particular may be important in shaping preparatory activity and processing contextual information in the pre-reach epoch. Consistent with this theory, presentation of a distractor auditory tone in the inter-trial period resulted in VIP but not SST activation. Together, these findings demonstrate that specific classes of inhibitory cells are recruited in a temporally divergent manner over the course of motor learning. This cell-type specific segmentation of inhibition may be an important synaptic mechanism for defining distinct temporal windows of preparatory motor processing in M2.

Title: Impaired motor adaptation in the absence of cerebellar signals in behaving monkeys

Authors: *S. ISRAELY[1], R. HAREL[2], F. MAWASE[3], Y. PRUT[1];
[1]Hebrew Univ. of Jerusalem, Jerusalem, Israel; [2]The Sheba Med. Ctr., Tel Hashomer, Israel; [3]Technion – Israel Inst. of Technol., Haifa, Israel

Abstract: The cerebellum plays a major role in motor learning and adaptation. In human and non-human primates, cerebellar control of motor output is primarily mediated through its impact on the motor cortex. However, little is known about the way that cerebellar signals shape motor cortical activity to allow efficient adaptation to external perturbations. We addressed this question by studying the changes in motor behavior and motor cortical activity during a motor adaptation task, while manipulating cerebellar outflow. Monkeys (n=2) were trained to wear an exoskeleton (KINARM system), and make center-out movements to 1 of 8 pre-cued targets and adapt to a velocity-dependent force field (FF). A reversible block of cerebellar outflow was introduced using a High Frequency Stimulation (HFS) electrode chronically implanted in the ipsilateral superior cerebellar peduncle. We found that blocking cerebellar outflow during FF trials significantly limited motor adaptation, as manifested by an increase in residual errors (measured as the deviation from a straight path) relative to control FF trials. This effect was especially pronounced when errors were measured in the early phase of movement (up to 250 msec), which is largely dominated by feedforward control. Next, we used a state space model to quantify the properties of the adaptation process. We found that cerebellar HFS significantly limited adaptation through a reduction in sensitivity to errors (15.1%, and 21.2%, $p << 0.001$ for both monkeys), not by an increase in the rate of forgetting ($p=0.26$ and $p=0.46$). Finally, we ruled out the possibility that cerebellar HFS impaired adaptation by simply adding noise to the external perturbation. Although we found that applying HFS led to a significant increase in motor variability compared to control trials, this variability did not trigger an adaptive response, suggesting that HFS increased internal noise. Importantly, we found no correlation between the change in error sensitivity and the level of internal noise either during the control or the HFS trials. These results suggest that blocking cerebellar outflow leads to increased internal noise and decreased error sensitivity. The net outcome of these (at least partially independent) events is impaired motor adaptation.

Title: Global and subtype-specific modulation of cortical inhibitory neurons orchestratedby acetylcholine during motor learning

Authors: *C. REN[1], K. PENG[3], R. YANG[4], W. LIU[1], C. LIU[2], T. KOMIYAMA[1];
[1]Neurobio. Section, Dept. of Neurosciences, Ctr. for Neural Circuits and Behavior, [2]Univ. of California

San Diego, La Jolla, CA; [3]Interdepartmental Neurosci. Program, Yale Univ., New Haven, CT; [4]Sch. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA

Abstract: Inhibitory neurons (INs) consist of distinct subtypes with unique functions, and their subtype-specific modulation shapes excitatory circuits during various sensory and cognitive processes. Previous studies on INs mainly focused on single brain regions, and thus it remains unclear whether the modulation of IN subtypes occurs globally across multiple regions. Here, we monitored the activity of different cortical IN subtypes at both macroscale and microscale in mice learning a lever-press task. We found that learning evoked a global modulation of IN subtypes, not only in the primary motor cortex but throughout the cortex. The initial learning phase involved strong movement-related activation of vasoactive intestinal peptide-expressing inhibitory neurons (VIP-INs) and weak activation of somatostatin-expressing inhibitory neurons (SOM-INs). Furthermore, inactivating VIP-INs increased SOM-IN activity during movements and impaired initial learning. Concurrently, cortical cholinergic inputs from the basal forebrain were more active during the initial learning phase but became less engaged over learning. Manipulation of the cholinergic system impaired motor learning and differentially altered movement-related activity in cortical IN subtypes. Pharmacological manipulation of different cholinergic receptor subtypes further revealed that the cholinergic modulation of IN activity was largely through nicotinic receptors. These results reveal that motor learning involves a global and subtype-specific modulation on cortical INs mediated through the cholinergic system, which likely regulates the excitatory circuits distributed across the cortex.

Abstract: The pairing of a task and a sufficient level of stimulation, either natural or artificial, is known to elicit plastic changes in neural circuits. In particular, pairing vagus nerve stimulation (VNS) with behavior has been shown to drive cortical plasticity during auditory discrimination and motor tasks as well as promote functional rehabilitation after injury. It remains unclear, however, whether the plasticity inducing mechanism is related to activation of neuromodulatory centers or the optimization of arousal state, underscoring the need to better understand the mechanisms by which stimulation of peripheral

nerves acts to drive plasticity in neural circuits and enhance behavioral performance. Here, we evaluate how acquisition of a novel motor task is modulated by VNS presented prior to task performance (i.e. priming) similarly to stimulation presented during task performance (i.e. peristimulus) and if these gains are mediated by changes in the engagement of neuromodulatory centers, arousal mechanisms or some combination of the two. Male Long-Evans rats (n = 27) weighing 200-250g were operantly trained to perform a reach and pull task that required them to pull with a predetermined force to receive a pellet reward. Successful acquisition of thes task was determined when they were able to pull with greater than 120g of force on more than 75% of trials over a 10 session period. Rats were randomly assigned to one of 5 cohorts to measure the effects of VNS and arousal based stimulation on learning rate: 1) priming VNS, 2) peristimulus VNS, 3) priming vibrotactile, 4) peristimulus vibrotactile and 5) unstimulated control. Rats in the VNS cohorts were implanted with a bipolar cuff electrode on their left vagus nerve while those in the vibrotactile cohorts wore a sweater with a vibrotactile stimulator placed at the base of their neck. Priming VNS (800uA, 30Hz, cathode leading biphasic pulses 100us/phase) and vibrotactile stimulation were delivered for 120s prior to the start of training, whereas peristimulus VNS (same parameters as priming) and vibrotactile stimulation were delivered for 500ms immediately following each successful pull. We compared the number of sessions to reach task proficiency and variations in pulling force between rats in each cohort. Preliminary data suggests there is no difference in the number of sessions to reach task proficiency or success rates between cohorts suggesting that an arousal based mechanism may be responsible for reported performance improvements.

Title: Reachmaster3d, an experimental platform capable of the precise 3d measurement of whole-arm kinematics as rodents perform freely-behaving reaches.

Authors: *B. NELSON[1], S. IBRAHEEM[2], E. NGUYEN[3], K. E. BOUCHARD[4];
[1]Univ. Of California, Berkeley Neurosci. Grad. Program, Berkeley, CA; [2]Electrical Engin. and Computer Sci., [3]Univ. of California, Berkeley, Berkeley, CA; [4]UCSF, UCSF, San Francisco, CA

Abstract: Reaching is an essential behavior occurring in three dimensions (3-D). Rodents perform dexterous reaching behaviors, however rodent reaching has mainly been quantified during low-dimensional behavioral tasks and resulting kinematic measurements are not-in 3-D. There exists a need for behavioral assays, using high-dimensional tasks, to measure whole-arm reaching kinematic variables in 3-D during freely-behaving reaching. Here we present ReachMaster-3D, a novel assay capable of measuring reaching 3-D kinematics from freely-behaving male rats reaching to a handle varied in position

from 0 to 3 task dimensions. We examine measures of task performance and effect of task complexity on trajectories and velocities extracted using the ReachSplitter-3D system. We then use 3-D kinematic variables within current motor control models to quantify the effects of task dimension on kinematic variability.
ReachMaster and the accompanying ReachSplitter3D library produce robust (<4mm) 3-D kinematic (position, velocity, acceleration) predictions across 27 unique whole-arm and body segments during continuous reaching experiments in an unsupervised manner. To perform this task we developed a behavioral classification pipeline to classify and finely segment reaching behaviors using supervised learning. Using as inputs 3-D kinematics and accompanying sensor data from the ReachMaster assay into a set of pre-trained random forest classification algorithms that separate out unique reaching phenotypes at sub-millisecond temporal resolution, we show that ReachSplitter-3D reliably distinguishes between behavioral subtypes during reaching. We then present a model that performs event detection and segmentation within our high-dimensional time-series datasets. We analyze resulting segmented kinematics across similar reaching classes using trajectory minimization and second-order feedback control models across two unique task paradigms. Our central hypothesis is that modulation of task dimension structures variability in the 3-D kinematics of rodents. Our current research extends the current understanding of freely-behaving rats reaching in 3-D task environments, necessary for modern translational research in kinesiology and neurophysiology of reaching that seeks to fully rehabilitate or restore natural reaching behavior in humans. Our future research will seek to uncover cortical surface representations of kinematic variables during reaching in rodents utilizing the novel research methods shown.

Title: Evolution of gross forelimb and fine digit kinematics during skilled reaching acquisition in rats

Authors: *A. BOVA[1], K. FERRIS[1], D. K. LEVENTHAL[2];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Neurol., Univ. of Michigan, Ann Arbor, Ann Arbor, MI

Abstract: The ability to learn dexterous motor skills is a fundamental aspect of human behavior. However, the underlying neural circuit mechanisms for dexterous skill learning are unclear. Advancing our understanding of motor skill learning requires the integration of modern neuroscientific techniques

with a rigorously characterized dexterous task. The development of automated rodent skilled reaching with paw tracking allows detailed analysis of how reach-to-grasp kinematics evolve during learning. We assessed how both 'gross' forelimb and 'fine' digit kinematics changed as rats learned skilled reaching. We found that improvements in fine motor control evolved on a longer timescale than improvements in gross motor control. These results suggest that gross and fine motor components of dexterous skill are learned over different timescales to improve performance.

Surgery, UCSF, San Francisco, CA

Abstract: Cervical spinal cord injury (SCI) leads to difficulty in controlling hand function, largely due to a reduced ability to perform individuated finger movements. Specifically, impairment in the ability to accurately coordinate skilled hand actions (e.g., precision grip between the thumb and index digits) is a well-established deficit of injury. Nonhuman primate models of SCI provide a tractable means to evaluate the effectiveness of novel treatment interventions. However, detailed temporal information (weeks to months) of hand movement kinematics during recovery is lacking; there is little information on the precise time course with which control improves, nor how recovered abilities quantitatively compare to hand performance before injury within the same subjects. Here we explored the use of DeepLabCut, an open-source deep learning toolset and markerless tracking system, in combination with a standard behavioral task to quantify nonhuman primate performance in a precision grip task. We examined two monkeys (1 SCI impaired and 1 unimpaired) on a Brinkman Board task, which involves retrieving rewards from shallow wells of varied sizes and orientations. Simultaneous recordings were made from two different angles (from the side and top of the hand motion) using two GoPro Hero7 Black cameras (1920 x 1080 pixels, 120 fps). Four neural networks were trained (corresponding to the four potential animal and camera angle combinations) and 400 manually annotated images were used to train each of

the networks. Parameters included in the tracking were the knuckles and the fingernails of each of the individual digits. This allowed target parameters to be tracked on the remaining frames. The outputs of each of the deep learning models were then subjected to further kinematic analysis. Specifically, three different behavioral outcomes were quantified for assessment of dexterous hand movement: the unimpaired subject had max finger separation of 0.78 cm, max middle digit extension of 4.93 cm, and preshaping distance change of 1.16 cm; the impaired subject had max finger separation of 0.89 cm, max middle digit extension of 4.06 cm, and preshaping distance of 1.18 cm). Our preliminary results suggest that this approach is a possible method to examine performance over the SCI recovery period. In future work, we plan to apply this analysis in the same subjects in order to quantify and compare long-term changes in motor control before SCI and during recovery.

Title: Dopaminergic control of the primary motor microcircuits during motor skill learning.

Authors: *J. COUSINEAU, J. BAUFRETON, M. LE BON-JEGO;
Inst. des Maladies Neurodégénératives, Bordeaux, Bordeaux Cedex, France

Abstract: Parkinson’s disease (PD) is a neurodegenerative disorder affecting predominantly dopaminergic neurons from the midbrain. In addition to motor deficits, impairment of motor skill acquisition is also a recurrent feature in PD. Evidence tends to show that the primary motor cortex (M1) could be a putative target for deep-brain stimulation in PD patients. M1 is instrumental for both the acquisition and the maintenance of motor skills. It receives direct dopaminergic inputs from the midbrain which are crucial to learn a new motor skill confirming the potential role of M1 in cognitive deficits of PD. In M1, cortical GABAergic parvalbumin-positive (PV) neurons are known to exert a strong regulation over cortical activity and are recruited for motor execution. They also feature a specific extracellular matrix, called perineuronal nets. This matrix, wrapping the somata and proximal dendrites, mainly of PV neurons, is known to limit plasticity phenomena. We hypothesized that dopamine in M1 plays a crucial role in acquiring new motor skills through the modulation of PV neurons activity. Using ex vivo electrophysiology, imaging, and optogenetics in mice performing a skill reaching task, we investigated the structural, neuronal, and synaptic plasticity of M1 microcircuits, particularly on PV neurons and perineuronal nets, exerted by dopamine inputs. We first demonstrated that training mice to learn a new skill reaching movement induced a decrease in the excitability of M1 PV neurons and in the synaptic transmission of PV to pyramidal cells. In addition, we found that motor skill learning induced a

decrease in the intensity of perineuronal nets, which may allow the opening of a plasticity window in M1. Moreover, in M1 dopamine-depleted trained mice, PV excitability, synaptic transmission and perineuronal nets expression are altered. Our data provide a better understanding of the role of dopamine in motor skill learning.

Title: Striatal dopamine dynamics during skilled motor learning in mice

Authors: C. D. PHILLIPS[1], D. K. LEVENTHAL[2], *C. R. BURGESS[1];
[1]Michigan Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI; [2]Neurol., Univ. of Michigan, Ann Arbor, Ann Arbor, MI

Abstract: Coordinated multi-joint limb and digit movements - “manual dexterity” - underlie both specialized skills (e.g., playing the piano) and more mundane tasks (e.g., tying shoelaces). Impairments in dexterous skill cause significant disability, as occurs with motor cortical injury, Parkinson's Disease, and a range of other pathologies. Clinical observations, as well as basic investigations, suggest that cortico-striatal circuits play a critical role in learning and performing dexterous skills. Furthermore, dopaminergic signaling in these regions is implicated in synaptic plasticity and motor learning. Nonetheless, the role of ventral and dorsal striatal dopamine (DA) signaling in manual dexterity remain poorly understood. Here, we use fiber photometry paired with the genetically encoded dopamine sensor dLight to investigate striatal DA release as mice learn and perform single pellet skilled reaching. DA release in ventral striatum is tightly linked with reach initiation early in learning but decreases as the DA response shifts to the trial onset cue. In dorsal striatum, DA release dips slightly prior to reach onset before increasing during reaching. Reach onset-linked DA release in both areas shifts towards lower latency as skill improves. These findings suggest that DA dynamics during skilled motor behaviors change with learning and are differentially regulated along the dorsal-ventral striatal axis.

Title: Differences of initial and corrective directional tuning in M1 during precision reaching

Authors: *K. SCHWARTZE, W.-H. LEE, K. CHATLEY, A. ROUSE;
Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Precision reaching tasks often require corrective submovements for successful completion. Most studies of reaching have focused on single initial movements, and the cortical encoding model was implied to be the same for all submovements. However, corrective submovements may show different encoding patterns from the initial submovement across the population. We compared individual neuron's preferred direction, depth of modulation, spatial location, and speed between initial and corrective submovements as well as how corrective submovements overall might exhibit an independent encoding pattern. Two rhesus macaques were trained to perform a precision center-out task designed with small targets to encourage correction. Neural activity from single units in primary motor cortex and associated behavioral data were recorded to evaluate movement characteristics. Neural population data and individual neuronal firing rates were examined for encoding differences between initial and corrective submovements identified with a peak finding algorithm to identify peaks in hand speed. Individual neurons were fit with a linear regression model that included the two-dimensional reach direction, hand position, and hand speed to predict firing rate. For both initial and corrective submovements, the largest effect remained movement direction. However, the influence of reach direction decreased with corrective submovements owing to increased information regarding speed and position of the hand in the workspace. While a majority of neurons did retain the same directional tuning, we observed a significant subset changed their preferred direction up to 180° between initial and corrective submovements. The depth of modulation in a neuron's firing rate between the preferred and anti-preferred reach directions also showed considerable variation between initial and corrective, especially when adjusted for movement speed. There were both individual neurons that were mainly active only during initial submovements and others with significantly increased gain in firing rate for the small corrective submovements. These findings all suggest that different neural encoding patterns exist for initial and corrective submovements within the cortex. The overall variance in firing rate was nearly as large for the corrective submovements even though they were considerably smaller amplitude. We hypothesize that this variation in how neurons change to encode small, corrective submovements might allow for a larger portion of the neural space being used to encode a greater range of movements with varying amplitudes and levels of precision.

Title: Npas4 expression in somatostatin-expressing interneurons regulates excitatory-inhibitory remodeling in the primary motor cortex during motor learning

Authors: *P. SERRANO[1], J. YANG[1], X. YIN[1], S. CHEN[2];
[2]Dept. of Cell. and Mol. Med., [1]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Motor learning requires repetitive training to acquire highly skilled and reproducible movements. This learning process has been shown to trigger cell-type specific remodeling of excitation and inhibition among different neuronal cell types in the primary motor cortex (M1). Specifically, dendritic spines of M1 pyramidal neurons (PNs) undergo reorganization that coincides with subtype-specific remodeling of two major inhibitory interneurons: the somatostatin-expressing inhibitory neurons (SOM-INs) and parvalbumin-expressing inhibitory neurons (PV-INs). More importantly, during motor learning, SOM-mediated inhibition plays a key role in regulating the learning-induced spine reorganization and motor skill acquisition. However, the molecular mechanisms underlying the motor learning-induced excitation-inhibition remodeling remain poorly understood. Here, we identified that the activity-dependent transcription factor *Npas4*, is specifically expressed in SOM-INs, but not in PV-INs or PNs, during motor learning. Combining *in vivo* two-photon imaging with a head-fixed pellet reaching motor learning task, we found that both regional knockout (KO) and SOM-IN specific KO of *Npas4* impaired motor learning by altering spine elimination during the learning-induced spine reorganization process. Moreover, to investigate the functional role of NPAS4 in SOM-INs, we employed a newly developed NPAS4-driven Robust Activity Marking (NRAM) System to identify NPAS4-expressing neurons in awake and behaving mice. Combined with *in vivo* calcium imaging of SOM-INs, we identified NPAS4-expressing SOM-INs ($NRAM^+$ SOM-INs), labelled during the early phase learning, and monitored their activity throughout the entire motor learning process. We found a reduction in the activity of $NRAM^+$ SOM-INs during reaching-related events compared to NRAM-negative SOM-INs. In addition, we observed that a large percentage of the $NRAM^+$ SOM-INs continuously showed lower activity during reaching-related events as training progress. Together, our results suggest that NPAS4 triggers a learning-specific transcription program in a distinct population of SOM-INs, which leads to reduction of inhibition to downstream PNs and promote stabilization of task-related spines throughout the course of motor learning.

Title: A role for hypothalamic orexin neurons in forelimb motor adaptation

Authors: *D. DONEGAN[1], C. KANZLER[2], J. BUSCHER[1], P. VISKAITIS[1], E. BRACEY[1], O. LAMBERCY[2], D. BURDAKOV[1];

Abstract: Performing goal-directed movements in daily life requires our brains to adapt motor commands to reduce movement errors. Motor adaptation involves several behavioral and neural mechanisms, as identified in both human and animal models. However, the role of the hypothalamus in such skilled motor behaviors is unclear, despite accumulating evidence linking hypothalamic orexin/hypocretin neurons (HONs) to the motor system. Here, we demonstrate the involvement of HONs in forelimb movements and motor adaptation through a new force-field-based mouse model of motor adaptation that shares behavioral features observed in humans. Distinct HON activity patterns accompanied forelimb movements and motor adaptation. Optosilencing of these signals reduced the rate of motor adaptation by influencing sensory error-based adaptation. Unexpectedly, the optosilencing affected neither task execution rates nor motor outputs in tasks without adaptation, suggesting that the HON signals identified here are not required for general motivation. Thus, we identified a hypothalamic substrate that regulates motor adaptation.

Abstract: Motor behaviour analysis is essential to biomedical research and clinical diagnostics as it provides a non-invasive strategy for identifying motor impairment and its change caused by interventions. State-of-the-art instrumented movement analysis is time- and cost-intensive, because it requires the

placement of physical or virtual markers. As well as the effort required for marking the keypoints or annotations necessary for training or fine-tuning a detector, users need to know the interesting behaviour beforehand to provide meaningful keypoints. Here, we introduce unsupervised behaviour analysis and magnification (uBAM), an automatic deep learning algorithm for analysing behaviour by discovering and magnifying deviations. A central aspect is unsupervised learning of posture and behaviour representations to enable an objective comparison of movement. Besides discovering and quantifying deviations in behaviour, we also propose a generative model for visually magnifying subtle behaviour differences directly in a video without requiring a detour via keypoints or annotations. Essential for this magnification of deviations, even across different individuals, is a disentangling of appearance and behaviour. Evaluations on rodents and human patients with neurological diseases demonstrate the wide applicability of our approach. Moreover, combining optogenetic stimulation with our unsupervised behaviour analysis shows its suitability as a non-invasive diagnostic tool correlating function to brain plasticity.

Title: Impedance Control Networks for Modeling Spinal Segments

Authors: *F. MARCONI[1], S. MELL[2], P. RYALI[1], A. ESPINOZA ORÍAS[3], J. L. PATTON[4]; [1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Rush Univ., Chicago, IL; [3]Rush Univ., CHICAGO, IL; [4]Sensory Motor Performance Prog, Rehab Inst. Chicago, Chicago, IL

Abstract: Impedance Control Networks for Modeling Spinal Segments FrancescoMarconi, StevenMell, ParthaRyali, AlejandroEspinozaOrías, James Patton Exonet is anetwork of impedance elements (springs)that are able toproduce acomplex forceand torque patternamongst rigid bodies by varying the origins, attachments, and equilibriumpoints of impedance elements. One possible aspect of anExoNET model is tounderstand therelationbetweenstructure and muscular control of the spine. Forces developed by the momentarm and multiple stretched impedances cause torque. While wearable limbexodevices havebeendeveloped using this concept, this project focuses onunderstanding the torques possiblewhile controlling motionof spinal segments. We have reproduced the basic impedance networkbetweenthe lower and upper vertebral segments. This process required modifying the existingalgorithm towork with varying origins and attachments of the impedance elements inthenetwork. The second stepwas tomodify the algorithm towork ina3D environment. Finally, theimpedance elements were made togenerate both tensile and compressive forces toapproximate the constitutive equations of the intervertebral discs and articular surfaces; thenwill be used toreproduce more accurately the behavior of

anintervertebral disc. The resultingmodeling framework canbe used tounderstand the equilibrium control of physiologicalmovements and more importantly, evaluate pathological conditions and their surgicalinterventions. The resulting model allows new understanding with low computational burden,and should provide anew way tounderstand how equilibrium point control canbe achieved bythe nervous system.Supported by NIDILRR 90REGE0005-01

Title: Age differences in adaptation of medial-lateral gait parameters during split-belt treadmill walking

Authors: *T. FETTROW[1], K. E. HUPFELD[1], H. REIMANN[2], J. T. CHOI[1], C. J. HASS[1], R. D. SEIDLER[1];
[1]Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL; [2]Dept. of Kinesiology and Applied Physiol., Univ. of Delaware, Newark, DE

Abstract: Title: Age differences in adaptation of medial-lateral gait parameters during split-belt treadmill walkingAuthors: Tyler Fettrow[1], Kathleen Hupfeld[1], Hendrik Reimann[2], Julia Choi[1], Chris Hass[1], Rachael Seidler[1]1. Department of Applied Physiology and Kinesiology, University of Florida, Gainesville, FL 32605, United States2. Department of Kinesiology and Applied Physiology, University of Delaware, Newark, DE 19713, United States
Character Count: 2094/2300 Walking is inherently unstable, and more so in the medial-lateral (ML) direction than in the anterior-posterior direction. Therefore, ML control of balance must be actively controlled and adapted in different walking environments. A common method to assess gait adaptation is the split belt treadmill (SBT) paradigm. In this paradigm individuals must adapt their gait pattern to two treadmill belts moving at different speeds; then, when the belts return to the same speed, aftereffects of the adaptation are observed. Historically, SBT studies have focused on anterior-posterior (AP) spatiotemporal gait parameters because SBT is primarily an AP perturbation, but it is important to understand whether and how ML control adapts in this scenario. Furthermore, we know older adults struggle with the control of balance, so here we seek to determine whether ML balance adaptation differs in older age. We performed an analysis of SBT-induced changes in gait parameters including variables which inform us about ML balance control in younger (N=31; Age=22.3±3.9) and older adults (N=21; Age=71.7±4.6). We calculated the change relative to the average of the baseline slow condition for each

foot and each condition. Then, we calculated symmetry between the feet for seven gait parameters, three of which inform us about ML control of balance. Our primary finding is that younger adults showed sustained asymmetric changes in these ML balance parameters during the split condition of the SBT. Specifically, younger adults sustained a greater difference between their fast stance foot and their upper body, relative to the slow stance foot, in the ML direction. This finding when considered within the context of extant modeling work suggests that younger adults may be exploiting passive dynamics in the ML direction during the SBT which may be more metabolically efficient, whereas older adults seem to be more concerned about symmetry of the balance parameters. This also suggests that not all asymmetry has negative consequences, especially considering imposition of external constraints (SBT).

Title: Ultrasound echogenicity-based sensing and control of functional electrical stimulation to correct ankle joint dorsiflexion

Authors: Q. ZHANG, K. LAMBETH, A. IYER, Z. SUN, *N. SHARMA;
Biomed. Engin., North Carolina State Univ., Raleigh, NC

Abstract: Drop foot is a typical symptom of weakened or paralyzed dorsiflexor's function after cerebral accidents and neurological disorders, which usually causes abnormal gait and ground tripping. Functional electrical stimulation (FES) is a potential technique for reanimating paralyzed muscles and correcting drop foot. FES induces orthotic effects at the ankle, and its closed-loop control is necessary to modulate stimulation intensity in response to time-varying physiological changes of the targeted muscles. Conventional closed-loop control relies mainly on ankle kinematics feedback, which may not wholly capture time-varying changes in muscle activation. Motivation exists to directly measure FES-evoked muscle activation and use it in closed-loop FES. Indeed invasive physiological measurements are feasible, but non-invasive measurements are preferable given comfort and reduced risks of infection with non-invasive sensing. In this study, we explored the use of ultrasound (US) echogenicity as an indicator of FES-evoked muscle activation. We hypothesized that including US echogenicity for estimating FES-evoked muscle activation would improve FES-elicited ankle control compared to an FES control approach without activation measurement feedback.A new sampled-data observer (SDO) was derived to estimate the muscle activation continuously from US echogenicity that was sampled at the rate of 50 Hz from the beamformed and processed images. The proposed US-based FES control was validated through treadmill walking experiments where five participants without disabilities walked at the speed of 0.6 m/s. The desired ankle joint trajectory during the walking swing phase was generated online based on the thigh

and shank orientations and angular velocities. The participants were asked to avoid voluntary dorsiflexor contraction during the swing phase. Three 2-minute walking trials that follow the 'FES off--FES on' sequence were collected. The experimental results show that the root mean square error (RMSE) between the desired and actual trajectories when applying the US-based FES control is 2.120.59, which is 20.5% ($p<0.01$) significantly less than the RMSE of the traditional FES control. The use of FES increased the mean dorsiflexion angle during the swing phase from -16.04 (without FES; the negative sign represents the plantarflexion) to -6.87 (with FES), which confirmed the effectiveness of using FES to correct drop foot. Our findings highlight the benefits of including muscle activation feedback measured by the US echogenicity and provide the potentials of the US-based FES control framework to achieve ground clearance for patients with drop foot.

Title: Changes in postural control and kinematic variables in response to ankle joint taping in professional basketball players

Authors: Z. ÖZTÜRK[1], *E. YıLMAZ[1], G. YıLMAZ[1], I. B. KUNT[1], T. D. AKSOY[2], B. YALÇıN[1], H. ARGUNşAH[1];
[1]Acıbadem Mehmet Ali Aydınlar Univ., Istanbul, Turkey; [2]Dubai Col., Dubai, United Arab Emirates

Abstract: The major reason for recurrent ankle sprains, the most common cause of injury in team sports, is the chronic instability of the ankle joint, which could be related either to peroneal muscle weakness, proprioceptive deficits, or mechanical instability. Furthermore, it is a common injury for athletes who perform cutting maneuvers, landings, or frequent jumps or make contact with other players. In basketball, handball, soccer, and volleyball, ankle sprains represent from 60 to 90% of the injuries, and the 75% of the athletes affected have relapses that can force them to give up their competitive practice. For these reasons, several external ankle support systems have been designed. These systems attempt to support the ankle joint during rehabilitation and to prevent injury or its recurrence. Ankle taping has been one of the most common ankle support systems because it has been effective in restricting joint motion. The main purpose of ankle taping is to restrict ankle inversion and plantar-flexion motion. Non-elastic adhesive taping is used to prevent recurrence after an ankle sprain. Such taping restricts ankle inversion, as a prophylactic effect, reduce inversion movement speed and reduce the incidence of sprains. The reduction is generally greater for athletes with a history of ankle sprain, although positive effects have also been shown for those with no prior injury. However, it is not exactly clear if the ability for ankle taping to reduce the prevalence of ankle sprains is due to the mechanical restriction provided by the tape and/or due to the proprioceptive value of the adhesive tape. The purpose of this study is to investigate the effects of ankle taping on professional basketball players' postural control during the landing phase of the high jump and the potential for reducing the risk of injury. At the end of this study, the expectation is to

determine a significant difference between taped and non-taped subjects with the comparison of the kinematic data of ankle, knee, hip, and the mass center of gravity. Xsens MVN wearable motion capture system is used for data collection. It is a commercial, inertial sensor-based and portable motion capture system for full-body motion analysis. 12 elite male basketball players will participate in the study, and these players will perform five jumping trials with ankle taping and five jumping trials without ankle taping. According to the initial results, kinesio taping has the potential to increase strength and better performance and balance immediately after the application. In the frontal plane, taped participants were less ankle joint inversion (mean difference= 4.1 degrees SD= 0.658).

Abstract: Surface electromyography (EMG) can provide information regarding the force output of a muscle and is known to be a reliable predictor of joint torque during isometric conditions. In contrast, predicting joint torque during movement through EMG alone is more complex. Muscle properties, like the force-velocity and force-length relationships, may alter the EMG-torque relationship during movement conditions, though the exact effect of movement on EMG-torque relationship has been investigated only sparsely. During movement, muscle activation is not the only source of joint torque; external factors such as the mechanics of the environment and external power from the environment contribute to the measured torque at the joint. This makes it difficult to distinguish the torque due to muscle activation and determine the EMG-torque relationship. We have recently developed a method that can decouple the torque generated from the muscle from that generated by the external environment. Our objective was to determine whether the EMG-torque relationship differed during movement compared to isometric conditions, by leveraging our method to decouple muscle activation torque from external sources.
A pre-existing dataset which contained ankle muscle EMG and ankle torque recordings, as well as ankle impedance estimates from 10 subjects, while they produced cyclic contractions during both isometric conditions and imposed cyclic movements was used. The isometric EMG-torque relationship was computed by fitting an impulse response function (IRF) between the triceps surae EMG and the measured torque. For the movement trials, the torque due to muscle activation was first computed by subtracting off the torque due to the external environment, which was computed by convolving the impedance with the imposed movement. The movement EMG-torque relationship was computed by fitting a time-varying IRF between the triceps surae EMG and the torque due to muscle activation. We assessed the ability of

each model to predict torque during movement by computing the percentage of torque variance accounted for.
The EMG-torque models differed in the movement condition compared to the isometric condition. During isometric conditions, the isometric model was able to account for 86 ± 2% of the torque variance. During the movement task it was only able to account for 68 ± 6% of the variance. In contrast the time-varying movement model was able to account 87 ± 3% of the torque variance. These results demonstrate that the EMG-Torque relationship varies during movement, and this dynamic behavior must be accounted for to accurately estimate the user intent and volitional torque generated by subjects.

Title: Restoring sensory feedback through a wearable non-invasive neurostimulation system improves functional outcomes in people with diabetic peripheral neuropathy

Authors: *L. CHEE[1], G. VALLE[2], S. RASPOPOVIC[3];
[2]Lab. for Neuroengineering, Dept. of Hlth. Sci. and Technol., [3]Dept. of Hlth. Sci. and Technol., [1]ETH Zürich, Zürich, Switzerland

Abstract: Diabetic peripheral neuropathy (DPN) is a common complication of diabetes and results in loss-of or abnormal sensation in extremities such as the feet and hands. Individuals with DPN have a decreased overall walking speed and are at a higher risk of falls because of decreased balance and postural control. Although these deficits are well documented, common interventions target the management of diabetes through narcotics or lifestyle changes and do not address the problem of sensory loss. A fully-portal system (called NeuroLegs) was designed to restore the lost or abnormal tactile and proprioceptive sensations in DPN patients with the goal of improving their functionality. NeuroLegs consists of a peripheral module on each leg as well a central control module. Each peripheral module consists of a force-sensorized insole and flexion-sensorized, electrode integrated sock connected to a portable electronics box secured around the ankle. This box communicates wirelessly with the controller in the central control module that processes the raw sensor data and controls the stimulator secured around the waist. The electrodes in the sock are placed around the ankle in a way that directly targets the branches of the tibial nerve that innervate the foot sole and the peroneal nerve that innervates the dorsal side of the foot. This allows for somatotopic tactile (foot sole force) feedback and position (ankle flexion) feedback. The NeuroLegs hardware is accompanied by custom designed software for sensation calibration and characterization so that details about the perception of the elicited sensation can be

recorded and analyzed. There is also a phone app for real-time monitoring of the sensors and fine adjustment of the stimulation. The complete NeuroLegs system is being implemented in DPN patients where performance in standard functional and balance tasks, walking kinematics, and metabolic consumption are being evaluated in order to develop a wholistic understanding of what is possible with sensory feedback. Developing a rough understanding of the currently unknown effects of sensory feedback will allow for better designed studies that focus on how sensory restoration can improve specific aspects of daily life in DPN patients.

Title: Investigation of Glenohumeral Internal Rotation Deficit Tendency of Adolescent Female Volleyball Players with Inertial Measurement Unit Based Motion Capture System during Passive and Dynamic Movements

Authors: E. YıLMAZ, *Z. ÖZTÜRK, E. KARAKAŞ, Y. EFE, B. YALÇıN, H. ARGUNşAH; Acıbadem Mehmet Ali Aydınlar Univ., Istanbul, Turkey

Abstract: Athletes who perform frequent overhead throwing and hitting motions are at high risk for shoulder injuries. Glenohumeral internal rotation deficit (GIRD) is common among volleyball players and is an adaptive process in which the dominant shoulder experiences a loss of its internal rotation (IR). GIRD can be defined by a loss of >20° of IR compared to the contralateral shoulder. The glenohumeral joint carries an important role in over-shoulder athletes. The increase in the external rotation within the glenohumeral joint, the more velocity the athlete can generate when throwing. This motion, when performed frequently, results in a difference in the range of motion (ROM) on the glenohumeral joint. This change of the ROM is defined as GIRD. From a sports medicine realm, the GIRD condition can create a basis for further injuries and early detection methods are required. This study hypothesizes that the sedentary participants and female volleyball players have different functional and anatomical shoulder joint range of motion values. This study aims to create a scientific basis for injury risk prediction of the dominant shoulder and determine the glenohumeral internal rotation deficit tendency of the elite volleyball players non-invasively. This study hypothesizes that volleyball players are prone to develop angular differences in dominant and non-dominant shoulders' range of motion during passive and active movements. Twelve age matched adolescent female players (age of 17.6±0.4, BMI of 21.11±1.08 and height of 170.6±1.7cm) performed jump serve, strike of the ball, horizontal internal- external rotation and internal- external rotation movements and group-based data were analyzed. This experimental study collected bilateral kinematic data from both dominant and non-dominant shoulders of 12 participants wirelessly with Xsens MVN. Each movement performed five times and the average value was calculated for each participant. T-test paired sample for means for dominant and non-dominant shoulders results indicated that ROM did not vary during flexion (dominant: 170.2°±4.5; non-dominant: 171.3°±6.1;

p=0.086). Contrarily, significant differences were obtained during Shoulder Horizontal Internal Rotation (dominant: 27.5°±8.3; non-dominant: 36.8°±7.9; p=0.0053). Shoulder Horizontal External Rotation was not significantly different (dominant: 92.7°±4.1 non-dominant: 89.3°±6.3 p=0.052), Shoulder Internal Rotation was significantly different (dominant: 54.3°±9.0; non-dominant: 65.2°±11.2; p=0.0000) motions and similarly Shoulder External Rotation was significantly different (dominant: 98.6±2.5 non-dominant: 90.3°±6.36.7, p=0.0032).

Title: Perturbation-induced motor adaptation in monkeys during walking

Authors: *R. WEI, O. STANLEY, *K. CULLEN;
Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Introduction: Walking is one of the most practiced motor skills in daily life. It often takes place in unpredictable conditions (e.g. uneven surfaces). To maintain balance during walking, the brain integrates sensory signals from visual, somatosensory, and vestibular sources. Walking in different conditions puts different demands on the control of head movements to stabilize and maintain posture. This includes potential contributions of the angular and linear vestibulocollic reflexes (aVCR and lVCR) to head pitch on trunk, which exhibit different gain and phase characteristics dependent on the frequency of stimulation. Here we investigate the motor strategy nonhuman primates use to adapt to unpredictable conditions during walking.Method: Two rhesus macaques (1 male, 1 female) sat in a specially-built primate chair in which their heads could be free, fixed, or constrained to move only along the pitch rotation axis. The chair was mounted onto a linear sled, allowing the monkeys to walk along a 3.5-meter linear track, the ends of which could be rotated to enable bidirectional locomotion. 5 N perturbations were applied to the chair while the monkeys walked quadrupedally along the track. The Python package DeepLabCut was used to extract the animals' 3D posture for gait analysis. The motion was recorded by 4 high-speed cameras before, during, and after applying perturbations. Gyroscopes and accelerometers were used to record 3D linear and rotational head and body motion. Result: We observed that during resistive force perturbations: 1) monkeys' walking speeds decreased 2) stance duration increased 3) amplitude of hip joint movement decreased 4) head movement showed less fluctuation of pitch velocity. Furthermore, we observed an aftereffect of increased walking speed as well as increased linear and angular head motion after load release.Conclusion: Our results suggest monkeys adjust their motor commands to reduce detected discrepancy between predicted and actual leg movement during locomotion. The observed aftereffects suggest these changes are centrally controlled strategic adaptation rather than temporary

reflexive adaptations. These findings indicate this straightforward paradigm can help advance our knowledge of the coordination of gait and balance.

Title: Somatosensory biases, sensitivity, and adaptability during post-stroke walking

Authors: *C. ROSSI[1,2], N. M. HILL[2], J. KELLER[2], I. M. SPEARS[1], K. A. LEECH[3], A. J. BASTIAN[2]; [1]Johns Hopkins Univ., BALTIMORE, MD; [2]Kennedy Krieger Inst., Baltimore, MD; [3]USC, Los Angeles, CA

Abstract: Somatosensory function is important for motor learning and, vice versa, learning of new movements can alter somatosensation. The bidirectional relationship between sensation and movement, including the neural substrates involved, is yet not fully understood. Here we explored this relationship by studying the sensory deficits that result from cerebral stroke, and how these deficits affect the motor and sensory learning driven by split-belt adaptation.

We first developed an adaptive forced choice task that measures sensation of leg motion speed during walking. Participants with cerebral stroke and healthy age-matched controls walked on a split-belt treadmill and reported which leg they felt was faster for a range of speed combinations. We found that controls had low biases and small just noticeable differences (JNDs) in leg speed sensation, whereas participants post-stroke could have large biases and JNDs. Note: a large bias indicates that a person senses that their leg speeds are equal when in reality they are not; a large JND indicates that a person cannot perceive small changes in leg speed. Participants-post stroke varied in their impairments: some showed both worse bias and JND than controls, others were impaired in only one domain, and still others showed no impairment.

We then studied how cerebral stroke and resulting sensory deficits impact split-belt adaptation. This type of learning is not limited to the motor domain: healthy adults also develop the false perception that the belts move at similar speeds during split-belt walking. Participants post-stroke and controls walked with the treadmill belts at different speeds for 10 minutes. We measured split-belt-induced changes to leg speed sensation bias (using our task), and walking pattern. Both groups adapted their gait during split-belt walking and exhibited aftereffects in their walking pattern. All participants also changed leg speed sensation bias. This demonstrates that the mechanisms underlying the sensory and motor learning driven by locomotor adaptation are intact in people with cerebral stroke, suggesting that they are mediated by noncerebral structures and unrelated to the level of leg speed sensory impairment. Furthermore, our results indicate that split-belt adaptation can be used to temporarily change motor asymmetries or sensory

biases in post-stroke walking, suggesting it may be a useful tool for sensorimotor rehabilitation.

Title: Analyzing the Scale-dependent Force Contributions of Rat Hindlimb Muscles During the Swing Phase of Locomotion

Authors: *F. YOUNG[1], A. J. HUNT[2], M. C. TRESCH[3], C. HECKMAN[4], H. J. CHIEL[5], R. D. QUINN[1]; [1]Mechanical and Aerospace Engin., Case Western Reserve Univ., Cleveland, OH; [2]Portland State Univ., Portland, OR; [3]Biomed. Eng, Physical Med. and Rehab, Physiol., [4]Dept. of Physiol., Northwestern Univ., Chicago, IL; [5]Case Western Res. Univ., Cleveland, OH

Abstract: We have developed a process to analyze the relationship between the size-scale of an animal and the resulting activation profiles of individual hindlimb muscles. Large animals, which have heavy limbs, are able to use the inertial properties of their body to aid in motion. In contrast, smaller animals must rely on the elastic properties of their muscles to generate motion due to their lightweight limbs. Across size scales, the relationship between passive elastic and inertial properties changes dramatically. We are interested in the ramifications of scale-dependent relationships on the activation profiles of muscles because we hypothesize that they are the primary constraints for the types of control schemes that animals use for locomotion.
This work presents a neuromechanical model of the rat hindlimb with thirty-eight Hill-type muscles. Passive limb properties are calculated through an optimization process to replicate experimental hindlimb data. By working in a neuromechanical simulation environment, Animatlab, we are able to control muscle contractions via a simulated nervous system. The advantage of this environment is its ability to unify the neural and mechanical aspects of motion, providing insight into the spinal control systems that regulate locomotion.
Using a bottom up approach, we are able to determine the necessary motoneuron activation profiles to replicate a desired trajectory. We believe that the shape of these activation profiles will predictably change as the ratio of elastic and inertial forces shifts as a result of the size-scale of an animal. Our preliminary results demonstrate clear differences in the activation profiles of animals as a result of their scale-dependent properties: elastic properties dominate at small scales, whereas inertial properties dominate at large scales.

Title: Anticipatory gait adjustments during curb negotiation in response to the expectation for future stepping maneuvers

Authors: *C. CUI, A. KULKARNI, S. RIETDYK, S. AMBIKE;
Purdue Univ., West Lafayette, IN

Abstract: In daily activities, one often has to quickly adapt gait to sudden changes in the environment and simultaneously maintain gait stability. However, there is a potential trade-off between stability and maneuverability: high gait stability also resists voluntary maneuvers. Therefore, the purpose of our study is to investigate whether gait stability is actively modulated when there is high maneuverability demand in the future. We examined whether gait stability while stepping down from a curb changed when the next step could involve a foot targeting task. A target was projected at the preferred foot landing area of the step immediately after stepping down. Fourteen healthy adults (26.3$\pm$3.3 yrs.) participated in this study. In Baseline, subjects approached, stepped down from a 15 cm curb, and continued walking. Subjects then performed three target conditions in block-randomized order: Fixed target, Anterior-shift target, and Lateral-shift target. Heel contact while stepping down the curb could trigger an anterior or a lateral shift in this target, requiring quick maneuvers during the subsequent step. The probability of target shift was 50%. To isolate the effect of expected target shifts, we used the trials when the target did not shift and computed double support duration and the average gait speed. We also computed synergies in ground reaction forces during double support that stabilize whole-body linear and angular accelerations to quantify gait stability while stepping down. We found that compared with Baseline (1.6 m/s), gait speed was reduced for all target conditions ($p<0.01$), and it was slowest for the Lateral-shift condition (1.5 m/s). The double support duration increased from Baseline (102 ms) for all target conditions ($p<0.01$) and was longest for the Lateral-shift condition (110 ms). We also found that the synergy stabilizing angular motion about the anterior-posterior axis decreased for all target conditions compared to Baseline ($p<0.01$). Thus, anticipation of future gait maneuvers changed spatiotemporal gait characteristics and reduced the stability of angular motion in the frontal plane. While spatiotemporal changes are most pronounced for lateral maneuvers, the stability reduction is a general anticipatory synergy adjustment, independent of the direction of the upcoming maneuver. This novel finding demonstrates how gait stability is managed during complex maneuvers. We intend to determine the functional benefit of the reduced stability in performing the maneuvers, and whether stability reduction induces a cost for older or pathological populations in the form of increased fall risk.

Title: Advanced 3D vector space analysis to determine posture and gait dynamics

Authors: *J. FUNG[1,2], G. SORRENTO[3], V. GOUSSEV[2];
[1]McGill Univ., Montreal, QC, Canada; [2]Res. (site of CRIR and CISSS Laval), Jewish Rehabil. Hosp., Laval, QC, Canada; [3]Krembil Brain Inst. (CRANIA), Univ. Hlth. Network (UHN) Toronto Western Hosp., Toronto, ON, Canada

Abstract: INTRODUCTION: In functional locomotion, stability and mobility must be maintained despite small kinematic disturbances or control errors. Many complex, non-linear dynamical systems approaches have been used to quantify gait stability and disturbance. We propose a novel approach based on vector space analysis (VSA) to illustrate stability of the body's center of mass (CoM) and coordination of body segments and joint angles using 3D phase diagrams, which can distinguish the gait performance between healthy subjects and persons with chronic stroke. **METHODS:** Participants with chronic stroke and age-matched healthy controls walked at their preferred, comfortable speed on a servo-controlled and self-paced treadmill while viewing a 3D-animated virtual reality scene that was coupled to the instantaneous speed. They were instructed to maintain a comfortable, preferred speed (self-paced). Body motions were captured with a 6-camera VICON MX system and analyzed based on a 41-marker, Plug-in Gait model. The body's CoM and lower limb joint angles were computed and normalized in time to the stride cycles of the individual paretic limb (for stroke participants) or the equivalent right/left limb (for healthy controls). Velocity data were obtained by differentiating position/angles in time, and smoothed with a low-pass filter of 10 Hz. The VSA involves plotting 3D velocity vectors along with 3D mean trajectory points to construct a 3D phase diagram that embeds the 6D data set. This output is essentially a 3D plot of the velocity-position coordination of CoM or joint angles. The 3D velocity vector projections in each axis across the gait cycle were then squared and averaged. The mean sums of squares were then calculated for each direction and summed to represent the mean total kinetic energy related to the unit mass. The combined specific positional and kinetic energy can be evaluated using the mean Sobolev norm. **RESULTS:** The proposed VSA show distinct between-group differences in phase diagrams and Sobolev norms. The CoM velocity vectors are markedly increased in the mediolateral direction in the stroke participants compared to healthy control, indicating a compromise in mediolateral stability. Stroke participants show lower Sobolev norms, particularly in the paretic limbs of low functioning participants walking at slow speeds. **CONCLUSIONS:** VSA in 3D can reveal the dynamics of limb coordination and stability control during gait, as well as any disturbance such as coordination impairments or mediolateral instability in people with chronic stroke.

Title: Gait characteristics of adults walking with and without shoes.

Authors: *C. CHAU, A. PETE, M. ANDRADA, K. CIULLA, S. DONACHIE, P. SAWCHUCK; Nazareth Col., Rochester, NY

Abstract: The purpose of this study is to compare the kinematic and spatiotemporal parameters of locomotion in healthy adults with and without shoes. This study will help establish normative data. Six healthy adults age 22-23 were studied. Each subject completed three trials of walking on a level hard surface at self-selected speed whilst wearing socks and shoes and whilst wearing socks only. Kinematic data were recorded with 3D Motion Capture system (Vicon, Oxford, UK) using 11 cameras. Twenty-three retro-reflective markers were placed on pre-determined anatomical landmarks of the trunk, pelvis, and lower extremities using the modified Vicon lower extremities Plug-in gait model. Eight body segments were reconstructed. Anatomical joint angles were calculated. Spatiotemporal and kinematic gait parameters were processed utilizing the Vicon Nexus software. The variables analyzed include cadence, velocity, step length, stride length, swing and stance duration (expressed as a percent of cycle duration), pelvis, hip, knee, and ankle joint angular excursion. The Vicon Polygon software was used to generate averaged joint angular plots. Paired t-tests were used to compare gait parameters with and without shoes. Preliminary results showed that when walking without shoes, there was a statistically significant decrease in stride length (-10 cm), hip and knee joint angular excursion (-1.85 and -9.01 degrees, respectively). A decrease in step length (-6 cm), velocity (-0.16 m/s), swing duration (-2%), and an increase in stance duration (+ 2%) were clinically significant (Cohen's d). The preliminary findings showed gait changes when healthy adults walked without shoes as compared to with shoes. The findings are consistent with existing literature and suggest an increase in instability in gait without shoes[1]. Shoes have been suggested to offset the effects of external perturbations, allowing for the preservation of biomechanical stability[2]. In addition to biomechanical factors, possible differences in cutaneous input between the two conditions may also have partially contributed to the changes in locomotion.

Title: Walking metabolic cost increases when synchronizing your steps to invariant or white noise visual cues but not pink noise

Authors: *A. CHARLES, P. ANTONELLIS, N. STERGIOU, A. D. LIKENS;
Biomechanics, Univ. of Nebraska, Omaha, Omaha, NE

Abstract: Introduction: Walking exhibits natural variations (i.e., stride length, stride duration) over several gait cycle repetitions that have a pink noise temporal structure. It has been hypothesized that these natural variations are associated with health, and their deterioration leads to disease. Thus, to restore healthy variations, previous studies have suggested synchronizing steps with variable external cues that have a pink noise structure. However, the influence of walking with such external cues on the metabolic cost of walking remains unclear. Therefore, this study aimed to investigate the effect of walking synchronization with cues that have various temporal structures on metabolic cost. **Methods**: Twenty-three participants performed four 12-minute walking trials on a 200-m indoor track, wearing footswitches on both of their heels. The Cosmed K5 recorded the metabolic rate. First, participants completed a self-selected pace trial (SPW), where the mean and standard deviation were computed from the baseline condition using a custom MATLAB code, in which inter-stride intervals were calculated. Those values were then used to create the three remaining trials where visual cueing was implemented. Then, the participants were instructed to synchronize their right heel strike with a bar moving vertically on augmented reality glasses. Participants walked under three visual conditions: pink noise, invariant (like the classic metronome), and white noise cueing. The order of conditions was randomized for each participant. **Results/Discussion:** Our data were analyzed with a Bayesian repeated-measures ANOVA. Relative to the SPW, both invariant and random conditions increased metabolic cost, unlike pink noise that was not different from SPW. These findings demonstrate that random and invariant visuals cueing are more costly metabolically as compared to self-selected pace walking. In addition, these results support the optimal human movement variability hypothesis, which suggests that optimal healthy variability is temporally structured, demonstrating pink noise. Therefore, implementing variable pink noise visual cueing in gait rehabilitation protocols would promote effective interventions without increasing metabolic cost.

Title: Ot^+ pvn neurons regulate aggression and dominance hierarchy in wild-derived female mice.

Authors: *Y. SOFER, N. ZILKHA, S. CHUARTZMAN, T. KIMCHI;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Aggression and dominance hierarchy are basic social behaviors essential for the survival and reproductive success of most mammalian species. Typically, they are displayed whenever conspecifics have to compete for limited resources, such as food, water, territory, or access to mates. As a result, intra-sexual competition is higher in males compared to females as fertile females are a limited resource to males. Thus, males often express higher level of aggression and are most likely to form dominance hierarchy in a group. Therefore, most studies of the biological basis of intra-sexual aggression and dominance hierarchy have been focused on males. However, it has long been observed that females can also form dominance hierarchies. In this study, we aimed to investigate the role of OT^+ PVN neurons in the aggression of wild-derived female mice by comparing them to males. Wild-derived mice were chosen for their higher levels of aggression compared to the lab mouse strains, which might have lost these behavioral traits due to artificial selection and socially restricted environment while in captivity. We found that OT^+ PVN neurons of wild-derived females are activated during social interaction. Moreover, dominant (alpha) wild-derived females had more OT^+ PVN neurons than subordinate (sub) females in the group. In order to manipulate OT^+ PVN neurons, we established a wild-derived OT:Cre mouse line by backcrossing wild mice with transgenic lab mice, and validated its phenotype resembling that of the wild-derived mice.Using these novel wild-backcrossed OT:Cre mice, we virally ablated or activated OT^+ PVN neurons and performed a standard resident-intruder (RI) assay to examine territorial aggression towards adults and pups. In wild-derived females, we found that ablation of OT^+ PVN neurons reduces both adult and pup-directed aggression, whereas activation of this neuronal population promotes aggressive behavior. In contrast, similar manipulations of OT^+ PVN neurons in wild-derived males seem not to affect either of these aggressive behaviors. Finally, we found that genetic ablation of OT^+ PVN neurons abolishes the formation of dominant hierarchy in groups of wild-derived female mice. In contrast, male group dynamics are unaffected by the same manipulation. On the other hand, activation of OT^+ PVN neurons promotes dominance hierarchy in groups of wild-derived females without affecting groups of wild-derived males. These findings emphasize the importance of investigating both sexes in ethologically-relevant animal models and social contexts, in the study of socially relevant neuromodulators.

Title: Oxytocin modulates an inverted U relationship between the rewarding properties of social interaction and the dose of those interactions

Authors: *J. H. TAYLOR, S. A. FEKADESELLASIE, E. BROWNE, N. POURSHIRAVI, M. WELCH, K. L. HUHMAN, H. E. ALBERS;
Georgia State Univ., Atlanta, GA

Abstract: Although the rewarding properties of social interactions are well known, the relationship between the "dose" of social interaction (e.g., its duration and/or intensity) and the rewarding properties of those interactions has not been systematically evaluated. In the present study, we tested the hypothesis that there is an inverted U-shaped relationship between the dose of social interaction and its rewarding properties. More specifically, we propose that as the dose of social interaction increases, the rewarding properties of those interactions initially increase, then level off, and eventually decline. Using both an operant social preference test (OSP) and a conditioned place preference test (CPP), we exposed male and female Syrian hamsters to increasing doses of social interaction. In the OSP, social dose was operationalized as the intensity of the social stimulus. Specifically, we exposed hamsters (*Mesocricetus auratus*, n=80 males and 61 females) to either soiled bedding, a confined same-sex conspecific, or social interactions with one, five, or twenty same sex conspecifics. In the CPP, social dose was operationalized as frequency. We exposed hamsters (n=41 males and 40 females) to one, three, six, or nine days of social interaction with a same sex conspecific. In both the OSP and CPP, a robust inverted U-shaped dose response curve was observed as a function of social dose in males and females. Previously, we have shown that activation of oxytocin receptors in the ventral tegmental area (VTA) is necessary for the rewarding properties of social interactions. In the present study, we microinjected oxytocin (9 uM in saline) or saline into the VTA just prior to each of one, three, or six days of social interaction. We found that oxytocin injected into the VTA prior to three days of social interactions with same-sex conspecifics significantly increased the rewarding properties of those social interactions in females but not in males. These data support the hypothesis that there is an inverted U-shaped dose response curve between the dose of social interaction and its rewarding properties in males and females and that this dose response curve is modulated by oxytocin in the VTA in a sex-dependent manner.

Title: Assessing the translational aspects of targeting the oxytocin system for Alcohol Use Disorder in socially-housed prairie voles (Microtus ochrogaster)

Authors: *S. POTRETZKE, A. E. RYABININ;
Dept. of Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The broad and severe impact of Alcohol Use Disorder (AUD) necessitate development of efficacious treatments. Oxytocin (oxt)- a nonapeptide hormone with central roles in social behaviors- has drawn interest as a promising target of pharmacotherapy for AUD with its implicated role in mediating the processes associated with drug use and its social effects, which may serve to bolster abstinence. Oxt has been shown to decrease alcohol craving in humans and alcohol consumption in rodents. Results from our laboratory show repeated intraperitoneal (i.p.) oxt treatments to decrease drinking in socially-housed prairie voles and mice. However, whether intranasal (IN) administration- a translationally relevant route- is effective in decreasing alcohol consumption, whether IN oxt is able to act centrally and whether a small molecule can be designed to optimize pharmacokinetics remain to be determined. In this investigation, we tested whether IN oxt decreased alcohol consumption in prairie voles (*Microtus ochrogaster*)- a socially monogamous rodent species with demonstrated translational validity to humans through common mechanisms regulating social behaviors. Male and female cagemates underwent a continuous access two-bottle choice (CA-2BC; 5% alcohol, water) procedure to establish baseline measures of consumption, followed by treatment with oxt (5mg/kg or 10mg/kg, IN) or saline using a mixed cage design- with treated and untreated (control) animals housed in the same cage which more appropriately models human patients during medication-assisted maintenance of abstinence. Measures of consumption and behavior were recorded. The 10mg/kg dose significantly decreased alcohol consumption during the first hour after treatment. A recent study implicated the Receptor for Advanced Glycation End products (RAGE) in mediating the transfer of oxt into the brain. To test this, voles were given 1mg/kg of the high affinity, permanent RAGE antagonist FPS ZM1 (i.p.) or saline prior to treatment with 25µL oxt-(*leucine*-5,5,5-d_3, *glycine*-2,2-d_2) trifluoroacetate salt (oxt-d5, IN; 80IU/1mL). Concentrations of endogenous oxt and oxt-d5 simultaneously analyzed using liquid chromatography mass spectrometry. As a centrally acting nonapeptide oxt receptor agonist, LIT-001 offers the possibility of a more suitable pharmacokinetic profile, but still requires evaluation. Using a similar CA-2BC mixed-cage design, preliminary results indicate LIT-001-induced sustained decreases in alcohol consumption. Collectively, these results will serve to clarify whether oxt is a promising target for pharmacotherapy for AUD.

Title: Impact of perigestational opioid exposure on juvenile play behavior, oxytocin receptor binding, and oxytocin neuronal number in male and female rats

Authors: *M. E. VOGT, H. J. HARDER, C. T. SEARLES, M. G. GOMEZ, A. J. AUSTIN, A. Z. MURPHY;
Georgia State Univ., Atlanta, GA

Abstract: Social behavior is an essential component of individual survival and reproductive success in rodents. Proper development of social behavior in adulthood can occur only when rodents experience rewarding social play during adolescence. Juvenile play behavior is mediated by several neurotransmitter systems, including endogenous opioids and oxytocin. Clinically, children exposed to opioids *in utero* have a harder time making friends and tend to spend more time alone, suggesting social behavior is less rewarding to these children. To elucidate the underlying neural mechanisms whereby opioids modulate social behavior, we developed a preclinical model in which female rats are exposed to clinically relevant levels of morphine prior to and throughout gestation, ending when pups are postnatal day 6. Juvenile play behavior of adolescent pups was observed at 25, 35, and 45 days of age. Our data show females exposed to opioids perigestationally had a significant reduction in social play, with a corresponding increase in time spent alone. Morphine-exposed females also initiated fewer pins and nape attacks. Together, this data suggests females perigestationally exposed to morphine are less motivated to participate in social play, potentially due to an alteration in the reward circuitry as a result of developmental morphine exposure. As oxytocin is a major neurohormone implicated in social reward and has been shown to interact with the endogenous opioid system, we are currently assessing changes in oxytocin expression and receptor binding in brain regions mediating social reward, including the nucleus accumbens and hypothalamic nuclei, across development following perigestational morphine exposure.

Title: Do gonadal hormones mediate sex differences in sociability?

Authors: K. HICKS[1], R. WITMER[1], X. CAMBI[1], M. BARNETT[2], E. BLUNT[1], D. RETTE[1], S. NIDORF[1], ***H. LOPEZ**[1];
[1]Neurosci., [2]Psychology, Skidmore Col., Saratoga Spgs, NY

Abstract: Sociability - or the motivation to seek out social contact and interaction - is a core facet of social behavior. In non-human models, sociability is typically defined behaviorally as approach towards same-sex conspecifics and can be assessed using the 3-chamber sociability apparatus. We have previously observed a prominent sex difference in sociability between male and female rats when tested in this apparatus; males show significantly higher sociability compared to females. In this study, we explored whether this sex difference is mediated by the activational effects of testosterone or estradiol. Forty-eight male and forty-eight female Wistar rats were assigned to one of four treatment groups: 1) intact + vehicle,

2) gonadectomy (GDX) + vehicle, 3) GDX + testosterone propionate (TP; 500 μg/kg), 4) GDX + estradiol benzoate (EB; 20 μg/kg). GDX occurred on post-natal day (PND) 21, and hormone/vehicle treatment was administered daily between PND 35-48. On PND 46, subjects were run through an elevated plus maze (EPM) to assess general anxiety. On PND 47-48, sociability was assessed using the 3-chamber apparatus, with investigation time (of either a same-sex target or empty cage) being the principal dependent variable. Results revealed no significant effect of experimental treatment on anxiety in the EPM. With regards to sociability, we again found a significant sex difference, with males exhibiting more social investigation than females. However, there were no effects of treatment on sociability in males. In contrast, females did show significant treatment effects. GDX females given either vehicle or TP (but not EB) engaged in more social investigation than intact controls. This finding supports the hypothesis that estradiol may inhibit sociability. This work may help researchers better understand the relative utility and value of the 3-chamber sociability paradigm, and potentially clarify the role that gonadal hormones play in regulating social motivation during adolescence.

Title: Relationships between social rank and hypothalamic peptides in male and female mice

Authors: *H. FULENWIDER, A. RYABININ;
Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Social hierarchies are a feature of virtually all animal groups. The varying social ranks of subjects within these groups can significantly affect an individual's physical and mental health, with the lowest-ranked individuals, or subordinates, typically suffering the most adverse effects. More specifically, these subjects have been shown to exhibit various stress-related pathologies, such as increased hypothalamic-pituitary axis (HPA) activity, increased amygdalar corticotropin-releasing factor (CRF) levels, and even increased levels of drug intake, when compared to higher-ranked subjects. The goals of the current study were to characterize the formation and maintenance of social hierarchies in group-housed male and female C57BL/6J mice. We also aimed to investigate the relationship between social rank and hypothalamic oxytocin (OXT) and vasopressin (AVP) levels, two peptides with established roles in both social behaviors and the stress response. Mice were housed in same-sex groups of 4 in moderately enriched environments (48 x 37.5 x 21 cm, two fluid channels that allow for tracking of individual fluid intake, a curved plastic tube, a cotton nestlet square, and 1 bag of shredded paper nesting material). In these experimental conditions, neither male nor female mice exhibited severe agonistic interactions.

However, when social rank was measured by the tube test, we observed a consistently subordinate animal within each group. After approximately two weeks of tube tests, animals were euthanized and brains extracted, fixed, and sectioned for OXT and AVP immunohistochemistry (IHC). We found that the subordinate females had significantly more AVP+ cells in the paraventricular nucleus of the hypothalamus (PVN) compared to higher-ranking subjects. In contrast, subordinate males had significantly less AVP+ cells in the supraoptic nucleus (SON) compared to their higher-ranking counterparts. Lastly, we also found that both subordinate males and females had significantly more OXT+ cells in the SON than higher-ranking subjects. Overall, these findings demonstrate that there are relationships between social rank and hypothalamic AVP and OXT levels. Future studies will aim to assess these peptide levels in plasma as well, and to characterize whether these altered peptide levels are the product or cause of an individual's social rank, as well as to assess whether subordinates exhibit increased depressive- and/or anxiety-like behaviors compared to higher-ranking subjects.

Title: Social environment alters behavior and dopamine D1 receptor density in female prairie voles (Microtus ochrogaster)

Authors: *N. S. LEE[1], C. Y. KIM[2], A. K. BEERY[3];
[1]Psychological and Brain Sci., Colgate Univ., Hamilton, NY; [2]Neurosci. Program, Dept. of Psychology, Smith Col., Northampton, MA; [3]Dept. of Integrative Biol., UC Berkeley, Berkeley, CA

Abstract: Prairie voles (*Microtus ochrogaster*) are socially monogamous rodents that also exhibit selective, long-lasting preferences for same-sex peers. Adult social relationships appear to be maintained by selective aggression in prairie voles, whereby once paired with new opposite- or same-sex partners, they display aggression toward conspecifics outside of their pair. In contrast, socially non-monogamous meadow voles (*Microtus pennsylvanicus*) rely on social tolerance rather than selective aggression to maintain their peer relationships. Despite the species-specificity of the role of selective aggression, investigation into the necessity and sufficiency of dopamine signaling in the formation of new relationships provides evidence of relationship type-specificity: Prairie vole mate bonds are dependent on dopamine, whereas peer relationships in both prairie and meadow voles are not. However, prairie vole peer relationships appear to be intermediate between prairie vole mates and meadow vole peers in terms of reward value. Rather than using exogenous pharmacological manipulations to assess dopamine signaling, the current study assessed endogenous structural changes in dopamine D1 receptor density across different social environments, including long-term maintenance of prairie vole peer relationships, prolonged social isolation, and mixed-litter groups. Unlike in prairie vole mate bonds, prairie vole peers

did not exhibit upregulated D1 binding after extended housing with new same-sex partners compared to controls paired with same-sex partners since weaning. However, social isolation upregulated D1 binding in prairie voles, consistent with correlations between binding and individual behavior in partner preference and social interaction tests that suggest that higher D1 binding correlates with more anti-social behaviors and fewer social behaviors. There were no housing or sex differences in behavior in the partner preference test, and all groups displayed robust preference for a partner over a stranger. Housing did impact stranger-directed social investigation in social interaction tests, with males exhibiting more sniffing than females, and group living females exhibiting more sniffing than control females. This study informs our understanding of the neural and behavioral consequences of different social environments in a highly social species. This study also contributes to growing evidence that the mechanisms underlying reproductive and non-reproductive relationships are distinct, and that elucidation of the latter is necessary to fully understand the mechanisms underlying social behavior.

Title: Dissecting the contribution of host genetics and the microbiome in complex behaviors

Authors: *S. W. DOOLING[1,2,3], S. A. BUFFINGTON[1,4,3], M. SGRITTA[1,3], C. NOECKER[5], O. D. MURILLO[2], D. F. FELICE[1,3], P. J. TURNBAUGH[5,6], M. COSTA-MATTIOLI[1,2,3];

Abstract: The core symptoms of many neurological disorders have traditionally been thought to be caused by genetic variants affecting brain development and function. However, the gut microbiome, another important source of variation, can also influence specific behaviors. Therefore, it is critical to unravel the contributions of host genetic variation, the microbiome, and their interactions to complex behaviors. Unexpectedly, we discovered that different maladaptive behaviors are interdependently regulated by the microbiome and host genes in the *Cntnap2*$^{-/-}$ model for neurodevelopmental disorders. Using several independent approaches, we found that the hyperactivity phenotype of *Cntnap2*$^{-/-}$ mice is caused by host genetics, whereas the social behavior phenotype is mediated by the gut microbiome.

Interestingly, specific microbial intervention with *L. reuteri* selectively rescues the social deficits and related changes in social-reward mediated synaptic transmission in *Cntnap2*$^{-/-}$ mice through upregulation of metabolites in the tetrahydrobiopterin (BH4) synthesis pathway. Independent of any microbial intervention, treatment with BH4 selectively rescues social deficits in mouse models for neurodevelopmental disorders. In addition, inhibition of BH4 synthesis prevents the *L. reuteri* mediated rescue of social deficits. Overall, our results suggest that both the brain and the gut microbiota may need to be targeted to fully and effectively reverse the core symptoms associated with some neurological disorders. Indeed, our findings that behavioral abnormalities could have distinct origins (host genetic vs microbial) may change the way we think about neurological disorders and how to treat them.

Title: Age-associated differences in social fear response are not dependent on the gut microbiota

Authors: *N. L. RITZ[1], C. S. M. COWAN[1], M. BROCKA[1], N. THUENE[1], J. NAGPAL[1], M. RODRIGUEZ ABURTO[1], D. A. SLATTERY[2], J. CRYAN[1];
[1]APC Microbiome Inst., Univ. Col. Cork, Cork, Ireland; [2]Univ. Hosp. Frankfurt, Frankfurt Am Main, Germany

Abstract: Increasing evidence points towards a role of the gut microbiome in psychiatric disorders. Social anxiety disorder (SAD; or social phobia) is a common mental illness characterized by persistent fear of social situations which can severely limit the ability of sufferers to function in society. It has a high lifetime prevalence, but the currently available treatment options are limited and unspecific. The role of the microbiome in SAD is unknown. Moreover, although the microbiome has been implicated in fear responses and social behaviour, there is limited understanding of its role in social fear behaviours. To this end, we investigated whether microbiota depletion could alter social fear response in a mouse model of SAD. As fear responses vary across ages, we assessed the impact of microbiota depletion with antibiotics (ampicillin 1 g/L, vancomycin 500 mg/L, imipenem 250 mg/L, gentamicin 1 g/L) in male C57Bl/6J mice at two ages (30-day-old and 70-day-old; n=8-12). To induce appropriate social fear during conditioning, mice received foot shocks (2-4, 1 s, 0.6 mA) upon interaction with an unfamiliar conspecific. The following day, all mice underwent social fear extinction via six sequential social interaction tests with novel conspecifics introduced in each trial. Social interaction time between the experimental and conspecific mice was then measured. As expected, in control adult animals there was a significant extinction of social fear. In juvenile animals, this effect was exacerbated by decreased time spent in social interaction extinction trials with the conspecific mouse post-conditioning. However, antibiotic treatment

did not alter extinction behaviour in either age group. These data indicate that the response to social fear is affected by the age of the individual but is not modulated by microbiota depletion. Further research must be done to better understand the biological underpinnings that drive this age-associated social fear behaviour and investigate if there is a role of the microbiome in inter-individual differences.

Title: The effects of early life adversity on risky decision-making and the orbitofrontal cortex transcriptome in male and female rats

Authors: *E. ORDOÑES SANCHEZ[1], C. C. BAVLEY[1], R. KARBALAEI[1], J. FLOWERS II[1], A. R. BONGIOVANNI[1], A. INGRAM[1], A. JEAN-LOUIS[1], A. CROSBIE[1], N. SEKHAWAT[1], C. S. ARDEKANI[1], M. E. WIMMER[2], S. B. FLORESCO[4], D. A. BANGASSER[3];
[2]Psychology, [3]Dept. of Psychology and Neurosci. Program, [1]Temple Univ., Philadelphia, PA; [4]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Early life stress stemming from poverty can have lasting effects that persist into adulthood. In order to study this form of stress in rats and how it affects cognitive processes related to substance use disorder (SUD), we used the limited bedding/nesting (LBN) model, in which dams and pups are exposed to a low resource environment from postnatal day 2-9. Previous work in the lab found that LBN reduces impulsive choices in males but not females, as measured with a delay discounting task. Here we tested whether LBN exposure would also alter risky choice behavior in a probability discounting (PD) task. In PD, a rodent must choose between two levers: a certain lever (always delivers 1 pellet) versus a risky lever (*sometimes* delivers four pellets). Odds of earning the large reward varied across five blocks (100%, 50%, 25%, 12.5%, 6.25%). We found that all LBN rats choose the risky lever less often than controls when the probability of earning a large reward was low [$F(4,376)=2.845$, $p=.024$]. A brain region important in mediating both impulsive and risk-based decision-making processes is the orbitofrontal cortex (OFC). To assess mechanisms by which LBN may affect these processes we completed RNA-sequencing on OFC tissue from adult rats (male control n=5; female control n=5; male LBN n=5; female LBN n=5). We used rank-rank hypergeometric overlap (RRHO) analysis to compare overall gene expression patterns in males and females induced by LBN. We found that LBN induced sex-specific changes in transcription. Specifically, we see a distinction between genes upregulated in males and downregulated in females due to LBN. We next narrowed our analysis to genes showing a significant difference between control and LBN and found 161 differentially expressed genes (DEGs) in males and

138 DEGs in females. These gene changes were largely sex-specific with only 18 common genes altered by LBN. KEGG pathway analysis revealed “retrograde endocannabinoid signaling” was significantly enriched in males but not females (adjusted p=.01), which may drive behavioral changes induced by LBN in males. Future studies aim to validate top gene targets, including one involved with the endocannabinoid system, with RNAScope. Collectively, these results suggest that LBN reduces impulsivity and risky decision making, protecting against cognitive changes that are related to risk for SUDs. Although initially unexpected, these findings add to a growing body of literature supporting the stress inoculation hypothesis: that some early adversity promotes later resilience. Understanding mechanisms that promote this stress resilience can lead to better treatments for SUD.

Title: Crf infusion into the medial septum modulates hippocampal cholinergic transmission in rats

Authors: *A. KNIFFIN, M. TARGUM, D. BANGASSER, V. PARIKH;
Psychology and Neurosci. Program, Temple Univ., Philadelphia, PA

Abstract: The cholinergic septohippocampal pathway (SHP) modulates hippocampal-dependent mnemonic processes, including spatial and contextual memory. Previously, studies have shown that rats exhibit impaired spatial memory on the novel object location task after 100 ng infusion of corticotropin releasing factor (CRF) into the medial septum (MS). However, a clear sex difference emerged at a low dose of CRF (3ng), with only males exhibiting impaired spatial memory. The mechanism by which MS CRF may be affecting spatial memory is unclear but could involve changes in hippocampal acetylcholine (ACh) levels, given that CRF_1 receptors are present on cholinergic neurons in the MS. Here we tested whether CRF in the MS can alter hippocampal cholinergic transmission via *in vivo* electrochemical recordings with choline sensitive microelectrodes. Adult male and female rats underwent intracranial infusions of artificial cerebral spinal fluid (aCSF) and CRF into the MS using a within-subject design. Basal changes in cholinergic transmission were recorded for 30 minutes following each infusion in the dorsal hippocampus. Depolarization pulses with potassium chloride were applied to stimulate ACh release locally in the terminal fields. MS CRF (100ng) infusion reduced the amplitudes of depolarization-evoked cholinergic transients by 25% (2.27±0.35 vs 3.01±0.37 with aCSF; t10=1.85; p=0.09) and this effect was similar between the two sexes. At this dose, changes in resting cholinergic levels tended to decline over the monitored 30-minute period following CRF infusion. Preliminary data in male rats

revealed no suppression of signal amplitudes with a low dose (3ng) CRF infusion, suggesting the effect of MS CRF on hippocampal cholinergic transmission are presumably dose-dependent. The clearance time of cholinergic signals remained unchanged between manipulations, indicating no disruption of transporter-mediated clearance mechanisms. Ongoing studies are examining the effects of low-dose CRF in female rats to investigate the above-mentioned sex differences in spatial memory performance. Taken together, our findings thus far indicate the MS CRF exerts an inhibitory effect on hippocampal cholinergic transmission in a dose-dependent manner. Future studies to delineate the mechanisms by which CRF regulates septohippocampal cholinergic circuitry may aid in the development of novel treatments for stress related psychiatric disorders as well as contribute to the basic understanding of stress-mediated changes in hippocampus-dependent cognitive functions.

Title: Sex differences in the effects of acute stress on cognitive flexibility in rodents

Authors: *A. T. GARGIULO, I. C. RAVAGLIA, A. C. HAWKS, L. A. GRAFE;
Bryn Mawr Col., Bryn Mawr, PA

Abstract: Stress-related psychiatric disorders such as Post-Traumatic Stress Disorder (PTSD) and Major Depressive Disorder (MDD), of which cognitive impairment is a key phenotype, are twice as common in women compared with men. However, the literature describing the effects of stress on cognition and the potential sex differences associated with this relationship is equivocal, and the neurobiology underlying these sex differences is not fully understood. We are interested in probing how stress affects cognitive flexibility, which is the ability to adapt cognitive processing strategies to face new conditions in the environment; this skill is crucial in normal daily functioning. To explore sex differences in how stress affects cognitive flexibility, we trained adult male and female Sprague-Dawley rats (N = 48) to complete an automated attentional set-shifting paradigm, with acute stress applied prior to testing. Specifically, rats were first trained for 3 days in the automated attentional set-shifting task. On the fourth day, rats were exposed to acute (30-min) restraint stress prior to testing on the set-shifting paradigm. As gonadal hormones are known to influence the stress response, we tracked the estrous cycle using vaginal lavage in our female rats. Following testing, rat brains were extracted and immunolabelled for *c-fos* (a marker of neural activity) in the prefrontal cortex, which is a critical brain region in executing the cognitive flexibility task. Our results indicate that female rats consistently show higher stress behavior throughout restraint than males, and this varied by phase of the estrous cycle. In addition, females made more perseverative errors and displayed more omissions in the attentional set-shifting task than males, and these results again varied by estrous phase. Lastly, *c-fos* immunoreactivity in the prefrontal cortex after the attentional set shifting task differed by sex. The results suggest that there are sex differences in restraint stress behavior, subsequent cognitive flexibility, and neural activity. Moreover, it appears that

female gonadal hormone status influences these measures. Further research should examine the mechanisms by which stress acts on the brain in females and males to influence cognition.

Title: Stress Influences on the Explore-Exploit Tradeoff in Reward-Guided Decision Making of Mice

Authors: *D. MUELLER, C. CHEN, A. BANO, E. WOOD, N. M. GRISSOM;
Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Stress has been implicated in changes in decision making, but the implementation of such changes via computational processes of reinforcement learning remains unclear. Stress causes a widespread refocusing of cognitive resources, and alters numerous factors playing into decision making. Acute stress increases selection of more valuable options, which has been interpreted as increased reward sensitivity. Acute stressors also increase habit over goal-directed actions, decreasing the flexibility of behaviors. Therefore, altered choices after stress could either be due to an increase in reward sensitivity, or a decrease in willingness to switch from a previously chosen option, or both. We examined the effects of acute saline injection stress as part of a behavioral pharmacology experiment on decision making in mice in a restless bandit task. This translational task involves repeatedly selecting between two illuminated squares on a touchscreen operant chamber, which are rewarded probabilistically. This bandit task is “restless” because the reward probability of each choice changes randomly and independently across trials. This encourages animals to continuously sample the choices and learn about the current best choice. To maximize reward, animals have to balance between exploiting a current high-value option and exploring potential better alternatives. We hypothesized that acute stress would increase reward sensitivity, leading mice to exploit more choices following rewarded trials (win-stay). Thirty-two 129/b6j F1 mice (16 male and 16 female) were tested on restless bandit schedules with and without saline injection prior to testing in a within-subjects design, to habituate animals to injections for future behavioral pharmacology experiments. We are currently examining success at obtaining rewards, win-stay/lose-shift behavior, locomotor activity within the chamber, and reaction times for choices and reward retrieval. Our preliminary results indicate that acute injection stress negatively impacted the performance over chance for both male and female mice across sessions, with cumulative impacts of each injection. Along with this, we found that animals showed reduced locomotor behavior in the chamber after saline injection. As hypothesized, acute injection stress appears to increase win-stay behavior, which may prevent animals from exploring to maximize changing reward values. The repeated nature of the injections are intended to induce adaptation or habituation, which may alter the effect on decision making over time.

Title: Sex Differences in the Impact of Prenatal Stress on Spatial Memory

Authors: *T. BUCK[1], K. LOTESTO[1], *M. S. SODHI[2];
[2]Mol. Pharmacol. and Therapeut., [1]Loyola Univ. Chicago, Maywood, IL

Abstract: Prenatal stress is a risk factor for several psychiatric disorders. Prenatal restraint stress (PRS) alters brain development and has long-term effects on behavior, including increased risk aversion, impaired spatial memory and social interaction deficits. Accumulating data indicate that altered glutamatergic transmission in the hippocampus mediates the long term pathology associated with PRS in mice. A post-transcriptional process known as RNA editing regulates the trafficking and function of AMPA glutamate receptors (AMPARs), which are critical for synaptic plasticity, learning and memory. Altered RNA editing of AMPARs and other synaptic proteins may contribute to stress-induced behavioral impairment. We exposed pregnant C57BL/6J and Swiss-Webster mice to restraint stress from GD7 until birth, and evaluated spatial learning, locomotor activity and risk aversion in the offspring. We also tested metabolic activity using the Phenomaster system in the mice at 80 weeks of age. In contrast with Swiss-Webster mice, C57BL/6J mice did not display social interaction deficits after exposure to PRS. Female C57BL/6J adult mice exposed to PRS had improved performance in spatial reversal in the Morris water maze ($p<0.05$), while PRS males showed persistent spatial memory in the reversal task ($p<0.05$), indicating a reduced ability to adapt their behavior in response to a change in the environment. Altered spatial memory was not observed in these mice later in life (80 weeks). Males and females exposed to PRS showed similar increases in risk aversion in the light/dark box and open field tests ($p<0.05$) at 80 weeks, with no accompanying changes in locomotor activity ($p>0.1$). No alterations in metabolic activity were observed with PRS. Analyses of gene expression within the corticolimbic regions of the brain are ongoing to identify molecular pathways impacted by PRS that produce long-term impairments in spatial learning and risk aversion. Moreover, we report improved resilience to prenatal stress in C57BL/6J mice relative to Swiss-Webster mice. Future analyses of genomic differences between inbred strains of mice may reveal pathways that confer relative resilience to the detrimental effects of PRS.

Title: GABAA receptor positive allosteric modulation has anti-depressant effects, pro-cognitive effects and reverses neuronal atrophy in a mouse model of chronic stress

Authors: *A. BERNARDO[1], P. LEE[2], M. MARCOTTE[1], Y. MIAN[3], Z. A. KHAN[3], D. SHARMIN[3], J. M. COOK[3], E. SIBILLE[1,2], T. PREVOT[1,2];
[1]camh, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada; [3]Univ. of Wisconsin-Milwaukee, Mikwaukee, WI

Abstract: Chronic stress is a recognized risk factor for developing anxiety and depression. Each of these is linked to reduced cognitive performance and neuronal atrophy, further contributing to the complexity of the pathologies. Both anxiety and depression display a reduced number of GABAergic neurons, reduced GABA release and altered GABAA receptor (GABAAR) functioning. Functionality of GABAARs are essentially related to which α subunits are present within the GABAAR: α1 subunit potentiation is associated with sedation, α2/α3 potentiation with anxiolytic effects and α5 potentiation with cognition. Current GABAergic drugs, such as benzodiazepines, target GABAAR α subunits indiscriminately resulting in several side effects, limited anxiolytic effects and little cognitive benefit. Here we hypothesize that a positive allosteric therapy targeted to α2/α3-GABAAR and α5-GABAAR devoid of α1-GABAAR activity will overcome benzodiazepine limitations. This approach will be clinically relevant and address unmet cognitive impairment therapy needs, and reverse neuronal atrophy which contributes to overall symptomatology. We investigated two enantiomers GL-I-54 and GL-II-73, and their combined use as a racemic mixture (termed GL-RM) because of the desirable positive allosteric modulation profile when combined (α2/3/5-GABAAR and α5-GABAAR respectively). Using the unpredictable chronic mild stress (UCMS) model in C57BL6 mice (50% female; N=48 per study) we assessed anxiolytic (using elevated plus maze, novelty suppressed feeding and phenotyper test), anti-depressant (using sucrose preference and forced swim test) and pro-cognitive effects (Y maze) of GL-RM with acute or chronic administration. Neurotrophic effects were investigated in the chronic treatment study using Golgi Staining and Neurolucida for quantification to view neurons in the prefrontal cortex and hippocampus (CA1 region). Results found GL-RM has anti-depressant and pro-cognitive effects in both acute and chronic studies. Golgi staining found dendritic spine density reduced by UCMS was recovered with chronic GL-RM treatment demonstrating a neurotrophic effect of chronic GL-RM. Results support the value of a therapy with a α2/3/5-GABAAR selective profile to overcome chronic stress-induced mood symptoms, cognitive deficits, and detriments in neuronal morphology. These studies overall demonstrate the usefulness of targeting the GABAergic system as a treatment avenue for stress-related disorders, with symptomatic and disease-modifying effects.

Title: Mitochondria-associated CB1 receptors regulate cognitive effects of stress

Authors: *U. SKUPIO, R. SERRAT, A. ERASO PICHOT, A. C. PAGANO ZOTTOLA, F. JULIO KALAJZIC, A. CANNICH, J. WELTE, L. BELLOCCHIO, F. CHAOULOFF, G. MARSICANO; INSERM U1215, Bordeaux Cedex, France

Abstract: Behavioral and cognitive response to stress requires high cellular activity in the brain, which depends on energetic support provided by mitochondria. The endocannabinoid system, which is implicated in stress response, has been reported to directly regulate mitochondrial energetic activity and memory via the type-1 cannabinoid receptors (CB1) associated with the brain mitochondria membranes (mtCB1, Hebert-Chatelain et al., 2016). In the present study, we aimed to evaluate the involvement of the endocannabinoid system in the regulation of cognitive stress effects in adult male mice. We used the novel object-recognition (NOR) task as a model of non-aversive memory to investigate the underlying mechanism of the deleterious effect of stress (single 0.5 mA foot-shock for 2 s) or corticosterone administration (10 mg/kg, sc) on memory consolidation and retrieval. To examine the role of different CB1 pools in this effect, we used a combination of transgenic mouse models (based on C57BL6/J strain) and viral approaches *in vivo* to specifically delete or re-express CB1 in different neuronal populations and subcellular compartments (9-16 mice per experimental group). Our results show that both stress and corticosterone induce impairment of NOR memory consolidation and retrieval and that these alterations are mediated by mtCB1 receptors in specific populations of noradrenergic and GABA-ergic cells, respectively. Interestingly, we found that CB1 receptors present in other neuronal populations are not involved. Overall, by underlying the key involvement of mitochondria-associated CB1 receptors, this work provides a novel outlook on the mechanisms linking stress to cognitive impairment. Thus, these data might pave the way for the development of new therapeutic strategies for the treatment of detrimental effects of stress on cognition.

Title: Sleep restriction on sweeteners consumption and delta Fos expression

Authors: *F. GARCÍA-GARCÍA[1], **L. A. LOPEZ-MUCIÑO**[2], M. E. ACOSTA-HERNANDEZ[2], A. VENEBRA-MUÑOZ[3];
[2]Hlth. Sci. Inst., [1]Univ. Veracruzana, Xalapa, Mexico; [3]Univ. Estatal del Estado de Mexico, Toluca, Mexico

Abstract: Adolescence is a critical period in development because it enhances vulnerability towards reward-driven behaviors, and a voluntary sleep restriction occurs (SR). Different studies suggested that SR is a factor that elicits drug consumption, although the neuronal basis remains poorly understood. Additionally, SR favors the preference for palatable foods. For example, sweeteners are known to have a high preference value due to their high sweetness. The present study's objective was to determine whether SR enhances sweeteners consumption and the association with ΔFosB expression in the brain reward circuit. Adolescent Wistar rats (30-60 PND) were housed in individual cages and divided into two groups; control (Ctrl) and SR (4 h/7 days by gentle handling method), matched for mean body weight. The free-selection bottle test was used to determine the preference and intake of each solution. Both groups were divided into 3 subgroups of 8 animals as follows: 1) two bottles of plain water, 2) a bottle of plain water and a bottle of sucrose (1%), and 3) a bottle of plain water and a bottle of Stevia extract (0.05%). At the end of each treatment, brain sections were collected and processed for ΔFosB immunohistochemistry. The analyzed brain regions were the prefrontal cortex (PFC), nucleus accumbens (NAc), central amygdala (CaA), and ventral tegmental area (VTA). No differences were found in fluid intake for each solution between the control and SR groups. However, the number of ΔFosB positive cells was increased in the PFC and NAc Core in the SR group exposed to 0.05% Stevia. On the other hand, a reduction in the number of ΔFosB positive cells in NAc Core and NAc Shell of rats with SR exposed to 1% sucrose was found. In conclusion, SR did not enhance the intake of sweeteners. However, there was a differential ΔFosB expression in brain areas involved in decision making, motivation, and evaluation of salient stimuli, depending on the type of sweetener.

Title: The ability of sleep deprivation to impair performance on behavioral tasks is altered in mice that overexpress Bmal1 in skeletal muscle

Authors: *A. TUCKER, I. NICHOLS, K. N. PAUL;
UCLA, Los Angeles, CA

Abstract: Sleep is a phylogenetically conserved behavior necessary for survival. While chronic insufficient sleep has negative effects on health and well-being, acute sleep loss has negative effects on memory and cognition. In the current study, we use behavioral tests to assess memory function in mice that overexpress the circadian timing gene, *Bmal1*, in skeletal muscle. Recent studies reveal that the overexpression of *Bmal1* in skeletal muscle reduces homeostatic sleep responses to acute sleep loss. In behavioral tests in mice, sleep deprivation immediately after memory acquisition has been shown to negatively impact memory consolidation. Thus, we hypothesized that if *Bmal1* muscle overexpression mice require less recovery after sleep deprivation, they also would not experience the negative cognitive impacts of this sleep deprivation. We examined memory via two behavioral tests — the Novel Object Recognition Test, which measures recognition memory, and the Novel Location Recognition test, which measures spatial memory. In the Novel Object Recognition test, we found that 6 hours of sleep deprivation was unable to disrupt novel object recognition in either *Bmal1* muscle overexpression mice or wild-type littermates (two-way ANOVA: 'Condition' $F_{(1, 18)} = 0.01781$, p=0.8953; 'Genotype' $F_{(3, 18)} = 0.1545$, p=0.9254, 'Condition * Genotype' $F_{(3, 18)} = 0.2354$, p= 0.8705). However, we found that 12 hours of sleep restriction immediately after memory acquisition disrupted novel object recognition during the testing phase in wild-types (paired t-test: p=0.0278/ t=2.886, df=6), but significantly improved novel objection recognition in Bmal1 muscle overexpression mice (paired t-test: p=0.0352, t=2.708, df=6) (two-way ANOVA: 'Condition' $F_{(1, 12)} = 0.01995$, p=0.8900; 'Genotype' $F_{(1, 12)} = 0.5189$, p=0.4851 ; 'Condition x Genotype' $F_{(1, 12)} = 5.529$, p= 0.0366). In the Novel Placement Recognition test, sleep deprivation significantly increased novel location recognition (two-way ANOVA: 'Condition' $F_{(1, 10)} = 9.227$, p=.0125; 'Genotype' $F_{(1, 10)} = 0.02929$, p= .8673 ; 'Condition x Genotype' $F_{(1, 10)} = 0.9798$, p=.3456). Posthoc analysis revealed a significant improvement in sleep-deprived wild-types (t=2.676, df=6, p=0.0367) but not in sleep-deprived *Bmal1* muscle overexpression mice (t=1.881, df=4, p=.1331). These results suggest that skeletal muscle *Bmal1* confers resistance to recognition memory deficits caused by sleep deprivation, but not spatial memory deficits.

Title: Light has color-dependent effects on sleep in Drosophila melanogaster

Authors: S. M. BOND, D. SIRTALAN, D. A. SKEELE, H. HUANG, D. R. POSSIDENTE, *C. G. VECSEY;
Neurosci., Skidmore Col., Saratoga Springs, NY

Abstract: Sleep is a poorly understood, evolutionarily conserved state that has profound health impacts. An emergent cause of human sleep disruption is evening exposure to blue-enriched light from screens on smartphones, computers, and TV. In contrast to blue light's alerting effect, red light may promote sleep. The exact molecular pathways behind light color's impacts on sleep are not fully elucidated. Therefore, we conducted an exploratory study on the sleep effects of blue and red light in the model organism *Drosophila*. To investigate whether blue and red light alter sleep in a time-dependent manner, we examined sleep after light color exposure through all 12 hours of daytime, for 3 hours in the fly's subjective morning, and 3 hours in the evening. Experiments were performed on male and female ($n \geq 24$ for each sex) wild-type Canton-S (CS) flies and ones with a mutation in the *white* gene (w^{1118}) that cannot transport precursors to form screening pigment in the compound eye, resulting in white eyes. Sleep was measured for two full baseline days of 12:12 white light/dark (LD), six experimental days of blue/dark or red/dark exposure, followed by two recovery days of LD. Sleep data from the blue- and red-light days were compared with data from the final baseline day to characterize the sleep effects of these light colors. Here, we show that daytime blue light reduced sleep during exposure in wild-type *Drosophila*, and this effect was consistent with blue exposure in just the morning, evening, or for all 12 hours of daytime. Our data demonstrate that blue light also has nighttime sleep-inhibiting effects in *Drosophila*. Blue light for 12 hours reduced nighttime sleep on the second day of exposure in CS flies. Interestingly, blue light's wake-promoting effects in CS flies were not seen in w^{1118} flies, despite both strains experiencing some common sleep-promoting effects. When flies were exposed to daytime red light, sleep was reduced during exposure, and this was observed in both CS and the w^{1118} flies. Furthermore, red light's daytime sleep-inhibiting effect was specific to the evening and immediately followed by a sleep rebound in both strains. Ultimately, we establish that *Drosophila* sleep, much like human sleep, is altered by light in a wavelength-specific manner, and some of these light color effects on sleep differ based on the time of exposure. Additionally, our differing results between wild-type flies and w^{1118} mutants in response to blue light imply that some of blue light's sleep effects are mediated by a pathway that is altered by the w^{1118} mutation, such as the compound eye. Future studies will show how light color information is detected by the fly brain and transmitted to sleep centers.

Title: Mir-190 acts during pupation to regulate sleep behavior in drosophila melanogaster

Authors: *E. J. RIVERA-RODRÍGUEZ, L. C. GRIFFITH;
Brandeis Univ., Waltham, MA

Abstract: Sleep is a widely conserved behavior, known to influence many cognitive and physiological functions. Studies have implicated microRNAs in the regulation of gene expression changes that control sleep behavior. The Griffith lab screened a library of 141 microRNA sponges using the fruit fly *Drosophila melanogaster*, in order to find microRNAs involved in sleep regulation (Goodwin et al., 2018). This screen showed miR-190 to be involved in the regulation of sleep. Flies expressing the miR-190 sponge (*miR-190SP)* in a pan-neuronal manner showed decreased and fragmented sleep, as well as changes in other sleep parameters. Spatial and temporal mapping of its locus of action demonstrates that miR-190 is required during the pupal stage, in a population of neurons that transcribe both glutamatergic and cholinergic genes, but only express glutamatergic proteins (*Glu^{Ach}* cells). Thermogenetic activation of this population of cells by means of dTRPA1 results in a decrease and fragmentation of sleep, phenocopying miR-190 knockdown. At the molecular level, RNA sequencing of both pupal brains and adult heads showed that pan-neuronal expression of *miR-190SP* induces an upregulation of multiple genes, among those *mid*, a T-box transcription factor previously shown to operate as a suppressor of glutamatergic fate. *Glu^{Ach}>mid* overexpression phenocopied miR-190 knockdown with animals showing a decrease in total sleep and sleep fragmentation. Taken together, our results suggest that miR-190 acts during development in *Glu^{Ach}* cells to allow their glutamatergic differentiation and specify the activity of the adult arousal system and adult sleep behavior.

Abstract: Ample evidence suggests that sleep facilitates the consolidation of newly learned skills. However, the neurophysiological correlates and neural mechanisms underlying the consolidation of new

experiences during sleep are not yet fully understood. One of the leading hypotheses related to this mnemonic process posits that the neural populations involved in encoding the newly acquired knowledge and experiences are repeatedly reactivated during a subsequent sleep period. Such reactivation constitutes an opportunity to reprocess new memories and optimize their storage using the brain network recruited during the initial learning phase. The research in our and other laboratories has shown that the spontaneous reactivation of new memory traces is linked to sleep spindles - bursts of thalamocortical activity at 11-16 Hz occurring during non-REM sleep. Sleep spindles vary in their frequency, amplitude, and duration, and form distinct spatial and temporal patterns. However, there is no unitary view on whether all, or only some types of spindles are associated with memory reactivation processes. Here, we tested our new hypothesis that clustering of spindles into trains (i.e., less than 6 s apart) is crucial for efficient reprocessing of motor memories in humans. To this end, we conducted a sleep study in which we recorded brain activity using electroencephalography (EEG) and functional magnetic resonance imaging (fMRI) simultaneously. These simultaneous recordings allowed us to conduct EEG-informed analyses of the fMRI data and estimate changes in activation patterns across the entire brain during spindles. Before the sleep, participants (n=26) were trained on a 5-element sequence of finger movements, tapping it repeatedly on a keyboard with their left hand, and then retested 24 hours later. Spindles were either clustered into trains or occurred in isolation (more than 6 s apart). Our results reveal that the onset of spindle trains, as compared to the isolated spindles, was associated with greater brain activity in key regions involved in motor sequence learning, including the thalamus, sensorimotor cortex, and striatum. Moreover, the onsets of longer trains were associated with a stronger effect, and participants with longer spindle trains exhibited greater activation within the same network; the latter effect being lateralized to the sensorimotor regions contralateral to the performing hand. These findings suggest that reactivation of the newly encoded motor memory is initiated with the first spindle of the trains, whereas spindles followed by longer trains may be more effective in triggering memory reprocessing and consolidation of procedural memories.

Care Ctr., Ulaanbaatar, Mongolia; [8]Brain science, Ulaanbaatar, Mongolia

Abstract: Objectives: The aim of the study was to determine the quality of sleep and its risk factors in middle-aged Mongolian women. **Materials and methods**: A cross-sectional study were conducted among females aged between 40-65 years in the pre-, peri-, and post-menopausal status. Data was collected using a predesigned questionnaire which included general information, reproductive history, and body measurements along with standardized questionnaires such as the PSQI, Menopause Rating Scale and WHOQOL-BREF. The data analysis was conducted on 351 women. **Results**: Participant's blood pressure (p=0.003) and body mass index (BMI) (p=0.02) was significantly high in perimenopausal women. Average PSQI score in pre-, peri- and post-menopausal women were 6.59, 7.03, and 7.17 respectively. The somato-vegetative (p=0.003) and psychological (p=0.025) symptoms were significantly severe in perimenopausal women. The menopausal symptom severity frequency was significantly higher in perimenopausal women (p=0.017). Most of the participants answered well in both general quality of life and health related quality of life. However, the average of domain scores of WHOQOL-BREF was less than 80% at all menopausal stages. No correlation found to sleep quality either menopausal symptoms or quality of life. The menopausal symptoms (MRS total) (p=0.02) and sexual activity per month (p=0.005) has a significant influence on the overall quality of life. Sexuality had a significantly negative effect on psychological health (p=0.03). The age, occupation, menopausal stage, MRS-somatovegetative symptoms had a significant effect on health-related quality of life ($p<0.05$). **Conclusion**: In conclusion, middle age Mongolian women have poor quality of sleep. However the sleep quality was not the valuable factor for quality of life or menopausal symptoms severity. This however needs confirmation in other, better-designed clinical studies.

Title: Medullary adrenergic C1 neurons activity oscillates during sleep state transitions and arousal in rats

Authors: *G. M. P. R. SOUZA[1], R. L. STORNETTA[2], D. S. STORNETTA[1], S. B. G. ABBOTT[1]; [2]Pharmacol., [1]Univ. of Virginia, Charlottesville, VA

Abstract: Introduction: Sleep-wake behavior are associated with changes in sympathetic nerve activity (SNA) controlling blood flow to vital organs and muscle. SNA regulating blood pressure (BP) is controlled by adrenergic neurons in the ventrolateral medulla (RVLM), termed C1 neurons. C1 neurons are regulated by inputs from hypothalamic and brainstem regions that control arousal state, such as the orexin/hypocretin neurons. Thus, we hypothesized that C1 neurons mediate changes in SNA that accompany changes in sleep-wake state and vigilance. **Methods:** To test this hypothesis, we recorded the real-time activity from C1 neurons using fiber photometry in freely behaving rats while monitoring the

vigilance states. C1 neurons were targeted with GCaMP7s by microinjection of AAV_1-syn-FLEX-jGCaMP7s in the RVLM of Tyrosine Hydroxylase-Cre transgenic rats and an optical fiber was implanted above the injection site. Rats were fitted with a EEG/EMG head stage to monitor sleep-wake state and a radio telemetry probe to record BP. Normalized fluorescence changes are expressed as Z-score (mean ± SD), paired t-test were used to determine statistically significant differences. **Results:** In all cases, C1 activity as measured by GCaMP7s florescence was increased by acute isovolemic hypotension induced by sodium nitroprusside (2.1 ± 0.5 *vs.* -0.92 ± 0.4, $p<0.0001$, n=5). Similar to SNA in different stages of sleep and wake, C1 neuron activity increased during transitions from NREM to wake (-0.60 ± 0.1 *vs.* 0.59 ± 0.2, $p<0.0001$, n=6) while their activity decreased during transitions from wake to NREM (0.34 ± 0.2 vs. -0.32 ± 0.2, $p<0.0001$, n=6). C1 neurons activity increased during transitions from NREM to REM sleep (-0.74 ± 0.1 *vs.* 0.77 ± 0.1, $p<0.0001$, n=6) and decreased in transitions from REM to wake (0.58 ± 0.2 vs. -0.59 ± 0.2, $p<0.0001$, n=5). Arousal induced by air-puff delivered during NREM sleep caused a significantly greater change in C1 neuron activity than during spontaneous NREM-to-wake transitions (-0.78 ± 0.1 *vs.* 1.56 ± 0.4). **Conclusion:** C1 activity exhibit a pattern of activity that is similar to SNA during changes in sleep-wake state and in response to a stressful stimulus, consistent with the hypothesis that these neurons are responsible for arousal-related changes in SNA. The magnitude of the change in C1 activity during transitions to wakefulness appears to be associated with arousal intensity.

Title: Peripartum estradiol fluctuations impact sleep actigraphy and neural plasticity during a hormone-simulated pseudopregnancy in female Syrian hamsters

Authors: J. E. CORBIN*, C. MERRILL*, K. C. HARRIS, M. A. HORTON, H. C. MORRIS, E. K. HAUGHEE, L. E. BEEN;
Haverford Col., Haverford, PA

Abstract: During the peripartum period, hormone levels fluctuate dramatically. Estradiol, in particular, increases throughout pregnancy, peaking in the third trimester; after birth and the expulsion of the placenta, however, estradiol levels quickly drop to pregravid levels and remain suppressed until ovulation resumes. Pregnant and postpartum people report clinically-significant disruptions in their sleep, and high levels of estradiol have been reported to suppress sleep in other contexts. However, it is unknown how peripartum estradiol fluctuations impact sleep. We therefore used a hormone-simulated pseudopregnancy model in female Syrian hamsters to test the impact of peripartum estradiol fluctuations on sleep actigraphy and neural plasticity. Adult female Syrian hamsters (n = 24) were ovariectomized and given daily hormone injections to approximate estradiol and progesterone levels during the peripartum period. Following this simulated pregnancy, one group of females was withdrawn from estradiol to simulate the

rapid decline in estradiol during the postpartum period, while one group continued to receive estradiol injections. Both groups were compared to a “no hormone” control that was ovariectomized and received vehicle injections throughout the simulated pregnancy and postpartum period. 24-hour video recordings of subjects in their home cages were taken at seven timepoints: twice prior to the initiation of hormone injections, twice during the early pregnancy stage, twice during the late pregnancy stage, and once during the postpartum period. At the conclusion of the experiment, hamsters were euthanized via intracardial perfusion and brains were processed for immunohistochemical localization of cFos, a marker of neural activation. High levels of estradiol during “late pregnancy” decreased total sleep time and sleep efficiency, and increased locomotion during the white light period. These differences persisted into the postpartum period for females who continued to receive estradiol, but not in females who were withdrawn from estradiol. cFos counts are still in progress, but preliminary results suggest that activation of dorsal raphe neurons may vary by hormone condition. Together, these results suggest that high estrogen levels in late pregnancy disrupt sleep, but postpartum estrogen withdrawal may ameliorate these disruptions, possibly via estradiol-mediated plasticity in dorsal raphe neurons.

Title: Psychometric properties of the PSQI in the Mongolian general population, prevalence of sleep quality, and nonorganic sleep disorders

Authors: *E. TUMURBAATAR[1,2], E. BAT-ERDENE[1], O. DAMDINBAZAR[3], T. AMARTUVSHIN[4], M. DASHTSEREN[4], G. TUMUR-OCHIR[5], D. BOLDBAATAR[6], T. JADAMBA[7], B. LKHAGVASUREN[8,1];

Sci., Ulaanbaatar, Mongolia; [7]Mon TimeLine Res. center, Ulaanbaatar, Mongolia; [8]Dept. of Psychosomatic Med., Intl. Univ. of Hlth. and Welfare Narita Hosp., Narita, Japan

Abstract: There has been no report on sleep disorders and no validated tool for the screening of sleep quality in Mongolia. The aim of this study was to determine the prevalence of nonorganic sleep disorders and sleep quality among the general population using the Pittsburgh Sleep Quality Index (PSQI) followed by a structured psychiatric interview for low sleep quality individuals. This nationwide population-based cross-sectional study was carried out between August and October 2020 and consisted of 964 participants (74% women, mean age: 40.72±14.34) who were randomly selected from 64 clusters in 10 sites of Mongolia. 27.9% of the study participants were evaluated as having nonorganic sleep disorders based on the diagnostic guidelines of the International Classification of Diseases, Tenth Edition, Clinical Modification (ICD-10). The prevalence of nonorganic sleep disorders differed in age ($p < 0.001$).

Nonorganic sleep disorders were related to age, employment, diastolic blood pressure, sleep quality, and quality of life. The mean PSQI total score was 5.61±3.36 and 42.2% of the participants were classified as poor sleepers by a cut-off point of 5. An overall Cronbach's α was 0.73. Both exploratory and confirmatory factor analyses of PSQI indicated a two-factor solution. The results suggest that the prevalence of nonorganic sleep disorders in the general population of Mongolia was 27.9%, while the prevalence rate of poor sleep quality was 42.2% in the general population. The Mongolian version of the PSQI provides an important tool for screening of sleep quality and demonstrated good construct validity for use in the general population of Mongolia.

Title: High fat diet feeding blunts AgRP neuron response to cold

Authors: *J. D. DEEM, K. OGIMOTO, B. PHAN, H. HUSSAIN, P. P. GUNDAPANENI, M. W. SCHWARTZ, G. J. MORTON;
Univ. of Washington, Seattle, WA

Abstract: To defend energy homeostasis in the cold requires energy expenditure (to support thermogenesis) and energy intake increase, enabling core temperature to be maintained with no change to body fat stores. When acutely housed at a mild cold (14°C), mice increase both food intake and heat production rapidly (~minutes), and these responses occur in parallel. We hypothesized a role for Agouti-related peptide (AgRP) neurons in this response and find their activity is regulated by thermal sensory input, and they increase activity, measured by Fos induction and fiber photometry, upon cold sensation. By inhibiting AgRP neurons during acute cold exposure, we also find this increase in AgRP neuron activity is required for the hyperphagic response to cold. Recent evidence found high-fat diet (HFD) feeding reduced AgRP neuron responsiveness to gastric hormones and standard chow diet presentation, and we hypothesized that their response to cold might also be blunted. We find that although 12-week HFD-fed mice exhibit intact thermogenic responses to cold and defend a normal core body temperature, they fail to increase energy intake (12.43±0.48 for 22°C vs. 13.49±1.54 kcal for 14°C; p=ns) and consequently experience weight loss not observed in chow-fed controls (body weight change: 0.16±0.15g for chow vs. -0.49±0.23g for HFD; p=0.05). This effect is present even after a shorter, 2-week exposure to HFD-feeding, implying a role for diet separate from obesity in the phenotype. To investigate whether HFD-feeding disrupts thermal regulation of AgRP neuron activity, using *Agrp*-Cre/GFP marker mice, we find acute cold exposure rapidly induces Fos (a marker of neuronal activation) in chow-fed mice, but this response is lacking in HFD-fed mice. This effect correlates with a failure to increase hypothalamic *Agrp* mRNA even after five days of mild cold exposure (22°C vs. 14°C; 0.19±0.07 vs. 0.24±0.09; p=ns). Further testing will determine how the food intake response to cold has become uncoupled from other thermoregulatory responses following HFD. Therapeutic strategies that block compensatory hyperphagia in this setting may be an effective way to achieve and maintain weight loss.

Title: A single dose of the probiotic Enterococcus faecium selectively activates c-Fos along the gut-brain axis

Authors: *E. E. BAUER, A. SHOEMAN, A. FRESE, V. TAPPA, J. LABRADOR, G. RUMMEL, A. NIGG, K. HALFHILL, T. J. BUHR, M. LYTE, P. J. CLARK;
Iowa State Univ., Ames, IA

Abstract: Probiotics can exert a wide range of effects on the host, including altering brain function and behavior, via modulation of the microbiome-gut brain axis. The mechanisms of actions by which probiotics influence the gut-brain axis are still incompletely understood. As such, we chose to examine the effects of probiotics on the brain and gut shortly after administration. Indeed, certain probiotics can broadly, yet selectively, elevate neural activity in a within minutes of introduction via the vagus nerve. The present study aimed to examine the possible short-term effects of acute exposure of the probiotic *Enterococcus faecium* on neural activity in both the brain and gut. Adult male CF-1 mice were divided into three groups (n=18): Probiotic Gavage (10^9 CFUs *Enterococcus faecium* in PBS/ mouse), Vehicle Gavage (PBS/ mouse), and Control (handling only) group. To evaluate the acute temporal effects of a single dose of probiotic, these three groups were sampled at 3, 5, and 7 hours (n=6) proximate to the gavage time point. c-Fos immunohistochemistry on gut and brain sections was used as a marker of neural activity and c-Fos/tyrosine hydroxylase co-labeling revealed dopaminergic or noradrenergic activity. Preliminary results suggest that that a single dose *E. faecium* had very little effect on c-Fos most regions of interest in the brain or gut. However, in the gut, cecal crypt c-Fos was elevated at 3 and 5 hours after probiotic administration. In the brain, c-Fos/tyrosine hydroxylase co-labeling was elevated in the locus coeruleus 7 hours after probiotic administration. These preliminary data suggest that a single oral gavage of *E. faecium* selectively alters c-Fos along structures of the gut-brain axis. Results of this study may collectively provide insight for future mechanistic work regarding the elucidation of the pathways by which probiotics can influence brain function and behavior via the microbiome-gut brain axis.

Title: Fats and Sugars Recruit Distinct Gut-Brain Circuits To Control Food Intake And Reward

Authors: M. MCDOUGLE, A. DE ARAUJO, M. VERGARA, M. YANG, G. DE LARTIGUE;
Pharmacodynamics, Univ. of Florida, Gainesville, FL

Abstract: The high-fat high-sugar food environment has been implicated as a driver of the obesity epidemic. Nodose ganglia (NG) neurons transmit post-ingestive signals, including fat and sugar intake, from the gut to the brain. Previous data revealed distinct vagal circuits are required for post-ingestive fat and sugar reinforcement, but whether these signals converge onto overlapping reward circuits is unclear. **Methods**: To address this, we used FosTRAP mice to genetically label whole-brain neuronal responses to discreet time-restricted stimuli. Using genetic-encoded reporter (tdTom) expression and cFos immunolabeling we compared neural responses to intragastric stimuli at two separate timepoints in the same animal. **Results**: Repeated intragastric infusion of the same macronutrient resulted in high colocalization between tdTom and cFos labeling (>70%) in neurons of a previously identified gut-reward circuit (NTS, PBN, SNc, dorsal striatum). Equicaloric infusion of fat or sugar at two separate timepoints significantly reduced colocalization of tdTom and cFos labeling (<30%), suggesting that fat and sugar recruit parallel but largely distinct reward circuits. Viral-mediated caspase ablation of sugar-sensing NG neurons abolished activation of the reward circuitry for sugar, but not fat; confirming this is a vagally-mediated mechanism. Optogenetic stimulation of fat-sensing NG neurons is sufficient to condition operant behavior. Microdialysis in response to equicaloric intragastric infusions of fat or sugar resulted in similar dopamine efflux in the dorsal striatum. To obtain the same level of dopamine efflux, more calories of an equicaloric fat-sugar combination are required, correlating with compensatory increased intake of fat-sugar solution. **Conclusion**: There are labeled lines for vagally-mediated fat or sugar reward. Reduced reward in response to fat-sugar combinations may explain the inclination to overindulge in high-fat high-sugar foods, and have broad implications for the pathogenesis of obesity.

Title: Exposure to a highly palatable diet changes maternal feeding pattern of hyperglycemic rats

Authors: G. P. OLIVEIRA[1,2], A. G. CRUZ[1,2], G. V. SILVA[1], M. G. MARTINS[1,2], B. C. WOODSIDE[3], ***A. C. I. KISS**[1,2];
[1]UNESP Botucatu, Botucatu, Brazil; [2]Univ. of São Paulo (USP), São Paulo, Brazil; [3]Concordia Univ., Montreal, QC, Canada

Abstract: Maternal metabolic and nutritional balance are key factors for a healthy pregnancy and lactation. Diabetes, a common disorder of maternal metabolism, results in a marked change in energy balance, leading to adaptations that may have long-lasting consequences for both the maternal and fetal organisms. Plus, the metabolic impairment caused by maternal diabetes may be aggravated by inadequate eating habits. However, the effects of their combination have not been fully explored yet. In previous studies, we demonstrated that maternal snack intake aggravates the glucose intolerance of hyperglycemic rats. However, it remains a question whether their pattern of food intake is related to this outcome. Therefore, our aim was to evaluate the effects of maternal mild hyperglycemia associated with snack intake during pregnancy and lactation on maternal feeding pattern. In order to achieve this goal, female Sprague-Dawley rats were mated and assigned on pregnancy day (PD) 0 either to standard chow (n=27) or standard chow plus snacks (n=25) (potato chips and 1,5% sucrose solution) from PD 0 to lactation day 14. Mild hyperglycemia was induced through the administration of streptozotocin (STZ, 35 mg/kg, i.p. diluted on citrate buffer 0.1M pH 4,5) on PD 7. Thus, 4 experimental groups were formed: Control (n=14), Control-snack (n=13), STZ (n=13), and STZ-snack (n=12). An oral glucose tolerance test was performed on PD 15. Dams gave birth naturally and litters were culled to 8 pups (4 males, 4 females). Food intake and body weight were measured daily throughout pregnancy and lactation and dams weight gain was calculated. Data on daily food consumption was used to calculate total caloric intake, as well as the percentage of calories coming from each diet component: chow, potato chips, and sucrose solution. The proportion of calories from specific macronutrients and feed efficiency were also calculated. All experimental procedures were approved by the local ethics committee (Protocol 1134). As expected, snack intake aggravated maternal glucose intolerance of hyperglycemic dams. Snack-fed rats, regardless of metabolic state, presented higher caloric intake and reduced chow intake, which was associated with a significant decrease in the proportion of calories coming from carbohydrates and protein, and an increase in the proportion of calories from fat intake. Hyperglycemic dams fed with snacks presented a different feeding pattern, eating more calories from chow than normoglycemic dams. In conclusion, snack intake during pregnancy and lactation changed the feeding pattern of hyperglycemic rats, which might have contributed to the aggravated glucose intolerance in those dams.

Title: Hypothalamic orexigenic neuronal populations in regulation of high fat food intake

Authors: *E. SENOL[1,2], Y. FU[1,2,3];
[1]Physiol., Natl. Univ. of Singapore, Singapore, Singapore; [2]Inst. of Mol. and Cell Biol., Agency for Science, Technol. and Res., Singapore, Singapore; [3]Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore

Abstract: Global epidemic of obesity is mainly resulted from over-consumption of high-caloric food, which is rewarding and reinforcing. High-caloric food is preferentially chosen over regular food, and is also used for generating conditioned place preference (CPP). Although several major hypothalamic orexigenic neurons have been identified, how they differentially participate in behavioural outputs related with consuming high fat food is still unclear. By staining for cfos after letting mice consuming either normal chow or high fat diet (HFD) after overnight fasting, we found that tuberal nucleus somatostatin (^{TN}SST) neurons, but not lateral hypothalamus GABAergic (^{LH}VGAT) neurons or zona incerta GABAergic (^{ZI}VGAT) neurons or ^{ARC}AgRP neurons, showed specific higher cfos-positive population after consuming HFD. Subsequently, to understand the effect of the post-ingestive mechanisms on ^{TN}SST activity, we designed an experiment where different caloric content liquids have been administered to the mice by gavaging and quantification of cfos positive SST neurons in TN region showed no significant difference. This result suggested that the caloric content of the infused liquid did not affect ^{TN}SST activity and the response to HFD mainly through pre-ingestive or consummatory mechanisms, not post-ingestive mechanisms. Further in vivo microendoscopy imaging of ^{TN}SST neurons showed that the majority of them showed preferential response to HFD without consuming it. The preferential response of ^{TN}SST neurons did not dictate preferential choice of HFD in hungry mice, because chemogenetically inhibiting ^{TN}SST or ^{LH}VGAT or ^{ARC}AgRP neurons all resulted in less consumption of HFD in hungry mice, and activating either of these four neuronal populations in sated mice all led to preferential consumption of HFD. Interestingly, only inhibiting ^{TN}SST neurons, but not other two neuronal populations, abolished CPP resulted by HFD, suggesting an unique role of ^{TN}SST neurons in associative learning related with HFD food. Therefore, we revealed an unique HFD-specific response of ^{TN}SST neurons, and suggest that choosing HFD is not dictated by a specific hypothalamic orexigenic neuronal population, but reinforcing effect of HFD specifically requires ^{TN}SST neurons.

Title: Effect of metformin on spontaneous activity in rats with metabolic syndrome

Authors: *A. VAZQUEZ-ALVAREZ, G. FERNANDEZ-SAAVEDRA, C. REYES-VAZQUEZ, D. BARRERA-OVIEDO;
Univ. Nacional Autonoma de Mexico, Mexico D.F., Mexico

Abstract: Metabolic syndrome is a condition where there are at least three diseases (insulin resistance, diabetes, hypertension, central obesity, hypercholesterolemia or hypertriglycemia) that increase the risk of cardiovascular disease. Metformin is a biguanide used in the treatment of type 2 diabetes and it also has antineoplasic properties. The objective of this work was to determine spontaneous activity in a model of metabolic syndrome. Adult male Wistar rats that were fed a hypercaloric diet enriched with 15% lard and water with 15% sucrose, were used and streptozotocin (35 mg/kg) was administered intraperitonealy. Control rats ingested a normal diet (Laboratory Chow Purina). Rats with metabolic syndrome had insulin resistance, hyperglycemia, hypercholesterolemia, and hypertriglycemia. Metformin (100 mg / kg) was administered orally to a group of rats with metabolic syndrome. The spontaneous activity was assessed in an AccuScan Open Field Locomotor Activity equipment, for one hour between 10 am and 2 pm. An increase in horizontal activity, number of movements, time in movement, stereotyped activity and displacement was observed in rats with metabolic syndrome relative to control rats and a decrease in activity in rats with metabolic syndrome who were administered metformin ($P < 0.05$). This indicates that metformin helps control hyperactivity associated with metabolic syndrome.

Title: Fatty acid synthase expression in POMC neurons is necessary for glucose homeostasis and insulin release

Authors: L. A. LEON-MERCADO, C. LORD, C. LIU, C. LEE, K. W. WILLIAMS, Z. HE, A. TINAJERO, C. LIMBOY, S. LEE, J. K. ELMQUIST;
Intrnl. medicine, Ctr. for hypothalamic research, UT Southwestern Med. Ctr., Dallas, TX

Abstract: Proopiomelanocortin (POMC) neurons in the arcuate nucleus of the hypothalamus are necessary to coordinate satiety signals, energy expenditure and glucose homeostasis. The alteration of energy sensing mechanisms in POMC neurons can lead to dysregulation of food intake, body weight, and nutrient availability and uptake. Previous evidence suggests that central fatty acid metabolism is involved in the regulation of food intake and glucose homeostasis. Fatty Acid Synthase (FASN) has been proposed as an energy sensor, since central FASN inhibition causes loss of bodyweight, acute anorexia, increased energy expenditure and alterations in glucose homeostasis. However, the specific hypothalamic neuronal populations underlying the metabolic effects of FASN inhibition are not fully defined. We hypothesized that FASN acts in POMC neurons to sense nutrient availability and adjust food intake and glucose homeostasis in response to metabolic challenges. For this purpose, we took advantage of our constitutive

and adult tamoxifen induced POMC-Cre mouse models to delete FASN from this neuronal population. We found that FASN deletion in POMC neurons reduced fat depots and impaired food intake. Furthermore, these animals had impaired glucose tolerance and altered carbohydrate metabolism that was accompanied by deficiencies in glucose-induced insulin release, further changing fat metabolism and leptin release. Together, our data indicates that FASN expression in POMC neurons serves as a nutrient sensing mechanism to precisely control glucose homeostasis through the autonomic nervous system and contributes to the understanding of the link between lipid metabolism in POMC neurons and glucose-induced insulin release

Title: Cholinergic neurotransmission controls biosynthesis of small-intestinal endocannabinoids in obesity

Authors: *C. WOOD, N. V. DIPATRIZIO;
Div. of Biomed. Sci., Univ. of California, Riverside, Riverside, CA

Abstract: Rationale: The endocannabinoid (eCB) system is an endogenous lipid signaling system that controls food intake and energy balance. In diet-induced obesity (DIO), the eCB system becomes dysregulated in the brain and peripheral organs and contributes to overeating. For example, we reported that the eCB 2-arachidonoyl-*sn*-glycerol (2-AG) is elevated in the small-intestinal epithelium of mice fed a high-fat/high-sucrose western-style diet (WD) when compared to control mice fed a standard rodent diet (SD). Overactive 2-AG signaling drives hyperphagia in DIO animals by activating local cannabinoid receptor subtype-1 (CB_1R). Moreover, efferent vagal cholinergic neurotransmission controls 2-AG production in the small intestine in rats, which drives overeating after a fast. We now tested the hypothesis that cholinergic signaling at muscarinic acetylcholine receptors (mAChRs) leads to increased biosynthesis of 2-AG in the small-intestinal epithelium, which may drive hyperphagia in DIO. **Methods:** Male 8-week-old C57BL/6 mice were maintained on WD for 60 days. Littermates maintained on SD served as controls. Animals received IP injections of DAU5884 (a selective m_3 mAChR antagonist), pirenzepine (a selective m_1 mAChR antagonist), or vehicle 30 minutes prior to harvest. Levels of 2-AG in the small intestinal epithelium were quantitated by ultra-performance liquid-chromatography/tandem mass spectrometry (UPLC-MS/MS). The activity of biosynthetic and degradative enzymes for 2-AG, diacylglycerol lipase (DGL) and monoacylglycerol lipase (MGL), respectively, were analyzed via UPLC-MS/MS-based assays of enzyme activity. **Results:** WD-fed mice exhibited elevated levels of 2-AG and

DGL activity in the small-intestinal epithelium, which was blocked in mice pre-treated with DAU 5884 or pirenzepine. There were no significant differences in activity of MGL between groups. **Conclusions:** These results suggest that in DIO, excessive cholinergic activity at m_3 and m_1 mAChRs in the intestinal epithelium drives increases in biosynthesis of 2-AG. Activation of these G_q-coupled mAChRs initiates the PLC-dependent generation of 1-stearoyl-2-arachidonoyl-*sn*-glycerol (SAG), which is subsequently converted to 2-AG by DGL. The functional consequences of this heightened signaling on feeding behavior in DIO and roles for the efferent vagus nerve in these processes are currently under investigation.

Title: Effects of herpes simplex virus I inoculation on feeding behavior in C57BL/6 mice

Authors: *J. E. HASSELL, Jr[1], C. S. NIEMEYER[1], L. MERLE[2], A. N. BUBAK[1], D. RESTREPO[2], M. A. NAGEL[1];

Abstract: Herpes simplex virus type 1 (HSV-1) is the most common cause of viral encephalitis that presents with seizures, alterations in consciousness, and focal neurological deficits; brain imaging shows inflammation of the temporal lobe(s) and viral DNA is present in cerebrospinal fluid. Prolonged sequelae include cognitive deficits, as well as changes in mood, sleep, and energy levels that do not localize to the temporal lobe. Murine studies of HSV-1 infection show that multiple brain regions beyond the temporal lobe are infected; however, these studies did not characterize nuanced behavioral changes associated with these other infected brain regions. Our preliminary studies show that intranasal HSV-1 infection of mice leads to a striking localization of HSV-1 antigen in the bilateral dorsomedial hypothalamus and lateral hypothalamus, associated with microglial activation. Because these regions are associated with feeding behaviors, we hypothesized that these infected mice would have altered motivation to feed and decreased food intake. Furthermore, because neuroinflammation can contribute to alterations in these behaviors and persistent CNS inflammation has been observed up to 60 days after HSV-1 infection, we expect to see long-term feeding behavior deficits well after productive HSV-1 infection has resolved. To test this hypothesis, we mock- or HSV-1-infected mice intranasally. We examined food intake using feeding experimental device 3 (FED3) automated feeders continuously prior to infection, during acute infection, and 30-60 days after infection when HSV-1 has established latency. Specifically, we assessed meal size, meal intervals, and circadian patterns of eating. Additionally, we examined HSV-1 induced sickness behavior as demonstrated with conditioned flavor taste preference changes. Overall, the results of the current study would corroborate alterations in feeding behavior with the neuroanatomical sites of HSV-1 infection and inflammation, broadening the spectrum of postviral sequelae.

Title: Control of feeding behavior by delivery of modified retroAAV to the gastrointestinal tract to specifically target vagus nerve afferents.

Authors: *R. MARONGIU[1], J. WANG[1], S. UNDA[1], J. BARBERA[1], L. VELAZQUEZ[1], N. DE SILVA[1], W. TOWER[1], R. LI[2], M. JIMENEZ-GONZALES[2], S. STANLEY[2,3], M. G. KAPLITT[1]; [1]Neurolog. Surgery, Weill Cornell Med., New York, NY; [2]Diabetes, Obesity and Metabolism Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY, New York, NY; [3]Nash Family Dept. of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Appetite is tightly regulated in order to ensure appropriate levels of nutrients in the body. The gut mediates short-term feedbacks to satiety circuits in the central nervous system (CNS), including the nucleus of solitary tract (NTS) and the hypothalamus, through the gastrointestinal branches of the vagus nerve to regulate food intake. However, preclinical and clinical reports employing external vagal nerve and gastric electric stimulation to modulate vagal neuron control of appetite generated inconsistent results and the pathways regulating these feedbacks are not fully understood.To address some of the limitations in these studies, we used our expertise in AAV-mediated gene delivery to access the CNS through the vagus nerve and assess if chemogenetic activation of vagal neurons is sufficient to regulate food intake and neuronal activity in CNS satiety nuclei in wild type (wt) mice. We injected retrograde AAV vectors (AAVrg) carrying the chemogenetic hM3Dq transgene (for neuronal activation), or mCherry as a control, under the chicken beta-actin promoter into the corpus of the stomach ($2x10^{12}$ vg/ml). Interestingly, our AAVrg exclusively transduces vagal sensory afferent neurons, which have their cell bodies in the nodose ganglion (NG) and project one axonal branch to the visceral organs and the other one to the NTS in the brainstem. Activation of afferent vagal neurons by hM3Dq following acute CNO injection (1 mg/Kg, i.p.) significantly reduces feeding behavior in normally fed or overnight fasted wt mice compared to control mice injected with mCherry or AAVrg.hM3Dq mice treated with saline. Additionally, chronic chemogenetic activation of transduced vagal sensory neurons reduces body weight gain in wt mice fed with high fat diet, indicating that regulation of satiety pathways can significantly be achieved by our AAVrg approach.Next, we tested if chemogenetic activation following single CNO injection of vagal sensory neurons regulates the neuronal activity in the NTS and indirectly in specific hypothalamic nuclei. We found that acute activation of vagal afferent neurons significantly increases c-Fos expression in the NTS, in the dorsal-medial and ventral-lateral nuclei of the ventral-medial hypothalamus (VMH) and the arcuate segments (ARC) of the hypothalamus compared to control mice.In conclusion, our AAV-mediated specific activation of vagal afferent neurons in the stomach is sufficient to significantly reduce

food intake and weight gain and to activate the NG, NTS, VMH and ARC nuclei in wt mice. Our study also suggests that the macro-circuit gut-NTS-VMH is linked to the VMH-ARC microcircuit.

Abstract: Motivational symptoms such as fatigue, anergia, and amotivation are seen in many disorders including depression, multiple sclerosis, Parkinson's disease, schizophrenia, and chronic fatigue syndrome. Animal studies of effort-based choice behavior have been used to provide models for effort-related aspects of motivation in humans. One way of assessing effort-based choice is using progressive ratio (PROG) tasks, which are useful in exploring activational aspects of motivation and exertion of effort. Previous studies showed that a low effort bias can be induced in rodents by injecting the vesicular monoamine transport (VMAT-2) inhibitor tetrabenazine (TBZ), which can be reversed by drugs that are known as dopamine transport (DAT) inhibitors, including methylphenidate, lisdexamfetamine, GBR-12909, and PRX-14040. Although methylphenidate has been shown to reverse the effort-related effects of TBZ in several fixed-ratio (FR) schedules, its influence on both male and female rats performing on other schedules remains unknown. Rats were assessed using a modified PROG which was developed to study the effects of altering ratio requirements of PROG tasks. The modified PROG schedule had a gradually increasing the ratio increment (e.g., FR1, FR5, FR9, etc.) as a way of increasing the work requirement. In the present study, the ability of methylphenidate to reverse the effort-related motivational effects of TBZ was assessed using the modified PROG. TBZ (1.0 mg/kg) decreased lever pressing in both males and females. Methylphenidate was co-administered at doses ranging from 1.0-4.0 mg/kg, and it successfully reversed the effects of TBZ at the highest dose for males but at the lowest dose for females, which suggests a sex difference in the dose/response function for methylphenidate. When methylphenidate was administered alone at doses ranging from 0.5-4.0 mg/kg, strong sex differences were observed. There was a substantial increase in lever pressing in males at the highest doses, however, variable effects were found

in females. Future studies are focused on obtaining electrophysiological markers of the exertion of effort during instrumental tasks, and the effects of drugs on these biomarkers.

Title: Mild maternal separation in mice of both sexes affects the dopaminergic system and has an impact in adulthood on vigor to approach or to escape motivational stimuli

Authors: *C. CARRATALÁ-ROS[1], P. MATAS-NAVARRO[1], A. MARTÍNEZ-VERDÚ[1], E. ARIAS-SANDOVAL[1], R. OLIVARES-GARCÍA[1], J. D. SALAMONE[2], M. CORREA[1];
[1]Area de Psicobiologia, Univ. Jaume I, Castellon DE LA Plana/Castello DE LA Pla, Spain; [2]Dept Psychological Sci., Univ. of Connecticut, Storrs Mansfield, CT

Abstract: Early-life stress affects brain development and induces long-lasting effects that can lead to psychiatric disorders such as depression. Little is known about the effect of early-life stress on motivational processes such as effort-based decision-making, which often is impaired in people with depression. Mesolimbic dopamine (DA) regulates behavioral activation and effort in motivated behaviors. Stress can produce opposite effects on DA release depending on its intensity and duration. Maternal Separation (MS) is as an early-life stressor that can alter brain function permanently. Using CD1 male and female mice, we evaluate the impact of early and mild MS (PND3 to 5, 90 min each day), on selection of effortful responses in adulthood under positive or aversive experimental conditions. In a three-choice-T-maze, the preference of mice for active reinforcers such as a running wheel (RW) versus sedentary ones was evaluated, and in a forced swim task (FST), time dedicated to vigorously escape or passively floating was measured. In addition, we studied if MS interacts with DA depletion in adulthood, administering tetrabenazine (TBZ), a VMAT-2 inhibitor that induces fatigue and anergia in rodents and humans. We also assessed the impact of MS on DA-related markers such as the cerebral dopamine neurotrophic factor (CDNF) on nucleus accumbens core (Nac), shell (NacSh) and anterior cingulate (Cg). Both males and females spend more time in the RW and less time eating or sniffing a neutral odor in the T-maze, independently of separation. However, separated mice of both sexes spent more time in the RW, and climbing in the FST compared to non-separated mice. Only among males, TBZ reduced time in RW, increased time eating, reduced climbing and increased immobility. Females were not affected by DA depletion. MS produced an increased in a CDNF marker in female separated mice both in Nac and

NacSh, suggesting that this neurotrophic factor may protect functions regulated by mesolimbic DA. We did not observe any effect of MS on CDNF in male mice. These results highlight the importance of early-life experiences, specifically MS, on establishing patterns of behavioral activation in different contexts, and the role of the DA system. Further studies should explore different times and durations of MS in order to better characterize this phenomenon and also to improve its translational potential.

Title: Behavioral and EEG effects of dopaminergic drugs that alter effort-related aspects of motivation: Implications for avolition and anergia

Authors: *J. D. SALAMONE[1], *R. A. ROTOLO[1], A. ECEVITOGLU[1], N. REN[1], R. E. PRESBY[1], C. CARRATALA-ROS[2,1], N. M. MEKA[1], S. M. SRINATH[1], E. ARIAS-SANDOVAL[2], A. YU[1], D. CANFIELD[1], M. CORREA[2], I. H. STEVENSON[1], J. J. CHROBAK[1];
[1]Psychological Sci., Univ. of Connecticut, Storrs Mansfield, CT; [2]Psychobiology, Univ. of Jaume I, Castello, Spain

Abstract: People with neuropsychiatric disorders such as depression, schizophrenia, and Parkinson's disease suffer from fatigue, anergia, apathy, and other motivational dysfunctions, which can be treatment resistant. To assess these motivational dysfunctions in animal models, tasks have been developed to measure effort-related choice, offering the option of high effort actions leading to more valued reinforcers vs. low effort/low reward activities. Such tasks are useful for preclinical studies related to drug development. A low effort bias can be induced in male and female rats by injection of the vesicular monoamine transport (VMAT-2) inhibitor tetrabenazine (TBZ), which induces depressive symptoms in people. By virtue of blocking vesicular storage, TBZ depletes DA and suppresses high-effort instrumental behaviors across multiple tasks. Suppression of lever pressing is also induced by injections of pro-inflammatory cytokines, which provide an inflammatory challenge. These deficits can be reversed by drugs that are dopamine transport (DAT) inhibitors. Because many drugs that block DAT act as major stimulants and produce undesirable side effects, there is a need to develop and characterize novel atypical DAT inhibitors with unique neurochemical profiles. Recent studies have shown that novel atypical DAT inhibitors, including modafinil analogs, also can restore motivational function, and increase selection of high-effort activity. Drugs that selectively stimulate serotonin and norepinephrine transmission are not effective in this regard. Other strategies being investigated involve the development of potential physiological biomarkers of the effects of drugs or other conditions that alter effort-related functions. Recent studies in our laboratory have focused on the electroencephalographic (EEG) and local field

potential (LFP) effects of TBZ and other drugs that affect DA transmission. In rats, there is a predominant peak in the alpha/theta frequency range (6-9 Hz) in medial prefrontal cortex that is suppressed by TBZ in male rats, but less so in females. It is possible that this research will identify new avenues for drug treatment of effort-related motivational symptoms in humans, including apathy, avolition, anergia, and COVID-related fatigue.

Title: The antidepressant bupropion enhances behavioral activation in a mouse model of effort-based decision-making: assessment of individual differences between choice and non-choice operant tasks and its relation with the cdnf-related marker

Authors: *E. ARIAS-SANDOVAL[1], G. D'ALOISIO[1], C. CARRATALÁ-ROS[1], A. MARTINEZ-VERDU[1], P. MATAS-NAVARRO[1], R. OLIVARES-GARCÍA[1], J. D. SALAMONE[2], M. CORREA[1]; [1]Univ. Jaume I, Castellon de la Plana, Spain; [2]Dept Psychological Sci., Univ. of Connecticut, Storrs Mansfield, CT

Abstract: Vigor, persistence, and work output are fundamental features of normal motivation. Nucleus Accumbens (Nacb) dopamine (DA) regulates behavioral activation and effort-related decision-making in motivated behavior. Impairments in DA transmission lead to symptoms such as fatigue, anergia and apathy. These motivational symptoms are seen in pathologies such as depression and are highly resistant to treatment. In the present study, we administered Bupropion (BUP; 0, 5.0, 10.0 and 15.0 mg/kg, IP) a DA uptake blocker used as an antidepressant, to enhance DA function in CD1 male adult mice. To evaluate the effect of BUP not only on effortful behaviors, but specifically on effort-based decision making, mice were split into two groups: the first group was trained in an operant chamber under a high effort progressive ratio schedule that, during 5 seconds, made available a bottle with a 10% sucrose solution (no-choice condition). The second group of animals was also trained in the same progressive ratio schedule for 10% sucrose, but additionally they concurrently had in the operant box a bottle with a 3% sucrose solution (choice condition). The presence of the free 3% sucrose solution led to a much lower baseline lever pressing in the choice condition, and mice consumed the same volume of both solutions (a total volume of fluid similar to the non-choice group). In a previous free-drinking choice test with no operant work required, all mice strongly preferred and consumed significantly more of the 10% sucrose vs the 3% sucrose solution. We further assessed individual differences in behavior (high and low responders) and on DA-related markers such as the cerebral dopamine neurotrophic factor (CDNF) on several brain areas. The dose of 10.0 mg/kg BUP significantly increased lever pressing for the high and low responders in the no-choice group, while for the choice group the effect of BUP depended on baseline

performance; high responders increased at 15.0 mg/kg, and low responders at 5.0 mg/kg. CDNF immunoreativity differences were found between high and low responders of both operant conditions in accumbens core and shell, and medial and lateral dorsal striatum, but not in anterior cingulate. These results indicate that individual differences in willingness to work are related to DA-related neurotrophic factors in ventral and dorsal striatum, and also that drugs acting on DA transmission may be effective for improving depressive symptoms related to amotivation and anergia

Title: Evaluating Common Behavioral Factors Underlying Chronic Pain and Depression that Contribute to Opioid Abuse

Authors: *C. O'BRIEN, U. MOHAMMED, R. VEMIREDDY, C. PIZZANO, J. MEJAES, D. BARKER;
Rutgers The State Univ. of New Jersey, Piscataway, NJ

Abstract: Chronic pain and depression are highly comorbid conditions with overlapping symptomologies. To determine which behavioral features best predict this overlap in mice, we modeled chronic pain using a spared nerve injury (SNI) model and depression using a learned helplessness paradigm. Mice in both groups were then subjected to the same battery of behavioral tests that measure depression-like behaviors, anxiety-like behaviors, mechanical pain responses, and thermal pain responses. Our results show that SNI and learned helplessness mice both exhibit anhedonic responses in the two-bottle choice, as compared to controls, but performed similarly in the elevated plus maze and open field tasks. Similarly, we found mechanical hypersensitivity in both SNI and learned helplessness mice, as compared to controls. However, thermal sensitivity was only observed in SNI mice. Next, to determine the common features of pain and depression that contribute to opioid abuse, we used a principal component analysis to determine which specific behavioral features best predicted the susceptibility to oral fentanyl consumption. Surprisingly, the principal component analysis revealed that a combination of heightened anxiety-like responses and hypersensitivity to pain best predicted increased opioid intake, whereas levels of anhedonia and behavioral despair carried less weight. These data show individual markers that may be key indicators of opioid abuse susceptibility. The combination of these behavioral features across painful and depressive-like states could help predict fentanyl consumption by highlighting individual phenotypic differences.

Br., IRP, NIDA, NIH, Baltimore, MD

Abstract: The Ventral tegmental area (VTA) has been proposed to play a role in pain, but the brain structures modulating VTA activity in response to nociceptive stimuli remain unclear. One unexamined route by which nociceptive information might reach and influence the VTA is through the lateral preoptic area (LPO). The LPO provides strong projections to VTA and receives direct inputs from the dorsal horn of the spinal cord. In the present study, we used anatomical, behavioral, and electrophysiological approaches to examine a possible role of projections from the LPO to the VTA in relaying nociceptive information to the VTA. By anatomical approaches, we that around 40% of LPO neurons innervating the VTA expressed the vesicular glutamate transporter 2 (VGluT2) and around 60% expressed the vesicular GABA transporter (VGaT). By fiber photometry calcium imaging, we characterized the responses of VTA-projecting LPO-VGluT2 and LPO-VGaT neurons in response to the optogenetic stimulation of peripheral nociceptors. We found that LPO-VGluT2 neurons synapsing on VTA neurons responded to nociceptive stimulation and conditioned stimuli predicting nociceptive stimulation. By independent optogenetic stimulation of VTA inputs from LPO-VGluT2 or LPO-VGaT, we found that VTA activation of inputs from LPO-VGluT2 neurons drove aversion, while VTA activation of inputs from LPO-VGaT neurons drove reward. By ex vivo electrophysiology, we observed that LPO inputs evoked EPSCs and IPSCs in VTA-dopamine, VTA-VGluT2 and VTA-VGaT neurons, with the strongest responses from both LPO-VGluT2 and LPO-VGaT neurons on VTA VGaT neurons. By ultrastructural analysis, we found that within the medial and lateral VTA, LPO-VGluT2 and LPO-VGaT neurons differentially established synapses on the cell bodies or dendrites of VTA-dopamine, VTA-VGluT2 or VTA-VGaT neurons. In summary, we found that (a) there is a complex circuitry between LPO glutamatergic and GABAergic neurons and the different subclasses of VTA neurons, and (b) the LPO-glutamatergic neurons synapsing on VTA neurons responded to nociceptive stimulation and conditioned stimuli predicting this

stimulation. We concluded that the pathway from LPO to VTA represents an important, yet previously undefined, interface between peripheral nociceptive information and the limbic system.

Title: The effect of the synaptojanin1 gene mutation on motivational behavior & cocaine seeking in mice

Authors: *J. I. MEJAES[1], J. SAENZ[2], S. V. ROZARIO[1], C. PIZZANO[1], C. O'BRIEN[1], S. BRYANT[1], P.-Y. PAN[2], D. J. BARKER[1];
[1]Psychology, Rutgers, The State Univ. of New Jersey, Piscataway, NJ; [2]Neurosci. and Cell Biol., Rutgers Univ. Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: The synaptojanin1 *(SYNJ1)* gene plays important roles in several dopamine-related disorders, such as bipolar disorder, schizophrenia, and parkinsonism. Recent evidence has demonstrated that Synj1 deficient mice (*Synj1+/-*), unlike their littermate controls (*Synj1+/+*), have reduced levels of striatal dopamine (DA), dystrophic changes in DAergic axons, and impairments in DAergic synaptic recycling. Despite these clear links to midbrain DA systems, the effect of *Synj1* mutations on motivation and rewarding behaviors has not been examined. Our objective was therefore to assess the role of the *Synj1* gene in a variety of behavioral tasks associated with mood, motivation, learning and reward. We subjected *Synj1+/-* male and female mice (n= 18) and their littermate controls (n=17), to a battery of behavioral tests used to assess specific features of these behaviors. Our results indicate that *Synj1+/-* mice exhibited normal anxiety like behaviors in the Elevated Plus Maze and Open Field Test. Additionally, *Synj1+/-* mice also displayed normal hedonic responses and reward seeking behaviors to sucrose in the Sucrose Preference Test, Operant Conditioning Paradigm and Progressive Ratio-Schedule Task. However, during the cocaine Conditioned Place Preference Paradigm (CPP), the *Synj1+/-* male mice did not develop the typical behaviors associated with cocaine-seeking. Moreover, unlike their littermate controls, *Synj1+/-* male mice did not exhibit a cocaine-induced increase in dopamine transporter (DAT) levels in the striatum and midbrain. Overall, these results suggest that the *SYNJ1* gene may affect specific types of reward processing via altering DAT-regulated DA signaling.

Title: L-type calcium channels mediate mood-related behavioral phenotypes in rats exposed to chronic unpredictable stress.

Authors: *N. KEBEDE[1], E. J. NUNES[1], N. A. ADDY[1], A. M. RAJADHYAKSHA[2];
[1]Dept. of Mol. Psychiatry, Yale Univ., New Haven, CT; [2]Dept. of Pediatrics, Joan and Sanford I Weill Med. Col. of Cornell Univ., New York, NY

Abstract: Exposure to chronic daily stressors can induce symptoms of depression and anxiety in susceptible individuals. In preclinical rodent models, chronic unpredictable stress (CUS) has been demonstrated to promote depression and anxiety-like behavioral phenotypes. The ventral tegmental area (VTA) to nucleus accumbens (NAc) dopaminergic pathway has been implicated in the neurobiological response to stress. Prior work has demonstrated a role of VTA L-type calcium channels (LTCCs) in regulating depression and anxiety-like behavior in rodents. Furthermore, VTA LTCCs have been shown to regulate dopamine (DA) signaling in the NAc. However, it is unknown whether LTCCs regulate behavioral responses to CUS exposure. Therefore, we tested the hypothesis that LTCC blockade would attenuate CUS induced pro-depressive and anxiogenic behavioral responses in female and male rats. Following 21 days of CUS exposure, female and male rats were tested on the sucrose preference test (SPT), elevated plus maze (EPM), and the forced swim test (FST). CUS exposure produced pro-depressive and anxiogenic-like behavior as demonstrated by decreased sucrose preference in the SPT, decreased time spent in the open arm on the EPM, and increased immobility time in the FST. Systemic administration of the LTCC blocker, isradipine, (0, 0.4, 1.2mg/kg, intraperitoneally (I.P.), 15 min prior) attenuated CUS induced pro-depressive and anxiogenic behavioral responses on the SPT, EPM and FST in both female and male rats. In contrast, in female and male control rats that had no CUS exposure, isradipine did not alter behavioral responses on the SPT or EPM, suggesting an interaction between CUS exposure and the ability of LTCCs to regulate pro-depressive and anxiogenic behavioral responses. In the FST, however, isradipine decreased immobility time in both CUS and control rats, suggesting that the FST may be a sufficient acute stressor to unmask LTCCs' ability to mediate responses to both acute and chronic stress. In ongoing experiments, we are investigating the effect of LTCC blockade via systemic isradipine (0, 1.2mg/kg, I.P.) on NAc DA release using fast-scan cyclic voltammetry (FSCV) in CUS and non-CUS exposed female and male rats.

Title: Balance of GABA and glutamate co-release in the lateral habenula mediates reward sensitivity

Authors: *N. RODRIGUEZ SOSA, S. SHABEL;
Univ. of Texas, Southwestern Med. Ctr., DALLAS, TX

Abstract: More than 300 million people in the world suffer from Major Depressive Disorder (MDD). For better treatment, we need an understanding of the circuits and mechanisms that underlie the disorder. Many brain regions contribute to the pathology of depression, but the lateral habenula (LHb) stands out because, in contrast to other regions, its activity increases during negative affective states. Additionally, hyper-activation of the LHb has been implicated in depression in humans. Significant input to this region comes from the internal globus pallidus (GPi), which is thought to drive LHb activity during negative feedback (aversive stimuli) and reduce its activity during positive feedback (reward). Interestingly, although GPi-LHb projections are predominantly excitatory, they co-release GABA with glutamate. GABA co-release from GPi is inhibitory and one of the few known sources of GABA in the LHb. In a rat model of depression, the ratio of GABA-to-glutamate in GPi-LHb is reduced. In contrast, antidepressant treatment increased the ratio in mice. I hypothesized that the ratio of GABA-to-glutamate released from the GPi regulates neuronal activity in the LHb, and the inability to increase the ratio during excessive excitatory input results in LHb hyperactivity and increases in depressive symptoms. To test this hypothesis, I determined if reduced GABA co-release from GPi-LHb projections increases depression-related behavior. Preliminary results suggest that reducing GABA co-release by knocking down the vesicular GABA transporter (VGAT) causes anhedonia in mice but has no effect on other depression-related behaviors. To test for a more specific role of GABA co-release in regulating behavioral sensitivity to positive and negative feedback, I tested the same mice in a risky decision-making task. VGAT knockdown mice were risk averse, consistent with altered sensitivity to positive and/or negative feedback. In combination with future experiments**,** I expect to identify the GPi-LHb circuit as a strong candidate for the development of new therapeutics for anhedonia and advance our knowledge of activity regulation in the reward system.

Title: Validation of brain-wide PHP.eB infectivity across outbred hybrid transgenic mouse lines for the study of appetitive aggression and complex social behaviors

Authors: *J. NAVARRETE[1], E. SZELENYI[1], A. ABANTO[2], V. TSAI[1], N. GOODWIN[1], S. A. GOLDEN[1];
[1]Biol. Structure, Univ. of Washington, Seattle, WA; [2]Biol., Grossmont Community Col., San Diego, CA

Abstract: Background
Neuropsychiatric disorders, such as depression and post-traumatic stress disorder, are commonly associated with maladaptive or inappropriate aggression that is demarcated as either reactive (defensive) or appetitive (rewarding). We have developed several behavioral procedures to examine appetitive aggression in outbred mice, which limits the use of common genetic tools that require inbred transgenic strains. To overcome this caveat, we recently established Cre x CD-1 F1 generation hybrids as a model system for studying complex social behaviors that allow genetic access to select cell types and circuits. Here, we assess and validate the use of systemic PHP.eB viral infections - initially optimized with inbred mice - using a new genetic tool and automated cell segmentation in outbred hybrid lines.

Methods
We created an optimized nuclear localization (oNLS) tag that shows enhanced nuclear restriction for brain-wide cellular segmentation. We packaged oNLS-PHP.eB and validated the brain-wide infectivity across outbred hybrid lines. Quantification of infectivity 3 weeks post-retroorbital infection was assessed on coronal brain sections ranging from 2.00 to -4.00 AP. Brain registration, anatomical annotation, and cell segmentation were performed using SMART (semi-manual alignment to reference templates) and QuPath, respectively.

Results
Preliminary results suggest subtle, but significant, differences in PHP.eB infectivity across hybrid lines.

Conclusion
Based on our preliminary results, careful assessment of PHP.eB infectivity across outbred and hybrid transgenic lines are required prior to use.

Title: Contribution of the amygdalo-cingulate pathway in depression, pain and their comorbidity

Authors: *L. J. BECKER, C. FILLINGER, R. WAEGAERT, P. HENER, B. AYAZGÖK, S. H. JOURNÉE, M. BARROT, P. VEINANTE, S. HUGEL, P.-E. LUTZ, I. YALCIN;
Ctr. Natl. De La Recherche Scientifique, Strasbourg, France

Abstract: Major Depressive Disorder (MDD) is a chronic and debilitating disease with poor treatment outcomes. It is often comorbid with chronic pain, resulting in an increased disability and poorer prognosis than either condition alone. Evidence from animal models and human studies suggest a crucial role of the anterior cingulate cortex (ACC) and the anterior part of the basolateral amygdaloid nucleus (BLA) in the development of MDD and in its comorbidity with chronic pain. Our team showed that lesion or inhibition of the ACC in mice alleviates anxiodepressive-like symptoms in chronic pain-induced depression model and that its repeated activation triggers these behaviors in naive mice. We highlighted a strong reciprocal connection between the ACC and the BLA, making this pathway a good candidate to begin the dissection of the ACC connectome in mood disorders and their comorbidity with chronic pain. First, we tested if the inhibition of the BLA-ACC connection could alleviate the anxiodepressive-like behaviors in our model of peripheral neuropathy. To inhibit the BLA-ACC connection, we injected an AAV5 coding for the archaerhodopsin in the BLA of C57BL6/J neuropathic mice and we delivered green light in the ACC during behavioral testing. While mechanical hypersensitivity and anxiety stayed unchanged, this manipulation improved the depressive-like behaviors induced by chronic pain. Conversely, we activated the BLA-ACC pathway to determine if its hyperactivity was sufficient to trigger depressive-like behaviors in naive mice. We injected an AAV5 coding for the channelrhodopsin in the BLA and delivered repeated blue light pulses in the ACC to activate the pathway. We showed that chronic activation of the BLA-ACC pathway selectively induces depressive-like behaviors. The need for a repetitive activation strongly suggest the involvement of plastic changes within the ACC. To test this, we conducted high-throughput RNA-sequencing in the ACC of the optogenetic-induced depression model. To uncover transcriptomic alterations relevant to the human pathology the results were compared with those obtained in severely depressed patients (Rank-Rank Hypergeometry Overlap method). We constructed gene network for both species (Weighted Gene Co-expression Network Analysis) and calculated their conservation rate. Our data highlight strong similarities in transcriptomic profile between optogenetic-induced depression in mice and MDD patients

Title: Examining the role of specific touch neurons in reward and stress resilience

Authors: *M. SCHAFFLER[1], J. ARNOLD[1], I. ABDUS-SABOOR[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Biol., Columbia Univ., New York, NY

Abstract: Social touch is rewarding, motivating social interactions and relationships, and can act as a stress buffer, regulating physiological and behavioral responses to short-term challenges. However, the skin-to-brain neuronal circuits by which touch is rewarding and promotes stress resilience remain unknown. Discovery of the specific peripheral neurons that play a role in the rewarding and/or anxiolytic nature of touch would be the first step in elucidating such a circuit. Social behaviors like hugging, huddling, and allo -grooming activate a wide variety of peripheral sensory neurons, but only a subset govern the pleasant nature of touch. Here, we focus on Mas-related G-protein coupled receptor B4 (MrgprB4) -positive sensory neurons in mice, as they project exclusively to the hairy skin (areas predominantly involved in social touch behaviors like allo-grooming), activate an affective touch pathway in the central nervous system, and share many functional and anatomical features with theorized affective touch neurons in humans.
We assessed the effects of optogenetic activation and genetic ablation of these MrgprB4+ neurons on stress- and reward-related behaviors in mice. Using transdermal optogenetics in a novel place preference paradigm, we found that activation of MrgprB4+ neurons promotes conditioned place preference, suggesting that activation of these neurons is rewarding. We also found that after 3 days of variable stress, mice with MrgprB4+ neurons ablated spent less time grooming in the sucrose splash test, indicating decreased self-care behavior, and had increased immobile time in the forced swim test, indicating increased helplessness in response to an aversive stimulus, relative to controls. These data suggest that MrgprB4 neurons are required for promoting resilience to stress.
Overall, our results indicate that activation of MrgprB4+ neurons is rewarding, and ablation of the same population increases stress susceptibility. These results further our understanding of the relationship between the peripheral nervous system and reward and stress, and could provide new therapeutic targets for treatment of mood disorders. We are currently testing whether specific activation of these neurons can rescue or prevent a stress-induced phenotype.

Title: Adaptive versus maladaptive forms of regret after chronic social stress

Authors: R. DURAND-DE CUTTOLI[1], F. MARTÍNEZ-RIVERA[1], L. LI[1], A. MINIER-TORIBIO[1], F. CATHOMAS[1], L. HOLT[1], F. YASMIN[1], S. O. ELHASSA[1], J. F. SHAIKH[1], S. AHMED[1], S. J. RUSSO[1], E. J. NESTLER[1,2], ***B. M. SWEIS**[1,2];
[1]Neurosci., [2]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Regret describes the phenomenon in which an individual recognizes that an alternative action could have led to a better outcome. The neurobiology of regret in mood disorders such as depression, and whether or not regret represents an adaptive or maladaptive process, remain poorly understood. By characterizing mice exposed to chronic social defeat stress (CSDS) on a novel neuroeconomic decision-making paradigm termed "Restaurant Row" (RRow), we demonstrate fundamentally distinct forms of regret between stress-resilient (RES) versus stress-susceptible (SUS) phenotypes, and establish a region-specific role for CREB, a key transcription factor implicated in chronic stress action. We subjected C57BL/6J male mice to CSDS and identified SUS and RES mice based on a rapid social interaction screen. We then characterized SUS, RES, and non-stressed control (CON) mice longitudinally on RRow. Mice have a limited time period each day to forage for their sole source of food by navigating a maze with four uniquely flavored and contextualized feeding sites, or "restaurants." Each restaurant has a separate offer zone (OZ) and wait zone (WZ). Upon entry into the OZ, a tone sounds whose pitch indicates how long of a delay mice will have to wait in a cued countdown should they choose to enter the WZ. We found that SUS mice were uniquely sensitive to regret type I: missed opportunities when rejecting high-value offers followed by encountering low-value offers. These scenarios capture risky decisions with poor outcomes to which neither RES nor CON mice were sensitive. Conversely, RES mice were more sensitive to regret type II: placing more weight on change-of-mind quit decisions in the WZ when correcting previous mistakes that followed accepting low-value offers in the OZ. SUS mice lost sensitivity to regret type II. Furthermore, RES mice were more sensitive to valuing past investments in the form of time already waited, or sunk costs, during these change-of-mind decisions. Overexpressing a dominant-negative form of CREB in the medial prefrontal cortex versus nucleus accumbens, a molecular manipulation known to promote SUS or RES respectively, differentially perturbed these distinct forms of regret. These data reveal new insights into how adaptive versus maladaptive stress responses are related to distinct forms of counterfactual thinking. The study provides a novel framework for understanding pathological versus healthy forms of regret that hinge on the framing of mistakes. This work can guide not only the development of new diagnostic tools or interventions for depression but can also steer psychotherapy toward unveiling distinct computations through decision narratives.

Abstract: While the underlying pathophysiology of major depressive disorder (MDD) is poorly understood, convergent evidence from preclinical and clinical research supports the notion that MDD is related to impaired structural and synaptic plasticity in key limbic regions. The extracellular matrix (ECM) of the brain represents a novel domain for study as it not only provides structural support, but also is intimately involved in regulating synaptic plasticity and remodeling. We analyzed transcriptional profiles of ECM-related genes from the nucleus accumbens (NAc) in postmortem brain tissue of humans with MDD as well as in mice exhibiting a depression-like behavioral abnormalities after exposure to chronic variable stress (CVS). We identified *Htra1*, an astrocyte-enriched secreted serine protease, as being significantly down-regulated in the NAc of males and up-regulated in females across both species. We found that selective manipulation of the *Htra1* gene in astrocytes within the mouse NAc bidirectionally controls susceptibility to stress in a sex-specific manner. Furthermore, direct manipulation of *Htra1* in astrocytes of the NAc, in conjunction with sub-threshold stress, influences medium spiny neuronal signaling. Our findings reveal a pivotal role of astroglia as well as the brain's ECM in mediating stress vulnerability that is impacted in a sex-specific manner and set the stage for novel therapeutic approaches for MDD.

Title: Characterizing Approach-Avoidance Biases After Chronic Social Defeat Stress

Authors: A. M. MINIER-TORIBIO, F. J. MARTINEZ, S. TOFANI, C. J. BROWNE, L. ROYCHOWDHURY, A. TORRES-BERRIO, E. J. NESTLER;
Neurosci., Mount Sinai Sch. of Med., New York, NY

Abstract: Under approach-avoidance scenarios, healthy individuals balance their decisions towards the most favorable outcomes. However, individuals with major depressive disorder (MDD) display blunted approach towards rewards and excessive avoidance. Here, we combined the platform-mediated avoidance (PMA) task (Bravo-Rivera et al. 2014) and chronic social defeat stress (CSDS), a well-validated model used to study MDD, to assess the impact of social stress on decision-making under approach-avoidance conflict in mice. Following CSDS, mice were classified as resilient (RES) or susceptible (SUS) based on a rapid social interaction screening test. Next, along with a control group (not receiving CSDS), RES and SUS mice were trained in the PMA task whereby they learn to avoid a tone signaling a footshock by losing access to pressing a lever for a saccharine-water reward. Lever presses and time on platform were recorded as approach and active avoidance learning, respectively. After ten days of acquisition, mice received four days of extinction, where the tones are not contingent with footshocks. While we did not observe significant differences in the acquisition of avoidance ($F_{(2,61)}$=0.2, p=0.86) or approach ($F_{(2,61)}$=1.7, p=0.19) among groups, SUS mice displayed elevated levels of freezing to the tone ($F_{(2,61)}$=4.2, p=0.02). Conversely, during extinction, RES mice showed reduced platform avoidance ($F_{(2,61)}$=3.1, p=0.05) and increased lever pressing ($F_{(2, 61)}$=6.5, p=0.003), suggesting facilitation of extinction learning. In contrast, SUS mice exhibited elevated avoidance and blunted lever pressing. Together, our results indicate that RES mice bias their behavior towards approach when contingencies change (i.e., extinction), whereas SUS mice bias their behavior towards avoidance. Ongoing experiments combining whole brain-wide mapping of neural activity and cell-type-specific chemogenetics aim to reveal the brain regions and cell types that signal these behavioral biases in SUS or RES phenotypes. This work provides a neurobehavioral profile of maladaptive decision-making after social stress, revealing novel neurobiological targets to treat MDD and other stress-related syndromes.

Title: FEDORA Long Noncoding RNA is a Cell-Type- and Sex-Specific Regulator of Mood

Authors: *O. ISSLER[1], Y. Y. VAN DER ZEE[1], S. XIA[2], A. K. ZINSMAIER[2], A. RAMAKRISHNAN[1], C. TAN[3], W. LI[3], M. SALERY[1], C. BROWNE[1], R. FUTAMURA[1], B. LABONTE[1], J. L. DUPREE[4], C. A. TAMMINGA[3], Y. DONG[2], J. MURROUGH[1], L. SHEN[1], E. J. NESTLER[1];
[1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Univ. of Pittsburgh, Pittsburgh, PA; [3]UT Southwestern, Dallas, TX; [4]Virginia Commonwealth Univ., Richmond, VA

Abstract: Major depressive disorder, the leading cause of disability worldwide, strikes women twice as often as men, yet the molecular mechanisms contributing to this sex difference are poorly understood. There is an urgent need for novel sex-specific molecular targets, which can aid the development of new diagnostics and therapeutics for depression. To gain insight into molecular processes associated with sex differences in depression, we explored the regulation of long noncoding RNAs (lncRNAs), a class of regulatory transcripts, in our postmortem brain RNA-sequencing dataset from depressed subjects compared to healthy controls. We found a robust baseline sex difference in lncRNA expression patterns across multiple brain regions in healthy controls, which was profoundly reverted in depressed subjects. Here we highlight one such lncRNA, which is expressed in lower levels in healthy women compared to men but is upregulated in depressed women only in multiple brain regions. Therefore, we named this lncRNA FEDORA (FEmale DepressiOn lncRnA). FEDORA arose in the primate lineage and is expressed primarily in oligodendrocytes and to a lower extent in neurons. To test if FEDORA has a sex-specific causal role in depression, we utilized a cell-type-specific viral approach to express it in the prefrontal cortex (PFC) of mice of both sexes. We found that expressing FEDORA exclusively in neurons promoted anxiety- and depression-like behaviors in females only, which mirrored the human sex-specific phenotype. These behavioral changes were associated with transcriptional changes that resemble the sex-specific transcriptional signature of chronic stress and were associated with changes in PFC pyramidal neuron electrophysiological properties. Expression of FEDORA in oligodendrocytes again had a female-specific effect on motivational behavior, which was associated with decreased myelin thickness and altered gene expression. Interestingly, we found that expressing FEDORA in oligodendrocytes had opposing effects on the transcriptome compared to its expression in neurons. Finally, we found that circulating FEDORA levels are elevated in depressed women only and that these levels are associated with response to the rapidly-acting antidepressant ketamine. Together, these findings offer further evidence that lncRNAs play key roles in shaping the sex-specific landscape of the brain and contribute to sex differences in depression. Our studies of FEDORA and other lncRNAs may lead to the identification of novel targets for the diagnosis and treatment of depression.

Title: Role of Histone 3.3 Lysine 27 Methylation and SUZ-12 in Conferring Enduring Stress Susceptibility

Authors: *A. TORRES-BERRIO[1], A. RAMAKRISHNAN[1], A. MINIER-TORIBIO[1], E. M. PARISE[1], F. J. MARTINEZ-RIVERA[1], C. J. BROWNE[1], O. ISSLER[1], Y. Y. VAN DER ZEE[1], O. SIAL[1], B. A. GARCIA[2], K. HELIN[3], S. SIDOLI[4], L. SHEN[5], E. J. NESTLER[1];

Abstract: Depression is a prevalent psychiatric disorder characterized by symptoms such as feelings of sadness, lack of interest or pleasure, and suicidal ideation. Many of these symptoms can last a lifetime and remain even after several courses of antidepressant treatments. Vulnerability to depression is associated with long-lasting changes in the transcriptional signatures of the nucleus accumbens (NAc), a brain region involved in reward and mood regulation, however, the molecular mechanisms underlying these alterations are not fully understood. Here, we characterized the enduring changes in histone modifications in the NAc of mice exposed to chronic social defeat stress (CSDS), a validated model for the study of depression-like behaviors that separate mouse populations into susceptible (SUS) and resilient (RES) based on a social interaction test (SIT), which is highly predictive of numerous other behavioral abnormalities. Tissue from the NAc of control (CON), SUS, and RES mice was collected either 24 hr or 4 weeks after the SIT and processed for histone profiling via mass spectrometry. In parallel, we mapped the genome-wide enrichment of the most changed histone modifications using Cleavage Under Targets & Release Using Nuclease (CUT&RUN). We found that CSDS alters the methylation (me) dynamics of lysine (K) 27 of the histone variant H3.3—the predominant form of H3 present in adult brain neurons. Specifically, we observed an increase in the abundance of H3.3K27me1 (which preliminary data suggest is selective for D1-type medium spiny neurons) and a decrease in the abundance of H3.3K27me2 in the NAc of SUS mice. Genomic distribution shows that H3.3K27me1 is primarily enriched in gene bodies and proximal promoters, suggesting its crucial role in determining stress-induced transcriptional profiles. In contrast, H3.3K27me2 is weakly deposited across intergenic regions. Changes in H3.3K27me1 and H3.3K27me2 are associated with increased expression of SUZ-12, a protein that controls H3K27 methylation in cultured cells by guiding the polycomb repressive complex 2 to precise genomic sites. We are currently manipulating SUZ-12 expression, and several mutant forms of the protein, in NAc in a cell-type-specific manner to assess their impact on H3.3K27 methylation and on CSDS-induced persistent behavioral alterations. Together, our results suggest that H3.3K27me1 and H3.3K27me2 are important chromatin “scars”. Understanding the molecular basis of these adaptations, including a possible role for SUZ-12, and identifying the genomic regions affected will shed new light on persisting forms of stress-induced pathology.

Title: Persistent transmission of paternal stress phenotypes to offspring are associated with brain transcriptomic alterations

Authors: *A. M. CUNNINGHAM[1], D. M. WALKER[2,1], A. RAMAKRISHNAN[1], H. M. CATES[3], L. SHEN[1], E. J. NESTLER[1];
[1]Icahn Sch. Med. At Mount Sinai, New York, NY; [2]Neurosci., Oregon Hlth. Sci. Univ., New York, NY; [3]Adelphi Univ., Garden City, NY

Abstract: Depression risk has long been known to be highly influenced by both genetic and environmental factors. More recently, it has been proposed that epigenetic mechanisms may also contribute, representing a third basis of risk. Previous studies on intergenerational trauma in rodents from our lab have shown that resilient and susceptible fathers exposed to chronic social defeat stress (CSDS) have different patterns of behavioral transmission and transcriptional changes in sperm. However, no studies to date have examined the persistent transmission of stress phenotypes to multiple litters and how these patterns may differ between resilient and susceptible lineages. To study this, male mice were exposed to 10 days of CSDS and subjected to social interaction testing to assess paternal phenotype. Males identified as resilient or susceptible to CSDS, as well as control F0 males, were allowed to mate 30 days after the stress. After F1 litter 1 was born, the same paternal paired were mated again to produce F1 litter 2. We found that while both resilient and susceptible fathers persistently transmitted altered stress phenotypes to female F1 offspring, only susceptible fathers persistently transmitted altered stress phenotypes to male offspring. To better understand how the brain transcriptome is altered by both paternal exposure to CSDS and offspring stress exposure we conducted RNA-sequencing of the prefrontal cortex and nucleus accumbens. We found a number of distinct transcriptomic profiles in resilient and susceptible lineages. Taken together, these studies advance our understanding of intergenerational epigenetic transmission of behavioral experience.

Title: Neuron-glia interactions regulate the onset of the antidepressant response

Authors: *V. YAO[1,2], A. ALY[3], S. KALIK[3], J. GRESACK[3], W. WANG[3], A. HANDLER[4], A. SCHAEFER[5], O. TROYANSKAYA[6,7], P. GREENGARD[3], ***R. U. CHOTTEKALAPANDA**[3];

Abstract: Commonly prescribed antidepressants, such as selective serotonin reuptake inhibitors (SSRIs) take weeks to achieve therapeutic benefits. The underlying mechanisms of why antidepressants take so long to reverse depressed mood are not understood. Using a single cell sequencing approach, we analyzed gene expression changes in mice subjected to stress-induced depression and determined their temporal response to antidepressant treatment in the cerebral cortex. We discovered that both glial and neuronal cell populations elicited gene expression changes in response to stress, and that these changes are reversed upon treatment with fluoxetine (Prozac), a widely prescribed selective serotonin reuptake inhibitor (SSRI). We reproduced the molecular signaling events regulated by fluoxetine in a cortical culture system and reveal that these signaling events are serotonin-dependent and require reciprocal neuron-glia communication. We demonstrate that chronic treatment with extracellular serotonin regulates temporal and activation of consequent FGF2 and BDNF signaling and show that autoregulation and cross-regulation between the two pathways are essential for the response. Mainly, FGF2 signaling directly regulates *Bdnf* synthesis in a neuron-glia dependent manner, which upon activation of BDNF-TrkB signaling contributes to long-term neuronal adaptations, through the expression of neuronal remodeling genes such as *S100a10*, eventually leading to improved mood. Thus, we show evidence that glial cells work in concert with neurons in a serotonin-dependent manner to facilitate response onset, shaping the subsequent neuronal response. Our studies provide molecular insight into the early phase of the antidepressant response, highlighting a fundamental role for neuron-glia reciprocal signaling, thus providing a novel avenue to mitigate delayed onset of antidepressant therapies.

Title: Role of adult hippocampal neurogenesis in the antidepressant effects of lactate

Authors: *A. CARRARD[1], F. CASSÉ[1], C. CARRON[1], S. BURLET-GODINOT[1], N. TONI[1], P. J. MAGISTRETTI[2], J.-L. MARTIN[1];
[1]Ctr. for Psychiatric Neurosciences, Lausanne, Switzerland; [2]BESE, King Abdullah Univ. of Sci. and Technol., Thuwal, Saudi Arabia

Abstract: Astrocytes are key players in energy metabolism and glutamate transport. In addition, growing evidence suggests that astrocytes are involved in the pathophysiology and treatment of depression. For instance, SSRIs stimulate lactate release from cortical astrocytes. Recently, we showed that acute lactate administration increased lactate concentration in the hippocampus and reduced immobility in the forced swim test (Carrard et al, Mol Psychiatry 2018). Further investigation of the antidepressant behavioral effects of lactate revealed that chronic administration of lactate improved depressive-like behavior in the corticosterone model of depression and in the open-space forced swim test. The antidepressant effects of lactate are associated with changes in the expression of specific target genes among which Hes5 and p11 are involved in adult hippocampal neurogenesis. These findings led us to investigate the role of adult hippocampal neurogenesis in the antidepressant effects of lactate.The involvement of adult hippocampal neurogenesis in the antidepressant effects of lactate was examined in the corticosterone model of depression. We found that chronic peripheral injection of lactate counteracted the decreased neural progenitor proliferation and survival induced by corticosterone treatment (Carrard et al., Mol Psychiatry 2021). In contrast, chronic administration of pyruvate did not produce antidepressant-like effects and did not prevent the inhibition of neural progenitor proliferation and survival induced by chronic corticosterone injection. Importantly, depletion of adult hippocampal neurogenesis by administration of the antimitotic drug temozolomide suppressed the antidepressant-like effects of lactate on behavioral despair and anhedonia in animals chronically treated with corticosterone.*In vitro* studies on hippocampal stem cell cultures revealed that corticosterone decreased cell proliferation and increased ROS production. Consistent with our *in vivo* observations, lactate but not pyruvate suppressed the effect of corticosterone on ROS production and partially counteracted the effect of corticosterone on stem cell proliferation. Similarly to lactate, NADH prevented ROS production elicited by corticosterone and partially reversed the inhibition of stem cell proliferation induced by corticosterone. Therefore, our data suggest that conversion of lactate to pyruvate with the concomitant production of NADH is necessary for the neurogenic and antidepressant effects of lactate. Collectively, these data emphasize the importance of adult hippocampal neurogenesis in the antidepressant effects of lactate.

Title: Effects of Pro- and Anti-Inflammatory Microglial Activation on Behavior in Female Mice

Authors: *M. TSYGLAKOVA, E. H. HURST, N. L. STOREY, J. R. RAINVILLE, G. E. HODES; Virginia Tech., Blacksburg, VA

Abstract: Depression and anxiety are common and debilitating mood disorders, that are more prevalent in females than males. Stress is a trigger for many mood disorders and has effects on plasticity in the brain's reward circuitry, including nucleus accumbens (NAc). We previously demonstrated that 6 days of variable stress sex specifically regulates glutamatergic pre-synaptic components in the NAc, and induces depression-associated behavior only in female mice.
Microglia become activated in response to injury or stress. Interestingly, in patients with MDD, microglial activation in response to stress has been observed in brain regions associated with MDD, including the reward circuitry. Such region-specific microglia activation suggests a potential microglial involvement in stress susceptibility. To investigate microglia activation and its effects on stress susceptibility, we conducted a series of experiments, combining a variable stress paradigm with pharmacological means of manipulating activation of microglia in female mice. Variable stress consisted of three different stressors: foot shock, restraint tube and tail suspension. Each stressor was administered for one hour, and stressors alternated each day for either 3 or 6 days. In the first experiment, we blocked pro-inflammatory activation of microglia with minocycline administered in the drinking water to female mice, which underwent 6 days of stress. Next, we administered rosiglitazone, PPARs-γ agonist, in the drinking water to promote anti-inflammatory microglia activation in female mice, which underwent 6 days of stress. Lastly, to promote pro-inflammatory microglia activation, i.p. injections of LPS were administered to female mice, followed by three days of stress. To access behavioral effects of pharmacological treatments, we conducted a series of behavioral tests, including novelty suppressed feeding, social interaction, forced swim test and splash test. Our results indicate that each pharmacological treatment had behavior specific effects in female mice. To investigate the effects of pharmacological treatments along with variable stress on microglial population in the NAc of female mice, we used IHC analysis for expression of ionized calcium binding adaptor molecule 1 (Iba1) and CD68 in the NAc. We calculated the area of CD68 inside microglia and the area of microglial cells; and performed skeleton and sholl analysis to access the complexity profile of microglial cells. Our preliminary results indicate that minocycline combined with stress decreased the total area of CD68 inside microglia. Microglial analysis from the brains of mice treated with rosiglitazone and LPS is ongoing.

Title: Neural Progenitor Cells derived from Lithium Responsive and Non-responsive Bipolar Disorder Patients Exhibit Differential Neurotoxic Responses to Methamphetamine

Authors: *H. MISHRA[1], **A. MANDYAM**[1], M. MCCARTHY[2];
[1]UCSD, San Diego, CA; [2]VA San Diego Healthcare Syst., San Diego, CA

Abstract: Bipolar disorder (BD) is a genetically inherited mood disorder that affects around 1-2% of the population. BD is characterized by two states: mania and depression. Lithium is a mood stabilizer commonly used to treat BD, and often controls symptoms. However, 33% of patients do not respond to lithium and psychiatrists must often test different doses of lithium and other drugs to determine an effective treatment. Given that death by suicide is 10-30 times higher in BD patients, determining lithium responsiveness more quickly would aid psychiatrists to treat BD more efficiently. There are no reliable biomarkers for predicting lithium response. In order to discover biomarkers, recent studies have developed a novel biological model for BD by using induced pluripotent stem-cell (iPSC) technology. This study used neural progenitor cells (NPCs) derived from iPSCs from lithium responsive (Li-Rs) and lithium nonresponsive (Li-NRs) BD patients and age-matched control subjects. Methamphetamine is a drug that upregulates the neurotransmitter dopamine and produces cell death at high concentrations. A similar upregulation of dopamine is observed in the manic phase of BD, therefore, we used methamphetamine to model neuronal damage associated with mania and determine whether cell death varied between Li-R, Li-NR and control NPCs. NPCs from each group were incubated with methamphetamine (1 mM) or saline for 24 hours. Afterwards, digital images were collected under standardized conditions using a brightfield stereomicroscope. NPC counts were quantified with ImageJ in a blinded fashion. Analysis showed that the number of NPCs from control subjects and Li-NR was significantly reduced after exposure to methamphetamine ($p<0.05$). However, the number of NPCs from Li-R did not differ between saline and methamphetamine conditions ($p>0.05$), suggesting that Li-R NPCs were resistant to methamphetamine-induced cell death. Therefore, our study reveals a difference in cell death in the context of increased dopamine induced by methamphetamine, a model for mania in NPCs from Li-R and Li-NR BD patients. Understanding the mechanisms underlying reduced cell death by methamphetamine in Li-R NPCs could help identify biomarkers for lithium responsiveness. Pharmacogenomic markers for lithium responsiveness are unavailable and incompletely investigated, therefore the current *in-vitro* system can be further researched to eventually implement a more efficient screening process for identifying lithium responsiveness.

Title: Relationship between judgment of social interactions in virtual reality and neural responses to self and other pain images in children with disruptive behavior disorders

Authors: J. BRICKMAN[1], R. MCCARTHY[1], G. RODRIGUEZ[1], Z. WOOD[3], K. MILLER[3], D. NEUMANN[2], W. KRONENBERGER[1], T. A. HUMMER[1];

Abstract: Virtual reality (VR) technology has potential for clinical use in the assessment and treatment of children with disruptive behavior disorders (DBD). Previous research indicates that children with DBD experience deficits in empathy and social perspective taking that lead to attributing hostile motivations to others' behavior. In the brain, children with DBD have shown decreased sensitivity to others' pain. This study investigates whether the neural response to self and other physical pain is related to the attribution of more hostile intentions by virtual characters. Nineteen children (ages 9-12; 14 males, 5 females) with a diagnosed DBD underwent fMRI while viewing blocks of images depicting pain-inducing and non-pain activities. Images were accompanied by instructions to imagine the image happening to oneself (Self Pain) or to a novel VR character (Other Pain). Subsequently, participants were asked to complete a task in a virtual school cafeteria. During this scene, a virtual counterpart interfered with their goal (e.g., by bumping into them). Participants then completed ratings of the counterpart's intentions and the usability of the VR task and headset. On a 1-100 rating scale, participants rated the VR as highly enjoyable (mean=99.2, SD=2.9) and easy to use (mean=90.8, SD = 19.1). Ratings of "meanness" of the virtual counterpart were highly variable across the sample (mean=71.3; SD=36.7). During fMRI, participants had strong responses to both Self and Other pain in visual and emotional regions. Higher meanness ratings of the virtual counterpart were associated with greater activation in response to Self Pain in several clusters in the anterior cingulate cortex ($p<.01$, $k>1000$ voxels). However, no such relationship was present in the Other Pain condition. Additional fMRI and VR analysis is ongoing. These results indicate that, in children with DBD, neural sensitivity to their own imagined physical pain is associated with a greater likelihood to infer that others are inflicting intentional social pain. Further, combining VR and fMRI methods holds promise for understanding the neural circuitry underlying social-cognitive and behavioral deficits. The next avenue in this ongoing research aims to determine whether experiencing VR scenes from the counterpart's point of view can improve social perspective-taking abilities in children with DBD.

Title: Effects of deep brain stimulation treatment for refractory obsessive-compulsive disorder on ventral striatal field potentials

Authors: *A. S. WAITE[1,2], N. PROVENZA[1,2], Y. FAN[1], E. DASTIN-VAN RIJN[1,2], W. K. GOODMAN[3], S. A. SHETH[3], D. BORTON[1,2,4];

Abstract: About 10-20% of patients with obsessive-compulsive disorder (OCD) have treatment refractory illness. For these patients, deep brain stimulation (DBS) therapy is a viable treatment option. The current DBS therapy framework is primarily open-loop, in which the clinician episodically titrates stimulation parameters based on behavioral responses. This limits titration to only being available in the clinic, whereas a quantitative measure would enable titration to occur continuously. Investigation of the precise effects of DBS on neural oscillatory activity during DBS may yield insight into control signals (e.g. neural signatures of therapeutic effectiveness or adverse effects) and inform a closed-loop neuromodulation framework. Here, we identify trends in relative power for specified frequency bands as a result of changes to DBS delivery parameters in patients with refractory OCD, in order to identify frequency bands that could be used in a closed-loop DBS feedback system. Three participants were implanted with the Medtronic Summit RC+S device enabling the delivery of therapeutic stimulation while simultaneously sensing local field potentials (LFPs) on neighboring contacts. In-clinic programming sessions were used to compare changes in LFP data as a result of DBS amplitude changes. Relative power was calculated offline using windowing and a moving average filter throughout the session. Additionally, a single median value was calculated for LFP relative power at each DBS amplitude. Short term amplification of DBS amplitude resulted in suppression of the delta and theta band relative power, as well as enhancement in the gamma band relative power in two participants. Relative power changes between two participants followed similar trends in the previously mentioned frequency bands, however different stimulation amplitudes caused significant changes for each patient. Relative power at different stimulation amplitudes were compared with 0 mA stimulation amplitude acting as a baseline. Delta, theta, and gamma band LFP oscillations displayed significant changes in oscillatory patterns in the short term that could be used as an input for an initial closed-loop DBS paradigm. Future experiments will continue to explore these relative power changes coupled with clinical measures of OCD.

Title: Characterization of the effects of deep-brain stimulation of the mouse internal capsule on brain-wide neural circuits and compulsive behavior

Authors: *B. J. G. VAN DEN BOOM[1,2], A. ELHAZAZ FERNANDEZ[1], P. RASMUSSEN[1], E. H. VAN BEEST[1], A. PARTHASARATHY[1,2], D. DENYS[1,2], I. WILLUHN[1,2];
[1]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [2]Dept. of Psychiatry Amsterdam UMC, Amsterdam, Netherlands

Abstract: Deep-brain stimulation (DBS) of the internal capsule (IC) is an effective treatment for otherwise therapy-resistant patients suffering from different psychiatric disorders, most notably for patients with severe obsessive-compulsive disorder (OCD). IC-DBS is thought to recruit cortico-striatal circuits, but understanding of the specific mechanisms of action of DBS is insufficient. Here, we systematically examined the effects of different IC-DBS parameters on brain-wide neuron-population activity in mice (wide-field calcium imaging of GCaMP6 in dorsal cortex). Furthermore, we investigated DBS effects on neural-circuit activity (one-photon calcium imaging using miniaturized fluorescence microscopes) and compulsive-like behavior in SAPAP3 mutant mice ($SAPAP3^{-/-}$), a versatile model for OCD, that, similar to patients, exhibit compulsive behavior (excessive grooming) and functional deficits in cortico-striatal circuits. Single-cell analyses of cortico-striatal circuits revealed distinct differences in spontaneous activity between $SAPAP3^{-/-}$ and wild-type mice, potentially responsible for compulsive grooming. IC-DBS immediately and selectively reduced compulsive grooming in $SAPAP3^{-/-}$ in an intensity-dependent manner and, similar to OCD patients, compulsive behavior reinstated promptly after cessation of DBS. IC-DBS induced instant homogeneous activity patterns in neuron-populations across the dorsal cortex, while single-cell analyses of cortico-striatal circuits revealed complex heterogeneous responses in the spatiotemporal domain. Overall, we identified several functional principles: Increasing current intensity 1) dose-dependently recruited neurons, both by exciting and inhibiting cells, 2) recruited overlapping but not identical ensembles of neurons, and 3) substantially modulated cortico-striatal activity but maintained an excitation/inhibition (E/I) balance. 4) A neuron's recruitment directionality (excited or inhibited) remained consistent across current intensities, and 5) neurons were recruited either briefly upon DBS onset or throughout the DBS period. Our findings demonstrate that IC-DBS reduces excessive grooming in $SAPAP3^{-/-}$, and indicate recruitment of cortico-striatal circuits as a mechanism for it. We identified general functional principles of IC-DBS, which suggest that anti-compulsive effects of IC-DBS may manifest by means of modulating impaired prefrontal cortex activity, while maintaining E/I balance. Although IC-DBS is an effective therapy, understanding its underlying mechanisms has the potential to significantly improve its efficacy.

Abstract: The gut microbiome is impacted by environmental exposures and has been implicated in many health conditions. United States (US) military Veterans are a unique population in that their military-related exposures can have consequences for both physical and mental health. Nevertheless, the gut microbiome of this population has been understudied. In this study, we describe the exposures, health conditions, and medication use of Veterans in the US-Veteran Microbiome Project (US-VMP), and examine the associations between these characteristics and the gut microbiota. This cohort included 331 US Veterans seeking care in the Veterans Health Administration that were 83% male with an average age of 47.6 ± 13.4 years. The cohort displayed a high prevalence of posttraumatic stress disorder (49.8%), traumatic brain injuries (76.1%), multiple chronic diseases, and high use of prescription medications (74.9%). We report significant associations between the gut microbiota composition and gastroenteritis, peripheral vascular disease (PVD), bipolar disorders, beta-blockers, serotonin and norepinephrine reuptake inhibitors (SNRI) antidepressants, diabetes medications, opioids, and proton pump inhibitors. Many of the Veteran characteristics examined were also associated with shifts in specific taxa. We also found that PVD and cardiovascular disease (CVD) were associated with lower gut microbiota α-diversity, while vitamin use was associated with higher α-diversity. Our study contributes novel insights into how the unique exposures of Veterans correlate with the gut microbiome and, in line with previous findings with other population-level studies of the microbiome, confirms that medication use has important effects that should be considered in studies of the human gut microbiome.

Title: Effects of age and sex on behavioral measures of sensation/novelty seeking in rats

Authors: *K. ISHIWARI, M. C. TURK, H. M. BOOL, R.-Y. SHEN, S. HAJ-DAHMANE, J. B. RICHARDS;
Pharmacol. and Toxicology, Univ. at Buffalo, Buffalo, NY

Abstract: Sensation/novelty seeking (SNS) is associated with elevated risk for drug abuse, especially in adolescents and young adults. In humans, SNS peaks in mid- to late adolescence and subsequently declines into adulthood and is generally higher in men than in women. However, relatively few studies have examined age- and sex-related differences in SNS in rodents, and such studies, using various behavioral paradigms, have yielded mixed findings. The present study examined the effects of age and sex on two behavioral measures of SNS in rats, locomotor response to novelty and operant responding for a sensory reinforcer, which have previously shown to measure overlapping but different aspects of SNS. Male and female Sprague Dawley rats were tested in the two behavioral tasks in sequence, starting at postnatal day [PND] 32 (periadolescence, male: n=15, female: n=15), PND 72 (young adulthood, male: n=13, female: n=12), or 6 months of age (adulthood, male: n=15, female: n=14). In the locomotor response to novelty test (1 session), rats were tested for locomotor activity for 18 min in novel plastic chambers equipped with an infrared motion-sensor system. In the light reinforcement test, which measured operant responding for a light stimulus, animals were placed in dark operant chambers with poke holes in the left and right walls for 18 min per session. In the initial habituation phase (6 sessions), rats' snout-poke responses had no consequences. During the following light reinforcement phase (6 sessions), snout-pokes into one of the holes, designated active, produced a 5-sec illuminance of the lights in the ceiling and the back wall of the chamber according to a variable-interval 1 min schedule of reinforcement, while pokes into the other inactive hole had no consequences. Contrary to our expectations, the results of the locomotor response to novelty test found no significant differences in the total distance traveled among the three age groups or between the sexes. However, the results of the light reinforcement test showed that rats' operant responding for light was influenced by both sex and age. Females made more responses for light than males overall, while no significant effect of sex was found on preference for light (active - inactive responses). In addition, in both sexes, both the number of active responses and preference for light peaked in young adulthood and declined in adulthood, although this age-related change reached statistical significance in males only. Thus, our results indicate that, in rats, aspects of SNS measured by operant responding for purely sensory stimuli peak in young adulthood and decline in adulthood, while this decline may be slower in females.

Title: Electrophysiological Correlates of BIS/BAS: A Systematic Review

Authors: *M. L. DARWIN, D. B. DAVALOS;
Psychology, Colorado State Univ., Fort Collins, CO

Abstract: The Behavioral Inhibition System/Behavioral Activation System scale (BIS/BAS scale; Carver & White, 1994) is a self-report measure of personality that has evolved into a widely-used assessment tool extending over various domains of neurobehavioral research. The BIS and BAS characterize individual differences in threat and reward-mediated behavioral responses to environmental cues, respectively. As the literature currently stands, reports of electroencephalographic (EEG) indices of BIS and BAS in association with the BIS/BAS scale are mixed. EEG indices appear to differ depending on a number of methodological factors and are periodically inconsistent within similar study designs. The wide-spanning methodological incongruences across studies that seek to relate self-reported levels of BIS and BAS with EEG outcomes presents a challenge in interpreting results on a study by study basis. The importance of investigating the electrophysiological correlates of the BIS/BAS scale lies in the need for a standardized, empirically-supported methodology that elicits a strong relation between self-report, electrophysiological, and behavioral manipulations, and the need to further determine the ability of the scale to adequately predict behavioral outcomes in differing situational contexts. The current systematic review provides a report of the assorted findings throughout the literature regarding scores on the BIS/BAS scale and related EEG correlates. Results from twenty empirical studies are included in this review. Measuring the EEG correlates of BIS may be most practical when either investigating the interaction between perceived threat, arousal, and negative stimuli, or the subsystem's sensitivity to the detection of behavioral outcomes that are incongruent with what was expected. High BAS is consistently predicative of higher alpha activity in the absence of a behavioral task. Within a task-based design, measurement may be most practical when aiming to bridge EEG indices of BAS with situational factors that allow for positive reinforcement of behavioral outcomes and within the context of positive emotional stimuli. Further discussion arranges the findings to best determine the behavioral conditions that are associated with each electrophysiological correlate and provides recommendations for subsequent uses of the BIS/BAS scale in light of these conclusions.

Abstract: Integrating nanobiology into wearables could introduce new pathways for extending actual noninvasive and nonintrusive monitoring of physiological states, treatment effects and pathogens or toxins impact. However, sophisticated procedures with the use of large equipment, and different technologies, generally make difficult real time detection of these “nano-agents” of air in freely moving individuals. Here, we describe our e-connected lightweight wearable device, that detects at room and outside temperature in breath of humans, SARS-CoV-2 within 3 min, requiring no user intervention other than turn on the device and breath. Series of biomarkers are currently tested and related to the brain.

Title: A taste for blood: chemosensing in the oral cavity-choroid plexus circuit regulates the addictive properties of systemic nicotine

Authors: *S. CALIGIURI[1], P. J. KENNY[2];
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Dept. of Pharmacol. and Systems Therapeut., ICAHN Sch. of Med. At Mount Sinai, New York, NY

Abstract: The gustatory system guides ingestive behaviors to ensure survival, ie: reinforcing intake of sweet, salty, & umami flavors, which represent carbohydrates, electrolytes, & protein respectively, while avoiding strongly sour & bitter tastes which through evolution often represented spoiled or poisonous compounds. Intriguingly, the majority of addictive drugs are classified as bitter tasting alkaloids. The relevance of the gustatory system to substance use is supported by the recent discovery of taste receptor expression outside the oral cavity; this suggests that the taste receptors may respond to circulating drugs consumed via different routes. As such, the gustatory system may not only apply to ingestive behaviors, but general consummatory behaviors which include substances of abuse. We propose that the bitter taste receptor chemosensory network facilitates the satiety/aversion response to alkaloid drugs like nicotine, as part of the evolutionary defense mechanism. Here, we provide evidence that the bitter taste receptors (T2Rs) are targets of alkaloid drugs of abuse; when the G-protein to which the bitter taste receptors (T2Rs) couple, α-gustducin (Gnat3), is knocked down via CRISPR in STC-1 cells, intracellular calcium was lower versus eGFP knockdown cells ($p<0.05$). In mice (n=120), pharmacological antagonism of T2Rs, global KO or CRISPR mediated knockdown of Gnat3, the valence of an otherwise aversive dose of nicotine became preferable in a conditioned place aversion protocol (+12%), enhanced oral nicotine intake (>2-fold), & elevated intravenous self-administration of nicotine (>2-fold). The location of the T2Rs that may regulate this phenotype is the oral cavity-ventricular connection. AAVs injected into the 4th ventricle of the brain resulted in robust expression in the oral cavity; likewise, PRV tracing indicated a connection of the tongue to the nearby nucleus of the tractus solitarius (NTS). This suggests direct communication & connection of the oral cavity to this hindbrain region known to regulate nicotine aversion/satiety. When Gnat3 was knocked down in this specific oral-4th ventricle connection using CRISPR technology (n=40), the increase in nicotine taking behaviors was again observed. These behavioral findings were accompanied by reduced neuronal recruitment in bitter responsive cells of the NTS as well as altered cholinergic subunit expression in the choroid plexus of the 4th ventricle. These data highlight a new chemosensory system consisting of the T2Rs that may modulate nicotine taking behavior & moreover that the gustatory system may not only guide ingestive behavior, but consumption of substances via different routes.

Title: Defining the role of purinergic signaling in the medial habenula

Authors: *Y.-C. CHEN[1], D. J. RINDNER[2], T. S. HNASKO[3], G. LUR[4], C. D. FOWLER[5]; [1]Neurobio. and Behavior, Univ. Of California, Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California, Irvine, CA; [3]Neurosciences, Univ. of California San Diego, La Jolla, CA; [4]Neurobio. and

Behavior, Univ. of California, Irvine, Irvine, CA; [5]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Tobacco smoking is one of leading causes of preventable death worldwide, and nicotine is considered to be the primary reinforcer of tobacco dependence. In these studies, we sought to assess the role of purinergic signaling on neuronal activity in the medial habenula. Brain sections from male and female wildtype mice were sectioned, and neurons in the medial habenula were examined with patch clamp electrophysiology. Initial studies characterized the baseline firing rates and the effects of a receptor agonist on cholinergic habenular neurons. Next, since the medial habenula has been highly implicated in mediating symptomology associated with nicotine withdrawal, we then examined the effects of purinergic receptor activation on neuronal firing during a state of nicotine withdrawal in both sexes. We found that purinergic signaling mediates neuronal activity of the medial habenula, with differential effects occurring during nicotine withdrawal. Together, these data contribute to our understanding of the factors mitigating withdrawal effects that may underlie the nicotine dependence state.

Title: Intrinsic excitability of indirect pathway spiny projection neurons in the dorsomedial striatum is increased at early and decreased at protracted abstinence from repeated methamphetamine administration

Authors: *S. CHOI[1], Y. DU[2], S. M. GRAVES[2];
[1]Pharmacol., [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Methamphetamine (meth) is a potent psychostimulant and the number of persons suffering from a meth use disorder is increasing in the US (NSDUH 2018; Winkelman *et al., JAMA Netw Open* 1:e183758). The dorsal striatum is an important component of the basal ganglia that is predominantly composed of GABAergic direct pathway spiny projection neurons (dSPNs) which express D1 dopamine receptors and indirect pathway spiny projection neurons (iSPNs) which express D2 dopamine receptors (Gerfen and Surmeier, *Annu Rev Neurosci* 34:441 2011). The dorsomedial striatum (DMS) in particular is associated with goal-directed behavior; optogenetic stimulation of dSPNs in this region is reinforcing whereas optogenetic stimulation of iSPNs is aversive (Kravitz *et al., Nat Neuro* 15:816 2012). In a self-administration model both D1 and D2 receptor antagonism attenuate meth-seeking behavior after 21 days of abstinence (Caprioli et. al, *J Neurosci* 37:1014 2017) and chemogenetic inhibition of DMS dSPNs

decreases cocaine-seeking in rats exhibiting a 'high risk' phenotype (Yager *et al.*, *Addict Biol* 24:251 2019). These data indicate that the DMS is involved in reinforcement and maladaptive behaviors associated with addiction; however, stimulant-induced dysfunction of DMS SPNs is understudied. To begin to address this knowledge gap mice expressing eGFP and tdTomato under control of the *Drd2* and *Drd1a* receptor regulatory element, respectively, were administered saline or meth (2 mg/kg; i.p.) for 10 consecutive days in their homecage and *ex vivo* brain slices prepared after 1 or 21 days of abstinence; iSPNs and dSPNs were patched in whole-cell configuration and intrinsic excitability assessed by depolarizing current injection. After 1 day of abstinence DMS iSPN intrinsic excitability was increased resulting in more action potentials generated in response to depolarizing current injections whereas after 21 days of abstinence intrinsic excitability was decreased. In contrast to the changes in DMS iSPNs, DMS dSPN intrinsic excitability was unchanged at both abstinence time points. Further study is needed to determine the behavioral consequences associated with the observed changes. Nonetheless, our results indicate that meth-induced DMS striatal dysfunction, with respect to intrinsic excitability, is specific to iSPNs with opposite effects at early *versus* protracted abstinence.

Title: Manipulating brain activity to rescue drug-induced cognitive deficits.

Authors: *M. PRATELLI[1,2], N. C. SPITZER[1,2];
[1]Neurobio. Section 0357, Div. of Biol. Sci., The Univ. of California, San Diego, La Jolla, CA; [2]Kavli Inst. for Brain & Mind, San Diego, CA

Abstract: Drugs of abuse share the ability to induce widespread neuroplastic changes upon repeated intake. This affects the functionality of brain circuits, induces behavioral alterations and can lead to addiction. Since drug intake alters neuronal activity, we asked if prolonged drug exposure induces a form of activity-driven neuroplasticity called neurotransmitter switching (NTS). NTS occurs when a group of neurons loses the neurotransmitter it was expressing and gains a new one, and has been shown to affect behavior. We used two drugs known to increase the activity of prelimbic cortex (PrL) glutamatergic neurons upon acute intake: phencyclidine (PCP), a NMDA receptor antagonist, and methamphetamine (METH), a DAT blocker that increases extracellular monoamines. Repeated administration of PCP or METH for 10 or 7 consecutive days respectively, causes ~600 PrL glutamatergic neurons to express the inhibitory transmitter GABA, its synthetic enzyme and its vesicular transporter. These neurons show decreased expression of the vesicular glutamate transporter, indicating that neurotransmitter switching has occurred. We then used an RNA interference strategy to prevent PrL glutamatergic neurons from gaining

GABA upon PCP exposure. This intervention prevented the appearance PCP-induced deficits in the novel object recognition test and spontaneous alternation task, indicating a causal link between NTS and cognitive deficits. Since NTS is driven by changes in neuronal activity, we asked if it can be prevented by counteracting PCP- and METH-induced increases in PrL pyramidal neuron activity. We used a chemogenetic strategy to selectively increase the activity of parvalbumin-positive (PV+) interneurons *during* drug exposure. PV+ neurons can suppress glutamatergic neurons' hyperactivity, as they provide feed-forward inhibition of pyramidal cells. This strategy prevented the appearance of both NTS and drug-induced cognitive deficits. We then tested whether the same strategy can be used *after* drug exposure to reverse the switch and the cognitive deficits. Two days after the end of drug treatment, mice were started on a protocol of daily chemogenetic stimulation for an additional 10 days. Remarkably, this approach reversed both NTS and cognitive deficits in mice previously treated with either PCP or METH. We next tested the effect of clozapine, a pharmaceutical known to block the PCP-induced increase in PrL activity. Treating mice with clozapine for 14 days *after* the end of PCP exposure also reversed both the NTS and cognitive deficits. These results suggest that targeted manipulation of electrical activity can reverse drug-induced cognitive deficits by reversing NTS.

Title: Cellular and Molecular adaptations in D2-MSNs of the Nucleus accumbens associated with individual differences in cocaine-seeking behavior.

Authors: *J. PARRILLA-CARRERO[1], M. EID[1], Y. S. CHAO[2], A. THOMAS[1], O. P. CULVER[1], R. CHANDRA[3], M. LOBO[4], T. C. JHOU[1];
[2]Neurosci., [1]Med. Univ. of South Carolina, Charleston, SC; [3]Anat. and Neurobio., Univ. of Maryland Baltimore, Baltimore, MD; [4]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Of all individuals who experiment with cocaine, only a fraction subsequently progress toward developing cocaine addiction. Although it is clear that vulnerability to cocaine addiction results from predisposing factors, it remains unclear how these influence cocaine addiction. A major challenge in differentiating these possibilities is our limited knowledge of the cellular/molecular changes associated with individual differences in brain circuitries related to motivated behavior. Using the runway model of cocaine self-administration, here we demonstrated that cocaine seeking varies significantly among rats. To further determine why the motivation to seek cocaine may be much more robust in some individuals than in others, we then evaluated D2 medium spiny neurons (D2-MSNs) excitability in the medial

nucleus accumbens shell (mNACshell) in ex vivo preparations. Notably, we found that low- but not high-seeker rats displayed increased excitability in D2-MSNs, which manifest as a greater basal firing rate, higher glutamatergic synaptic drive, and decreased long-term depression (LTD). Besides, we found that in the mNACshell, low-seeker rats showed greater levels of RhoA activity, whereas high-seeker rats showed lower levels of RhoA activity relative to saline-control rats. Further characterization of this cellular alteration revealed that cell-type-specific up or down-regulation of RhoA activity in NACshell D2-MSNs decreases or increases cocaine-seeking behavior, respectively, by altering D2-MSNs excitability. Altogether, these results identified RhoA as a critical mediator of D2-MSN excitability and suggest that enhanced RhoA signaling in this cell population decreases cocaine-seeking behavior.

Title: The basolateral amygdala influences the activity of dorsolateral striatum medium spiny neurons via direct projections to the nucleus accumbens core

Authors: *A. BELIN-RAUSCENT, B. J. EVERITT, D. J. BELIN;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Although the basolateral amygdala (BLA) does not project directly to the anterior dorsolateral striatum (aDLS), it bidirectionally gates the response of subpopulations of medium spiny neurons (MSNs) in the aDLS to their major glutamatergic input from the cortex. The remote control whereby associative information processed in the amygdala can influence the neural locus of control of habits may be a mechanism by which the amygdala gates the progressive devolution of control over the aDLS during the development of drug seeking habits characteristic of addictive behaviour. Our recent investigations of the neural mechanisms underlying this functional control have shown that, in drug-naive rats, electrical stimulation of the BLA applied 100 to 300 milliseconds before that of the motor cortex 1 (M1) elicits a bidirectional regulation of spike probability of the aDLS MSNs. While the control exerted by the BLA over aDLS MSNs has been shown to depend on a polysynaptic functional network that involves antecedent glutamatergic mechanisms in the core of the nucleus accumbens (AcbC), the nature of the amygdalo-striatal circuit by which this control is mediated has not been defined. Here we used projection-specific expression of channelrhodopsin to investigate the role of the BLA -AcbC pathway in mediating the control by the BLA of aDLS MSNs activity.In anaesthetised rats, optogenetic stimulation of terminals of the AcbC-projecting BLA neurons was combined with extracellular *in vivo* recordings of the activity of the MSNs in the aDLS evoked by electrical stimulation of M1. Photostimulation of the terminals of BLA neurons in the AcbC was sufficient to induce bidirectional modulation of the activity of aDLS MSNs:

aDLS MSNs were shown either to up or down regulate their spike probability following photostimulation of the BLA-AcbC pathway.These data demonstrate that the BLA can exert control over the physiology of the aDLS indirectly through its direct projections to the AcbC. Further experiments will establish whether the AcbC mediates this influence on the aDLS via its connectivity with the ascending dopamine-dependent spiralling circuitry shown to be necessary for the functional recruitment of aDLS dopamine dependent drug seeking habits.

Title: Effects of catharanthine on the mesolimbic dopamine system

Authors: *B. M. WILLIAMS[1], J. A. SAUNDERS[1], N. D. STEED[1], E. K. BALDWIN[1], S. LEE[1], E. Y. JANG[2], H. R. ARIAS[3], S. C. STEFFENSEN[1];
[1]Psychology and Neurosci., Brigham Young Univ., Provo, UT; [2]Pharmacol. and Drug Abuse Res. Group, Res. Ctr. for Convergence Toxicology, Daejeon, Korea, Republic of; [3]Pharmacol. and Physiol., Oklahoma State Univ. Col. of Osteo. Med., Tahlequah, OK

Abstract: Ibogaine is one of several indole alkaloids compounds that are found in the *Catharanthus roseus* plant, or commonly known as the Madagascar periwinkle. Ibogaine reduces opioid and alcohol withdrawal symptoms and decreases drug self-administration in both animal and human models. However, ibogaine has also been shown to induce heart arrhythmias and has hallucinogenic properties, which has resulted in ibogaine being classified as a Schedule 1 substance by the DEA in the United States. Catharanthine, an ibogaine analog, could be an alternative pharmacological treatment for addiction without the adverse side effects. The objective of this study was to evaluate the effects of catharanthine on dopamine (DA) transmission in the mesolimbic DA system implicated in drug reward. To accomplish these studies, we used fast scan cyclic voltammetry (FSCV) and microdialysis/HPLC in C57 mice. Superfusion of catharanthine (1-100 µM) inhibited evoked DA release in brain slices from the nucleus accumbens (NAc) of the striatum with an IC_{50} of 30 µM, as measured by voltammetry. Based on our previous studies, we hypothesized that catharanthine acts through inhibiting nicotinic acetylcholine receptors (nAChRs) or voltage-sensitive calcium channels, which we confirmed through testing the effects of dihydro-β-erythroidine hydrobromide (DHBE), an α4β2 nAChR antagonist, mecamylamine, a non-selective nAChR antagonist, α-conotoxin MII, a selective α6-nAChR antagonist, and cadmium, a voltage-gated calcium channel antagonist. Although mecamylamine did block catharanthine-induced inhibition of evoked DA release, the greatest effect was seen with DHBE, suggesting that catharanthine is more selective for α4β2/α4β4 nAChRs. Superfusion of MII and cadmium failed to significantly inhibit

catharanthine activity, suggesting that catharanthine is less selective for α6-nAChRs or voltage-gated calcium channels. Intraperitoneal administration of catharanthine into mice at 10 mg/kg increased basal DA in the NAc, as measured by microdialysis. These findings suggest that catharanthine may be a suitable pharmacological treatment for substance use disorders.

Title: Exploring novel therapeutic options for psychostimulant use disorder: an FSCV study on accumbens dopamine dynamics in rats

Authors: *M. HERSEY, A. H. NEWMAN, G. TANDA;
Medication Develop. Program, NIDA-IRP, Baltimore, MD

Abstract: Psychostimulant use disorder (PSUD) is an increasingly prevalent condition with significant medical and public health consequences worldwide. While misuse of illicit and prescribed stimulants is becoming increasingly common, there remains no FDA approved treatments for PSUD. Modafinil (MOD), a pharmaceutical agent currently approved for the treatment of narcolepsy and sleep disorders, has been suggested as a potential PSUD medication. However, in clinical trials its efficacy appears limited to subjects with PSUD diagnosis without comorbid alcohol use disorder. To broaden its efficacy, analogs of MOD with higher affinities for the dopamine transporter (DAT) than the parent compound and varying behavioral profiles have been synthesized as potential therapeutic options for PSUD. Like MOD, some of these novel compounds produce behavioral and neurochemical effects inconsistent with those elicited by typical abused psychostimulants. In this study, we explored the neurochemical underpinnings of psychostimulant actions by employing fast scan cyclic voltammetry (FSCV) for real-time investigation of evoked dopamine release and clearance in the nucleus accumbens shell (NAS) of Sprague Dawley rats. Preliminary FSCV data shows that pretreatments with the MOD-analogs JJC8-088 and JJC8-091 may produce divergent effects on NAS dopamine dynamics elicited by i.v. cocaine administration (0.1, 0.3, and 1.0 mg/kg). The MOD analog JJC8-088, demonstrates behaviors in rodents that resemble those of a typical, cocaine-like DAT inhibitor, and enhanced cocaine-induced increases in evoked dopamine release suggesting an additive effect of these compounds. JJC8-088 pretreatment also produced a modest effect on dopamine clearance. In contrast, the MOD analog JJC8-091, an atypical DAT inhibitor that elicits limited, if any, cocaine-like stimulant effects, produced mild reductions in cocaine-induced stimulation of evoked dopamine release. These findings, showing a reduction in cocaine neurochemical effects by pretreatments with JJC8-091, provide insight into the potential efficacy of atypical DAT inhibitors as therapeutic agents for PSUD. This work was supported by NIDA-IRP/NIH.

Title: Cocaine intake and craving is enhanced by presynaptic alpha-synuclein upregulation that regulates synaptic vesicle release onto VTA dopamine neurons.

Authors: J. F. HALE[1], A. E. LANE[2], ***D. LANE**[2];
[1]Pathology, Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA; [2]Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: The activity of ventral tegmental area (VTA) dopamine neurons is a balance of excitatory and inhibitory inputs that is disrupted with repeated drug use, causing a shift to increased glutamate activation of these cells. Dopamine neurons receive inputs from a large number of cortical and subcortical structures that control various aspects of motivated behavior including reward, aversion, compulsion, and association to environmental cues. We recently reported that drugs of abuse (both stimulants and opiates) amplify presynaptic alpha-synuclein levels in axon terminals making synaptic contacts with VTA dopamine neurons. Alpha-synuclein expression changes in response to neuronal activity and is highest in brain regions undergoing synaptic plasticity. Consistent with these ideas, we found dynamic shifts in alpha-synuclein levels within VTA axon terminals matching previously reported changes in cocaine mediated glutamate activity in this region. Repeated cocaine administration increased alpha-synuclein immunolabeling in glutamatergic axon terminals in the VTA when cocaine is systemically present. When mice were in withdrawal, alpha-synuclein levels decreased in glutamate, but increased in GABA axon terminals in the VTA. Our rationale is that dynamic expression of alpha-synuclein in specific VTA axon terminals after drug exposure positions it to fine-tune the complex afferent circuitry controlling dopamine activity, making alpha-synuclein a prime mediator for the progressive changes in behavior occurring with chronic drug use. To examine this further *in vitro* and *in vivo* glutamate release and cocaine intake was assessed using viral biosensors. VTA axon terminals with increased alpha-synuclein levels show greater glutamate release than in the absence of alpha-synuclein but only after cocaine treatment. The relationship between alpha-synuclein levels and glutamate release was not observed in vehicle controls. The effects of VTA alpha-synuclein on hedonic stimuli, including cocaine and sweetened condensed milk, showed that deletion of alpha-synuclein significantly decreased intake of both substances. Together the data suggest that cocaine-induced alpha-synuclein upregulation critically modulates motivated behavior by control of afferent input to VTA dopamine neurons.

Title: Blood alcohol concentration, open field activity, and c-Fos expression after oral exposure to 66% alcohol: Pharmacological or sensation-seeking effect?

Authors: *C. HAGEN, S. GUARINO, M. R. PAPINI;
Texas Christian Univ., Fort Worth, TX

Abstract: While rodents generally reject high concentrations of alcohol, recent experiments have demonstrated that alcohol at high concentrations can reinforce operant behavior. This suggests that alcohol even at high concentrations has rewarding properties. However, given the relatively small amounts consumed the mechanism underlying this rewarding effect is unclear. To further characterize this understudied phenomenon, Wistar rats were given access to either 66% alcohol or water in their home cages for one hour over the course of several sessions. The measured liquid displacement after alcohol sessions was similar to that after water sessions indicating that rats did not reject the 66% alcohol solution. In addition, exposure to an open field for 5 min after access to 66% alcohol resulted in increased activity relative to activity after access to water. Moreover, this increase was solely concentrated to the periphery of the field, suggesting that any amount of alcohol consumed did not cause motor impairment or anxiolysis, but instead promoted locomotor activity. This effect was also positively correlated with blood alcohol concentration indicating that it was a direct result of alcohol exposure. Finally, c-Fos immunoreactivity after exposure to 66% alcohol vs. water showed increased activation in the anterior cingulate cortex, insular cortex, and nucleus accumbens shell. These results further contextualize research showing that 66% alcohol can reinforce operant licking responses in rats and support the claim that higher concentrations of alcohol can be rewarding. The amounts consumed and the blood alcohol concentrations observed suggest that the reinforcing effect of 66% alcohol is probably more related to sensation seeking than to a pharmacological effect.

Title: Evaluation of endocannabinoid concentrations in alcohol-dependent rats.

Authors: *F. DI OTTAVIO[1], L. SANCHEZ-MARIN[2], F. J. FLORES-RAMIREZ[1], A. MATZEU[3], R. MARTIN-FARDON[4];
[1]Scripps Res. Inst., San Diego, CA; [2]Inst. de Investigación Biomédica de Málaga, Univ. de Málaga, Malaga, Spain; [4]Neurosci., [3]The Scripps Res. Inst., La Jolla, CA

Abstract: Alcohol is one of the most widely used psychoactive drugs worldwide. In the United States alone, alcohol use disorder (AUD) affects 14.1 million adults, and problems associated with AUD cost the US economy several billion dollars annually. Chronic and heavy alcohol consumption affect the reward system function, promoting a dependent state. Several studies have shown alterations of endocannabinoid (eCB) levels across various brain regions as a result of alcohol exposure. The present study examined concentrations of anandamide (AEA), palmitoylethanolamide (PEA), oleoylethanolamide (OEA), 2-arachidonoylglycerol (2-AG), and 1-AG in plasma in animals with a history of alcohol dependence. Male Wistar rats were trained to orally self-administer alcohol (10% w/v) daily in 21 consecutive sessions (30 min/day) and then made dependent via chronic intermittent alcohol vapor exposure (14 h vapor ON/10 h vapor OFF per day). A control nondependent group was kept in the vivarium and exposed to air only for the remainder of the study. At the end of the experiment, the animals were sacrificed at an acute abstinence point (8 h after the vapor turned OFF). Trunk blood was collected, and plasma was analyzed by liquid chromatography-dual mass spectrometry to determine eCB concentrations. The results showed lower levels of 2-AG and 1-AG and higher levels of AEA, PEA, and OEA in dependent rats compared with nondependent rats. These findings demonstrate that alcohol dependence results in alterations of the eCB system and suggest that targeting the eCB system could be beneficial for the treatment of AUD.

Title: FGF2/FGFR1 system in embryonic hypothalamus: Involvement in sexually dimorphic stimulatory effects of prenatal alcohol exposure on peptide-expressing neurons linked to alcohol consumption

Authors: N. YASMIN, G.-Q. CHANG, O. KARATAYEV, A. D. COLLIER, M. FAM, A. ONOICHENCO, N. KHALIZOVA, A. ALBEG, S. CAMPBELL, *S. F. LEIBOWITZ;
The Rockefeller Univ., New York, NY

Abstract: Prenatal alcohol exposure (PAE) is known to stimulate alcohol consumption in rat offspring and increase the risk for alcohol use disorder in humans. This phenomenon is believed to involve the stimulatory effect of PAE on neurogenesis and density of neurons in the lateral hypothalamus (LH) expressing orexigenic neuropeptides, including melanin-concentrating hormone (MCH) and orexin, which are known to stimulate alcohol intake. In rats, PAE increases the expression and density of these peptide neurons and alcohol drinking in a sexually dimorphic manner, consistently stronger in female than male offspring. With fibroblast growth factor 2 (FGF2) through its receptor FGFR1 known to stimulate neurogenesis, promote alcohol intake, and have sexually dimorphic properties, we investigated here the involvement of this FGF2/FGFR1 system in mediating this PAE-induced increase in density of these peptide neurons. Using qRT-PCR and RNAscope, we examined MCH-expressing neurons in the LH of female and male postnatal offspring of pregnant rats gavaged with a moderate dose of alcohol (2 g/kg/day) compared to vehicle from embryonic day 10 (E10) to E15 during peak neurogenesis. Our results show that: 1) PAE stimulates mRNA levels of FGF2 and FGFR1 along with MCH, the density of MCH neurons expressing FGF2 or FGFR1 transcripts, and the number of FGF2 or FGFR1 transcripts per MCH neuron; 2) these effects on FGF2 are sexually dimorphic, occurring in females but not males, while those on FGFR1 are similar in females and males; 3) these stimulatory effects of PAE on MCH neurons are mimicked by peripheral injection of FGF2 (80 µg/kg/day) in pregnant rats; 4) more detailed analyses of individual MCH neurons and their intracellular FGF2 and FGFR1 transcripts reveal specific sexually dimorphic changes, with PAE inducing in females but not males a strong, positive correlation between the number of FGF2 and of FGFR1 transcripts and PAE increasing in females but not males their number in the nucleus as well as cytoplasm, with males affected only in the cytoplasm; and 5) further analyses of the PAE-induced increase in density of MCH neurons and their number of FGF2 and FGFR1 transcripts reveal sex differences in their anatomical location, with females showing effects in both the dorsal and ventral areas of the LH while males respond only in the dorsal LH. We conclude that the FGF2/FGFR1 system is involved in mediating the PAE-induced increase in density of MCH neurons in females more than males and the sexually dimorphic nature of this phenomenon is attributed, in part, to sex differences in their ligand-receptor relationship, intracellular distribution of transcripts, and anatomical location of neurons.

Title: Sexually dimorphic behavior of Long-Evans rats on a novel task of maladaptive alcohol self-administration

Authors: *H. N. CARLSON, J. L. WEINER;
Physiol. and Pharmacol., Wake Forest Univ. Hlth. Sci., Winston Salem, NC

Abstract: The progression of recreational drinking to alcohol use disorder is characterized by loss of control over seeking, which involves continued use of alcohol despite a variety of negative consequences. However, due to a paucity of translational models for this aspect of alcohol use disorder, little is known about the circuitry underlying maladaptive alcohol seeking, which precludes the discovery of therapeutic targets. Though alcohol seeking is a common and important metric of animal models, there have been few efforts to parse this construct into more specific facets of motivated behavior. Increased seeking might result from disinhibition, in which the distinction between appropriate and inappropriate behavior is known but overridden, or discrimination failure, in which the distinction between when it is appropriate or inappropriate to drink becomes unclear. The present study proposes a novel maladaptive alcohol self-administration task (MAST), which will be used to assess motivation and inhibitory control across several dimensions of seeking behavior. Furthermore, despite rising rates of alcoholism among women in the human population, translational research endeavors on sex differences in alcohol-related behavior remain sparse. In the present study, we compare cohorts of male and female Long-Evans rats on a novel model of alcohol seeking, the maladaptive alcohol-seeking task (MAST). Two cohorts, one male and one female, (n=8) were brought in at approximately five weeks of age. Behavioral procedures were identical between groups and all phases of training, acquisition, maintenance, and experimentation were performed concurrently on the same days to eliminate external variables. To assess the impact of acute stress on MAST performance, we administered counterbalanced doses of saline (control) and yohimbine (2mg/kg) 30 minutes prior to behavioral testing. We discuss sex differences in daily performance as well as in response to a pharmacological manipulation.

Title: Involvement of the kappa opioid receptor system in the vulnerability to develop compulsive alcohol drinking by the use of alcohol as a coping strategy

Authors: *L. MARTI-PRATS, C. GIULIANO, A. BELIN-RAUSCENT, M. FOUYSSAC, C. VELAZQUEZ-SANCHEZ, X. ZHANG, B. J. EVERITT, D. BELIN;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Only some vulnerable individuals who recreationally drink alcohol eventually lose control over their intake and develop compulsive alcohol seeking and drinking, in that it is maintained despite adverse consequences, a core characteristic of alcohol use disorder (AUD). It has been suggested that the initiation of alcohol use for emotion regulation, or as a coping strategy, plays a determining role in the vulnerability to develop AUD. Indeed, the recent increase in problem drinking in some individuals during the COVID-19 pandemic is further evidence that the use of alcohol as a coping mechanism exacerbates the vulnerability to AUD. However, the psychological and neural basis of this increased vulnerability have not been elucidated. Negative emotional states have been associated with a dysregulation of the dynorphin/kappa opioid receptor (KOR) system. We therefore tested the hypothesis that the KOR system plays a role in the engagement in alcohol drinking as a coping mechanism and the associated increased tendency to persist in drinking alcohol despite negative consequences. Sprague-Dawley rats were exposed to a novel procedure, based on Schedule-Induced Polydipsia (SIP), that enables the identification of individual differences in the reliance on alcohol to cope with distress. In SIP procedures, intermittent food delivery triggers a state of internal distress that some rats learn to cope with by developing adjunctive anxiolytic behaviours, such as excessive water intake. Some rats, referred to as water copers, learned to cope with the distress of the SIP procedure by adjunctively drinking water, as evidenced by a decrease in anxiety and corticosterone levels. In contrast, a subpopulation of rats, referred to as alcohol copers, never acquired adjunctive water drinking; they only developed an adjunctive, anxiolytic, polydipsic response when they had access to alcohol instead of water. While water and alcohol copers did not differ in their overall intake of alcohol, the latter specifically developed compulsivity in that they persisted in drinking alcohol when adulterated with quinine. Furthermore, alcohol intake was decreased only in alcohol copers by systemic administration of the KOR antagonist norbinaltorphimine, suggesting involvement of the dynorphin/KOR system in the use of alcohol to self-medicate distress. These results suggest that the acquisition of alcohol drinking through negative reinforcement-based self-medication is mediated by the dynorphin/KOR system and is a gateway to the development of compulsive drinking in vulnerable individuals.

Abstract: Drugs of abuse such as alcohol disrupt dopaminergic reward pathways, leading to maladaptive goal-directed behaviors. In both mammals and *Drosophila*, evidence suggests that dopamine also mediates ethanol-induced locomotor activity, however, the underlying neural circuitry remains poorly understood. Using flyGrAM, an automated group activity monitor, we investigated whether distinct populations of dopamine neurons are differentially recruited to support ethanol-induced activity in a dose-dependent manner. We then performed high-content behavior analysis using FlyTracker and Ctrax. We found that both the PAM and PPL1 subsets of dopamine neurons are involved in the ethanol response and have ethanol-dependent modulatory activity. Additionally, we discovered neuronal subsets with dynamic roles in modulating ethanol-induced activity. Specifically, increased dopamine neuronal involvement occurred at higher doses of ethanol, suggesting that more dopamine neurons are recruited at higher doses to counter the sedating effects of ethanol. Overall, this study clarifies our understanding of the dose-dependent activity of specific subsets of dopamine neurons and serves as a starting point for more detailed circuit analyses.

Title: Adolescent binge ethanol-induced dysregulation of histone marks may underlie myelin deficits

Authors: E. R. BROCATO[1], *J. WOLSTENHOLME[2];
[1]Pharmacol. and Toxicology, [2]Virginia Commonwealth Univ., Richmond, VA

Abstract: The prefrontal cortex (PFC) undergoes significant changes during adolescence, and alcohol exposure during this time is particularly damaging. Consuming alcohol, especially in binges, has been shown to negatively impact the adolescent brain, resulting in brain structural changes, decreased myelin, and memory deficits. Previously, we have shown that adolescent mice exposed to binge ethanol had

memory deficits that lasted into adulthood. Gene expression changes in the PFC were measured by microarray to uncover the mechanisms in which ethanol induces these behavioral changes, and results showed that binge ethanol decreased myelin-related gene expression as well as the expression of chromatin remodeling genes responsible for the methylation of histone 3 lysine 9 (H3K9). H3K9me3 is a repressive histone mark that results in transcriptional silence, and is needed for the differentiation of oligodendrocyte progenitor cells to mature oligodendrocytes. Specifically, H3K9me3 must be present at certain synaptic transmission-related genes to repress gene expression and allow oligodendrocyte differentiation to occur. Ethanol-induced dysregulation of H3K9me3 could result in decreased oligodendrocyte differentiation, leading to deficits in PFC myelin, which could ultimately underlie the persistent memory deficits of adolescents exposed to binge ethanol. To investigate this potential mechanism, binge levels of ethanol (4g/kg) or water were administered to adolescent mice. Twenty-four hours after the last dose of ethanol, RNA-sequencing was performed and showed that expression of genes required for oligodendrocyte differentiation and proliferation were impacted by adolescent binge ethanol. Chromatin immunoprecipitation coupled to sequencing (ChIP-seq) was also performed on the same PFC tissue to further investigate the link between ethanol-induced H3K9 dysregulation and myelin deficits. Here, I discuss how our lab is taking steps to understand how this epigenetic mechanism may underlie persistent memory deficits associated with adolescent binge ethanol. Abstract: Regular alcohol abuse lead to physical and mental dependency described like an alcohol addiction. The neuronal basis of this process are still poorly understood, thus, we investigated the behavioral and molecular consequences of the alcohol treatment. Mice injected (i.p) with ethanol (2 g/kg) for 7 days, developed context-independent sensitization of locomotor response observed after 7-day withdrawal; and it was further enhanced after 30-day incubation. Interestingly, this short protocol resulted in higher motivation for alcohol and increased alcohol seeking during withdrawal measured close-to-ethologic conditions in the IntelliCages. Alcohol sensitization was accompanied by structural (analyzed

with Serial Block-face scanning Electron Microscopy (SBEM)) and functional (whole-cell patch-clamp) changes of the central nucleus of the amygdala (CeA) glutamatergic synapses and decreased levels of the autophosphorylated form of αCaMKII. In agreement with this observation αCaMKII autophosphorylation-deficient heterozygote mutant mice (αCaMKII-T286A$^{+/-}$) showed enhanced sensitization as well as increased alcohol consumption in the IntelliCages, and surprisingly lower alcohol seeking during withdrawal and cue relapse. Funding: National Science Center, grant Preludium 2016/21/N/NZ4/03807.

Title: Alcohol exposure enhances neuronal excitability of anterior insular cortex-dorsolateral striatum circuit

Authors: *Y. YIN[1], S. ZHOU[1], D. HAGGERTY[1], B. K. ATWOOD[1,2], P. L. SHEETS[1,2];
[1]Stark Neurosci. Res. Inst., [2]Dept. of Pharmacol. & Toxicology, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Alcohol is the most abused addictive drug in the United States. Unfortunately, our understanding of alcohol-induced alterations to specific brain circuits remains incomplete. Numerous studies show that chronic alcohol exposure alters synaptic plasticity in the dorsolateral striatum (DLS), a subcortical region involved in the development of addiction. However, the effect of alcohol on cortical circuits that send projections to the DLS is poorly investigated. Here, we used intracranial injection of retrograde tracers, the drinking-in-the-dark (DID) paradigm for three weeks to model binge-like alcohol drinking, and whole-cell patch-clamp electrophysiology in acute brain slices to record the intrinsic properties of neurons in the anterior insular cortex (AIC) that send projections to the DLS (AIC-DLS neurons). Our results indicate that AIC-DLS neurons from DID-alcohol mice display a hyperpolarized voltage threshold action potential (AP) firing resulting in an increased frequency of APs in response to depolarizing current steps compared to DID-water mice. Surprisingly, DID had no effect on the excitability of neurons in the motor cortex that send projections to the DLS, suggesting that alcohol differentially alters DLS-projecting neurons based on cortical regions. We are currently exploring the possibility that alcohol induced changes to AIC-DLS neurons is driven by alterations to ascending synaptic inputs. The basolateral amygdala (BLA) is a brain region involved in alcohol use disorder, and our newest data show that the BLA sends direct projections to AIC-DLS neurons. Our goal is to measure changes in the synaptic plasticity of BLA inputs to AIC-DLS neurons in DID-alcohol mice. Moreover, alcohol consumption and pain are strongly comorbid. Measurement of reflexive withdrawal to mechanical

stimuli is frequently used to assess pain behavior. However, these tests do not measure the dynamic behavior of enduring pain to achieve a deliberate goal. Therefore, we tested one week DID animals in a paradigm involving active decision making to obtain reward (alcohol) under aversive temperatures, to quantify the effects of alcohol on motivation and pain tolerance. The results suggested that temperature changes had a main effect on the time they spent on the reward side, but there was no significant differences between DID-alcohol and DID-water mice. Overall, our results show that binge alcohol drinking enhances neuronal excitability of AIC-DLS circuit. However, one week of DID was not sufficient to significantly alter motivation for alcohol under aversive temperatures. We are currently exploring if extending DID to three weeks changes this behavior.

Title: Prenatal alcohol exposure differentially affects synaptic activity in striatal projection neurons and GABAergic interneurons in the developing striatum

Authors: *A. R. TOUSLEY, V. FERNANDEZ, P. W. L. YEH, H. H. YEH;
Geisel Sch. of Med. At Dartmouth, Hanover, NH

Abstract: Fetal alcohol spectrum disorders (FASD) are the most common non-genetic cause of neurodevelopmental disability worldwide. Delayed motor development is one of the earliest clinical signs of FASD, but how prenatal alcohol exposure (PAE) effects the neural circuits underlying early motor development is poorly understood. The functional maturation of neurons in the striatum, the input nucleus of the basal ganglia is closely related to the onset of complex motor abilities during development. Imaging studies have found striatal dysmorphology and changes to corticostriate connectivity to be associated with FASD diagnosis and symptom severity. Here we assess the effects of a brief prenatal binge exposure to ethanol on embryonic day (E) 13.5- to E16.5 on two cell populations within the developing mouse striatal microcircuit: striatal projection neurons (SPNs) and striatal GABAergic interneurons (GINs). Previous work indicated that though PAE does not to result in aberrant embryonic migration of Nkx2.1/Cre Ai14 GABAergic interneurons to the developing striatum, it does lead to presynaptic deficits in GABAergic and glutamatergic inputs to striatal GABAergic interneurons during the first two postnatal weeks. Here we show that PAE results in decreased GABAergic, but not glutamatergic synaptic inputs to developing striatal projection neurons (SPNs) during the first two postnatal weeks using whole cell voltage clamp recordings of spontaneous GABAergic and glutamatergic post-synaptic currents. On-going work will assess how these synaptic deficits may be related to changes

dendritic morphology of neurobiotin-filled SPNs, and the embryonic migration of SPNs as determined by alterations in the distribution of CTIP2 immunofluorescence on E16.5. Further work will investigate how changes in synaptic development and neuronal morphology may be associated with the onset of early motor behaviors. We are assessing early motor function using a series of brief behavioral tasks including: surface righting, negative geotaxis, horizontal/vertical screen tests prior electrophysiological recordings during the first two postnatal weeks. All experiments are performed in animals of both sexes, with a sample size of n=3 litters. Our results indicate that the synaptic development subpopulations of cells in the mouse striatum may be differentially affected by PAE. Future experiments will continue to explore the influence of PAE on the functional development of striatal neurons, to characterize the source of synaptic deficits and understand how synaptic deficits may be related to altered early motor development.

Title: Sex differentially interacts with multiple dopamine receptor subtypes to modulate cue-guided risk/reward decision making

Authors: *S. SCHOFIELD-LEWIS[1], J. SCHUMACHER[1], E. HU[1], S. B. FLORESCO[2];
[2]Psychology and Djavad Mowafaghian Ctr. for Brain Hlth., [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The ability to integrate cues from the environment to make more profitable decisions is a central behavioral adaptation in many organisms. Conditions involving pathophysiology of the dopamine (DA) are associated with suboptimal in risk/reward decision-making. Prior preclinical research on dopaminergic modulation of risk/reward decision making has used rodent assays that require the use of internal representations of reward history to guide optimal decisions (eg probabilistic discounting) rather than gathering information about the profitability of different options from external stimuli. To measure the latter type of decision making, our group has developed a rodent operant assay known as the "Blackjack" task in which rats use external cues to guide decision-making. Rats choose between a small/certain option (1 pellet at 100% probability) and a large/risky option (4 pellets, probabilistically). Different auditory stimuli signal if choice of the large/risky lever has good (50%) or poor (12.5%) odds of delivering the large reward. Well-trained rats show a strong bias toward the large/risky option on good odds trials and vice versa. Here, we investigated the specific contributions of different dopamine receptor subtypes in male and female rats, using systemic treatments with either amphetamine or D1, D2, D3, or D4 antagonists. Previous studies have shown D1 blockade reduces risky choice on a probabilistic discounting task. However, comparable doses of the D1 antagonist SCH23390 (0.001-0.01 mg/kg) did not alter choice on the Blackjack task, although a significantly higher dose (0.1 mg/kg) impaired choice. D2

antagonism reduced risky choice on good odds trials but increased risky choice on poor odds trials. D3 antagonist administration had no effect whereas moderate doses of a D4 antagonist improved decision making by reducing risky choice on poor odds trials. In females, a higher dose of the D4 blocker caused an generalized reduction in risky choice. Amphetamine increased risky choice on poor odds trials and had a more pronounce effect in females. Together these findings clarify how the dopamine system modulates cue-guided risk/reward decision making in a manner that is dependent on the decision making strategy employed, receptor subtype and sex.

Title: Differential effects of distinct forms of acute stress on reward-related decision making and response inhibition involving punishment

Authors: *G. LAINO CHIAVEGATTI[1], J. SCHUMACHER[1], G. L. DALTON[1], S. B. FLORESCO[2]; [2]Psychology and Djavad Mowafaghian Ctr. for Brain Hlth., [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Decision making involving choice between different actions that may yield rewards associated with costs or punishments is mediated by distributed circuits within the mesocorticolimbic dopamine system. Stressors can differentially alter how these systems regulate action selection in a manner depended on the type of costs that are being evaluated. Previous work by our group has shown that acute restraint stress does not alter preference for larger, uncertain rewards vs smaller/certain ones, but markedly reduces choice of larger rewards linked to greater physical effort costs. Yet, how stress may alter reward-related action selection in situations involving risk of punishment has yet to be fully explored. Here we examined how acute restraint and pharmacological stress influenced action selection on two tasks involving reward seeking under the risk of punishment in male and female rats. One series of experiments utilized a risky decision-making task involving choice between two levers: choice of a small/safe option always delivered one reward pellet, whereas choosing a large/risky option delivered three pellets but could also deliver foot shock with a probability that increased across blocks of trials (0, 25, 50, 75 and 100%). In well-trained rats, one-hour restraint stress made rats more punishment sensitive, markedly reducing preference for the larger reward associated with shock; an effect comparable across male and female rats. In contrast, the alpha-2 noradrenergic antagonist and pharmacological stressor yohimbine had minimal effects on choice. A second study used a behavior control task assessing ability to inhibit approach towards a readily available reward associated with punishment. Here, a food pellet was delivered in a food cup, and on 30 of 60 trials the rat merely had to approach it to retrieve reward. On the other 30 trials, a 12-s visual/auditory warning cue signaled food retrieval also delivered foot shock and

that approach must be withheld until cue termination. Restraint did not affect performance overall, but revealed subtle sex differences, whereby males were less likely to wait and received more punished rewards compared to baseline, whereas females showed the opposite effect. Yohimbine had no effect on behavioral control, but did increase overall locomotor activity. These findings suggest that restraint stress selectively amplifies how punishment influences cost/benefit decisions involving choice between rewards of different value, while having a minimal effect on inhibiting punished reward seeking. The mechanisms underlying this effect may relate to the increased risk aversion observed in individuals with depression

Title: Differential roles for dopamine D1 and D2 receptors across the dorsal and ventral medial prefrontal cortex in cue-guided, risk/reward decision making

Authors: *J. SCHUMACHER[1], M. VAN HOLSTEIN[1], F. CHARANIA[1], K. KALUARACHI[1], S. B. FLORESCO[2];
[1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Psychology and Djavad Mowafaghian Ctr. for Brain Hlth., Univ. British Columbia, Vancouver, BC, Canada

Abstract: Optimal risk/reward decisions often require organisms to synthesize information learned from past-experience as well as information provided by cues in the environment that inform about the likelihood of obtaining reward. Human neuroscience research uses paradigms that capture both these aspects of risk/reward decision making, however, rodent preclinical research has traditionally neglected the latter aspect. Previous studies using rodent behavioral assays such as probabilistic discounting that assess decisions guided by choice-outcome history, have shown that dopamine (DA) transmission within the medial prefrontal cortex (mPFC) differentially modulates optimal decision making via D1 and D2 receptors. The present study assessed the role of PFC DA on cue-guided, risk/reward decision making, using an assay colloquially named the “Blackjack task”. Rats choose between a small/certain option that always delivers 1 reward pellet and a large/risky option that delivers 4 reward pellets probabilistically. The probability associated with the large/risky lever is signaled by two distinct auditory stimuli that indicate good (50%) or poor odds (12.5%) of obtaining the larger reward. Choice on this task is differentially mediated by the prelimbic and infralimbic regions of the mPFC. Male and female rats were trained over several weeks at which point they showed a strong bias towards the large/risky option on good odds trails and the small/safe on poor odds trials. Blockade of D2 receptors in the prelimbic mPFC reduced choice of the large/risky option when the odds were favorable and impaired flexible adaptations to dynamic reward contingencies. In contrast, blockade of infralimbic D2 receptors increased risky choice

on poor odds trials in male rats. Surprisingly, blockade of D1 receptors in either region had no effect on choice. Together these results highlight a subregion and receptor subtype dependent role for DA transmission in the mPFC in modulating cue-guided risk/reward decision making. They further suggest that how mesocortical DA modulates risk/reward decision making can differ depending on whether decisions are guided by internal representations of reward history or by external cues.

Title: Firing features of basal amygdala neurons projecting to the dorsomedial striatum and prelimbic cortex in decision making under conflict

Authors: *C. PARDO-BELLVER[1], N. SOLARI[2], P. HEGEDÜS[2,3], B. HANGYA[2], N. HÁJOS[1]; [1]Lendület Lab. of Network Neurophysiol., [2]Lendület Lab. of Systems Neurosci., Inst. of Exptl. Med., Budapest, Hungary; [3]János Szentágothai Doctoral Sch. of Neurosciences, Semmelweis Univ., Budapest, Hungary

Abstract: In daily life, animals are faced with innumerable decisions as they interact with the environment. Decisions should be made in unfamiliar situations, without any prior knowledge, or based on previous experience; yet this cognitive process is always influenced by emotional and motivational factors. Thus, decision-making requires the interplay of multiple neural structures. Recent human studies suggest an important role for the amygdala in guiding more sophisticated action-selection processes underlying decisions. The aim of this research is to understand affective aspects of circuit mechanisms underlying value-based decisions and whether they can be effectively controlled by amygdalar networks, particularly by the amygdalostriatal and amygdalocortical pathways, under risky conditions. To investigate this, we used a combination of optogenetics, electrophysiology and a risk-taking behavioural paradigm. The identity of the neurons projecting from the basal amygdala (BA) to the dorsomedial striatum (DMS) and from the BA to the prelimbic cortex (PrL) was distinguished by opto-tagging, after injecting mice with retrograde-transported virus in the DMS and PrL, and revelling their presence in the BA. At the same time, we implanted a custom-made microdrive (32 electrodes and a built-in optic fibre) into the BA. We trained mice in a risk-taking gambling task, in which they have to choose between a safe-small reward and a larger reward that might be swapped with a punishment (air-puff). The head-fixed mice chose which side to lick (left or right, as signalled by discriminative auditory cues) knowing that licking to the risky side rewards them with a larger amount of water that sometimes is replaced by a punishment. During the task we recorded the spiking activity in the BA and analysed the data using built-

in and custom-made scripts. Our results so far show that around 30% of the recorded neurons change their firing in relation to the task. The neurons in the BA show a wide range of responses. The most common is the inhibition upon reward delivery, but we also found neurons that increase their firing and, rarely, neurons showing side-specific activity. Additionally, we found neurons activated by sound and punishment. Although we have identified several opto-tagged neurons, their particular contribution to the task is still uncertain. The wide range of responses in the activity of the BA during a risk-taking task suggests that the BA has a critical role in processes underlying decisions. However, further analysis is required in order to understand the actual complexity of the proposed network.

Title: Neurophysiological markers in the corticostriatal network associated with impulsive choice behavior during a delayed discounting task.

Authors: M. J. FRANCOEUR, S. HULYALKAR, J. CRAMER, D. RAMANATHAN; Psychiatry, Univ. of California San Diego, San Diego, CA

Abstract: Impulsivity, acting prematurely without consideration of future consequences, is usually considered maladaptive and is a central feature in brain injury and neurological disorders including attention deficit/hyperactivity disorders, substance abuse, Parkinson's, schizophrenia [(1-3)]. The corticostriatal pathway is critical for reward related behaviors, but little is known about neural correlates of impulsive behavior. We record local field potentials (LFP) from the corticostriatal network during a delayed discounting task and compare to single unit activity recorded from orbitofrontal cortex, anterior cingulate cortex, and nucleus accumbens during the same task to identify neurophysiological signatures associated with impulsive choice. During the delayed discounting task rats must choose between two reward locations: one location immediately leads to a small reward (1x) and another to a delayed (2 or 10s) large reward (3x). The temporal delay is adjusted within-session from 2 to 10s after 75 trials. While rats perform the task, we record LFP from 32 brain areas simultaneously (9 rats) or single units (6 rats per area) and time-lock activity to behavioral events. Overall rats show significant temporal discounting (ANOVA $p<.05$), making 60% (+/- 12) high value choices during 2s delay trials and only 40% (+/- 8) on 10s trials. We found an initial burst of theta/alpha activity during the choice selection followed by sustained beta activity coinciding with reward in the corticostriatal network (across 80 sessions). Beta activity is stronger for the immediate, low value reward compared to the delayed, high value reward. We collected 900 neurons from each area (~150 per rat) and found activity correlated to choice selection, the length of delay, anticipation, and reward value (high or low). We find evidence that the assigned value of reward is de-valued as delay length increases. Changes in electrophysiology correspond to trial x trial changes in discounting behavior as confirmed by correlational analyses. We have identified

neurophysiological markers in vivo that can be used as assays for pharmacological testing. Studying neural responses during tests of impulsivity will help inform where behavioral inhibition is impaired. [1]Dalley, Everitt, & Robbins (2011). Title: Sex differences in dopaminergic regulation of risky decision making.

Authors: *A.-R. WHEELER[1], L. M. TRUCKENBROD[1], A. M. BOEHNKE[2], E. M. COOPER[3], C. A. ORSINI[3];

Abstract: Risky decision making reflects the ability to weigh decisions based on risk versus reward. This process is crucial to navigating everyday circumstances, and impairments are implicated in many psychiatric conditions such as substance use disorders. Previous research has shown that dopaminergic neurotransmission modulates risk-based decision making by acting on brain regions within the mesocorticolimbic circuit, such as the basolateral amygdala (BLA). The majority of these studies, however, have only used male subjects. Given that there are sex differences in risk taking and dopaminergic manipulations of risk taking, it is prudent to determine whether similar dopaminergic mechanisms are involved in female risk taking. To do this, male and female rats were trained in the Risky Decision-making Task (RDT) in which rats choose between a small, safe food reward and a large, risky food reward that is accompanied by an increasing risk of mild footshock punishment. In Experiment 1, rats were trained in the RDT and then received systemic injections of the D2 dopamine receptor (D2R) agonist bromocriptine prior to RDT testing. Bromocriptine decreased lever pressing for the large, risky reward in both male and female rats, but affected choice behavior in females at lower doses that were ineffective in males. To determine the neural substrate underlying such sex differences, rats in Experiment 2 were trained in the RDT and then received intra-BLA infusions of the D2R agonist quinpirole prior to RDT testing. Intra-BLA infusions of quinpirole decreased choice of the large, risky reward (decreased risky choice) in females, but had no effect in males. Further, this reduction in risky choice in females was accompanied by an increase in sensitivity to punishment and a decrease in sensitivity to rewards relative to vehicle conditions. In the final experiment, rats received intra-BLA infusions of the D2R antagonist eticlopride prior to being tested in the RDT. Eticlopride had no effect on risky choice in male or female rats. Considered together, these data indicate that sex differences in risk

taking may be due to differential D2R sensitivity in the BLA, with greater sensitivity in females contributing to phenotypical female risk aversion. Future experiments will use a similar experimental design to investigate the role of D1 dopamine receptors in the BLA in risk taking in males and females and evaluate whether sex differences in dopaminergic input to the BLA contributes to differential BLA D2R sensitivity between sexes.

Title: Cognitive relationships underlying risky decision making in male and female rats

Authors: *L. M. TRUCKENBROD[1], E. M. COOPER[2], A.-R. WHEELER[1], C. A. ORSINI[2];
[1]Neurosci., [2]Psychology, Univ. of Texas, Austin, TX

Abstract: The ability to properly evaluate the relative potential risk or reward of our actions is a hallmark of healthy cognitive function. Previous work has shown that individual differences in risk-based decision making (risk taking) are associated with cognitive ability in other executive functions, which, collectively, has implications for identifying vulnerabilities that may predispose individuals to develop neuropsychiatric diseases. Notably, the majority of these studies have been conducted in males, despite sex differences in risk taking. To address this, we behaviorally characterized male and female Long-Evans rats in a rodent model of risky decision making ("Risky Decision-making Task"; RDT) in which rats choose between a small, "safe" reward and a large, "risky" reward accompanied by an increasing probability of a mild footshock delivery. After reaching behavioral stability in the RDT, rats were tested in a battery of cognitive tasks to identify relationships between risk taking and several measures of executive function in both males and females. Replicating previous work, females were more risk averse than males in the RDT. There were no sex differences in impulsive choice, risk taking involving uncertainty of reward delivery, working memory ability, or motivation to work for a food reward. Females, however, displayed greater cognitive inflexibility than males in a set-shifting task. Although there were no significant correlations between choice behavior in the RDT and probability discounting, there was a near significant sex-specific correlation with risk taking and impulsive choice in females, such that greater risk aversion was associated with greater impulsive choice. Similarly, greater risk aversion predicted better working memory ability only in females. In contrast, greater risk taking in males was associated with a greater number of errors during set shifting. There was no relationship between risk taking and motivation to work for food in either sex. Overall, our data suggest that distinct underlying cognitive processes mediate risk-based decision making in males and females. Specifically, the ability to make adaptive risk-based decisions in males appears to depend on the ability to flexibly shift behavioral

responses as choice contingencies change. Alternatively, female risk taking may depend on the ability to retain information about past outcomes in working memory to guide future choice behavior. Future studies will examine whether such sex differences in the cognitive mechanisms underlying risk taking are mediated by distinct neural processes in brain regions such as the basolateral amygdala.

Abstract: The hippocampus (Hc) and its associated functional brain networks are necessary for normal declarative/relational memory. Relational memory has been shown to improve throughout childhood, and these improvements may result from developmental changes to the Hc and its functional networks. However, neurodevelopmental changes to functional brain networks associated with hippocampal memory abilities are not well characterized, particularly in periadolescent individuals. Therefore, we used a cross-sectional approach to explore whether individual differences in hippocampal functional connectivity were associated with enhanced relational memory abilities in periadolescent children. To do so, we utilized preliminary data from our ongoing NIA-funded Polygenic Risk of Alzheimer's Disease in Nebraska Kids (PRANK) study, which is recruiting healthy periadolescent individuals in order to better understand how brain and cognitive development is affected by polygenic risk for Alzheimer's disease. The present work describes our preliminary findings examining whether individual differences in hippocampal resting-state functional connectivity (RSFC) covary with outcomes on a test of declarative/relational memory ability in periadolescent children. We conducted our analysis on preliminary data from healthy periadolescent participants (N=60; age 8-13 years). To assess declarative/relational memory ability, we used Cambridge Cognition's Paired Associates Learning (PAL) task. Resting-state functional MRI analyses were conducted using a seed-based approach with the bilateral hippocampus as the seed region of interest. Hippocampal RSFC data were then analyzed to determine their covariance with relational memory ability (operationalized as PAL performance). Broadly consistent with prior work, we observed patterns of hippocampal RSFC that overlapped ventral and lateral portions of the default mode network (DMN). In more novel findings, we also observed regional

covariance between hippocampal RSFC and performance on the PAL test of relational memory ability. Here we report preliminary findings of the ongoing PRANK study. Our initial observations are consistent with the perspective that hippocampal RSFC covaries regionally with hippocampal-dependent declarative/relational memory ability among periadolescent children. To understand whether this hippocampal network development is susceptible to genetic risk factors for AD, future work from the PRANK study will utilize participants' AD polygenic risk scores to determine whether those scores are related to individual differences in hippocampal RSFC.

Abstract: Cognitive abilities and the brain's intrinsic functional networks undergo change throughout the lifespan, but pathologies such as Alzheimer's disease (AD) alter normative developmental trends. It is possible that early-life brain and cognitive development modulates vulnerability to neuropathologies in later life. Here, we used a cross-sectional approach to characterize the organization of brain networks and memory abilities in periadolescent children. Data were drawn from the Polygenic Risk of Alzheimer's Disease in Nebraska Kids (PRANK) study. Our goal is to evaluate whether early-life functional brain development may modulate vulnerability to late-onset AD. To characterize the relationship between network properties of the brain and hippocampal-dependent memory, we studied cognitive and brain measures in a preliminary sample of periadolescent children (N=60) from the PRANK study. Cognitive assessment included a standardized, paired-associates learning task (from the CANTAB battery); the task requires hippocampal-dependent relational memory. Brain structure and function were assessed with MRI protocols adapted from the Human Connectome Project. Resting-state fMRI data were used to measure resting state functional connectivity which supported our investigation of brain network properties. Analysis focused primarily on the measurement of whole-brain network properties. We observed that periadolescent network organization exhibited segregation of functional networks that was qualitatively

similar to that previously reported in young adults. Analysis of the association between modularity and performance on the CANTAB task yielded a non-significant but numerically positive association. Our ongoing study measures the association of brain variables, cognitive performance, and AD polygenic risk score in periadolescent children. This preliminary analysis of brain and cognitive measures illustrates functional network properties of the periadolescent brain with a focus on associations with cognitive performance. Future directions include longitudinal analysis assessing the association between changes in modularity and changes in cognitive performance as well as examining the association between AD polygenic risk score and the same network properties.

Title: Measuring covariance between spatial working memory performance and resting state functional connectivity in periadolescent children: preliminary findings from the PRANK study.

Authors: *A. HELLER[1], C. PHIPPS[1], J. SEXTON[1], M. RAMIREZ[1], L. BEHM[1], T. DECESARE[1], J. BLAIR[2], A. MAERLENDER[3], V. PHATAK[1], J. CRAMER[1], D. MURMAN[1], D. WARREN[1]; [1]Univ. of Nebraska Med. Ctr., Omaha, NE; [2]Boys Town Natl. Res. Hosp., Omaha, NE; [3]Unversity of Nebraska Lincoln, Lincoln, NE

Abstract: Periadolescence is a neurodevelopmental period that can be characterized by expansive cognitive development and substantial changes to the brain's functional networks. These functional networks support cognition, and during periadolescence, the frontoparietal (FPN), default mode (DMN), and dorsal attention (DAN) networks exhibit within and between network changes associated with maturation of cognitive abilities, including various aspects of memory. Spatial working memory (SWM) is a cognitive ability involving the rapid, flexible storage and retrieval of (visuo)spatial information, and it is one type of memory that exhibits significant improvement during periadolescence. SWM ability in adults has previously been associated with differences in resting state functional connectivity (rs-FC) within the FPN and DMN. However, the relationship between SWM and FPN/DMN/DAN connectivity has not been characterized in the periadolescent epoch. The current study tested the association between rs-FC and SWM performance in a group of healthy periadolescent children aged 8 - 13 years (N=60). Participants completed the Cambridge Neuropsychological Test Automated Battery (CANTAB) implementation of a spatial working memory task, and they also underwent an MRI study to assess rs-FC. Analysis of covariance between rs-FC of the DMN and task performance (SWM) suggested greater

within-network connectivity was associated with greater SWM task performance; a similar pattern was observed in the (left) FPN. Further, there was some evidence that reduced between-network connectivity in regions resembling the DMN and FPN was also associated with greater SWM scores. Exploratory analysis of age and sex as covariates revealed patterns of varying rs-FC as well. Greater within-network connectivity in the DMN, DAN, and FPN was associated with greater age. Sex-associated differences were also observed, as males appeared to have greater connectivity to parietal regions in the DAN. Characterizing changes in these networks during periadolescence in relation to cognition is an important prerequisite to understanding whether the development of functional brain networks may reveal or drive late-life vulnerability to neurological diseases including Alzheimer's disease.

Abstract: Throughout development the brain undergoes significant structural and functional changes that are associated with substantial cognitive changes, and this maturational trajectory continues during the periadolescent epoch. One such change is the enhancement of relational memory abilities. The hippocampus is necessary for normal declarative/relational memory as demonstrated by the hallmark memory deficits of Alzheimer's disease and its accompanying hippocampal pathology. Vulnerability to AD and other memory deficits later in life may be modulated by childhood brain development, and this motivates investigation of the brain's developmental trajectory and associations with AD-vulnerable cognitive abilities including memory. Our ongoing NIA-funded study, the Polygenic Risk of Alzheimer's Disease in Nebraska Kids (PRANK) study, measures brain structure, function, and cognitive abilities in periadolescent children (age 8-13 years) and will tests whether these variables are associated with AD polygenic risk score. Here, we report preliminary data measuring hippocampal-dependent relational

memory in a task-based fMRI study using a subsequent memory paradigm. A periadolescent sample from the PRANK study provided data for the current project (N=60). MRI data were collected using protocols adapted from the Human Connectome Project. We tested hippocampal dependent relational memory using a subsequent memory task where participants were asked to study pairs of common objects while fMRI-BOLD data were collected. Participants then completed a memory test for the studied materials including two types of stimuli (studied match pairs or non-studied mismatch pairs). For subsequent memory (SM) of pairs there was preliminary evidence that successful SM was associated with increased activity in lateral prefrontal and lateral parietal regions consistent with the frontoparietal networks, in addition to other regions. Additionally, there was some evidence of regionally specific hippocampal activation (anterior hippocampus) associated with successful SM. Findings from this preliminary analysis are novel in this population but congruent with previous studies of older and younger individuals.

Title: Investigating the relationship between relational memory abilities and hippocampal volume in typically developing periadolescent children: preliminary findings from the PRANK study

Authors: *J. SEXTON[1], C. PHIPPS[1], M. RAMIREZ[1], L. BEHM[1], T. DECESARE[1], A. HELLER[1], A. MAERLENDER[2], V. PHATAK[1], J. CRAMER[1], J. BLAIR[3], D. MURMAN[1], D. WARREN[1]; [1]Univ. of Nebraska Med. Ctr., Omaha, NE; [2]Univ. of Nebraska at Lincoln, Lincoln, NE; [3]Boys Town Natl. Res. Hosp., Omaha, NE

Abstract: There are considerable changes in brain structure, brain function, and cognition during childhood. For example, the maturation of cognitive processes supporting memory for arbitrary relations continues during the periadolescent epoch. The hippocampus is necessary for normal declarative/relational memory, as seen by the dramatic memory deficits seen in patients with Alzheimer's disease (AD) and the underlying hippocampal pathology. It is hypothesized that vulnerability to AD could be modulated by early brain development, so understanding the developmental relationship between hippocampal volume and declarative/relational memory performance would provide an important baseline for comparison of different trajectories. The Polygenic Risk of Alzheimer's Disease in Nebraska Kids (PRANK) study is an ongoing NIH-funded study that assesses brain structure, brain function, cognition, and polygenic risk score for Alzheimer's disease in periadolescent children (age 8-13). Here, we provide early findings from a sample of subjects from the PRANK study (N=60) investigating hippocampal volume and relational memory. Cognitive variables included relational memory

operationalized as performance on the Picture Sequence Memory Task (PSMT) from the NIH Toolbox (a standard neuropsychological battery). Structural MRI data were collected using protocols adapted from the Human Connectome Project, and hippocampal volume was measured through manual tracing. We then tested the correlation between hippocampal volume (left, right, and bilateral) and performance on the relational memory task in periadolescent children and found preliminary evidence consistent with associations between hippocampal volume and memory performance on the PSMT. Findings from this preliminary analysis illustrate the relationship between brain structure and cognitive abilities during the periadolescent period, in particular, the association between declarative/relational memory and hippocampal volume. Our ongoing PRANK study measures cognitive abilities, brain structure and function, and Alzheimer's polygenic risk score in periadolescent children. Future work from this study will investigate whether polygenic risk for AD is associated with individual differences in brain structure and neuropsychological profile in early life.

Title: Latent states learning in changing environments

Authors: *L. Q. YU[1], A. R. VAIDYA[2], M. R. NASSAR[1];
[1]Dept. of Neurosci., [2]Dept. of Psychology, Brown Univ., Providence, RI

Abstract: People can learn flexibly and adaptively in response to changing environments, but there is great variability in the extent to which they do so. An important aspect of adaptive learning is the ability to infer the underlying causes of the outcomes in one's environment, which are known as latent states. Representation of latent states could allow the brain to effectively segregate perceptually similar outcomes according to the causes that gave rise to them, to reduce interference and thereby improve learning. Latent state representations have been identified in humans using fMRI in prefrontal regions that include the orbitofrontal cortex and dorsolateral prefrontal cortex. However, evidence for the functional significance of these representations has been limited due to a lack of behavioral variability in the tasks used to isolate them. We developed a novel predictive inference paradigm that requires participants to learn about outcomes from a generative structure that alternates between two stimulus-dependent outcome contingencies, either with a cue alerting the participant to the contingency change, or without a cue. A key advantage of our task over standard reversal learning paradigms is that it disentangles latent states from both stimuli and actions, thereby allowing us to test whether representations of latent state can explain differences in learning patterns across individuals and cue conditions. We collected behavior on this task

while 25 participants underwent fMRI scanning, and collected additional measures related to IQ, decision-making and cognitive functioning. We found that, on average, participants in both the cued and uncued conditions improved on a key behavioral readout of latent state learning: the error on the first trial in a state was progressively reduced after every instance of returning to that state, indicating that participants leveraged previous learning in that state in their responses. However, the degree to which people used latent states to learn varied across participants. Here we examine whether dynamic latent state representations in the brain (identified using representational similarity analysis of fMRI data) can explain these behavioral differences. In doing so, we provide a direct test of the functional link between latent state representations in the brain and the computational role they are thought to play in learning.

Title: Neural representations supporting valuation based on schemas and experience

Authors: *A. VAIDYA, D. BADRE;
Brown Univ., Providence, RI

Abstract: Judging the utility of complex real-world objects often depends on structured, schema-level knowledge about these objects and their relationship to current goals. This capacity allows us to make quick inferences about the value of options without any feedback or prior experience - enabling highly flexible behavior in response to novel problems. However, the representations the brain uses to achieve this rapid transformation of schemas to value judgments remains unclear. In an fMRI experiment, we asked twenty-three participants to make risk-based decisions about items based on values inferred from task knowledge and learned through direct experience. Using a behavioral model fit to these data, we generated trial-wise predictions for the values of items based on the experienced and schema-based values of options. In previously published work, model-based fMRI revealed that the ventromedial prefrontal cortex (vmPFC) encoded information about values inferred from schema-based knowledge as well as direct experience, and that schema-based valuation engaged communication between vmPFC and middle temporal cortex. In the current study, we have re-analyzed these data using model-based multivariate methods to test how patterns of voxel activity represent value signals that we predict are used for decision-making in this task. Model-based predictors were used to create trial-wise hypothesis representational dissimilarity matrices (RDMs) that we regressed against neural RDMs in an fMRI searchlight analysis. We find representations consistent with experienced and schema-based values are maintained in overlapping brain networks in prefrontal cortex and the precuneus distinct from representations of task-relevant semantic knowledge in middle temporal cortex. These results provide

new insight into the representational schemes used by different brain regions in the service of value judgement based on experience and structured world knowledge.

Title: Adaptive learning through temporal dynamics of state representation

Authors: *N. RAZMI[1], M. R. NASSAR[2];
[1]Dept. of Neurosci., Brown Univ., providence, RI; [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: People adjust their sensitivity to incoming information rapidly and in accordance with statistical properties of different environments. This adaptive learning behavior has been emulated in error-driven learning models by adjusting a parameter called the "learning rate ". Despite the success of this approach in explaining behavioral performance of humans, experimental studies have fallen short of finding a neural signature of this dynamic learning rate that persists across different statistical environments. Previously identified learning signals, such as the feedback locked p300, seem to relate to behavior differently in different environments. Here, we propose a new theoretical framework of adaptive learning by designing a neural network model that learns to map an internal context representation, or latent states, onto a behavioral response via supervised learning. We used a two-layer feedforward network in which latent states could be represented in the input layer. The "synaptic learning rate" used in our network was held constant – such that all learning dynamics are afforded by trial-to-trial adjustments of the latent state representation. We show our model can either increase or decrease learning through latent state transitions, depending on the structure of the environment. Such internally driven latent state transitions allow the model to achieve near optimal performance in predictive inference tasks across different environments. In an environment with changepoints, the pattern of activity in the latent state layer qualitatively matches dynamics of patterns of activation previously been observed in orbitofrontal cortex of humans, and yields faster learning in response to unexpected outcomes. In contrast, in an environment with one-off outliers, the network decreases learning from large errors through transient latent state transitions that partition learning from oddball events. The degree of latent state transition in our model is positively correlated with learning in the changepoint environment and negatively correlated with learning in the oddball environment, providing a potential mechanistic explanation for bidirectional signals such as the feedback locked p300, and providing a possible solution to the missing link between the neural signals of learning in the brain and the adaptive behavior they facilitate. In conclusion, we suggest that dynamic latent state representations can provide a coherent framework for linking neural correlates of adaptive learning across to their behavioral consequences across different statistical environments.

Title: Midfrontal theta relates to learning in a bidirectional and context dependent manner

Authors: *T. LI[1,2], M. SINGH[3], R. BRUCKNER[4,5], M. J. FRANK[2,6], M. NASSAR[1,2];
[1]Brown Univ. Dept. of Neurosci., Providence, RI; [2]Brown Univ. Carney Inst. for Brain Sci., Providence, RI; [3]Brown Univ. Undergraduate Dept. of Biol., Providence, RI; [4]Intl. Max Planck Res. Sch. LIFE, Berlin, Germany; [5]Freie Univ. Berlin, Berlin, Germany; [6]Brown Univ. Dept. of Cognitive, Linguistic & Psychological Sci., Providence, RI

Abstract: Theta band power over the mid-frontal cortex has been implicated in the neural basis of cognitive control. Existing theories have posited that theta may enhance learning in order to mediate behavioral updating. However, an alternate account is that theta plays a role in updating latent states, which reflect unobservable context and provide a way for the brain to learn different behavioral policies for different contexts. A role for theta in updating latent states could in principle promote either faster or slower learning, depending on exactly how latent states are updated. Here we re-analyze data from a modified predictive inference task where these two alternative accounts can be dissociated to determine whether theta is more closely related to the updating of behavior, or latent states. The task required participants to iteratively predict the aim of an unobservable cannon based on cannonballs shot from it. Predictions were made in two contexts that differed in the persistent versus transient nature of transitions of the latent state giving rise to cannonballs. In a changepoint context, the cannon occasionally re-aimed completely, producing changes in latent state that persisted in time, necessitating rapid behavioral updating. In the oddball context, surprising cannonball locations reflected one-off events, or transient changes in latent state, that should yield reduced behavioral updating. Recent modeling work from our group has suggested that normative behavioral adjustments in both environments can be achieved through adjustment of internal latent states that serve to partition learning across contexts to prevent interference. To examine whether mid-frontal theta is more closely related to adjustment of behavior or latent states, we first extracted theta power (4-7Hz) from the EEG responses for each channel, trial and time point and analyzed it using a mass univariate approach. Second, we examined how theta related to behavior by including it in a regression model that explained trial-to-trial variability in learning. We observed stronger theta signals during surprising trials in both contexts. However, we found that the relationship between theta power and learning depended on statistical structure. In the changepoint context, learning rate was positively correlated with theta signal strength, whereas in the oddball context, learning rate was negatively correlated with theta signal strength. Taken together, these results suggest that the theta signal does not directly reflect behavioral updating, but instead may reflect updating of latent states, which in turn can be used to adjust learning appropriately depending on the statistical context.

Title: Investigating the neuronal patterns underlying short term memory using a novel tactile task

Authors: *S. SOMECK, H. SLOIN, E. STARK;
Tel Aviv Univ., Tel Aviv, Israel

Abstract: The ability to store information for short periods of time and act upon that information is one of the most fundamental functions of living organisms. Persistent and sequential activity have been observed during short-term memory (STM) tasks in multiple animal species and brain areas. However, a causal relation between specific types of multi-neuronal patterns and STM maintenance has never been derived. Many STM tasks designed for lab animals can be performed successfully by "bridging" the delay: storing the sample or correct response using bodily configurations. To minimize the possibility of bridging, we developed a spatial tactile STM task for mice based on delayed comparison. The apparatus consists of a figure-8 maze with two pairs of motorized texture wheels situated 1.2 m apart. Each wheel-pair contains five distinct textures. In the full STM task, the animal has to turn right if the textures on the two wheel-pairs are identical, and left if the textures are distinct. The 25-combination delayed comparison design prevents response bridging and minimizes the possibility of sample bridging. Using a single pair of wheels yields a discrimination task on the same apparatus. Four mice learned the discrimination task within a week; after learning, the median number of trials per session was 133, and the median success rate was 83%. Two mice learned the memory task within two weeks (144 trials, 64% success). To establish a link between task performance and local network activity, we recorded multi-neuronal spiking activity from hippocampal region CA1 as the mouse learned the discrimination task (eight sessions). 138 of 170 well-isolated units had place-fields on the apparatus. During the sessions in which the animal already performed the task successfully, 27/63 (42%; five sessions) of the units exhibited task-oriented place fields: near the reward, choice or active wheels. In contrast, during the learning sessions, only 5/75 (7%; three sessions) units were task-oriented. The results suggest that CA1 place cells may be relevant to the spatial tactile task.To manipulate the local network at a high spatiotemporal resolution, we implanted μLED probes in the neocortex of two other freely-moving mice. Recording and manipulation sessions were carried out over three months. Synthetic multi-neuronal pyramidal cell spiking sequences were produced in the hippocampus.The combination of a novel behavioral task, high-density electrophysiological recordings, and neuronal-resolution optogenetic manipulations will allow determining which neuronal patterns underlie STM.

Title: Demonstrating the priming phenomenon in mice

Authors: *S. SIVRONI[1,2,3], H. SLOIN[1], E. STARK[1];
[1]Dept. of Physiol. and Pharmacology, Sackler Med. School, and Sagol Sch. of Neurosci., Tel Aviv Univ., Tel Aviv, Israel; [2]Mathematics, Afeka Tel Aviv Academic Col. of Engin., Tel Aviv, Israel; [3]Mathematics, The Open Univ., Raanana, Israel

Abstract: Priming is a form of implicit short-term memory (STM), defined as a change in the ability to process an object as the result of a recent encounter with that object. Priming is a key part of our daily life and has been studied extensively at the cognitive level. The hippocampus (HPC) and the posterior parietal cortex (PPC) are active throughout STM and during processing of sensory inputs and are thus possible loci for supporting priming. Yet currently, there is no information whatsoever about the electrophysiological basis of priming. Furthermore, there is no behavioral model for studying priming in lab animals. Here, we first developed a novel behavioral paradigm for studying priming in freely-moving mice. In the mouse priming task, the animals were exposed to three water ports. The mice had to associate a 5 kHz/300 ms auditory "target" stimulus with reward in the left port, and a 10 kHz/300 ms stimulus with reward in the right port. "Prime" stimuli were shorter (5-15 ms) tones that preceded the "target" stimuli. Two types of prime stimuli were used: congruent (same frequency as the target), and non-congruent. We defined "prime effect" as the difference in success rate between congruent trials and non-congruent trials. Four mice were trained on the auditory task. We found a consistent prime effect. Diagnosing behavioral priming in mice implies that priming is not limited to humans or primates. Next, we assessed neural correlates of auditory inputs in HPC. For that, we combined high-density silicon probe (64-128 sites, Diagnostic Biochips) recordings from freely-moving mice (n=3) with playback of auditory pure tones (2-16 kHz) and band-limited white noise. We discovered novel neural correlates of pure tones in HPC. In CA1 stratum oriens, pure tones induced auditory evoked potentials (AEP) that exhibited a positive peak ~20 ms after stimulus onset. The 20 ms from sound onset to AEP extremum was accompanied by increased spiking of CA1 pyramidal cells. AEPs were also observed in the dentate gyrus (DG), but with reversed polarity: negativity in the top half of the layer, and positivity in the bottom half. The results suggest that the HPC contains multiple distinct AEP generators. Together, the novel mouse model of non-conscious priming and the auditory responses observed in the HPC open the door for electrophysiological investigation of implicit STM in freely-moving mice.

Title: Cortical Sensing for determining the neural mechanisms underlying learning

Authors: *A. LEVI[1], E. STARK[2];
[1]Sagol school of neuroscience, Tel Aviv Univ., tel aviv, Israel; [2]Dept. of Physiol. and Pharmacol., Tel Aviv Univ., Tel Aviv-Yafo, Israel

Abstract: Despite the importance of learning, defined inter alia as the process by which organisms change their behavior as a result of experience, the underlying neuronal mechanisms are not fully understood. Learning is most commonly studied in animals using a standard paradigm in which an animal is required to learn the correct response to sensory stimuli. Indeed, correlative evidence linking changes in neuronal network activity following acquisition of stimulus-response associations is abundant. Nevertheless, a causal link between multi-neuronal neocortical activity and learning has never been demonstrated. Moreover, the way information available in neuronal patterns is utilized by downstream networks is unclear. Learning is intuitively viewed as the brain adapting to external stimuli, but all stimuli are eventually translated into neuronal activity patterns. Therefore, learning can be defined as the brain adapting to its own activity. To determine the neuronal mechanisms underlying learning, we conceived an approach we term Cortical Sensing. The idea behind Cortical Sensing is to bypass the sensory-to-neuronal transformation and directly generate coding-relevant neuronal activity patterns in the cortex of freely-moving mice. By using a host of different types of injected activity patterns and monitoring learning behavior, we can deduce which neuronal activity patterns can be learned best. For Cortical Sensing to succeed, a behavioral task that will guarantee ideal conditions for learning of a new set of rules is required. Specifically, to allow high-throughput screening of multiple activity patterns in the same animal and ensure recording and stimulation stability, single-session learning is required. We trained mice (n=3) on a binary discrimination task, in which the rules of the task change between days. Over multiple sessions, all mice learned that attention is needed in each session to learn whether a new set of rules controls the task. Eventually, all three mice exhibited single session learning of external visual stimuli. One CaMKII:ChR2 mouse that achieved single session learning was also subjected to Cortical Sensing experiments. Different types of neuronal patterns were induced in hippocampal CA1 pyramidal layer. The animal was able to learn a frequency dependent cortical rule, but unable to learn a rate dependent set of rules. Cortical Sensing is expected to shed light on the way the brain responds to its own pattern of activity and by that extend our knowledge of neural mechanisms underlying learning. Title: Functional connectivity of hippocampal subfields in an elderly population.

Authors: *L. EZAMA[1], E. PEREDA[1], J. A. HERNÁNDEZ-CABRERA[1], M. A. YASSA[2], N. JANSSEN[1];
[1]Univ. of La Laguna, San Cristóbal de La Laguna, Spain; [2]Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: One of the main risk-factors in many neurological diseases is the age of the person. Therefore, understanding how the brain ages could provide us with more information about many diseases. Previous literature in neuroimaging has highlighted the role of a brain structure called the hippocampus in aging (West, 1993; Jack et al., 1997; Driscoll et al., 2003). The hippocampus is composed of the subfields Cornu Ammonis; CA1, CA2, CA3 and CA4; the dentate gyrus and the subiculum (Cajal, 1911). The size of these subfields is very small (~ 1mm in cross section), and their folding pattern is conserved along the longitudinal axis of the hippocampus (Insausti & Amaral, 2004). However, due to the small size of these subfields, their changes throughout aging remain poorly understood. Other studies have suggested that the most notable changes in hippocampal volume occur in older age groups (Schuff et al., 1999; Resnick et al., 2000; Scahill et al., 2003; Stark et al., 2021). Thus, here we observed how aging affects the volume of hippocampal subfields, and how aging affects functional connectivity between hippocampal subfields and DMN regions. The dataset concerned a group of 77 healthy participants over 60 years old (BEACON dataset, UCI) assigned to two groups based on a mean split ("young" group, mean age 67 yrs; "old" group, mean age 77 yrs). Our structural analyses relied on Freesurfer (v6.0) and LME regression model including the fixed effect variables hemisphere (left vs right), age group (young vs old), hippocampal section (head, body, tail) and subfield (CA1, CA2/3, CA4, DG, ML, SUB, PRESUB). Our functional analyses relied on spatially-restricted ICA and Dual Regression to obtain functional connectivity between hippocampal activity clusters and DMN regions on a by-participant basis. The structural results revealed a significant triple interaction between age group, hippocampal section, and subfield ($F(6,2025)=7.14, p<0.0001$). Post-hoc comparisons revealed a significant reduction in the volume of subiculum in the body of the hippocampus between the old and the young group, and a significant reduction in volume of the CA1 subfield in the head of the hippocampus between the old and the young group. The functional results showed how the DMN relied primarily on activity in CA4, DG and presubiculum subfields, and less on CA1 and CA3. In addition, comparing this connectivity between the two different age groups we found that age mostly affected connectivity in the subiculum ($p<0.05$) and the CA4 ($p<0.02$) subfields. These results clarify how different subfields of the longitudinal axis of the hippocampus such as the CA4 or the Subiculum play a different role in the resting-state networks.

Title: Cracking the fundamental neural code of the hippocampal CA1 apical dendritic system: A non-linear transfer function for a key node in the hippocampal circuitry.

Authors: *S. GATTAS[1], A. A. LE[2], B. PRUESS[1], A. SWINDLEHURST[1], G. LYNCH[1], M. A. YASSA[3]; [1]Univ. of California, Irvine, Irvine, CA; [2]Anat. and Neurobio., Univ. of California Irvine, Irvine, CA; [3]Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: Mathematical formulas that fully capture the governing dynamics of synaptic transmission are required for a biologically realistic physical construction of brain networks as well as gaining insight into their fundamental operations. We investigated the feasibility of establishing such a formula - a transfer function for the CA3 to CA1 connection of the hippocampus. Contrary to the field's general belief, in vitro slice experiments indicated that these synapses behave in a nonlinear fashion. We used randomly spaced activation of CA3 projections and the Volterra expansion technique for nonlinear system identification of the CA3-CA1 system. The resultant transfer function reveals the operations the CA1 performs (i.e. attenuation, amplification, linear and nonlinear filtering based on inputs characteristics) and reproduced the continuous waveform of recorded CA1 fEPSP responses with minimal error. Surprisingly, the nonlinear component of the transfer function, which reflects the influence of the temporally adjacent inputs on the output, played an increasingly dominant role in shaping the waveform of responses with input magnitude. The transfer function reported here accurately reproduced fEPSPs collected from a second set of animals and thus appears to describe a fundamental rule for an essential link in hippocampal circuitry. This work paves the path to uncovering such rules for other components of the hippocampal network as well as other brain networks.

Abstract: Obstructive sleep apnea (OSA) is a sleep disorder characterized by frequent pauses in breathing during sleep causing intermittent hypoxia and sleep fragmentation. If left untreated, OSA is associated with damage to the hippocampus which is thought to underlie OSA-related cognitive impairment. The hippocampus, specifically the DG/CA3 subfields, are implicated in pattern separation—the ability to differentiate highly similar experiences as unique events. Recent research has demonstrated that overnight sleep supports mnemonic discrimination (a behavioral correlate of pattern separation) in young adults. However, less is known about the impact of sleep, or sleep disorders such as OSA, on mnemonic discrimination in older adults. Additionally, while recent work has demonstrated that OSA impacts sleep-dependent memory consolidation in several domains, it is unclear whether OSA impacts the consolidation of emotional memories which typically exhibit a sleep benefit. This study aimed to determine whether OSA severity influences sleep effects on mnemonic discrimination of highly similar emotional experiences in older adults. Eighteen cognitively healthy older adults (μ=73.1±5.3, 10F) were evaluated with overnight polysomnography and measures of OSA severity and blood oxygen desaturation were derived. Participants completed the emotional version of the Mnemonic Discrimination Task prior to and following overnight sleep. The Lure Discrimination Index (LDI) was derived to assess mnemonic discrimination and sleep-dependent memory consolidation was measured by calculating overnight change in LDI. Discrimination of highly similar negative stimuli significantly deteriorated following overnight sleep whereas positive and neutral stimuli were relatively preserved. Metrics of OSA severity were consistently positively associated with overnight change in LDI for negative high similarity stimuli. The frequency, duration, and extent of blood oxygen desaturations appear to drive this relationship. These data may suggest that while sleep is generally associated with a loss of high-fidelity negative memories in older adults, OSA severity may exert the opposite effect to promote overnight retention of highly detailed negative experiences. These findings further suggest that blood oxygen desaturation may be a mechanism by which OSA increases risk for mood disorders, such as depression which is associated with a negative memory bias.

Title: Latent anxiety in clinical depression is associated with worse recognition of emotional stimuli

Authors: *S. GRANGER[1], J. ADAMS[3], S. M. KARK[3], M. T. SATHISHKUMAR[3], I. Y. CHEN[3], R. M. BENCA[2], L. MCMILLAN[3], J. T. JANECEK[3], M. A. YASSA[4];

Abstract: Major Depressive Disorder, characterized by cognitive affective biases, is a considerable public health challenge. Past work has shown that higher depressive symptoms are associated with augmented mnemonic discrimination of negative stimuli. In contrast, anxiety symptoms have been associated with overgeneralization of emotional memories. Given the high comorbidity of depression and anxiety, it is critical to understand how cognitive affective biases are differentially associated with clinical symptoms. We used continuous measures of depression (Beck Depression Inventory [BDI-II]) and anxiety (Beck Anxiety Inventory [BAI]) to evaluate an adult sample (N=79; 18-41 years old, 58 female). Emotional lure discrimination performance and target recognition were tested using an emotional discrimination task. We applied exploratory factor analysis to questions from the BAI and BDI-II to uncover latent constructs consisting of negative affect, anhedonia, somatic anxiety, hyperarousal, and cognitive anxiety. We report evidence that anxious symptoms were associated with impaired recognition of negative items after accounting for depressive symptoms. Our exploratory factor analysis revealed that impaired negative item recognition is largely associated with somatic and cognitive anxiety factors. Interpretations in a mixed pathology sample, especially given collinearity among factors, may be difficult. We provide evidence that somatic and cognitive anxiety are related to impaired recognition memory for negative stimuli. Future clinical investigations should uncover the neurobiological basis supporting the link between recognition of negative stimuli and somatic/cognitive symptoms of anxiety.

Title: Redesigning Highly Superior Autobiographical Memory (HSAM) Assessment Tools with Confidence: The Event Recognition Task

Authors: *L. STITH[1], V. NYE[1], J. ADAMS[1], M. A. YASSA[2];
[1]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: Although impaired memory and amnesic syndromes have been highly researched and as a result have widespread literature, not much is known about superior forms of memory. One form of superior memory, known as Highly Superior Autobiographical Memory (HSAM), was first identified in an individual by Dr. James L. McGaugh and colleagues in 2006. Since then, dozens of people have contacted researchers, eager to find out if they too have this condition. The current HSAM assessment's limited pool of questions hinders individual performance on the test due to lack of specific knowledge, instead of measuring actual memory ability. In order to identify HSAM ability to further superior memory research, a reliable and valid test must be formulated. This study devised an assessment tool, the Event Recognition Task (ERT), with the goal of correctly identifying individuals with HSAM abilities. The ERT increases the pool of questions and implements a ranking system, allowing for subjects to choose preferred topics, reducing the effect of the subject's specific domain knowledge on performance. Questions are selected based on custom-weighting that takes into consideration individual expertise and preferred topics. Additionally, the ERT assesses confidence ratings, a novel measurement in HSAM individuals. We describe the ERT and its properties, as well as benchmark it against the original assessment tools. We hope the ERT and its adaptive design will be a more valid way to detect and assess HSAM memory abilities due to the assessment being personalized for each study participant and removing the effect of specific domain knowledge and expertise on memory performance.

Title: Modulating amygdala activation to traumatic memories with a single ketamine infusion

Authors: *O. DUEK[1], Y. LI[2], C. GORDON[3], B. KELMENDI[2], S. L. AMEN[2], J. H. KRYSTAL[2], I. LEVY[4], I. HARPAZ-ROTEM[2];
[1]Yale Med. Sch., New Haven, CT; [2]Yale Univ. Sch. of Med., New Haven, CT; [3]Yale Sch. of medicine, New Haven, CT; [4]Section of Comparative Med., Yale Sch. of Med., New Haven, CT

Abstract: NMDA receptor antagonists have a vital role in extinction, learning, and reconsolidation processes. During the reconsolidation window, memories are activated into a labile state and can be stored in an altered form. This concept might have significant clinical implications in treating PTSD.

Using amygdala activity as a major biomarker of fear response, we tested the potential of a single subanesthetic intravenous infusion of ketamine (NMDA receptor antagonist) to enhance post-retrieval extinction of PTSD trauma memories. Post-extinction, ketamine recipients (vs midazolam) showed a lower amygdala and hippocampus reactivation to trauma memories. Post-retrieval ketamine administration was also associated with decreased connectivity between the amygdala and hippocampus, with no change in amygdala-vmPFC connectivity, which suggests that ketamine may enhance post-retrieval extinction of PTSD trauma memory in humans. These findings demonstrate the capacity to rewrite human traumatic memories and to modulate the fear response for at least 30 days post-extinction.

Title: Exogenous administration of βeta-hydroxybutyrate (BHB) improves cognition in healthy participants

Authors: *A. C. GLUECK[1], D. Y. HAN[2];
[1]Neurol., Univ. of Kentucky, Lexington, KY; [2]Neurol., Univ. of Kentucky Dept. of Neurol., Lexington, KY

Abstract: βeta-hydroxybutyrate (BHB) is a ketone body produced by the liver in a process known as ketogenesis. During periods of fasting or carbohydrate caloric restriction, ketones are used as an alternative fuel source throughout the body including the brain. Although glucose is the brain's principal energy source, when limited, ketones derived from fats become the primary energy source. Exogenous BHB is safe to administer orally, and enhances energy and physical performance. While growing evidence indicates significant cognitive improvement in animal models following ketone elevation, and in clinical human samples, such as in Alzheimer's disease and severe traumatic brain injury, there is limited literature demonstrating beneficial neurocognitive effects of exogenous administration of ketones in nonclinical samples. Twenty-six healthy participants were randomly assigned to receive a single dose exogenous administration of 11.7g of BHB or a flavor matched placebo. One-hour after ingestion, participants in the BHB condition demonstrated a significant 11-point Standard Score (SS; M=100, SD=15) improvement in memory ($t(13)= 2.48$, $p < 0.05$; $d = 0.77$) and a 15.86-point SS improvement in processing speed ($t(13)= 4.28$, $p < 0.01$; $d = 1.10$) compared to baseline. Participants in the control condition demonstrated a significant 16-point SS improvement in processing speed from baseline ($t(11)= 3.49$, $p < 0.01$; $d = 0.82$) to post-intervention. Changes in processing speed are to be interpreted with caution however, as there appears to be a measurement practice effect potentially confounding these results. Additionally, participants in the BHB condition demonstrated significantly higher BHB blood

levels (M=1.24 mM, SD=0.58) compared to the placebo condition (M=0.27 mM, SD= 0.12) 1-hour following ingestion ($t(24)= 5.68$, $p <0.001$, $d= 2.33$). Results of this pilot study suggest exogenous administration of BHB may have positive effects on cognitive performances in nonclinical participants. More research is needed to further explore the potential benefits and pitfalls of exogenous BHB administration in nonclinical participants and additional clinical populations.

Title: Disordered network stability during associative learning in schizophrenia

Authors: *E. MERAM, S. BAAJOUR, A. CHOWDURY, J. STANLEY, V. DIWADKAR;
Psychiatry and Behavioral Neurosciences, Wayne State Univ., Detroit, MI

Abstract: Background: Schizophrenia (SCZ) is characterized by impairments in associative learning (Diwadkar et al., 2008) but the stability of brain network topology induced *during* phases of learning has not been investigated. Here, we used the graph theoretic measure of betweenness centrality (BC), a metric that indexes the "integrative value" of a node, to summarize brain network topology in four different conditions of an object-location associative learning paradigm: Memory Formation (MF), Post-Encoding Consolidation (PEC), Retrieval (MR), and Post-Retrieval Consolidation (PRC) (Rubinov and Sporns, 2010; Baajour et al., 2020). We then characterized the stability of network topology by assessing the changes in the rank ordering by BC across task phases.
Methods: fMRI data were collected from 59 subjects (32 SCZ, 18<Age<50, 3T Siemens Verio). During MF, nine unique objects were presented in their associated locations (3x3 spatial grid) for naming. During PEC, participants covertly rehearsed memoranda. During MR, locations were cued, and participants were required to name the associated object. The instruction-free PRC epoch was identical to PEC. fMRI data were processed in SPM12. For each condition, time series data were extracted from 90 cerebral nodes. In each participant and for each condition, BC was estimated for each of these 90 nodes. Then, in each group and condition, we ranked nodes based on their estimated BC. Next, we computed the standard deviation (s.d.) of each node's rank across task conditions. Finally, from the observed s.d.s, we identified "stable" (low s.d.) and unstable (high s.d.) nodes in each group.

Results: Patterns of relative "stability" and "instability" were complex. SCZ were characterized by high stability in occipital nodes, but instability in multiple task-relevant frontal and temporal lobe regions, including the right inferior frontal operculum and left fusiform gyrus. By comparison, HC were characterized by stability in multiple regions in the frontal lobe and basal ganglia, including the left middle frontal gyrus, left caudate, and right pallidum. Regions of high stability for both groups (HC, SCZ) tended to be uniformly high-rank *or* uniformly low-rank across task conditions.
Discussion: Occipital nodes relatively peripheral to the essentials of paired-associate learning were highly ranked in SCZ, and *also* highly stable. This observation suggests that learning redirects functional network structure in SCZ toward an emphasis on brain regions that are relatively peripheral to task requirements. The results emphasize the contextual dynamics of the "dysconnection syndrome" that is SCZ.

Title: Tuned to learn: An anticipatory hippocampal convergence state conducive to memory formation revealed during midbrain activation

Authors: *J.-H. POH[1], M.-A. T. VU[5,1,2], J. K. STANEK[1], A. HSIUNG[1], T. EGNER[1,3], R. A. ADCOCK[1,3,4,2];

Abstract: The influence of neuromodulatory activity on hippocampal processing has been a long-standing question in memory research. While there is robust evidence that functional interaction between the dopaminergic midbrain and the hippocampus supports enhanced learning during a motivated state, the mechanism by which midbrain activity influences hippocampal state remains ambiguous. In the current work, we identify a neural signature within the human hippocampus that may provide a candidate mechanism accounting for neuromodulatory influence on hippocampal processing - an anticipatory convergence state. This convergence state was expressed in the hippocampus while awaiting valuable information, predicted later memory, and also accounted for the relationship between midbrain activation and enhanced learning. To examine this modulatory influence on the hippocampus, we leveraged endogenous neuromodulation associated with intrinsic motivation - During fMRI, participants viewed trivia questions eliciting high or low curiosity, each followed seconds later by its answer. We reasoned

that memory encoding success requires a convergence of factors, and as such, hippocampal states associated with remembered trials would be less variable than forgotten ones. Using a novel multivariate approach, we measured convergence by quantifying the typicality of spatially distributed patterns. We found that hippocampal states showed greater convergence under high than low curiosity during anticipation of trivia answers,. Crucially, convergence in the hippocampus increased with greater midbrain activation and uniquely accounted for the association between midbrain activation and subsequent memory recall. We propose that sustaining a convergence state in the hippocampus reflects a modulatory mechanism that links the cascade from motivation, to midbrain activity, to enhanced memory formation.

Title: Individual differences in anterior and posterior hippocampal connectivity and their relationship to memory specificity and generalization

Authors: *L. FRANK, D. ZEITHAMOVA;
Univ. of Oregon, Eugene, OR

Abstract: The hippocampus aids in remembering individual experiences (memory specificity) as well as linking across those experiences to form generalized knowledge (memory generalization). How can the hippocampus support both memory functions? Prior work indicates functional dissociations between the anterior and posterior hippocampus such as distinct connectivity profiles and distinct levels of granularity in memory representations. In this study, we tested the hypothesis that anterior and posterior hippocampal connections will differentially predict behavior, such that anterior hippocampal connections will track with memory generalization while posterior hippocampal connections will track with memory specificity. Participants completed a battery of memory assessments across two sessions that included measures of both memory specificity and generalization. Factor analysis was used to derive individual scores of memory specificity and generalization abilities. A subset of participants returned for a third session to undergo MRI, including a resting-state scan. We then correlated individual differences in whole-brain connectivity with the anterior and posterior hippocampus during rest with individual differences in memory scores. Partially consistent with our hypothesis, we found posterior hippocampal connections (but not anterior hippocampal connections) predicted memory specificity. However, both anterior and posterior hippocampal connections predicted memory generalization, albeit through interactions with distinct regions. These findings provide new probes into the hypothesized functional dissociations of

anterior and posterior hippocampus and indicate that hippocampal interactions with distinct regions may support the complementary functions of memory.

Title: Differential effects of content and location overlap on learning and memory

Authors: *B. CHALOUPKA, D. ZEITHAMOVA;
Univ. of Oregon, Eugene, OR

Abstract: Similarity and overlap of information play a role in learning and memory in two well-established yet conflicting ways: they can facilitate new learning, but also lead to interference. In two studies, we aimed to reconcile this conflict by examining multiple dimensions of overlap. In the first study, we tested the effect of content overlap (same visual stimuli) and spatial overlap (same locations) on new learning. We utilized a novel grid learning task in which participants learned a grid of object-location associations, and then learned a second grid to measure facilitation or interference. The second grid overlapped with the first in stimuli, locations, both or neither. We found that a common set of stimuli between the two grids hindered learning of the second grid while a common spatial pattern between the two grids facilitated learning of the second grid. We found no interaction, indicating that these effects are independent and additive. In the second study (in progress), we added a third dimension of overlap: the shape of the grid. We again found that content overlap had a detrimental effect while spatial overlap had a facilitatory effect on learning of the second grid, replicating our results from the first study. However, the facilitatory effect of location overlap was numerically smaller when the second grid was shaped differently than the first. This suggests that the facilitatory effect of spatial overlap may be dependent on an overlapping context, potentially reflecting changes of location coding when the shape of the environment is altered. Collectively, our results demonstrate the nuance of overlap as a factor in learning and memory: some forms of information overlap, such as content overlap, can cause interference, while other forms, such as spatial overlap, can provide a framework into which new information can be easily integrated. The facilitatory effect of spatial overlap may be due to the early stages of a spatial schema, which has been shown to provide a framework into which new information can be easily integrated.

Title: Hippocampal representations switch from errors to predictions during acquisition of predictive associations

Authors: F. AITKEN, ***P. KOK**;
UCL, London, United Kingdom

Abstract: We constantly exploit the statistical regularities in our environment to help guide our perception. For instance, hearing a particular jingle will prime our sensory systems for the sight (and taste!) of ice cream. But how does the brain acquire and exploit knowledge about these regularities in a changing environment? The hippocampus has been suggested to play a pivotal role in this process. That is, it has been shown to be involved in learning novel associations between arbitrary stimuli, as is required for acquiring many predictive contextual cues. On the other hand, the hippocampus has also been suggested to play a role in exploiting such predictive associations after learning is done, through pattern completion driven retrieval. This raises the question of how the hippocampus balances encoding of new predictive associations with the retrieval of existing ones, a question that has been much discussed in the context of episodic memory but has not been sufficiently considered in the context of perceptual predictions. Here, we present the results of two high resolution human fMRI studies (N=24 for both experiments) directly investigating this. Participants were exposed to auditory cues that predicted the identity of an upcoming visual shape (with 75% validity). On each block of trials (32 trials per block in Experiment 1 and 128 in Experiment 2) new auditory cues were presented, such that novel associations would have to be learnt. Using multivoxel decoding analysis, we found that the hippocampus initially preferentially represented unexpected shapes (i.e. those that violated the cue regularities), but later switched to representing the cue-predicted shape regardless of which was actually presented. These findings are in line with the hippocampus switching between encoding and retrieval modes depending on contextual novelty. That is, when stimuli or associations are novel, hippocampus is in an encoding mode, and is mainly driven by sensory signals that provide the opportunity to update our model of the world, i.e., prediction errors. However, once learning is complete and stimuli are no longer novel, the hippocampus is mainly in retrieval mode, retrieving predicted stimuli based on contextual cues to optimally guide perception. Furthermore, in this latter phase, we found increased informative connectivity between the posterior subiculum and the early visual cortex (V1), potentially reflecting hippocampal predictions being relayed to visual cortex. These findings demonstrate a role for the hippocampus in both acquiring and exploiting predictive associations, and a switch between these modes depending on whether learning is ongoing or complete.

Abstract: Given the lack of experimental methods, we know remarkably little about the neuronal encoding of language at the level of single neurons. In the present study, we exploited the ability to record from single neurons in the human medial temporal lobe, which respond selectively to certain people, animals or places. Some of these 'concept cells' respond to both pictures of individuals (e.g. Jennifer Aniston) as well as textual information (e.g. the text 'Jennifer Aniston'). We here asked whether these cells can also be activated by pronouns that refer to the preferred concept of a cell. Are concept cells activated during reading of nouns and pronouns in sentences?
We tested whether concept cells that are activated by a preferred noun, are re-activated by pronouns (e.g. 'he', 'she') that refer to that noun. We first identified concept cells in the medial temporal lobe of 12 epileptic patients implanted with electrodes as part of their treatment. We obtained ethical approval to use a version of the electrode (Behncke-Fried) that includes a number of microwires so that we could record from single units. We then visually presented two sentences, word-by-word (0.5s per word) on a computer screen. The first sentence contained two nouns and the second sentence contained one pronoun, referring to one or both of the previously presented nouns (for example '*Jennifer Anniston* and *Barack Obama* walked into a bar. *She* sat at the table.'). The subject had to indicate to whom the pronoun referred. Our results show that concept cells (n = 29) gave robust responses to the nouns, and that there was a significant difference between the responses to the pronouns ($p < 0.05$, paired t-test). Concept cells were only re-activated by pronouns that referred to the preferred noun of the cell. A decoder analysis confirmed this result by showing that the same neural activity pattern as response to the noun presentation was also present during the pronoun presentation, but only when it referred to the preferred noun. This implies that these cells are involved in a rapid and dynamic form of memory processing, which is necessary for processing text. The results of this study help us understand the role of the medial temporal lobe in the fast memory processes necessary for language comprehension.

Title: The direction and timing of cortical traveling waves modulates human memory processes

Authors: *U. MOHAN[1], H. ZHANG[2], J. JACOBS[1];
[1]Biomed. Engin., Columbia Univ., New York, NY; [2]Amazon Corp., Seattle, WA

Abstract: Human behavior requires a complex set of interactions across brain regions. To support the diverse demands of everyday life, the brain must dynamically coordinate neural activity across various regions with diverse functional roles. One potential mechanism for this coordination are traveling waves of brain oscillations, which propagate across the cortical surface. We identified two functional roles for traveling waves in humans by comparing how the direction and timing of traveling-wave propagation related to distinct memory processes, using direct human brain recordings. When the brain exhibits traveling theta- and alpha-band waves that propagated in a posterior-to-anterior direction both before and during stimulus presentation, subjects were 1.4-1.8 times more likely to remember a viewed word compared to waves moving in other directions. Our results suggest that the propagation direction of low frequency oscillations is a new indicator of how oscillations sequentially engage distinct brain networks to support memory encoding. We found that the propagation direction of low frequency traveling waves could be modulated by applying direct cortical stimulation at specific frequencies and locations relative to the regions where traveling waves propagated. Additionally, during the retrieval of working memories, the phase of traveling waves predicted the timing of a subject's memory recall. These findings demonstrate that traveling waves coordinate neuronal activity across widespread regions to support memory processes by directing when distinct brain regions activate and the sequence of interactions.

Title: Human hippocampal ripples are associated with the formation and retrieval of spatial memories

Authors: *L. KUNZ[1], B. P. STARESINA[2], P. C. REINACHER[3], A. SCHULZE-BONHAGE[3], J. JACOBS[1];
[1]Dept. of Biomed. Engin., Columbia Univ., New York, NY; [2]Univ. of Birmingham, Birmingham, United Kingdom; [3]Univ. of Freiburg, Freiburg, Germany

Abstract: Sharp-wave ripples are a neural network phenomenon that has been studied most extensively in the rodent hippocampus (Buzsaki, Hippocampus, 2015). They occur preferentially during immobility or sleep, when the activity sequences of single neurons replay the content of previous experiences (Colgin, Nat Rev Neurosci, 2016). Recent studies in both rodents and humans indicate that ripples also play a role in wake behaviors such as the planning of future navigation trajectories (Diba & Buzsaki, Nat Neurosci, 2007) as well as the encoding and retrieval of episodic memories (Norman et al., Science, 2019; Vaz et al., Science, 2020). The relevance of hippocampal ripples for human spatial memory remains poorly understood, however. In this study, we therefore examined the prevalence of ripples in the human hippocampus during a spatial memory task. We acquired intracranial EEG in 20 epilepsy patients, implanted with intracranial depth electrodes for diagnostic purposes, while the patients performed a spatial memory task in a virtual environment (Kunz et al., Neuron, 2021). In this task, the patients first learned the locations of several different everyday objects in the virtual environment. During each of multiple test trials, the patients were then asked to remember the location of a given object, navigated to the remembered object location, received feedback about their response accuracy, and collected the object from its correct location to further improve their spatial memory performance. Following previously established techniques (Norman et al., Science, 2019; Chen et al., Cell Reports, 2021), we identified human ripples in the local field potentials of bipolar recordings from the left and right hippocampus. Our results show that ripple rates were specifically increased during the retrieval periods of the task. Across trials, higher ripple rates during retrieval were associated with better spatial memory performance, suggesting that human hippocampal ripples support the recall of spatial memories. Furthermore, the rate of ripples during resting periods of the task increased over time, which may indicate that human hippocampal ripples are involved in the offline consolidation of spatial memories. Overall, our results thus help translate the functional role of ripples in the rodent hippocampus to the human brain. They also contribute to a growing body of evidence that ripples in the human hippocampus play a role in human memory.

Title: Traveling waves in the monkey frontoparietal network predict recent reward memory

Authors: *E. ZABEH, N. FOLEY, J. JACOBS, J. GOTTLIEB;
Columbia Univ., NewYork, NY

Abstract: Neural communication is critical for cognitive function but its mechanisms are not well understood. Recent studies suggest that a common form of neural communication is through traveling waves (TWs) -- patterns of neural oscillations that propagate continuously within local brain areas as well as between distant brain areas. Here we show that TWs are robust in microarray recordings of monkey frontal and parietal areas, where they predict sensitivity to recent reward history. On each trial, monkeys viewed a visual cue signaling a probabilistic reward and, after a brief delay period, made a visually guided saccade to obtain the reward. Analysis of anticipatory licking behavior showed that the monkeys anticipated the cue-predicted rewards and were also influenced by the (irrelevant) prior reward, consistent with previously documented biases produced by reward history. Analysis of oscillatory activity revealed pronounced TWs in local field potentials (LFP) recorded with Utah arrays in the dorsolateral prefrontal cortex (dlPFC) and in the parietal area 7A. TWs were present in most trials, were most prominent at 10-35 Hz (the dominant LFP frequency), had typical speeds of 0.1-0.3 cm per second and they generally propagated in one of two directions, which followed the anatomy of the principal and intraparietal sulci. Moreover, TWs were pronounced before the appearance of the reward cue and their features related to the monkeys' prior trial reward memory, being more frequent on trials in which the monkeys' anticipatory licking correctly reported the prior trial reward versus trials in which licking was not consistently related to the rewards. Pre-cue TWs arose de novo on each trial rather than being passive continuations of responses to the prior reward, and TWs at other timepoints did not encode cue or saccade target location, reward magnitude, probability or expected value. These findings indicate that TWs are prominent features of local neural activity and that their features correlate with specific cognitive processes such as the representation of recent rewards.

Title: Hippocampal-neocortical oscillatory dialogue for memory consolidation

Authors: *P. DAHAL[1], O. RAUHALA[1], D. KHODAGHOLY[1], J. GELINAS[2];
[1]Electrical Engin., Columbia Univ., New York, NY; [2]Columbia Univ. Med. Ctr., New York, NY

Abstract: Understanding the mechanism behind the formation, consolidation and retrieval of memory is of critical importance. The two-stage hypothesis of memory consolidation proposes that labile, episodic memories are gradually converted into stable, long-term representations through a coordinated dialogue between the hippocampus and the neocortex during sleep. However, the exact mechanisms that underlie consolidation and retrieval (reconsolidation) is not yet fully understood. Using large-scale, high-resolution intracranial electrophysiological recordings in freely-behaving rats, we investigated the functional and behavioral relevance of dynamic oscillatory coupling among hippocampal ripples, spindles and cortical ripples during NREM sleep. We demonstrate that hippocampal-cortical coupling exists through ripple-ripple, ripple-spindle and ripple-spindle-ripple coupling. Individual patterns of NREM sessions transitioning to REM revealed that the rate and coupling of these oscillatory events are dynamically regulated across the sleep structure. To determine the relevance of hippocampal-cortical dialogue to memory, we compared the oscillatory properties in a hippocampal-dependent versus independent navigational maze task. We observed that the rate of hippocampal ripples increases during sleep following learning, regardless of the task. Ripple-spindle and ripple-ripple coupling increased following learning (consolidation), both showing a higher modulation in the hippocampal-dependent task. During sleep following retrieval (reconsolidation), we observed a decrease in ripple-spindle coupling whereas ripple-ripple coupling peaks with highest modulation. Our results suggest that ripple-spindle coupling may play an important role as priming of the functional network connectivity for consolidation. Ripple-ripple coupling gradually increased and is further enhanced by reconsolidation implicating a mechanism that cements the transfer of memory traces to the neocortex.

Title: Simultaneous stimulus modulation of both oscillations and aperiodic electrophysiological activity in human visual cortex

Authors: *M. W. PRESTON[1], N. SCHAWORONKOW[2], B. VOYTEK[3];
[1]Neurosciences Grad. Program, Univ. of California San Diego, La Jolla, CA; [2]Dept of Cognitive Science, Univ. of California San Diego, La Jolla, CA; [3]Cognitive Sci., Univ. of California San Diego Dept. of Cognitive Sci., La Jolla, CA

Abstract: Decades of research have linked neural oscillations to memory encoding and retrieval However, recent work has highlighted the importance of non-oscillatory, aperiodic activity in working memory. Here, we hypothesize that both oscillations and aperiodic activity are modulated during memory

encoding paradigms. We further hypothesize that commonly-applied spectral analysis techniques conflate these two signals leading to misrepresentations of their respective roles in encoding. This study aims to disentangle the role of oscillations and aperiodic activity by leveraging the SpecParam toolbox (Donoghue et al., 2020) in conjunction with human intracranial EEG (Fellner et al., 2019) and simulated neural data. Intracranial EEG was available from patients with pharmaco-resistant epilepsy during a subsequent memory paradigm (n=13). Low-frequency oscillations (peak 8–20 Hz) were evident at baseline and exhibited desynchronization during stimulus presentation. Concurrently, the aperiodic exponent was significantly reduced, resulting in a 'flattening' of the power spectrum. Exponent changes were associated with a rotation of the spectrum about a given frequency axis, generally ~40 Hz. We simulated neural time-series with 1/fX scaling and oscillations to investigate how these empirically-observed phenomena interact to influence measures of band-power. Oscillatory de-/synchronization affected spectral power within a limited frequency range, while exponent changes affected broadband power across all frequencies (4–100 Hz). These spectral signatures were distinct from that of evoked responses, which manifest as power increases at low frequencies only (<30 Hz). Commonly-applied spectral analysis techniques were unable to disambiguate oscillatory de-/synchronization, exponent changes, and evoked responses when these processes affected spectral power within overlapping frequency ranges. Our results suggest that consideration of aperiodic activity is critical when measuring oscillations and electrophysiological signatures of memory encoding.

Title: The memory gene KIBRA regulates experience-induced changes in hippocampal neural activity during sharp-wave ripples

Authors: *L. QUIGLEY, R. PENDRY, M. MENDOZA, L. VOLK, B. PFEIFFER;
Neurosci., UT Southwestern Med. Ctr., Dallas, TX

Abstract: Revealing how molecular interactions within single cells contribute to experience-dependent changes in circuit-level neural activity across large-scale brain networks is a major challenge in neuroscience. Disorders of complex cognition have substantial genetic contributions and ultimately manifest via emergent properties of dysfunctional neural networks. Here we investigate *in vivo* network dysfunction following removal of the synaptic scaffolding protein KIBRA. Variants in the KIBRA gene are linked to normal variation in human memory performance, and mice lacking Kibra show substantial impairment in learning and memory in addition to impaired synaptic plasticity. KIBRA is a synaptically localized scaffolding protein that regulates AMPA receptor trafficking. In addition, KIBRA and the protein complexes it organizes are associated with multiple neuropsychiatric disorders known to have synaptic/circuit etiologies. However, the role of KIBRA in regulating circuit dynamics is unknown. Thus, elucidating KIBRA's role in experience-dependent changes in network function is likely to reveal fundamental links between plasticity, memory, and neurological disorders. Particularly relevant for the study of network-level memory processes are hippocampal sharp-wave/ripple (SWR) events, brief high-frequency oscillations that occur during offline states. Considerable evidence implicates SWRs as a mechanism for memory consolidation and retrieval in both rodents and humans, and synaptic plasticity is implicated in encoding recent experience in SWRs. To determine whether KIBRA-dependent plasticity mechanisms regulate behaviorally relevant circuit dynamics, we monitored simultaneous neural activity in both the hippocampus (HC) and frontal cortex (ACC) of mice with forebrain-specific deletion of KIBRA (KIBRA cKO) using *in vivo* electrophysiology in freely behaving mice before and after a novel experience. We found minimal gross differences in baseline hippocampal network function between WT and KIBRA cKO mice. When we examined SWR properties before experience, we found that most fundamental properties of SWR events and associated hippocampal network dynamics are intact in KIBRA cKO mice. However, when we quantified SWR properties during and after experience, KIBRA cKO mice failed to show experience-dependent modifications of SWR properties observed in WT mice that are consistent with information updating. These findings indicate a failure of hippocampal circuits to properly synchronize in response to experience in the absence of KIBRA and reveal network-level mechanisms by which KIBRA function may regulate memory consolidation.

Title: The role of theta synchrony in the formation of new audiovisual speech memories

Authors: *E. BIAU[1], D. WANG[2], H. PARK[3], O. JENSEN[3], S. HANSLMAYR[2];
[1]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [2]Ctr. for Cognitive Neuroimaging (CCNi), Univ. of Glasgow, Glasgow, United Kingdom; [3]Sch. of Psychology, Ctr. for Human Brain Health, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Recent studies showed that the brain takes advantage of the synchrony between rhythmic visual and auditory stimulations peaking at 4Hz theta rate to form new multisensory episodic memories. In our study, we extended this principle to the audiovisual speech domain where syllable boundaries naturally chunk and temporally align visual and auditory inputs on a common theta phase (respectively lip apertures and acoustic envelope modulations). We hypothesised that theta phase alignment across speech modalities increases the synchronisation of neural theta oscillations between the visual and auditory sensory areas in the neocortex. The synchronisation across sensory regions should facilitate binding of information taking place downstream in the hippocampus to form a new episodic memory. We designed a memory task presenting participants with short audiovisual clips of faces of speakers engaged in conversations, for which lip movements and auditory speech signals were either synchronous or asynchronous. In a subsequent retrieval test, participants were visually cued with a speaker's face picture and had to recall which auditory signal was associated with the cue during previous encoding. We recorded the participant's magneto-encephalogram signal (MEG) to address whether the oscillatory dynamics during encoding and retrieval predicted memory performances, depending on audiovisual speech synchrony. Preliminary behavioural results (n = 13) suggest that the theta asynchrony during audiovisual speech encoding decreased subsequent memory performance (i.e., lower correct response rates and longer reaction times) as compared to natural synchronous condition. Concerning the MEG results, we anticipate to find that the higher performance for synchronous speech stimuli is accompanied by increased theta power, and increased theta-to-gamma cross-frequency coupling in the medial temporal lobe.

Title: Local sleep or cognitive control? The role of frontal theta oscillations in the wake EEG during sleep deprivation

Authors: *S. SNIPES[1,2], R. HUBER[1,3];
[1]Child Develop. Ctr., Univ. Children's Hosp. Zurich, Univ. of Zurich, Zurich, Switzerland; [2]Dept. of Hlth. Sci. and Technol., ETH Zürich, Zurich, Switzerland; [3]Dept. of Child and Adolescent Psychiatry and Psychotherapy, Psychiatric Hospital, Univ. of Zürich, Zurich, Switzerland

Abstract: While most research into human theta oscillations (4-8 Hz) from surface EEG has been in the field of cognition, an isolated branch of research has instead identified a relationship between theta and sleep deprivation. As such, theta has been both related to increased cognitive load and increased sleep pressure, leading to conflicting interpretations of theta as a form of prefrontal control or as a form of local sleep. To disambiguate these interpretations, we first wished to determine if they correspond to the same type of oscillation or not, and what happens to theta under both high sleep pressure and high memory load. In an exploratory within-subject design, we compared frontal-midline theta (fmTheta) recorded during a short-term memory task with changes in theta following sleep deprivation (sdTheta). We recorded high-density EEG from 18 adults (18-25 y/o, 9 f) performing a Sternberg/match-to-sample task during 3 sessions at 3 levels of sleep pressure: baseline (BL, morning after 8h sleep), sleep restriction (morning after 4h sleep), and sleep deprivation (SD, 20h of wake). FmTheta was calculated contrasting within-session high-memory load to low-memory load retention periods. SdTheta was calculated comparing across-session SD retention periods to BL retention periods. We found that while fmTheta was localized to clusters of frontal and occipital channels, sdTheta increased in almost all frontal-central channels (see figure). Furthermore, the memory-load dependant difference in fmTheta disappeared during SD (Fig. A, right). The peak frequency of theta in high-load trials was 5.9 ± 0.9 Hz, and of SD trials was 6.3 ± 0.4 Hz (t=2.03, p=.058). From these results we can conclude that sdTheta is not simply an increase in fmTheta in the same frontal locations, but instead involves a greater cortical area. Whether or not they consist of fundamentally different kinds of oscillations remains undetermined, however the disappearance of memory-load dependant theta changes during sleep deprivation suggests that sdTheta either masks fmTheta, or that they may be to some extent mutually exclusive.

Title: Human hippocampal and cortical oscillations differentially signal surprise and uncertainty

Authors: *D. FRANK[1], J. SARNTHEIN[2], A. GIL-NAGEL[3], R. TOLEDANO[3], B. A. STRANGE[4]; [1]Univ. Politécnica De Madrid, Madrid, Spain; [2]Klinik fur Neurochirurgie, Universitatsspital Zurich, Zurich, Switzerland; [3]Hosp. Ruber Internacional, Madrid, Spain; [4]Lab. for Clin. Neurosci., Univ. Politecnica De Madrid, Pozuelo DE Alarcon, Spain

Abstract: To adaptively encode information into memory, the hippocampus should be able to extract statistical regularities in the environment and generate possible outcomes. Indeed, previous fMRI findings show that the anterior hippocampus tracks the expected uncertainty of an event in a given context (Strange et al., 2005). Such generative hippocampal responses can then inform cortical processing of upcoming sensory inputs. Here, we used intracranial EEG to examine the pre- and post-stimulus temporal dynamics underlying hippocampal and visual ventral regions' sensitivity to contextual uncertainty (Shannon's entropy) and surprise (a given event's improbability). Thirteen medication-resistant epilepsy patients participated in the experiment. All patients had depth electrodes implanted in the anterior hippocampus, seven patients also had contacts in occipital cortex, and six patients had contacts in the fusiform. On each trial, patients were presented with a coloured shape, and performed a match-to-sample task. Two colours and two shapes were combined to form four possible stimuli per block. In each block, there are likely and unlikely stimuli, varying surprise within-block; the entropy of stimuli varied across blocks (different probability distribution of the four stimuli in each block). Time-frequency analysis utilized a trial-wise GLM approach, with two predictors of interest: entropy and surprise. Furthermore, we detected hippocampal ripples and examined their occurrence frequency as a function of entropy and peri-stimulus time. In response to entropy, we found a positive association with gamma oscillatory power in occipital cortex around 700ms pre-stimulus. In the hippocampus, we observed an earlier (800ms pre-stimulus) negative association between entropy and gamma. Furthermore, hippocampal ripples were most frequently detected in high entropy trials, in the same pre-stimulus time-bin. Consistent with previous findings, we also found a positive association between surprise and hippocampal theta and gamma oscillations, from stimulus onset until 300ms post-stimulus. In the fusiform, there was a negative association between surprise and low frequency power (5-25 Hz) around 600ms post-stimulus. Overall, these results suggest an occipital and hippocampal anticipatory signaling of an upcoming stimulus, tracking uncertainty. Once the stimulus has been presented, there is a prediction error/validation response in the fusiform and hippocampus, tracking surprise.

Title: Theta-gamma phase amplitude coupling in human hippocampus supports auditory short-term memory retention.

Authors: *A. BORDERIE[1], P. ALBOUY[1], B. TILLMANN[2], A. CACLIN[3];
[1]Ctr. de recherche CERVO, Quebec, QC, Canada; [2]INSERM, LYON cedex 07, France; [3]INSERM, Bron, France

Abstract: Phase Amplitude Coupling between theta and gamma oscillations has been hypothesized to implement the retention of information during short-term memory [1]. However, the role of theta-gamma coupling in short-term memory functions, still needs to be confirmed. In this study, we investigated if auditory and hippocampal theta-gamma PAC supports WM information and its relation to participants' performance. **Objective:** We aimed to identify PAC markers that predict participants' auditory WM performance. We aim to improve our understanding about the functional role of PAC during three well characterized stages of WM: 1) Encoding; 2) Maintenance, and 3) Retrieval [2] in primary auditory regions, hippocampus, and in the ventral auditory pathway. **Participants:** We analyzed a large sample (16 drug-resistant epileptic subjects) of iEEG data recorded while patients volunteered to perform auditory WM tasks. The recordings were collected from left, right lateralized or bilateral implantations in the auditory cortex, hippocampus, and inferior frontal regions, as identified from pre- and post-implantation structural MRI. **Task:** The tasks consisted of comparing sequences of piano tones presented in pairs. The memory load was manipulated (3, 6 items) as well as the duration of the silent retention period between the to-be-compared sequences (2, 4, 8 s). **Hypotheses:** We hypothesize that theta-gamma coupling should increase with increasing memory load and increasing duration of the retention period. Moreover, we expect to observe PAC in auditory cortices during encoding of the sounds, and in hippocampal and inferior frontal regions during memory retention. **Results:** Time frequency analyses during the encoding period of the task show that each tone was encoded by a transient gamma burst in the auditory cortex, while the entire sequence elicited sustained theta oscillations in the ventral auditory stream. During the retention period, theta-gamma PAC strength in auditory and hippocampal regions was correlated with the participants' performance. Moreover, when looking at the statistical dependency between the occurrence of gamma burst as a function of the phase of the theta oscillation, we found that items were encoded in a sequential manner in the hippocampus for correct trials and in a random manner for incorrect trials. **Outcome:** This study expands our knowledge about the functional role of brain oscillation as a biological mechanism for brain information processing and integration. Moreover, it clarifies the role of cross-frequency dynamics in working memory functions in humans [1]. 1.Lisman and Jensen (2013). Neuron 2.Baddeley, A. (2010). Curr Biol

Title: Information flows from hippocampus to cortex during replay of verbal working memory items

Authors: V. DIMAKOPOULOS[1], P. MEGEVAND[2], L. STIEGLITZ[1], L. IMBACH[3], ***J. SARNTHEIN**[1];
[1]Universitatsspital Zurich, Zurich, Switzerland; [2]Neurol. Dept., Geneva Univ. Hosp., Geneva, Switzerland; [3]Schweizerisches Epilepsie Zentrum, Zurich, Switzerland

Abstract: Introduction: The maintenance of items in working memory (WM) relies on a widespread network of cortical areas and hippocampus where synchronization between electrophysiological recordings reflects functional coupling. We investigated the direction of information flow between sensory areas and hippocampus during encoding and maintenance of WM items. Methods: Participants (N=15) performed a WM task where a string of letters was presented all at once, rather than sequentially, during the encoding period. Participants mentally replayed the letters during the maintenance period. We recorded sEEG from the hippocampus, scalp EEG and, additionally in 3 participants, cortical electrodes (ECoG). Results: When analyzing the information flow to and from auditory cortex by Granger causality, the flow was from ECoG over auditory cortex to hippocampus with a peak in the 8-18 Hz range while letters were presented. This flow was subsequently reversed during maintenance while letters were maintained in memory. The same pattern appeared to and from hippocampus with ECoG over occipital-parietal cortex. For scalp EEG, the pattern appeared on temporal sites, albeit in the 4-12 Hz theta-alpha range. Whereas the pattern was significantly structured for correct trials, it was unstructured for incorrect trials. Conclusions: The functional interaction between hippocampus and cortex and the reversal of information flow provide a physiological basis for the encoding of memory items and their active replay during maintenance.

Title: Noise ain't noise: dissociating the contributions of learning imprecision and choice inconsistency in impulsivity

Authors: *V. SKVORTSOVA, T. HAUSER;
Univ. Col. London, London, United Kingdom

Abstract: Objective. Impulsivity is a well-established personality trait that plays an important role in many psychiatric disorders. However, its underlying neurocomputational mechanisms are poorly understood. Previous works linked impulsivity to exploration via increased *choice stochasticity*[1]. Recently, we showed that imprecision in the learning process (random variability in the update of action values following feedback) account for a large portion of exploratory decisions previously attributed to choice stochasticity[2]. Furthermore, learning noise explained fluctuations within the dorsomedial prefrontal cortex and pupil responses associated with the noradrenergic system linked to impulsivity.[2] Here, we studied whether impulsivity is associated with increased learning imprecision rather than choice stochasticity. **Methods.** Subjects (N=392) completed an online restless two-armed bandit task with continuous drifting payoffs and a self-report Barratt Impulsiveness Scale[3] (BIS).To dissociate overt exploration from learning imprecision, we fitted subjects' choice behaviour with a 'noisy' reinforcement learning (RL) framework which allows for a stochastic update of the values at each trial[2]. **Results.** In line with previous findings[2], the 'noisy' RL model better explained choices relative to an exact model (Pexc=0.99). Learning imprecision accounted for >70% of the decisions classified as exploratory by the exact model. Total BIS score was positively associated with the learning noise parameter (p=0.032) when controlling for age, gender, IQ, choice stochasticity (softmax parameter), and learning rate. Learning noise was strongly associated with a BIS subscale related to *motor impulsiveness* (p =0.0003). When accounting for learning noise, softmax parameter showed no correlation with any BIS scales (all $p>0.06$). Individuals with high BISmotor showed an increase in fraction of exploratory decisions explained by learning noise (78.9±2.1% vs. 71.0±2.0%, p=0.009). We replicated these results in an independent sample of subjects (N=2202) with a short version of the task (www.brainexplorer.net) (association of learning noise with BISmotor p=0.0001; BIStotal p=0.004; choice stochasticity with BISmotor p=0.27, BIStotal p=0.05). Together, these findings provide evidence that learning noise, rather than choice inconsistencies account for inter-individual differences in impulsivity and could be a marker of noradrenergic dysfunction. **References.** 1. Title: Identifying coordinated systems during gambling feedback: Integrating EEG/ERP amplitude and phase synchrony measures of reward and loss processing

Authors: *A. A. VIVINO, D. BUTLER, A. PAVULURI, E. M. BERNAT;
Psychology, Univ. of Maryland, Col. Park, College Park, MD

Abstract: While EEG/ERP studies have identified several electrophysiological correlates of reward and loss processing, how these correlates interact to facilitate learning from rewards and losses remains unclear. Here, we examine an array of both previously reported low-frequency and newly assessed high-frequency differences between loss and reward processing in a simple gambling feedback task and use exploratory factor analysis (EFA) to investigate interrelationships among effects across frequencies, scalp regions, and measurement domains. We considered loss-gain differences in total power oscillatory activity and interchannel and intertrial phase synchrony (ICPS and ITPS) within five frequencies (delta, theta, alpha, beta1, and beta2). To isolate the loss-gain differences within each frequency, we band-pass filtered the total power signal in feedback-locked epochs and then applied a series of one-factor principal components analyses in each filtered spectrum, resulting in one measure of loss-gain amplitude differences in each frequency band. Then, we applied these solutions to ICPS and ITPS transforms, yielding associated measures of functional connectivity between the prefrontal, medial frontal, sensorimotor, and centroparietal cortices and the consistency of activity between trials. In line with previous findings, centroparietal delta and medial frontal beta2 power were significantly increased after rewards (ps < .001, r_bs ≥ .54), while medial frontal theta and sensorimotor alpha and beta1 power were greater after losses (ps < .001, r_bs ≥ -.36). In the theta band, the medial frontal cortex and DLPFC show greater coordination following losses (p < .001, r_b = -.76). In the beta1 band, the medial frontal cortex appears to integrate information from the DLPFC and the sensorimotor cortex (ps < .001, r_bs ≥ -.45), a process that correlates strongly (rs ≥ .52) with increased ITPS in beta2 oscillations over the right lateral DLPFC following gains (p = .014, r_b = .21). In total, 17 significant individual measures were included in an EFA (principal axis factoring; promax rotation). A significant four-factor model explaining 41% of the total variance resulted, with factors corresponding to a high-frequency reward-learning system, a secondary low-frequency reward system, a theta-dependent loss-control system, and a motor maintenance system. These results mark a significant step forward by assessing together a broader array of both widely studied and emerging measures sensitive to reward/loss processing, and by describing the interrelationships among these measures to characterize differentiable coordinated systems underlying reinforcement learning.

Title: Assessment of a digital behavior change program for weight loss: effects on executive function, mood and quality of life

Authors: *E. S. MITCHELL[1], H. BEHR[1], J. LEE[2], S. ANDERSEN[3], A. HO[1], A. MICHAELIDES[1]; [1]Noom Inc, New York, NY; [2]Stanford Univ., Palo Alto, CA; [3]Attain Focus, Comack, NY

Abstract: Introduction:Previous studies suggest that cognitive behavior therapy and weight loss can modify cognition and brain activity. This pilot study compares the effects of a 16 week behavior change weight loss program to digital education on cognition and behavior. Methods: Forty-four subjects (BMI > 25, aged 18-60) were randomized to 16 weeks of Noom Healthy Weight program or a control (branded health newsletters). Each subject attended at least 4 of 5 visits to evaluate cognition and weight (baseline, 4, 8, 12, and 16 weeks). Baseline characteristics and behavior were summarized using descriptive statistics. Correlations of baseline BMI and resting state EEG were analysed via mixed model with age and gender as covariates, using overweight (BMI: 25-29.9) or obese (BMI>30) categories. Repeated measures ANOVA explored post-hoc differences between groups from baseline to 16 weeks. Results: At baseline the control group (n=23) had an average weight of 219±48 lb, and an average age of 41±9 years. The intervention group (n=21) and an average weight of 205±43 lb, and an average age of 46±8 years. Baseline BMI correlated to resting state parietal alpha asymmetry; $F(1, 40) = 4.1248$, $p = 0.049$ and resting state parietal alpha asymmetry standard; $F(1, 40) = 4.1214$, $p = 0.049$.The control group gained, on average, 0.5 lb while the intervention group lost, on average, 7 lb. Mood (PANAS) and Quality of Life (PANAS) did not change over time or between groups. The Flanker task revealed overall Group differences in accuracy: congruent correct responses (p=0.017) but no Group*Time interaction (p=0.834). A similar finding was observed in congruent incorrect responses: Group differences were significant (p=0.011) but not over time (p=0.743). Reaction time in the Flanker task was significant between groups (p=0.01) and also via a Time interaction (Group*Time, p=0.029). Specifically, control reaction time did not change over the five sessions while the intervention decreased reaction time over 16 weeks.Conclusion:Noom’s behavior change weight loss program improves executive function processing, but not mood or quality of life. Future studies will address whether longer term interventions yield other effects related to mood and quality of life.

Title: Human intracranial recordings reveal mixed coding of reward and salience prediction errors in fronto-insular cortices

Authors: *C. HOY[1], D. KING-STEPHENS[3], K. D. LAXER[3], J. J. LIN[4], R. T. KNIGHT[2];
[1]Helen Wills Neurosci. Inst., [2]Helen Wills Neurosci. Inst. and Dept. of Psychology, Univ. of California, Berkeley, Berkeley, CA; [3]California Pacific Med. Ctr., San Francisco, CA; [4]Departments of Neurol. and Biomed. Engin., Univ. of California, Irvine, Irvine, CA

Abstract: Prediction errors are critical computations underlying reinforcement learning (RL) and cognitive control. The valenced scalar value and non-valenced magnitude of reward prediction errors (RPEs) play complimentary roles in learning and behavioral adaptation, but their corresponding neural circuitry is not clear. Medial prefrontal cortex (MPFC) and insular cortex (IC) are key regions for performance monitoring and encode both RPE value and magnitude. These signals are hypothesized to modulate top-down control in lateral prefrontal cortex (LPFC), but it is unknown how these circuits interact. Here, we track RPE value and magnitude representations across MPFC, LPFC, and IC using intracranial EEG (iEEG) recordings in 10 patients with pharmacoresistent epilepsy (mean ± SD [range]: 35.2 ± 13.1 [21-57] years old; 1 woman). Patients performed an interval timing task with a difficulty manipulation designed to dissociate RPE valence and magnitude, and computational modeling of individual patient behavior yielded single-trial estimates of expected value, which was then contrasted with the actual outcomes to obtain scalar RPE values and magnitudes. iEEG data were preprocessed by removing epileptic and artifactual channels and epochs, bipolar re-referencing, bandstop filtering to remove line noise, and excluding behavioral outliers. We then extracted high frequency band (HFB) power known to correlate with local population activity using multi-taper filtering in 10 Hz sub-bands from 70-150 Hz, which was log transformed, segmented relative to feedback, and baseline corrected via z-score against a bootstrapped distribution of baseline values derived from -0.25 to -0.05 s pre-feedback. HFB power was predicted using single-trial RL features in sliding window multiple regression analyses (HFB power averaged in 50 ms windows, stepping by 25 ms from 0 to 0.6 s). All three regions showed large proportions of electrodes (~30-40%) coding for valenced and non-valenced RPEs. These representations were separate in some electrode, but we also observed electrodes showing mixed selectivity to both RPE features. Surprisingly, IC showed the largest proportion of RPE sensitive sites, as well as the greatest proportion of sites coding for a mixture of both RPE features. Finally, onsets of RPE value effects were earlier in IC (mean ± SD: 0.212 ± 0.114 s) than MPFC (0.289 ± 0.127 s; $t(79) = 2.82$, $p = 0.018$, FDR corrected), supporting a leading role for the insula in RPE coding. Collectively, these results clarify the interactions between neural circuits representing reward and surprise.

Title: The relationships between iron status, cognitive performance, and smoking cessation in females.

Authors: *L. K. BOOZARY[1,3], R. CALDWELL[2], L. A. DE STEFANO[1], E. AUGER[1], J. J. C. WARING[3], A. BARNETT[2], M. J. WENGER[1], D. E. KENDZOR[3];
[1]Cell. and Behavioral Neurobiology, Psychology, [2]Univ. of Oklahoma, Norman, OK; [3]TSET Hlth. Promotion Res. Ctr., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Objective: Research suggests that women are more likely than men to respond to financial incentives to quit smoking, despite having lower overall rates of smoking cessation. Animal models suggest that iron deficiency, which is most prevalent in women, may alter dopaminergic pathways involved in both reward processing and addiction. This proposes a potential mechanism driving the sex differences in cessation rates. The present study examines the extent to which iron status impacts ability to quit smoking. **Methods:** Participants were recruited from a local smoking cessation clinic and followed for 6 months post-quit (PQ). Visits were at baseline, 1-month, and 6-months PQ. At each appointment, participants performed cognitive tests, including the paired associates learning (PAL) and probabilistic selection task (PST), with concurrent EEG, then gave a small sample of blood. Expired carbon monoxide (CO) was used as the smoking outcome of interest. Spontaneous and task-related blink rate (BR) was used as an indirect measure of dopamine levels. The iron status variable of interest was percentile rank of the NHANES III age-, race-, and sex-adjusted distributions of serum ferritin (sFtP). Correlations and regressions examined the associations between iron status variables, and spontaneous and task-related BRs at baseline, and follow-up CO. **Results:** BR during PAL was positively related to sFtP (r = 0.42, p = .012), BR during PST was positively related to sFtP (r = 0.50, p = .003), and spontaneous BR was positively related to sFtP (r = 0.63, p < .0001). This suggests significant relationships between blood iron and dopamine levels. BR had a moderate negative relationship with baseline CO (r = -.40, p = .01), suggesting that lower dopamine levels are related to heavier smoking. Baseline CO and change to CO at 4-weeks PQ had a significant negative relationship (r = -.80, p < .0001), such that smoking more at baseline corresponded to greater change in CO at 4 weeks. After adjusting for baseline CO and sFtP, BR during PST predicted change to CO at 4-weeks PQ (β = -0.32, p = .03). After adjusting for baseline CO, sFtP was significantly predictive of BR during PST (β = 0.53, p = .0009). These results suggest that, even after adjusting for baseline CO, lower iron levels are associated with lower dopamine levels, and after adjusting for baseline CO and sFtP, lower dopamine levels are associated with a smaller reduction in smoking. **Conclusion:** The results from these analyses suggest that iron level predicts dopamine level, and that dopamine level predicts changes to smoking at 4-weeks PQ. Thus, being low in iron may represent an additional burden to females attempting to quit smoking.

Title: Reward feedback leads to exploratory random-walk behaviour

Authors: *A. ROTH[1,2], J. CALALO[1,2], R. LOKESH[2], S. SULLIVAN[2], M. CARTER[4], J. G. A. CASHABACK[2,1,3];
[1]Mechanical Engin., [2]Biomed. Engin., [3]Biomechanics and Movement Sci., Univ. of Delaware, Newark, DE; [4]Kinesiology, McMaster Univ., Hamilton, ON, Canada

Abstract: Exploration is critical for adaptation, from a baby learning to walk to a professional golfer adjusting their golf swing. Past work has shown greater exploration (statistical random walks) along task dimensions that have little bearing on task success (task-irrelevant) compared to dimensions that impact task success (task-relevant). These studies have only looked at exploratory random walk behavior only in the context of error-based feedback. Recently we suggested that exploratory random-walk behaviour may be driven by reinforcement-based feedback, but this idea has not yet been tested empirically. Here we test the notion that reward feedback leads to exploratory random walk behaviour. In both of our experiments, we predicted that reward feedback would lead to greater exploration along the task-irrelevant dimension. To investigate, participants grasped the handle of a robotic manipulandum and reached to a target without vision of their hand. Participants received reward feedback (pleasant sound, target briefly expanded, small monetary gain) when their final hand position (endpoint) hit the target. We calculated trial-by-trial endpoint autocorrelations to quantify random walk exploration. A higher autocorrelation indicates greater exploration. In Experiment 1, participants received reward feedback when they reached to a short rectangular target (task-relevant) or long rectangular target (task-irrelevant). Participants displayed greater exploration when reaching to the task-irrelevant target ($p = 0.001$). In Experiment 2 we aimed to replicate the first experiment while also controlling for size differences in the visually displayed targets. Here, participants received reward feedback and were shown the same short rectangular target (task-relevant) during both conditions. In one condition, the reward zone matched the displayed short rectangular (task-relevant) target. Unbeknownst to the participants, in the other condition the reward zone was a long rectangular target (task-irrelevant) even though the participants saw the short rectangular target. Similar to Experiment 1, participants showed greater exploration when reaching to the hidden task-irrelevant reward zone compared to the task-relevant reward zone ($p = 0.001$), despite observing the same short rectangular target. Interestingly, participants reported there were no differences between the two conditions (Fisher's Exact Test, p &lt 0.001), suggesting implicit processes contribute to reward-based exploratory behaviour. Collectively these results suggest reward feedback plays an important role in exploratory random walk behaviour.

Title: Hypothesis: valence-partitioned reinforcement learning binds value to the contents and context of conscious experience

Authors: *K. T. KISHIDA[1], L. P. SANDS, III[2];
[1]Physiol. and Pharmacology; Neurosurg., Wake Forest Sch. of Med., Winston Salem, NC; [2]Neurosci., Wake Forest Univ. Sch. of Med., Winston Salem, NC

Abstract: Conscious subjective experience is private and dynamic. This poses a significant challenge that has led neuroscientists to shy away from this 'hard problem' and instead focus their attention on the 'easier' problems of information representation and behavior. There is now a major gap in our understanding of the mechanisms underlying conscious subjective experience and its dynamic nature. Computational methods and data from a variety of tools for measuring human brain activity and behavior are beginning to link dynamic changes in subjective affect with reproducible neurobehavioral signals in humans. In particular, research applying computational reinforcement learning theory has shown tremendous utility in investigating human choice behavior and the role the dopaminergic system plays in dynamic behavioral control. A major problem in this line of work, however, pertains to the design and neural implementation of algorithms that explicitly track the statistics of costs or punishments. We propose and describe in detail "Valence-Partitioned Reinforcement Learning" as a candidate approach for optimally learning about rewards and punishments directly from experience. We show that VPRL learns about punishments faster than traditional TDRL and hypothesize neural systems that could execute this algorithm. Further, we propose a *Dynamic Affective Core Hypothesis* that integrates advances in our understanding of the representation of the content and context of conscious experiences with our nascent understanding about how these representations acquire and retain subjective value. We discuss the implications of this model for 1) typical dynamic conscious experiences in humans; 2) the dynamic subjective states experienced by humans afflicted with psychiatric conditions; and 3) its utility for further investigations into the mechanisms of conscious experience in humans.

Title: Reward is not enough: behavioral and neural evidence for valence-partitioned reinforcement learning in humans and subjective phenomenal experience

Authors: *L. P. SANDS, A. JIANG, K. T. KISHIDA;
Physiol. and Pharmacol., Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract: Dopamine neurons encode temporal difference reward prediction errors (TD-RPEs), which guide mammalian behavior by teaching the brain what actions lead to the most rewarding outcomes. That dopamine neurons encode TD-RPEs is well documented, but how the mammalian brain learns from punishment is less clear. Temporal difference reinforcement learning (TDRL) theory and its applications in neuroscience and artificial intelligence treat punishments as simply negatively signed rewards. However, dopamine neurons that encode TD-RPEs do not have the capacity to effectively differentiate magnitude variation in losses. We propose Valence-Partitioned Reinforcement Learning (VPRL) to hypothesize a TDRL based framework to account for how an organism might learn optimally about the statistical structure of punishments (and rewards) in parallel and based on experience. Here we test the specific hypothesis that, in humans, rewarding and punishing events are partitioned into two parallel and independent TDRL-based systems (via VPRL), and that these signals are then integrated to estimate the quality of states and actions experienced by the agent. We also test the hypothesis that signals generated during VPRL updating will drive subjective feelings as self-reported by individual participants. Two cohorts of human participants completed a probabilistic reward and punishment task while reporting (33% probability per trial) how they felt about outcomes. Cohort 1 performed the behavioral task only (n=42); cohort 2 replicated the behavioral task with functional MRI brain scanning (n=19). For both cohorts, VPRL better described participant choice behavior on the task compared to standard TDRL. Participants' learning rates and temporal discounting for rewards and punishments were asymmetric. We regressed the learned action values, RPEs, and punishment prediction errors (PPEs) derived from individuals' VPRL models on participants' subjective ratings and found that RPEs have a convex-like, and PPEs a concave-like, functional relationship to affective responses. Model-based fMRI analysis revealed that partially overlapping areas of dorsal and ventral striatum, cingulate cortex, medial prefrontal cortex, and insula track the set of VPRL prediction errors, learned action values, and associated subjective feelings. Taken together, our analyses provide evidence that humans partition rewards from punishments during learning from reinforcement and that a distributed network of subcortical, limbic, and prefrontal regions track prediction errors over rewards and punishments that differentially influence subjective feelings about choice behavior.

Title: Chromatin accessibility mapping reveals compound genetic effects at a schizophrenia GWAS risk locus impairing neurodevelopment and synaptic function in human neurons

Authors: S. ZHANG[1], H. ZHANG[1], *M. FORREST[2], Y. ZHOU[3], V. BAGCHI[2], A. KOZLOVA[1], M. DOS SANTOS[2], N. PIGUEL[2], L. DIONISIO[2], A. R. SANDERS[1], Z. P. PANG[4], X. HE[3], P. PENZES[2], J. DUAN[1];

Abstract: Genome-wide association studies (GWAS) of schizophrenia (SZ) and other neuropsychiatric disorders have identified hundreds of risk single nucleotide polymorphisms (SNPs). However, functional interpretation of these GWAS risk SNPs has been challenging. Recently, we described an approach to elucidate functional SNPs by their allele-specific open chromatin (ASoC) signatures (Zhang et al., Science 2020). Here, using ASoC mapping and CRISPR/Cas9 genome editing in NEUROG2 (NGN2)-induced excitatory neurons (NGN2-iNs), we aimed at making causal links between GWAS risk SNPs and SZ-relevant disease phenotypes. We initially identified thousands of ASoC SNPs in NGN2-iNs of 20 iPSC lines and found 31 credible functional SNP in 26 SZ risk loci (out of 108) that displayed ASoC. For the four SZ-associated ASoC SNPs (near VPS45, BCL11B, PRBML1/GNL3, and BAG5) that also replicated our previous ASoC results (Zhang et al., Science 2020) in neural progenitor cells (NPCs)-derived glutamatergic neurons, we performed multiplex CRISPRi/single-cell RNA-seq (CROP-seq) in NGN2-iNs and found three SNP sites exhibited cis-regulatory effects on their flanking gene targets. Since the VPS45 locus showed the strongest ASoC in ATAC-seq and transcriptional repression of cis-targets in CROP-seq, we further investigated the function of this ASoC SNP (rs2027349) by CRISPR/Cas9 editing. In NGN2-iNs derived from isogenic iPSC lines carrying the two different alleles of rs2027349, we found that risk allele A was associated with an increased expression of the bi-directionally transcribed genes VPS45 and AC244033.2 (the latter being a lncRNA), as well as a distal gene C1orf54. Notably, NGN2-iNs carrying risk allele A showed transcriptomic changes correlated with gene expression changes in post-mortem brains of SZ, bipolar disorder, and autism spectrum disorder. Phenotypically, NGN2-iNs with A allele exhibited increases in dendritic complexity, synaptic puncta density, neural firing rate, and the frequency of calcium transients. Moreover, RNA knockdown of each cis-regulated gene in risk allele-

carrying neurons partially rescued the risk allele A-associated phenotypic changes, suggesting a phenotypic contribution from all three genes. The influence of rs2027349 was further corroborated by transcriptomic modelling, brain chromatin interaction (Hi-C) data, and the assay of local chromatin accessibility in isogenic NGN2-iNs. Our study thus reveals a complex gene regulation process at a single SZ GWAS locus that impairs neurodevelopment and synaptic function, providing a mechanistic link between a noncoding SZ risk variant and disease-related phenotypes.

Title: Intronic haplotypes of ionotropic glutamate receptors are associated with schizophrenia

Authors: *A. BALIK[1], K. HIRSCHFELDOVA[1], V. KUCHTIAK[1], J. CERNY[2], J. HORACEK[3], L. VYKLICKY[4];

Abstract: Schizophrenia (SCH) is a severe mental disorder characterized by a high heritability rate. The heritable component of SCH as a polygenic trait is represented by numerous variants from a heterogeneous group of genes each contributing a relatively small effect. Genome-wide association studies revealed several individual loci contributing to disease susceptibility included ionotropic glutamate receptors (iGluR) genes. In SCH patients, various single nucleotide polymorphisms (SNPs) were found and analyzed already in genes encoding the N-methyl-D-aspartate receptor (NMDAR) subunits but less information is known about genetic variations of genes encoding the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPAR) and kainate (KAR) receptor subunits.
We analyzed sixteen iGluR genes in full length including extended promoter regions in 63 first-episode SCH patients and in 32 age and sex-matched healthy control subjects to determine sequence variability of iGluR genes. We aimed to describe the rate of genetic variability, its distribution, and the co-occurrence of variants in patients compared with controls, and to hallmark candidate risk variants or haplotypes. The cumulative effect of genetic risk in SCH was then estimated using a simple scoring model.

The GRIN2A-B and GRIN3A-B from the GRIN gene family as well as GRIK4 had noticeably increased genetic variation in SCH patients compared to the other studied genes. The fixation index statistic (Fst) highlighted eight intronic haplotypes and another four intronic SNPs within the sequences of iGluR genes associated with SCH ($p < 0.05$). The haplotypes were used in the proposed simple scoring model and further as a test of a genetic predisposition to schizophrenia. The positive likelihood ratio (LR) for the scoring model test reached 7.11. In the coding portion of iGluR genes, we observed the 41 protein-altering variants (38 missense variants, four frameshifts and one nonsense variant) that were not significantly associated with SCH. Using MRI scans of the brain, we also determine the BrainAge, a complex value, showing the in brain atrophy from normal brain aging expressed in years, which positively correlated with the increased number of intronic haplotypes in SCH patients. Our data suggest that some intronic regulatory regions of iGluR genes and their common variability are one of the components from which the genetic predisposition to SCH is composed.

Title: Genetic variations of NMDAR promoter regions in schizophrenia

Authors: *E. TOMOVIC[1], V. KUCHTIAK[1], K. HIRSCHFELDOVA[1], A. BALIK[2];
[1]Inst. of Physiol. CAS, Prague, Czech Republic; [2]BIOCEV, Inst. of Physiol. CAS, Vestec, Czech Republic

Abstract: Schizophrenia (SCH) is a severe psychiatric disease characterized by high heritability and early onset during puberty. It displays a complex phenotype and affects millions of people worldwide. So far, many risk genes and environmental risk factors have been identified. The prevalent hypothesis indicates that etiology involves alterations in excitatory glutamatergic signaling. Previous studies have shown that N-methyl-D-aspartate receptor (NMDAR) plays a role in the emergence and development of SCH because its pharmacologically induced hypofunction mimics clinical symptoms and cognitive deficits observed in SCH. NMDARs are hetero tetramers composed of two GluN1 subunits combine with two GluN2 or GluN3 subunits. During postnatal development, expression changes between GluN2A/B and GluN3A/B subunit that leaves NMDAR vulnerable if genetic changes compromise these processes. Many mutations found in SCH patients occurred in the promoter regions of the genes. However, their effect on the NMDAR expression was not always well characterized. Therefore, we performed targeted sequencing and genetic analysis of the promoter regions of NMDARs of SCH patients and corresponding healthy

controls. The highest number of SNPs was observed in GluN3B subunit, in total 27. We identified 7 SNPs in GluN1 promoter region, 10 in GluN2A, 13 in GluN2B and 8 in GluN3A. Some variants such as rs181870048 (GluN2A) and rs12338602 (GluN2B) had remarkably high in silico predictions of being deleterious. Then, we subcloned specific promoters containing different genetic variations into luc_reporter plasmid and performed a luciferase assay. We found that various genetic changes affected the expression activity of promoters. Since DNA methylation of regulatory regions of the gene also affects gene transcription and is one of the mechanisms by which environmental risk factors may contribute to the emergence of SCH, we also analyzed the methylation status of selected parts of the promoter regions using real-time PCR and bisulfite sequencing. We found the increased level of DNA methylation in GluN1 with the average Tm 74,8°C and GluN3B with the average Tm 76,79°C relative to average control Tm of 74,4°C and 75,93°C respectively. GluN2A with the average Tm 78,2°C1 showed the reduction of methylation level with the average control Tm being 78,61°C. These results suggest that both, genetic changes in the promoter region of the gene as well as the changes in methylation can modulate gene expression of NMDARs and thus may cause the hypofunction of the glutamatergic signaling that contributes to the emergence of SCH.

Abstract: Genetic factors have been shown to increase the risk of developing psychosis. Two patients with bipolar disorder with psychotic features and schizoaffective disorder, respectively, have been found by others to harbor a small supernumerary marker chromosome, which contains multiple genes from the

9p24.1 chromosomal region, including the gene encoding glycine decarboxylase (*GLDC*). GLDC is an astrocytic enzyme that degrades glycine, which is a co-agonist at the NMDA receptor. NMDA receptor hypofunction has been implicated in the pathophysiology of schizophrenia. In these patients, glycine augmentation of antipsychotic therapy with clozapine led to improvements of psychotic and mood symptoms. In order to elucidate the potential mechanism of such reversal of symptoms with glycine, we have generated copy number variant (CNV) mice with increased copy numbers of either the entire 9p24.1 region or of *Gldc* alone. These mice were developed by introducing loxP sites into the genome followed by *trans*-allelic recombination *in vivo*. CNV's were confirmed by comparative genomic hybridization. The goal of the current study was to determine whether glycine alone is sufficient to reverse schizophrenia-like phenotypes in these CNV mice harboring extra copies of the human 9p24.1 region or just of *Gldc*. Our hypothesis was that glycine alone would be sufficient to reverse at least some schizophrenia-like phenotypes in the CNV mice modeling the patients with the 9p24.1 CNV.In our studies, we included both male and female mice with 4 copies of the 9p24.1 region or with 4 or 2 copies (equivalent to wild type) of *Gldc* ($n \geq 8$). Mice were administered glycine in their drinking water for 21 days. Three hours before behavioral experiments they received glycine (or vehicle) by gavage. To assess glycine delivery, blood samples were analyzed with LC-MS/MS. Furthermore, glycine levels were also determined in hippocampus and prefrontal cortex. Behavioral testing included acoustic startle experiments to determine prepulse inhibition and pulse habitation, latent inhibition to conditioned freezing and working memory in the Y maze. The density and morphology of dendritic spines was assessed with Golgi staining. Experiments to date suggest that glycine has differential effects in different behavioral paradigm. Our results indicate that chronic administration of glycine in mice with an increased copy number of *Gldc*, thus presumably with higher rates of glycine degradation in astrocytes, may be sufficient to reverse at least some of the schizophrenia-like phenotypes observed.

Title: Density of somatostatin neurons in the dorsolateral prefrontal cortex of schizophrenia subjects

Authors: *S. DIENEL[1], K. FISH[2], D. A. LEWIS[2];
[1]Dept of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Dept Psychiatry, Univ. Pittsburgh, Pittsburgh, PA

Abstract: Background: Cognitive dysfunction in schizophrenia is associated with altered GABA signaling markers in the prefrontal cortex (PFC). For example, levels of somatostatin (SST) mRNA, expressed in a subset of GABA neurons, are markedly lower in PFC gray matter in schizophrenia. The density of SST mRNA+ neurons is also lower in schizophrenia. However, whether schizophrenia is associated with fewer SST neurons or a failure of certain SST neurons to express detectable levels of SST mRNA remains unknown. **Methods**: To identify all SST neurons, we used multiplex fluorescent *in situ* hybridization to simultaneously label neurons containing SOX6 (expressed in both SST and parvalbumin (PV) neurons) and vesicular GABA transporter (VGAT) mRNAs, neither of which appear altered in schizophrenia, and SST or PV mRNA. SOX6+/VGAT+/SST+ and Sox6+/VGAT+/PV- neurons were considered SST neurons. The density of labeled neurons was quantified in 30 matched pairs of schizophrenia and unaffected comparison subjects. **Results**: In DLPFC gray matter, mean density of SOX6+/VGAT+/SST+ neurons was significantly 31.3% lower in schizophrenia subjects ($p = 0.008$), but the density of SOX6+/VGAT+/PV- neurons (which includes all SST neurons regardless of SST mRNA level) did not significantly differ between subject groups ($p = 0.33$; Bayes' Factor in favor of null hypothesis = 3.01). Studies in the same cohort using high resolution imaging to quantify levels of SST per neuron are in progress. **Conclusions**: These findings indicate that the density of SST neurons is not altered in schizophrenia, but a subset of these neurons fail to express detectable levels of SST mRNA. The presence of a normal complement of SST neurons suggests that these neurons can be targeted by therapeutic interventions to improve cognitive dysfunction in schizophrenia.

Title: Investigation of gaba-ergic interneuron-localized gene expression in the subgenual cingulate cortex of postmortem subjects diagnosed with bipolar disorder and schizophrenia

Authors: *D. M. KROLEWSKI[1], M. WASELUS[1], V. KUMAR[1], R. M. MYERS[2], F. LEE[3], J. D. BARCHAS[3], A. SCHATZBERG[4], W. E. BUNNEY[5], H. AKIL[1], S. J. WATSON, Jr.[1];

Abstract: The human anterior cingulate cortex can be neuroanatomically subdivided, in relation to the corpus callosum, into dorsal (ACg) and ventral subgenual (SCg) components and is collectively well known to be involved in the regulation of emotional behaviors pertinent to mental illness. In a recently completed internal study, our laboratory has observed significant distributional mRNA differences related to GABA-ergic interneuron-localized transcripts, diagnosis, and anatomically distinct subregions within the ACg involving Brodmann's areas (BA) 24 and 32. To further characterize the cingulate cortex, the goal of the current study is to measure mRNA transcripts reflecting the same interneuron subpopulations within the SCg which also employ contrasting synaptic pyramidal cell connectivity. The latter include non-overlapping subpopulations identified by differential expression of parvalbumin (PV), somatostatin (SST), and vasoactive intestinal peptide (VIP). Our experimental methods combined the *in-situ* hybridization (ISH) technique using radiolabeled cRNA probes with 10 ɥm fresh-frozen SCg sections from control (n=20), schizophrenia (n=16), and bipolar disorder (n=22) subjects. Gray-scale optical density values are being used to determine potential diagnosis-related gene expression differences in PV, SST, and VIP mRNA spanning SCg subdivisions that include BA 33, 25, and ventral area 24. The results of this study will further our understanding how information processing may be dysregulated by way of GABA-ergic interneuron function in the SCg of bipolar and schizophrenic patients.

Title: Distinct molecular subtypes in schizophrenia show differences between polyA and riboZ RNAseq from dorsolateral prefrontal cortex

Authors: E. CHILDERS, E. F. BOWEN, H. RHODES, *R. GRANGER;
Dartmouth Col., Hanover, NH

Abstract: Distinct molecular subtypes in schizophrenia shows differences between polyA and riboZ RNAseq from dorsolateral prefrontal cortex. *E Childers, E Bowen, H Rhodes, R Granger Dartmouth College*
Well-documented evidence of the physiologic, genetic, and behavioral heterogeneity of schizophrenia suggests that diagnostic subtyping may clarify the underlying pathobiology of the disorder.
We have previously provided evidence (Bowen et al 2019) of two such subtypes based on Illumina array data from the dorsolateral prefrontal cortex (DLPFC) of post-mortem frozen brains of diagnosed schizophrenics and neurological matched controls. "Type 1" and "type 2" schizophrenics had DLPFC transcriptomes that were very similar to, versus radically different from controls, respectively.

In this study we asked whether the two distinct molecular subtype signatures could be identified in RNAseq datasets, using the same subjects but different RNA selection methods: polyA vs. riboZ. The subjects did cluster into two corresponding groups for both datasets, replicating and adding support to the previously published results. Specifics of the commonalities and differences between the two schizophrenic subtypes are further analyzed.

Biol., Johns Hopkins Univ., Baltimore, MD

Abstract: Schizophrenia is a complex neuropsychiatric disorder with sexually dimorphic features, including an increased incidence rate in males, earlier onset of disease in males, differential symptomatology and drug responsiveness. To date, only the prefrontal cortex has been examined by two large-scale transcriptome analyses for sex differences in schizophrenia. To gain novel insight into risk mechanisms underlying sexually dimorphic features of schizophrenia, we examine the BrainSeq Consortium RNA-sequencing and genotypes for the caudate nucleus (n=394), dorsolateral prefrontal cortex (DLPFC; n=360), and hippocampus (n=376) to characterize sex differences in schizophrenia by identifying genomic features (genes, transcripts, exons, and exon-exon junctions) predictive of sex, sex-specific expression in schizophrenia, and sex-interacting expression quantitative trait loci (si-eQTL). We find 442 unique genes with sex differences across brain regions, including ANK3, which showed male biased expression in the caudate nucleus. While our sex-by-diagnosis interaction model revealed only a handful of novel exon-exon junctions with statistical significance, a stringent comparison of schizophrenia dysregulation analyzed by sex identified dozens of sex-specific genomic features which are

enriched in transcriptional response of cellular stress. Our si-eQTL analysis revealed 142 unique genes, including the C4 allele which exhibited vulnerability to increased schizophrenia risk in male individuals. Overall, our results increase the number of annotated sex biased features, identified sex-specific schizophrenia genes, and provided the first annotation of si-eQTL in the human DLPFC and hippocampus. Altogether, these results point to the importance of sex informed analysis of sexually dimorphic traits and have the potential to inform therapeutics strategies in schizophrenia.

Title: Psychosis-associated V321L mutation in Neuregulin1 disrupts expression of a schizophrenia susceptibility gene network within the hippocampus and alters adult hippocampal neurogenesis.

Authors: *P. RAJEBHOSALE[1], A. JONE[2], K. JOHNSON[1], L. W. ROLE[1], D. A. TALMAGE[1]; [1]NINDS, NIH, Bethesda, MD; [2]State Univ. of New York at Stony Brook, Stony Brook, NY

Abstract: The Neuregulin1 (Nrg1) gene produces several structural isoforms of transmembrane (TM) proteins that are most popularly recognized as ligands for ErbB family of receptor tyrosine kinases. However, the type III isoform participates in bi-directional signaling acting as both a ligand (forward signaling) and a receptor (back-signaling) for ErbB4. Upon binding to ErbB4, Nrg1 undergoes regulated intramembrane proteolysis (RIP) by gamma secretase (γ-Sec). This cleavage generates a cytosolic intracellular domain (ICD) which can translocate to the nucleus. The psychosis-associated V321L mutation in Nrg1 disrupts cleavage by γ-Sec and thereby implicates nuclear back-signaling in the underlying pathology. Here we show that nuclear ICD clusters form phase separated condensates that localize to transcriptionally active compartments. Cultured hippocampal neurons stimulated with either soluble ErbB4 (sB4) or potassium chloride (KCl) showed an increase in nuclear ICD clusters, which could be blocked by pre-treatment with a γ-Sec inhibitor. Neurons from mice harboring the V321L mutation failed to show this increase. We investigated the effects of the V321L mutation on the dentate gyrus (DG) transcriptome using RNA sequencing (RNA-Seq). The DG is the gate for incoming input into the hippocampus, a function served by granule cells that are continually produced in the DG neurogenic niche. Pathway analysis of the differentially expressed genes in the V321L DG predicted dysregulation of neurogenesis, cell cycle regulation, dendrite morphogenesis, and differentiation which were confirmed by follow-up experiments. Additionally, we found that several known schizophrenia susceptibility genes were dysregulated. Chromatin immunoprecipitation enrichment analysis (ChEA) revealed many

upregulated genes shared common upstream regulators. Given this, we performed weighted gene correlation network analysis (WGCNA) to identify modules of genes whose expression is co-dysregulated. STRING analysis of statistically significant WGCNA modules showed significant protein-protein interactions within each module indicating common dysregulation of members of macromolecular complexes involved in the ubiquitin proteosome system, RNA splicing, chromatin modifying complexes and the endomembrane system. Taken together, our studies provide a mechanistic link between neurodevelopmental events and schizophrenia susceptibility genes and cellular functions. Ongoing studies are aimed at further investigating this link in an age, sex, and cell-type specific manner.

Title: The consequences of base rate neglect on sequential belief updating and real-world beliefs

Authors: *B. K. ASHINOFF[1,3], J. BUCK[1,3], M. WOODFORD[2], G. HORGA[1,3];
[1]Psychiatry, [2]Econ., Columbia Univ., New York, NY; [3]New York State Psychiatric Inst., New York, NY

Abstract: Base-rate neglect is a pervasive bias consisting of under-incorporation of prior knowledge into newly formed beliefs. Perhaps surprisingly, the underlying neurocomputational mechanisms of base-rate neglect remain poorly understood, and so are its effects on sequential belief updating and real-world beliefs. A Bayesian formalization of base-rate neglect predicts that, under this bias, belief trajectories should depend on the order in which evidence is presented; this should manifest as a recency bias defined by greater weighting of newer evidence and lingering uncertainty over time due to a form of prior-dependent updating, suggesting that base-rate neglecters may be prone to forming unusual long-term beliefs in the real world. We developed a novel 'urn-and-beads' task that systematically manipulated the evidence order of 8-sample sequences and used an incentive-compatible belief-elicitation procedure. Using both model-based and model-agnostic measures, our results in two independent online studies (n=151; n=116) confirm the prediction that base-rate neglect expresses itself as a recency bias and prior-dependent updating. Furthermore, while individuals exhibited base-rate neglect on average, there was substantial interindividual variability that scaled with the magnitude of the recency bias and prior-dependent updating. Given that base-rate neglect induces inaccurate beliefs, it is commonly framed as a suboptimal process. However, bounded-rationality computational models frame it as an optimal response to limited internal resources. Consistent with the latter notion, a noisy-sampling model whereby base-rate neglect results from rational discounting of noisy internal representations of prior probabilities provided an accurate description of our combined dataset (n = 267). Specifically, variability in probability

estimates correlated with base-rate neglect following the predictions of the noisy sampling model. This suggests that base-rate neglect may be driven by imprecision in the internal representation of prior knowledge. Finally, we examined self-reported propensity for unusual beliefs outside the laboratory and found that individuals with more base-rate neglect, and noisier prior representation, tended to report more unusual beliefs in their daily lives. Our results demonstrate a behavioral signature of base-rate neglect in sequential belief updating that conforms to Bayesian predictions and that this bias has a measurable influence on real-world beliefs. Further, our results suggest a candidate mechanism under which base-rate neglect reflects a rational response to an imprecise internal prior representation.

Title: Effects of prenatal cannabis vapor exposure on cognitive flexibility and in vivo cortico-striatal-thalamic network activity

Authors: *D. E. GINDER[1], H. R. WRIGHT[2], H. V. WEIMAR[2], A. N. MALENA[2], T. G. FREELS[3], R. J. MCLAUGHLIN[2];
[1]Exptl. Psychology, [2]Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA; [3]Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Widespread legalization of recreational cannabis has resulted in an increase of past-month cannabis use among pregnant women, yet the long-term effects of prenatal cannabis exposure on cognitive flexibility and its underlying neural substrates remains largely unknown. We have recently used passive cannabis vapor delivery in pregnant rat dams to reveal impairments in cognitive flexibility in cannabis-exposed offspring in adulthood. A network involving the medial prefrontal cortex (mPFC), nucleus accumbens (NAc), and medial dorsal thalamus (MDT) is known to critically orchestrate decision making under shifting environmental demands. However, we do not know the extent to which alterations in the cortico-striatal-thalamic network are associated with set-shifting impairments in cannabis-exposed offspring. In ongoing studies, we are measuring local field potentials (LFP) in the mPFC, NAc core and MDT during cue presentation, response selection, and reinforcer delivery in an automated attentional set-shift task that requires rats to shift away from a visual cue-based discrimination strategy to an egocentric spatial discrimination strategy to obtain a sucrose pellet reinforcer. In naïve male rats, we have shown that gamma power in the mPFC and NAc is decreased following acute cannabis vapor exposure, while gamma coherence between the mPFC and NAc is selectively enhanced prior to and during correct response trials in the set-shifting task. Thus, we predict that prenatal cannabis exposure impairs cognitive flexibility in adulthood by altering gamma oscillations within the corticostriatal circuit, which interferes with post-feedback updating of strategy selection. To test this hypothesis, female rat dams were trained to self-administer cannabis vapor (69.9% THC; 150mg/ml, 1-hr sessions, twice daily) or vehicle prior to and during the gestational period. At PND90, male and female offspring were trained in the set-shifting tasks,

and following successful acquisition, were implanted with a stainless steel electrode array targeting the mPFC, NAc core, and MDT. Following recovery, rats were re-acclimated to the task and LFP recordings are currently being conducted during the set shift and reversal learning phases of the task to determine whether the cortico-striatal-thalamic network is differentially recruited in cannabis- and vehicle-exposed offspring. Given the increasing rates of cannabis use among pregnant mothers, these studies will provide translationally relevant data regarding the cognitive effects of prenatal cannabis exposure and offer unique insight into possible neurobiological mechanisms that could underlie these effects.

Title: Medial Prefrontal Cortex Dysfunction Mediates Working Memory Deficits in Schizophrenia

Authors: *J. C. WILLIAMS[1,2], Z. J. ZHENG[1], J. R. LUCENO[1], P. N. TUBIOLO[1,3], R. B. GIL[1], R. R. GIRGIS[5,6], J. A. LIEBERMAN[5,6], A. ABI-DARGHAM[1], J. X. VAN SNELLENBERG[1,3,4];
[1]Psychiatry and Behavioral Hlth., Renaissance Sch. of Med. at Stony Brook Univ., Stony Brook, NY; [2]Biomed. Engin., [3]Dept. of Biomed. Engin., [4]Dept. of Psychology, Stony Brook Univ., Stony Brook, NY; [5]Dept. of Psychiatry, Columbia Univ. Vagelos Col. of Physicians and Surgeons, New York, NY; [6]The New York State Psychiatric Inst., New York, NY

Abstract: Schizophrenia (SCZ) is marked by deficits in working memory (WM), which are strongly predictive of poor functional outcomes, and effective treatments remain elusive. Reduced deactivation over the course of WM tasks in regions of the default mode network (DMN), including medial prefrontal cortex (mPFC), has been shown to correlate with reduced task performance in both patients and healthy individuals. However, it is unclear whether deficits in mPFC deactivation could explain impairments present in SCZ.
Medicated (n = 27) and unmedicated (n = 14) patients with SCZ (total n = 41) and matched healthy control subjects (HC; n = 40) performed a visual object *n*-back WM task across 4 fMRI runs, each comprising two 40 s 1-back and 2-back blocks. Deactivation during 1-back and 2-back blocks for each subject was quantified using a GLM framework in SPM12. An mPFC region of interest (ROI) was

employed from the Gordon (2016) parcellation by selecting prefrontal parcels in the DMN, dilating all parcels by 8 mm, and eroding the result by 5 mm. A total of 4,908 voxels (132.516 cm^3) within this mPFC ROI was then found to show significant deactivation during the 2-back task condition either across both groups (SCZ and HC) or within each group separately (assessed via NPC). From among these, a subset of 205 voxels (5.535 cm^3) showed significant associations between task performance and deactivation (FWER corrected with TFCE).
Group differences in mPFC deactivation (a single value for each subject obtained by averaging deactivation across all 205 voxels, above) and 2-back task performance were evaluated using a Welch's t-test and a Mann-Whitney-Wilcoxon test, respectively. MPFC deactivation was evaluated as a mediator of the impact of diagnosis on task performance using the CANlab M3 Mediation Toolbox, with significance evaluated using a BCa bootstrap procedure.
Relative to HC, patients with SCZ exhibited significantly worse performance (median 2-back proportion correct of 0.7813 in SCZ vs. 0.9141 in HC, $p = 0.0018$) and reduced mPFC deactivation during 2-back task blocks ($t_{77.578} = 2.1628$, $p = 0.0336$). Mediation analysis showed a significant indirect relationship between SCZ diagnosis and task performance mediated by mPFC deactivation, in addition to a direct relationship between group membership and task performance, establishing mPFC deactivation as a partial mediator (mediated effect $\beta = -0.0477$, $p = 0.0363$; direct effect $\beta = -0.1291$, $p = 0.0163$).
This work establishes mPFC dysfunction as a potential substrate for working memory impairment in schizophrenia, and a potential neuroimaging target for evaluating the effects of experimental drugs for treating these impairments.

Title: Response disinhibition as a mediator between sleep disruption and psychotic-like experiences in adolescents

Authors: *J. OUELLET, S. SPINNEY, T. PANCHADSARAM, R. ASSAF, S. POTVIN, P. CONROD; Univ. de Montréal, Montréal, QC, Canada

Abstract: Sleep has long been associated with psychosis with a significant portion of patients reporting comorbid sleep disturbances. Increasing evidence now suggests that sleep may also act as a causal risk factor in the development of psychosis. Sleep is also known to play a role if the development of key cognitive domains, which are known to be disrupted in psychosis. These cognitive domains include

inhibitory control. Psychotic-like experiences (PLEs), sub-clinical hallucinations and delusions, have been found to gradually increase in frequency and intensity over time in adolescents who go on to transition to psychosis. PLEs therefore offer an opportunity to identify and study at risk individuals before the onset of clinically recognisable symptoms. This study aimed to investigate the role of different aspects of response inhibition as mediators in the relationship between sleep and PLEs. A longitudinal cohort of 3779 high-school students (1727 girls [46%]; mean [SD] age, 12.9 [0.5] years) was recruited from 31 Montreal high-schools and assessed on a yearly basis over a five year period. A past-month sleep score was derived from a subjective sleep questionnaire while PLEs were assessed using the Adolescent Psychotic-Like Symptoms Screener. Inhibition was measured using the Passive Avoidance Learning Paradigm. Separate analyses were performed using a multi-level model and four different PALP performance metrics as mediators (i.e. commission and omission errors under reward and punishment conditions). Our model controlled for sex and time squared. Our results support a strong association of sleep and PLEs at the between-subject (B=-1.044; SD=0.145; p<0.001) and within-subject level (B=-0.110, SD=0.053, p=0.015). At the within-subject level, commission errors were associated with sleep disturbances under punishment condition (B=-0.016; SD=0.005; p<0.000) and with PLEs under reward condition (B=0.301; SD=0,126; p< 0.005). Under reward conditions, there was a lagged association of sleep disturbances with both commission (B=-0.02; SD=0.008; P=0.005) and omission errors (B=-0,048; SD=0,018; p=0.015). A significant mediated path revealed that poor sleep was associated with increased commission errors under reward conditions the following year, which is in turn associated with a concurrent increase in PLEs frequency (B=-0.006, SD=0.003, p=0.01). These results suggest that poor sleep may cause a deviation from normal cognitive development trajectories. This weakening of information processing may make individuals more vulnerable to delusions possibly by interfering with the maturation of inhibitory control.

Title: Utility and diagnostic accuracy of the MMSE and Penn CNB for cognitive screening of youth at-risk for psychosis.

Authors: *J. R. KANTOR[1], R. C. GUR[3], K. RUPAREL[1], M. E. CALKINS[1], S. TROYAN[1], A. M. PORT[1], T. M. MOORE[1], R. E. GUR[1], D. R. ROALF[2];
[2]Neuropsychiatry, [1]Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. Pennsylvania, Philadelphia, PA

Abstract: **Background**: Subtle cognitive impairment is evident in individuals at-risk for developing psychosis. Thus, it is of interest to find useful cognitive screening instruments that are time-efficient and reliably help identify patients who may be at risk. The Mini-Mental State Examination (MMSE) and the Penn Computerized Neurocognitive Battery (CNB) are two validated assessments used to measure cognitive impairment in patient populations. Here, we compare the utility and diagnostic accuracy of the MMSE (Folstein et al., 1975) and Penn CNB (Gur et al. 2014) in the screening of at-risk psychosis in a large mixed longitudinal sample of typically developing (TD) and at-risk psychosis (PS) individuals and provide a crosswalk between MMSE and CNB scores. **Methods**: Participants were assessed using clinical interviews, the MMSE and Penn CNB, and were classified as PS or TD at baseline based on the presence or absence of subthreshold psychosis spectrum symptoms. Participants returned for a follow-up visit and repeated testing and were classified as TD-TD, TD-OP (other psychopathology), TD-PS, PS-TD, PS-OP, or PS-PS based on baseline and follow-up diagnoses. Two-hundred twenty-nine (n=229) participants completed the MMSE at both visits and n=210 of these completed the Penn CNB at both visits. **Results**: PS-PS ($p<0.0001$) and PS-OP ($p=0.011$) had lower MMSE scores than TD-TD participants. On CNB Z-scores, PS-PS were less accurate than TD-TD ($p<0.0001$) and TD-OP ($p=0.0003$), and TD-PS were less accurate than TD-TD ($p=0.044$) and TD-OP ($p=0.030$). ROC analyses comparing TD-TD to PS-PS participants found that the MMSE had higher specificity (71%) than the CNB, while the CNB had higher sensitivity (66%). Calculated cut-off scores resulted in similar classification accuracy for both assessments. When using cut-off scores from both assessments in a stepwise manner, classification accuracy improved to 80%. MMSE scores were highly correlated with CNB Accuracy Z-scores ($r(208)=0.42$, $p=1.528 \times 10^{-10}$) and CNB Efficiency Z-scores ($r(208)=0.41$, $p= 5.456 \times 10^{-10}$). Equipercentile equating was used for score conversion. **Conclusions:** The MMSE and CNB were successful at identifying individuals who are at persistent risk for psychosis based on their cognitive impairment. We found the MMSE to be more accurate at identifying healthy individuals and the CNB to be more accurate at identifying individuals with clinical diagnoses, particularly psychosis-risk. Overall, our results indicate that both tests offer good diagnostic and classification accuracy for screening youth who may be at-risk for psychosis, performance on the two tests is positively correlated, and score conversion is feasible.

Title: The induced Roelofs effect in the psychosis continuum

Authors: *D. ESPOSITO[1,2], M. AMADEO[1], A. ESCELSIOR[3,4], A. INUGGI[3,4], M. AMORE[3,4], M. GORI[1];
[1]Unit for Visually Impaired People, Italian Inst. of Technol., Genova, Italy; [2]Dibris, Univ. di Genova,

Abstract: Visual estimation of a stimulus' azimuthal orientation is sensitive to task-irrelevant contextual information. For example, in a left-right discrimination task, the presence of a large frame surrounding the target stimulus, shifted some degrees away from the observer's visual midline, has a repulsive effect on the perceived target's side. This effect is called the "induced Roelofs effect", and it is believed it depends on the frame's ability to distort the egocentric reference frame by attracting the apparent visual midline. A previous study showed that schizophrenia, a condition associated with a weakened sense of self, is characterized by a larger induced Roelofs effect than that of the typical population. Here we assessed the induced Roelofs effect size in a group of typical controls, a group of people affected by schizophrenia, and a group of people affected by bipolar disorder. According to the hypothesis of a psychosis continuum, bipolar disorder lies at an intermediate stage between typical and schizophrenic conditions. We predicted that, if the induced Roelofs effect were related to the psychosis severity, the bipolar group's effect size would fall between the typical controls group and the schizophrenic group's effect sizes. Our results confirmed such prediction; we also found that induced Roelofs effect and left-right discrimination ability did not follow the same group-level pattern. These results suggest that the induced Roelofs effect may be used to quantify the degree of psychosis severity. Next, we will use Bayesian optimal observer modeling to evaluate the induced Roelofs effect in terms of balance between egocentric and allocentric reference frames.

Abstract: The neurovisceral integration model proposes a brain-heart linkage where prefrontal cortical brain areas related to executive functions are connected to midbrain areas that are responsible for the vagal control of the heart. There is evidence documenting autonomic dysregulation among patients with schizophrenia (SCZ) while much less is known in patients with Obsessive Compulsive Disorder (OCD). Both SCZ and OCD patients present deficits in the inhibitory control of saccadic eye movements related to prefrontal cortical areas. The current examined the association between autonomic activity and inhibitory oculomotor control in SCZ and OCD using indexes of heart rate variability (HRV) measured during the performance of saccade and antisaccade tasks. The results from 30 healthy controls (HC), 30 SCZ and 15 OCD patients confirmed the presence of a deficit in antisaccade task performance in schizophrenia and OCD ($F_{(2,72)} = 5.01$, $p < .001$). Electrocardiographic (ECG) recordings were used to determine autonomic activity during saccade and antisaccade task performance. RR intervals were detected in the ECG signal and used to measure the high frequency component of HRV, an indicator of parasympathetic activity. Results showed that schizophrenia and OCD patients had lower hfHRV during antisaccade task, ($F_{(2,72)} = 10.08$, $p < .001$). Mediation analysis was employed to further examine the connection between increased error rate in antisaccade task and decreased hfHRV in patients with schizophrenia and OCD. A specific relationship between inhibitory control and parasympathetic activity was documented, where hfHRV mediated the effect difference between both groups of schizophrenia and OCD patients and controls in antisaccade error rate (6.24 (5.69 - 6.79), t= 22.77 $p < .001$). Our results demonstrate that the higher the parasympathetic activation the higher the inhibitory control and suggest that parasympathetic activity, specifically the hfHRV, is a key feature for explaining the effect difference between patients and controls in inhibitory control.

Title: Using a B-SNIP biomarker fingerprint to stratify participants for clinical trials:testing the kynurenic acid hypothesis of cognitive impairment

Authors: C. A. TAMMINGA[1], M. E. HUDGENS-HANEY[2], B. A. CLEMENTZ[3], E. S. GERSHON[4], S. KEEDY[5], G. PEARLSON[6], M. KESHAVAN[7], S. K. HILL[8], R. SCHWARCZ[9];

Abstract: The brain concentration of kynurenic acid (KYNA), a metabolite of the kynurenine pathway of tryptophan degradation and antagonist of both N-methyl-D-aspartic acid and α7 nicotinic acetylcholine receptors, is elevated in the prefrontal cortex of individuals with schizophrenia (SZ). This increase is clinically relevant because hypofunction of these receptors is implicated in the pathophysiology and cognitive deficits of the disease. Two enzymes, kynurenine 3-monooxygenase (KMO) and kynurenine aminotransferase II (KAT II) play critical roles in regulating brain KYNA levels. Thus, a reduction in KMO activity, as seen in the brains of people with SZ, increases brain KYNA, and inhibition of KAT II, which produces most KYNA in the brain, could be a fundamentally new approach to treat cognitive impairments (Schwarcz et al., 2012). In examined postmortem SZ cases (BA6 region), the KMO SNP *rs2275163 CC* (but not KMO SNP *rs2275163 CT/TT*) is associated with reduced KMO mRNA expression enzyme activity and elevated KYNA levels. Moreover, and unrelated to a SZ diagnosis, this genotype reduces predictive pursuit function and worsens visuospatial working memory (Wonodi et al., 2011). Based on these results, we now compared a "biomarker fingerprint" of KMO SNP *rs2275163 CC* (the "high KYNA" phenotype) versus *rs2275163 CT/TT* in a large cohort (N=200/genotype) of SZ individuals belonging to Biotypes 1 and 2, as defined by the Bipolar and Schizophrenia Network for Intermediate Phenotypes (B-SNIP) consortium (Clementz, 2015). For this analysis, we conducted four separate canonical discriminant analyses with the biotype cases (each bootstrapped 1000x with 95% sampling), evaluating (i) cognition (BACS and Stop Signal Task), (ii) EEG (evoked and intrinsic activity), (iii) oculomotor function (pro-/anti-saccades and smooth pursuit), (iv) cortical thickness, (v) cortical surface area, and (vi) cortical and subcortical regional volumes. The results revealed a 0.7 SD separation between *rs2275163 CC* and *rs2275163 CT/TT* probands. Notably, probands with z-scores >0.5 had a >95% likelihood of carrying the *rs2275163 CC* genotype. The CC biomarker profile defines "high KYNA" and captures all such cases, secondary to any source. These findings support using biomarkers as co-primary outcome measures to select study populations for clinical trials designed to test KAT II-modifying cognitive enhancers, by recruiting "high KYNA" populations. This approach of prospective enrichment of the patient population through phenotyping is expected to reduce the size of trials as well as increase the likelihood of success by targeting SZ people with a "high KYNA" fingerprint.

Title: High density, high channel count flexible neural probes realized by integration to CMOS chips

Authors: *E. T. ZHAO[1], J. HULL[1], N. HEMED[1], A. HIERLEMANN[2], J. R. HUGUENARD[3], N. A. MELOSH[1];

Abstract: Development of ultra-small and flexible electronics have become a key research topic in neural interfaces; these devices have high spatiotemporal resolution and are able to intimately integrate with biological tissue, enabling tracking of individual neurons over weeks. A central challenge limiting the scalability of such devices is the development of high-density and high channel count input/output (I/O) connections between the flexible electrodes and downstream electronics. Here, we introduce a novel nanofabricated microstructure, facilitating connectivity between our neural probe and planar, high-density multielectrode arrays (HD-MEAs) with 34 µm pitch and 3396 individually addressable channels. To our knowledge this is the smallest pitch and highest channel count reported in literature. We realize this technology in two applications, intracortical probes and electrocorticography (ECoG) arrays, and through this are able to study brain-wide transitions that occur during epileptic seizures with unparalleled spatial resolution.

Title: Towards Automated Epileptic Seizure Detection in Electrically Active Implants

Authors: *A. BAHR[1], S. SIMMICH[2], J. SOLIS ARBUSTINI[1], R. RIEGER[2];
[1]Sensor Syst. Electronics, Inst. of Electrical Engin. and Information Technol., [2]Networked Electronic Systems, Inst. of Electrical Engin. and Information Technol., Kiel Univ., Kiel, Germany

Abstract: In recent years, the design of neural amplifiers has shown tremendous progress. The integration of thousands of recording sites into the electrode enables recordings with high spatial resolution [1, 2]. A key element was the integration of the neural preamplifier into the electrode itself. In future, it is expected that integration will extend to system level towards implantable systems. This will enable new electronically active implants, e.g. medical devices for epileptic seizure detection and treatment or

advanced BCIs.
Implantable systems require a very high energy efficiency to warrant long use time. Therefore, every subsystem has to be power-optimized. In this work, two key subsystems of an automated epileptic seizure detection system are analyzed resp. optimized: neural amplifier and intelligent signal processing unit. A systematic analysis of trends in integrated amplifier designs is performed [3]. Noise-Efficiency-Factor (NEF) is used as figure of merit as it combines the two most important parameters, the noise and the current consumption. The NEF shows a steady improvement over the last decades. In parallel, the area of the preamplifiers has been decreased significantly. Nevertheless, so far, no design has been published that achieves low area consumption and low NEF at the same time [3].
For the detection of epileptic seizures an ultra-low power convolutional neural network is designed [4]. It classifies human brain signals and is implemented on an ultra-low power RISC-V microcontroller. The performance of the classification is comparable with state-of-the art algorithms. Using an energy budget suitable for implantable systems automated epileptic seizure detection in implantable systems will be enabled in future [4].

Abstract: Chronic neural implants hold great potential for illuminating features of neural function, treating neurological disorders, and enabling the next generation of neuroprosthetics. Penetrating electrode arrays provide direct access to neural signals across the central and peripheral nervous system

with high temporospatial resolution. However, a consistent point of failure for chronically implanted microelectrode arrays is poor longevity and variability in functionality of these devices. The foreign body response (FBR) can cause glial scarring and neural cell loss near the electrode sites. The FBR begins with electrode insertion, when damage to the blood brain barrier activates astrocytes and microglia, and continues throughout the lifetime of the implant due to the persistent presence of the foreign material in the tissue. Efforts to mitigate the FBR have focused on things like: limiting insertion damage during implantation, reducing the mechanical mismatch between brain and implant, and suppressing the FBR by incorporating exogenous chemicals. Rather than relying on temporary interventions to limit the FBR, we proposed to chronically harness endogenous cortical function to improve the neural interface microenvironment. Here, we investigate the use of sub-threshold low-intensity pulsed ultrasound (LIPUS) to improve tissue health at the neural interface. LIPUS has recently been shown to have protective and healing effects in models of cerebral disease and injury, through promotion of brain-derived neurotrophic factor (BDNF) and other neurotrophic factors. Our studies demonstrate that periodic application of localized LIPUS to tissue at the neural interface can promote improved electrophysiology signal quality, as measured via signal-to-noise ratios, electrode single-unit yields, and histological evaluation of glial scarring.

Title: Chronicity of spinal cord injury on the lower urinary system in awake male Wistar rats: Cluster analysis based on the variables related to the technique.

Authors: *D. MEDINA AGUINAGA[1], J. GUMBEL[2], R. F. HOEY[3], C. HUBSCHER[4];
[1]Univ. of Louisville Anatom. Sci. & Neurobio., Louisville, KY; [2]Anatom. sciences and Neurobio., Univ. of Louisville, Louisville, KY; [3]Anatom. Sci. and Neurobio., Univ. of Louisville Sch. of Med., Louisville, KY; [4]Dept Anatom. Sci. & Neuro, Univ. Louisville Sch. Med., Louisville, KY

Abstract: Lower urinary tract (LUT) dysfunction after spinal cord injury (SCI) represents one of most disastrous consecuences over the quality of life of this population. Recently has been describe models for the study of LUTs and SCI in awake animals. However, these models were described on female rats, keeping a lack on the study of males with this important technique. The overall objective is to develop an

animal model of urodynamic study, including needle electromyography of the external urethral sphincter (EUS) in awake male rats with different grades of chronicity, as well as, to include variables related to the cystometric (CMG) and electromyographic (EMG) techniques on the data analysis to reduce the variability and improve the significance. All experiments were approved by the the University of Louisville Institutional Animal Use and Care Committee and carried out in accordance to the National Institutes of Health guidelines. A total of 180 adult male Wistar rats were used for the entirety of these experiments. Six timeline SCI groups included 3, 7, 14, 28, 42 and 84 dpi study endpoints as well as three surgical sham groups matched for endpoints 3, 14 and 42 dpi. The end point day, under isofluorane anesthesia, a PE-60 tubing was placed on the bladder dome and a pair of electrodes were stoked into the EUS and attached to the inguinal ligament and tunneled to the dorsal neck. Passed two hours, a CMG-EMG in awake and restrained rats was performed and 5 void cycles was recorder for further analysis. The CMG records were classified in five categories: non artifact CMG, artifact less than 30%, 30% to 60% of CMG artifact, 60% to 90% of CMG artifact, and 100% artifact. The EMG records were classified in four categories: Clear EMG with minimum movement artifact, EMG including important movement artifact which gone with signal filtering, EMG with important electrical background who includes phasical electric activity during void, and EMG without signal from the EUS. Results. 46 of 49 Sham animals presented voids during the experiment. 120 of 130 injured rats present voids. 14 of 49 present CMG artifacts in sham and 48 of 130 present CMG artifacts in SCI groups. 3 of 49 Sham present EMG artifacts and 12 of 130 SCI have EMG artifacts. The analysis of the CMG and EMG are in process. We present the first report of CMG and needle EMG in awake male rats. The technique implemented in our laboratory make possible to record EUS EMG during void in awake healthy and injured males with a high rate of success. Uninjured animals present higher rate of CMG pressure artifacts, probably caused for movement. Is necessary to refine the CMG technique for improve the quality of the pressure records and obtain more accurate results.

Title: Surgical Implantation of Flexible Penetrating Electrodes in Deep Brain with an Ultrasonic Vibration Insertion System

Authors: *R. S. CLEMENT[1], H.-J. KIM[2], **N. N. TIRKO**[3], S.-H. LEE[2], R. B. BAGWELL[1];
[1]Actuated Med. Inc., Bellefonte, PA; [2]Univ. of North Carolina, Chapel Hill, NC; [3]Actuated Med. Inc, Bellefonte, PA

Abstract: Actuated Medical, Inc. is developing a suite of neural implant insertion systems which utilize ultrasonic micro-vibration to reduce the forces necessary to penetrate and insert devices into neural targets (www.neuralglider.com). With rigid intracortical electrode arrays (IEAs) we have shown the approach reduces insertion force and tissue dimpling, without interfering with electrode integrity or performance. Here we present on the application of the ultrasonic insertion technology to the insertion of flexible neural probes targeting deep brain structures (e.g. Nucleus Accumbens, NAc). The single-shank polyimide probes are 10 mm long, 60 µm thick, with width tapered from 200 µm near the tip to 600 µm at the base, with 16 recording sites linearly arrayed near the tip (Figure 1A). Benchtop insertion tests were first performed in a 2-layer agar model representing meningeal (1.5% density) and underlying brain tissue (0.5% density) at insertion speeds of 50, 250, and 1000 µm/s. Samples were placed on a 10 g capacity load cell which measured the forces during probe insertion (Figure 1B). Ultrasonic actuation of the probes reduced the insertion force peaks by 80-90% at multiple insertion speeds (Figure 1C). In follow-up *in vivo* studies in rats (Sprague-Dawley, 250-300g), ultrasonic vibration enabled probes to be inserted through intact dura for placement in NAc (1.5 mm anterior to bregma, 2 mm right of midline and 7 mm ventral to cortical surface). Functional MRI (fMRI, 9.4T) in response to deep brain stimulation revealed that probes were placed more accurately when ultrasonic micro-vibration was applied during insertion (Figure 1D). Post implant histology revealed comparable or slightly less tissue response for probes inserted with ultrasonic micro-vibration vs. control (Figure 1E). Ultrasonic micro-vibration can simplify neural probe surgery in some cases by eliminating the dura removal step while also improving insertion of flexible probes.

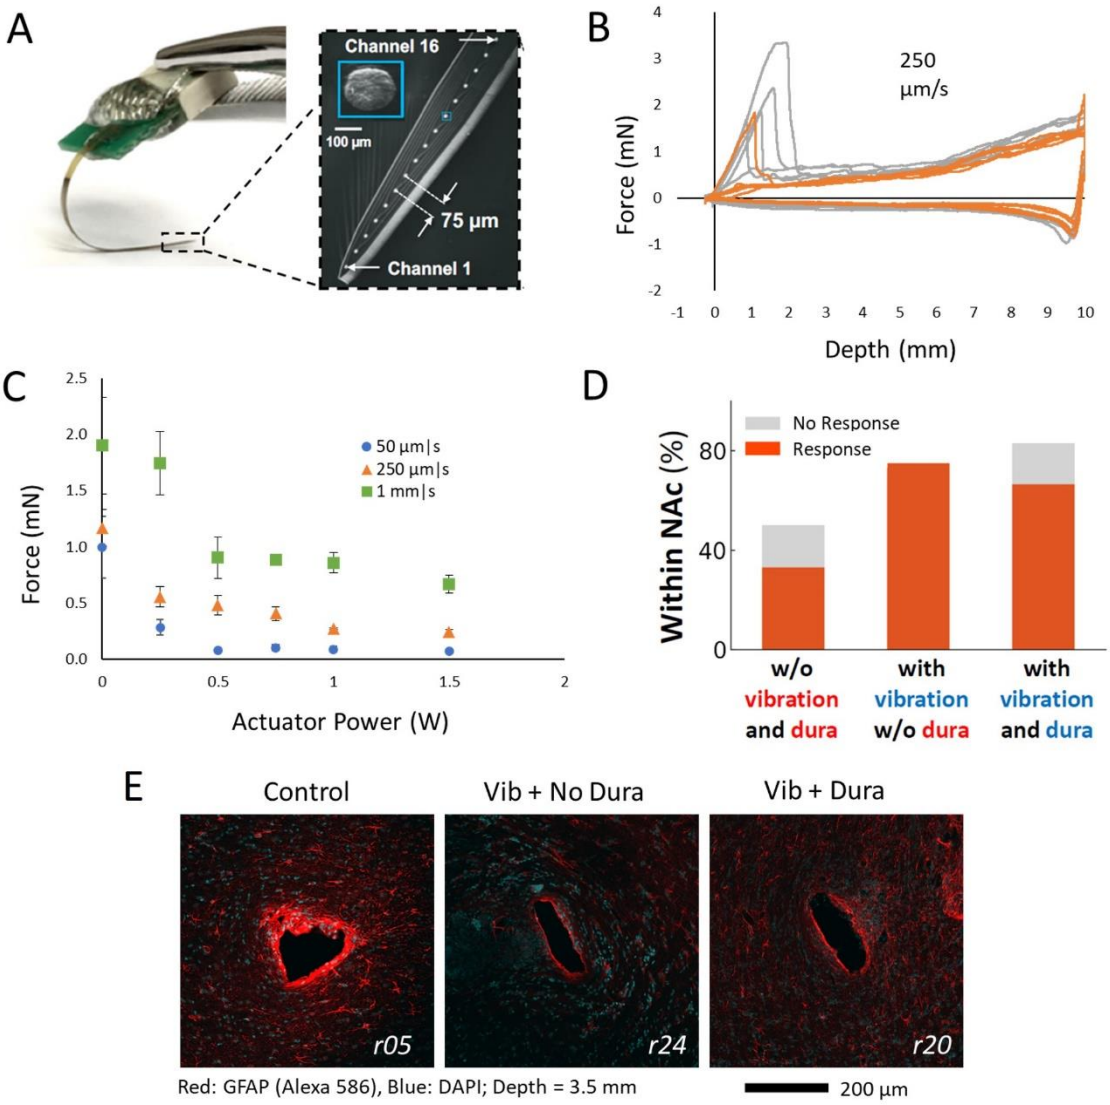

Figure 1. A) Flexible polyimide probes used in study. **B)** Insertion force profile showing insertion (positive force values) and retraction (negative force values) throughout 10 mm insertions into 2-layer agar model (orange with micro-vibration applied, gray: control). **C)** Summary of insertion force peak values for different insertion speeds and actuator powers (agar 2-layer model). **D)** Success rate of targeting NAc and activating in fMRI. Each group consists of 6 (control – no vibration), 8 (vibration without dura), 6 (vibration with dura); Female Sprague Dawley Rat (n=11), body weight 300g ~ 350g. **E)** Post implant histology images from each insertion condition; 3.5 mm below cortical surface.

Abstract: High-density surface electromyography (HDsEMG) enables the recording of myoelectrical activity patterns distributed across the skin surface of a muscle during contraction. Due to its ability to provide non-invasive recordings with high spatial fidelity, HDsEMG plays a potentially important role in clinical and neuroscientific research (e.g. identifying neuro-muscular junction location, measuring fiber conduction velocity, Motor Unit discrimination). However, HDsEMG currently has minimal applications in clinical settings. A major reason is the modest signal quality, especially during long-term recording, since these require stable electrode properties and a consistent skin-electrode interface.
We demonstrate here a novel “tattoo” electrode for HDsEMG recording that addresses these limitations. The superior recording performances of the tattoo electrode have been investigated and reported in our earlier work. Here, we explore the performance of the novel tattoo electrode to record HDsEMG signals during long-term wearing in daily life. We fabricated a 4cm×3cm tattoo grid on a deformable electronics membrane incorporating 64 electrodes (2mm diameter). Our dry HDsEMG grid exhibits easy layout programmability, skin breathability, substantial “stretchability” and superior skin conformity, while faithfully recording EMG signals during different levels of isometric contraction of the Medial Gastrocnemius of a healthy individual. The force and sEMG signals were recorded during multiple isometric, non-fatiguing plantarflexion contractions while tracking trapezoidal force-trajectories over various force ranges (20%MVC-100%MVC). 64 channel EMG data were recorded and digitized simultaneously using TMSi Refa-128™ amplifier and saved in a Windows PC. The recordings were performed with a gap of several hours with the tattoo electrode attached to the skin surface while the subject performed normal daily activities.
We have analyzed the sEMG signal during the steady-state part of the contraction force trajectory. Each channel was analyzed individually across the grid. The recordings were found to provide an accurate

representation of of the EMG spectrum, No significant difference in the signal to noise ratio, and spectral power of the recorded signal emerged, even during the next day recording while the tattoo being attached to the skin.
The tattoo grid electrode can potentially be used for recording HDsEMG from skin overlying superficial muscles for long-term recording. This tattoo electrode will potentially facilitate HDsEMG application in clinical scenarios, especially in tracking severe neuromuscular disorders, such ALS and SMA.

Title: In Vivo swine model of focal seizures for developing and validating Acoustoelectric Brain Imaging of Neuronal Currents

Authors: *R. WITTE[1], A. ALVAREZ[2], T. TRUJILLO[2], C. PRESTON[2], A. BURTON[2], D. MUSTACICH[3], M. WEINAND[4], K. GOTHARD[5], S. L. COWEN[6];

Abstract: A broad spectrum of brain disorders—from epilepsy to depression—are characterized by abnormal electrical conduction pathways. Although surface EEG is the gold standard for electrical brain mapping, it suffers from poor spatial resolution and inaccuracies, especially when resolving deep current sources. Our goal is to develop 4D transcranial acoustoelectric brain imaging (tABI), a disruptive technology that uses a focused ultrasound beam to map neuronal currents through the human skull at the millimeter and millisecond scales. This study describes an acute *in vivo* swine model of focal onset seizures for developing ABI and validating with high density surface recording. Following a bilateral craniotomy and exposure of the cortical surface, the snout area of the somatosensory cortex of three young farm swine was mapped by electrically stimulating (100 µs pulse at 0.5 Hz, 1-15 mA) the right or left snout using horizontally spaced needle electrodes with ~20 mm separation. Two 16-contact NeuroNexus grid electrode arrays with 4 mm inter-electrode spacing (CS2-2-4) were used to record evoked activity across the contralateral rostrum somatosensory area (0.1 - 0.8 mV peak). Following snout stimulation, an injection of 25 µL of bicuculline was topically applied to the somatosensory cortex to induce transient seizures that typically lasted between 5 and 10 minutes. Local field potentials (Intan) were acquired using before, during and after snout stimulation and seizure induction. Ictal spikes during focal onset seizures corresponded with travelling waves (1 - 2 m/s) that originated outward from the site of the bicuculine injection. For performing ABI, a custom 0.6 MHz 2D US array (126 elements, 18 X 7) with a conical standoff adapter (L=38 mm) was placed over the electrode array for delivering US pulses

(Vantage 64 LE) over the somatosensory cortex. High frequency acoustoelectric signals were recorded on a custom multichannel broadband differential amplifier (0.2 - 6 MHz) and NI DAQ system in 500 ms increments. Initial experiments suggested that the processed signals were near the limits of detection of the weak AE signal (less than 1 μV). In one experiment, a saline-soaked bone flap from an adult human skull was placed between the swine cortex and US array to assess the signal loss of the vibration potential due to the presence of bone (-3 dB/4 mm). Ongoing work is focused on improving the AE instrumentation and acquisition algorithms to dramatically amplify the AE signal and reduce background noise towards feasibility of a noninvasive ABI system designed for functional human brain imaging of neuronal currents.

Title: A flexible refractory period metric for spike sorting improves accuracy on brainwide electrophysiological datasets

Authors: *N. ROTH[1], .. INTERNATIONAL BRAIN LABORATORY[2], N. A. STEINMETZ[1];
[1]Biol. Structure, Univ. of Washington, Seattle, WA; [2]Intl. Brain Lab., London, United Kingdom

Abstract: The advent of increasingly large electrophysiological datasets has increased the need for quality metrics that automatically reject poorly isolated neurons. One key method estimates contamination by assuming that each neuron has a refractory period. However, existing methods cannot be applied without prior knowledge of the refractory period duration, limiting their usefulness in datasets that include neurons from multiple brain regions or cell types. Here, we describe a new metric which assesses contamination across a range of hypothetical refractory periods. We compute the maximum allowed number of refractory period violations for many period durations, then generate the likelihood of observing this number of violations via a Poisson process, at a maximum allowed contamination level. A neuron passes the criterion if the count of observed violations is lower than the maximum acceptable, for any choice of refractory period. This metric allows us to assess contamination without assuming a single fixed refractory period duration.To quantify how well this metric classifies neurons, we performed simulations of neurons with a range of true refractory periods, firing rates, and levels of contamination.

As expected, we find that for high firing rates, the metric rejects neurons with more than 10% contamination and passes neurons with less than 10% contamination, for a range of true refractory periods including those less than the traditional 2 ms assumption. When firing rates are low, the metric rejects neurons with brief true refractory periods, as we cannot be statistically confident that the lack of contamination did not arise by chance. As the true refractory period increases, neurons with low contamination begin to pass the metric. Thus, our metric has advantages for assessing neurons with both brief and long true refractory periods. To assess whether this metric improves performance on real datasets, we used data collected by the International Brain Lab across 278 brain regions. We found that true refractory periods were diverse across brain regions (mean ± s.e.m. in cortex: 2.63 ± 0.010 ms; hippocampus: 2.58 ± 0.021 ms; striatum: 2.92 ± 0.018 ms; thalamus: 1.82 ± 0.025 ms). We next compared the performance of the flexible refractory period metric with that of a fixed (2 ms) refractory period metric with equal contamination thresholds, and found that the flexible metric allows us to include 25% more neurons that would have been previously marked as contaminated, and rejects 15% that would have been previously marked as uncontaminated. Thus this new metric improves our ability to apply a single consistent set of quality metrics to brainwide data with high accuracy.

Abstract: 2D materials such as graphene offer an ideal platform for recording and culturing neural networks, regarding its exceptional neuronal affinity and the presence of readily accessible surface charges which give the unprecedented possibility to realize a direct electrical coupling with cells. In addition, graphene is highly flexible, optically transparent and could be transferred on a wide range of substrate to be combined with multiple electrophysiological tools.Here, we will present the cytocompatibility study of pristine monolayer graphene, and its significant advantage for neuroprostheses and *in-vitro* model networks. We will show that the neuronal affinity of graphene opens avenue of applications such for patterning long-lasting *in-vitro* neural networks [1], and for increasing life time of intracortical brain interfaces [2].
Moreover, the nano-structuration of large (mm²) CVD-grown graphene monolayers allows the fabrication of dense arrays of highly sensitive field effect transistors (G-FETs). Among their successful bio-integrations, the detection of action potentials in numerous electrogenic cells including neurons [3] has

paved the road for the high spatio-temporal and wide-field mapping of neuronal activity. We will show that ultimate sensing could also be achieved such the field effect detection of ion channel activity within neuron networks [4]. We are combining this ultra-sensitive neuroelectronics with microfluidic-designed neural network and numerous imaging methods for fundamental and applied research including brain-on-chip and *in-vivo* monitoring.

Title: Simple models of critical brain dynamics

Authors: *A. NANDA[1], G. JOHNSON[2], D. J. ENGLOT[2], M. RUBINOV[1];
[1]Vanderbilt University/ Biomed. Engin., Nashville, TN; [2]Vanderbilt university medical center, Nashville, TN

Abstract: A large body of work claims that neuronal dynamics are critical. These claims rest on putative signatures of criticality, including power-law scaling of neuronal avalanche size and duration distributions (Beggs *et al*. 2003), avalanche shape collapses (Sethna *et al.* 2001) and long-range temporal correlations (LRTCs) (Palva *et al.* 2013). However, studies typically do not assess the significance of these signatures against strong competing models of the data. Here, we assessed this significance by unbiasedly generating surrogate data from three such competing models: a *canonical* model that preserves the mean and variance at each timepoint and the covariance between adjacent timepoints); a *clustered* model that preserves the mean activity of spatial and temporal clusters, and a *mean signal* model, that preserves the average activity of each region. We compared these models using human stereotactic and intracranial EEG (Johnson *et al.* 2018; Goodale *et al*. 2020), and Monkey ECoG (Yanagawa *et al.* 2013) data. We observed robust signatures of criticality in the *canonical* model, but not in the *clustered* or *mean signal* models. Our results suggest that key signatures of criticality emerge from interactions of basic features of timeseries data. These results emphasize the importance of future rigorous tests of theories of higher-order brain activity and function against strong alternative models.

Title: Resting state dynamics from the perspective of structured flows on manifolds

Authors: *J. FOUSEK, G. RABUFFO, K. GUDIBANDA, H. SHEHEITLI, S. PETKOSKI, V. K. JIRSA;
Inst. de Neurosciences des Systèmes (INS) UMR1106, Aix-Marseille Univ., Marseille, France

Abstract: Fluctuations of brain activity at rest display correlations between areas involved in task conditions, and their temporal variability possesses functional significance. However, our understanding of the mechanisms underlying these spatio-temporal patterns is still incomplete.
Here we address the main empirical signatures of brain resting state data: bistability of single region activation, low-dimensionality of the global system dynamics, multistability of recurrent coactivation patterns, and their non-trivial temporal dynamics. These constitute the key features of what we describe as structured flows on manifolds (SFMs)[3].
We construct a whole brain network model[2] using 2D neural mass model[4] driven by noise to govern the regional dynamics coupled with a DTI-derived connectome, and equip it with BOLD observer model. The resting-state manifold is defined as the low-dimensional embedding (PCA) of the simulated trajectories. By scaling the coupling strength parameter *G* we find that the dimensionality of the system state space dynamics reduces for the same intermediate values of *G* where the main dynamical signatures of resting state are captured[1].
We then link the manifold subspaces with the clusters of the dynamic functional connectivity, thus separating the high- and low coactivition states. Next we map the complete manifold on which the structured flow (i.e., the dynamics) unfolds by sampling the fixed points of the system, and investigate the gradients of stability. Finally, we relate the characteristic frequency of a node to the stability and show that the model reproduces the gradient of the dominant frequency peak in the empirical data.
These results underscore the central role that the structural connectome plays in the symmetry breaking that shapes the manifold and the resulting structured flow which describes the resting state brain dynamics. All in all, we show in-silico the potential of SFMs formalism as a prime candidate to make current semi-formal descriptions using a variety of mathematical concepts such as attractor landscapes[5] explicit.

Abstract: *Introduction*
Identification of the epileptogenic network is crucial for planning surgical interventions in patients with drug-resistant focal epilepsy. The epileptogenic networks are defined by a network of brain regions involved in the production of epileptic activities called epileptogenic zones (EZ). Biomathematical modeling offers methods of causal inference for EZ network estimation by integrating multiple modalities such as magnetic resonance imaging (MRI), diffusion-weighted MRI (dMRI), stereo-electroencephalography (SEEG) and more. The virtual brain (TVB) (Jirsa et al., 2017) technique provides a whole-brain scale modeling approach to make such causal inference possible.
Methods
A VEP pipeline identifies the EZ network in epileptic patients, using patient-specific brain network models. Connections between regions are estimated through streamlined tractography from dMRI, together with the brain parcellation from T1-MRI. Each node contains a neural mass model (2D Epileptor) to represent neural dynamics in a brain region. We compute the source-to-sensor mapping based on a post-SEEG-implant computerized tomography in patients' T1-MRI space. We extract data features from SEEG recordings to fit the brain network model. Model inversion uses algorithms inside a Bayesian framework to obtain a maximum a posteriori estimate of the joint posterior distribution.
Results
We built a solid workflow to estimate the EZ network, for clinical pre-surgical evaluation. The core is the VEP pipeline which uses a patient-specific brain network model within a Bayesian framework to estimate the EZ network given individual SEEG, diffusion and structural MRI data. This workflow has been tested retrospectively in a cohort of 53 patients. The systematical evaluation shows good precision and acceptable recall, comparing VEP results to the routine clinical EZ prediction. The precision shows the VEP results are highly consistent (0.97) with the resected regions for the seizure-free patients. The precision decreased for the patients that are not seizure-free.

Conclusions
The workflow is currently applied prospectively in a clinical trial called Epinov, aiming for 300 patients. The VEP workflow is an important milestone for personalized epileptogenic network estimation and surgery strategy planning, considering patient specific data from multiple modalities. Each element uses current state-of-the-art technology, but can easily be extended and improved in the future. It provides a measure to further our understanding and knowledge for future fundamental improvement in both brain modeling and epilepsy studies.

London, London, United Kingdom; [8]Shirley Ryan AbilityLab, Chicago, IL

Abstract: Science currently lacks a theoretical framework to translate neuronal activity to psychological states. Here we try to overcome this limitation by taking a data driven approach. We assume that the extant fMRI literature (using Neurosynth database) provides a rich representation of brain states that can be used to identify fundamental mental domains and associated ontology. We first derive such a set of dimensions, then project task fMRI activity on them, and test consistency and interpretability of the approach.We used the full Neurosynth dataset (>14,000 studies) and resultant association maps to identify mental domains. Neurosynth association maps are, across-studies averaged, patterns of brain activity related to a particular term (pain, happy, etc.). After excluding uninformative maps, 1848 term-related maps were used to calculate their similarity matrix. The Louvain algorithm was applied, by sweeping Density and Resolution parameters between 0.05-0.3 and 0.5 to 3.0 respectively. The optimal number of clusters was 13. We averaged the maps within each cluster to obtain mental domain spatial patterns, and used Neurosynth to label each dimension with its associated ontology. We label the 13 Mental Domains (MD13) based on top 10 ranked terms: Theory of Mind, Movement/Sensation (MS), DMN, Task/Working Memory (TWM), Language (LNG), Reward, Auditory (AUD), Vision (VS), Attention,

Affect (AF), Episodic Memory (EM), Visuo-Spatial Attention (VSA), and Nociception (Noci).To illustrate decodability of task-fMRI within MD13 space we interrogated two studies: 1) a sound and voice differentiation study (block design, 86 subjects) [1], and 2) a pain, touch, vision, and audition differentiation study (event design, 14 subjects) [2]. We projected the BOLD timeseries on MD13, and examined the signal along each MD dimension.In study 1, vocal auditory stimuli have a high response on the AUD and LNG; for the non-vocal stimuli, the response was on AUD only, in studies 1 & 2. Discrimination using all MD dimensions was 0.96 (0.92 - 0.98). We also observed that during light stimulus response is on VS, and VSA. For the painful heat and the touch stimuli, the responses were on MS, AUD, AF, TWM, and Noci, with higher responses for pain on all of them. Since study 2 could not differentiate between touch and pain using standard GLM, we tested this contrast in MD space, Noci was best discriminant 0.88 (0.67 - 0.97).MD responses are compatible with what we know about the stimuli. The approach consistently maps brain activity onto MD defined ontological space, transforming brain activity to psychological interpretation.

Abstract: Introduction In the context of focal epilepsy, the *Virtual Epileptic Patient* (VEP) uses a large scale brain modeling approach to predict the spatio-temporal spreading of seizure activity (Jirsa et al., 2017). The localization of the epileptogenic zones (EZ) can be estimated by adjusting the predictions of

the model to the empirical stereo-electroencephalographic (SEEG) recordings of the patient. Precise estimates are crucial as they are indicative of candidate regions for resection. In this study, we used high-resolution neural field model (NFM) simulations to evaluate the robustness of the localization of EZ.
Methods To ensure computational tractability, the localization of EZ is currently implemented for a VEP with a generative neural mass model (NMM), in which brain connectivity is limited to global coupling between brain regions. To assess the quality of this estimation based on NMM, the estimation was performed on a series of data simulated with a neural field model (NFM), which, in addition to global coupling, considers the contribution of local coupling within brain regions to the global brain activity. A set of patients with different epileptic network spatial configurations were selected from the EPINOV trial. For each patient, various scenarios were considered in terms of the geometry of EZ (size, location) in relation with the specificity of the patient (geometry of the brain, implantation scheme).
Results The estimation procedure based on NMM was performed for each dataset simulated with a NFM. The robustness was evaluated based on the correctly identified EZ. For the frequent case of mesial temporal lobe epilepsy, simulated data show very realistic seizure propagation pattern along the cortical surface and VEP estimates of EZ were consistent with simulated ground truth.
Conclusions Overall, the results demonstrate that, given specific epileptic network spatial configurations, NMM may have limitations to capture some complex seizure patterns present in empirical SEEG data. By considering the contribution of both local and global coupling for the propagation of brain activity, NFM can account for a more detailed description of the brain dynamics, as the ones observed during epileptic seizures. The use of NFM for an accurate localization of EZ therefore represents a significative methodological advance to address in the future.

Title: Neuronal population tuning statistics to target and cues for a feedforward Convolutional Neural Network that learns to covertly attend

Authors: *S. SRIVASTAVA, M. P. ECKSTEIN;
Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Introduction: Attentional effects on perception, once thought to be exclusive to primates, have been more recently measured in simpler organisms such as fruit flies, dragonflies, and honeybees (Nityananda 2016). We investigate whether a simple convolutional neural network (CNN) trained to maximize the detection of a target in a 2-location yes-no task (Posner cueing) results in human-like cueing effects. We analyze individual neurons in the network to understand how they extract and integrate target and cue information.
Methods: We trained a CNN on 6000 images containing oriented lines embedded in noise. A box cue co-occurred with the target on 80 % of the trials. The CNN consisted of 3 convolution layers, with the first layer followed by max-pooling. The third convolution layer is followed by a dense layer and an output layer with 2 neurons. We evaluated human and CNN performance for a Posner cueing task with varying contrast of a peripheral box cue. We extracted responses of each neuron to these images and calculated neuron-specific cueing effects (areas under the ROC (AUROC) for valid vs. invalid cues). Next, for each neuron, we calculated the AUROC for detecting box presence or absence on either side, and the AUROC for detecting target or distractor presence on each side.
Results: The CNN trained to optimally detect the target results in a cueing effect comparable to humans and an optimal Bayesian model. Nineteen percent of the neurons in the dense layer showed positive and negative cueing effects with varying degrees (mean = 0.02; standard deviation = 0.10). Neurons with cueing effects detect both the target and the cue in isolation. The weights between the dense neurons and the two output neurons are correlated ($r=-0.64$, $p<0.0001$; $r=0.58$, $p<0.0001$) with the neuron-specific cueing effects. The convolution layer neurons are retinotopic, while the dense layer neurons are not. The first two convolution layers do not have neurons that integrate either the box or the target information from both the locations, or neurons integrating box and target information. Neurons integrating box and target information from one location first appear in the third convolution layer, and neurons integrating box and target information from both locations appear only in the dense layer. On retraining the network with varying cue validity, the mean ratio of the box cue tuning and the target tuning increases as the validity of the cue increases from 50% to 100%.
Conclusion: Our results show that a simple neural network can learn to utilize cues in a similar manner as humans and establish biologically plausible architectures and neuronal population properties to integrate target and cue information.

Title: Bump attractor dynamics underlying stimulus integration in perceptual estimation tasks

Authors: J. M. ESNAOLA-ACEBES[1,2], A. ROXIN[1,2], *K. WIMMER[1,2];
[1]Ctr. de Recerca Matemàtica, Bellaterra, Spain; [2]Barcelona Grad. Sch. of Mathematics, Barcelona, Spain

Abstract: Perceptual decision and continuous stimulus estimation tasks involve making judgments based on accumulated sensory evidence. Network models of evidence integration usually rely on competition between neural populations each encoding a discrete categorical choice. By design, these models do not maintain information of the integrated stimulus (e.g. the average stimulus direction in degrees) that is necessary for a continuous perceptual judgement. Here, we show that the continuous ring attractor network can integrate a stimulus feature such as orientation and track the stimulus average in the phase of its activity bump. We reduced the network dynamics of the ring model to a two-dimensional equation for the amplitude and the phase of the bump. Interestingly, these reduced equations are nearly identical to an optimal integration process for computing the running average of the stimulus orientation. They differ only in the intrinsic dynamics of the amplitude, which affects the temporal weighting of the sensory evidence. Whether the network shows early (primacy), uniform or late (recency) weighting depends on the relative strength of sensory stimuli compared to the amplitude of the bump and on the initial state of the network. The specific relation between the internal network dynamics and the sensory inputs can be modulated by changing a single parameter of the model, the global excitatory drive. We show that this can account for the heterogeneity of temporal weighting profiles observed in humans integrating a stream of oriented stimulus frames. Our findings point to continuous attractor dynamics as a plausible mechanism underlying stimulus integration in perceptual estimation tasks.

Title: An ultra-high-resolution imaging and segmentation pipeline of the cat lumbosacral spinal cord for accurate 3D finite element method models

Authors: *L. LIANG[1], A. FASSE[6], M. JANTZ[1], C. GOPINATH[2], F. LIU[2], T. NEWTON[6], C. ROWLAND[3], U. AGBOR[3], L. FISHER[2], M. CAPOGROSSO[4], E. NEUFELD[6], R. GAUNT[2], T. K. HITCHENS[5], E. PIRONDINI[2];

Abstract: Lower urinary tract (LUT) dysfunction affects 20-40% of the global population, and it significantly decreases the psychological and social well-being of individuals. Recent experimental works in cat showed that epidural spinal cord stimulation (SCS) can be effective in controlling LUT functions. However, experiments alone cannot feasibly address certain physiological questions or guide design decisions about contact size, location, and stimulation parameters. Thus, anatomically accurate computational models of the lumbosacral spinal cord are critical in accelerating the research and development of SCS. Common methods for building spinal cord models involve simplified geometric CAD models lacking anatomical details, or labor-intensive manual segmentation of magnetic resonance (MR) images. Here, we developed a novel imaging and segmentation pipeline that allows construction of high-precision models of the cat lumbosacral spinal cord. First, we obtained a CT scan (250μm isotropic) of *ex vivo* fixed lumbosacral cat spine tissue. Then, the tissue was soaked in 0.2% Gadavist (gadolinium contrast agent) that reduced the longitudinal relaxation time (T1) of the tissue by 80%, significantly accelerating MR image acquisition. The sample was then placed in Fomblin, which improved magnetic field homogeneity, for imaging. T2-weighted and fat-selective structural MR scans (50μm isotropic) were acquired in a Bruker vertical-bore 11.7T microimaging system. This ensemble of acquisitions enhanced contrast between tissues and facilitated rapid segmentation of vertebrae, gray matter, white matter, ventral/dorsal roots and rootlets, epidural fat, and CSF with a convolutional neural network (HardDNet variant) trained on a small set of manual segmentations. In addition, high-resolution diffusion-tensor imaging (200μm isotropic, 61 directions, multi-shell b=1000/3000) tractography was employed to automatically distinguish roots and rootlets of each spinal level. Finally, the 9 segmented tissue masks were used to create a high-definition 3D model to allow realistic simulation of SCS with finite element method. With this pipeline, we successfully replicated imaging and segmentation results in two cat spine samples. The shape, size, and locations of the tissue masks were validated against literature and dissections. This novel pipeline can be extended to efficiently create anatomically accurate spinal cord models at any spinal level of interest, and for various animal models to enable better understanding of SCS functional mechanisms, optimization of SCS protocols, and guide the design of spinal cord neuroprosthesis.

Title: Maximum Entropy-based connectivity estimators are robust to model mismatch

Authors: *A. HAYDAROGLU[1], T. A. VALIANTE[2];
[1]Univ. Col. London, London, United Kingdom; [2]Toronto Western Hosp., Toronto, ON, Canada

Abstract: Estimating the functional connectivity of populations of neurons from their activity is a critical problem when anatomical access to the population is not feasible. However, there is often a problem of "model mismatch" when the processes underlying the neural data are not fully explained by the assumed model of the connectivity estimation method used. This is common when methods make simplifying assumptions about the structure of the network, which introduces statistical bias and reduces accuracy. We show that connectivity estimation methods derived to maximize the entropy of the inferred probability distribution of network activity states are more robust to the model mismatch problem. We compare Maximum Entropy (MaxEnt) methods to commonly used Information Theory (IT) based methods on data with known ground-truth connectivity. Data is generated from two processes which have been shown to model biological neural activity under different contexts: Multivariate Autoregressive Models (MVAR) and Glauber Dynamics (GD). The former satisfies the assumptions of IT estimators, while the latter is a time-dependent sampling of a high-dimensional energy landscape which satisfies the assumptions of MaxEnt methods. On cross-validated experiments across a range of network sizes, random seeds and activity levels, MaxEnt estimators outperform Information Theoretic measures in GD datasets, while both methods perform similarly well on MVAR datasets. Thus, MaxEnt models show more robust performance in the presence of model mismatch, e.g. when the underlying process doesn't satisfy its assumptions. We also demonstrate how tuning of data preprocessing steps can improve the accuracy of MaxEnt methods. Furthermore, we show that when both MaxEnt and IT methods are applied to continuous signals, increasing the resolution of the digitization of signals reduces accuracy. This is unexpected since increased resolution makes more information available to the inference methods and may be expected to improve results. This work demonstrates the impact of the model mismatch problem on common connectivity estimation methods and presents novel, experimentally-relevant insights that highlight the robustness of Maximum Entropy models. The recent development of high-speed computers accelerating MaxEnt estimations (such as commercially-available quantum annealers) makes MaxEnt methods a promising choice for analysis on high-dimensional neural datasets and applications in clinical settings. Our ongoing work is aimed at applying these methods to the diagnosis of neurodegenerative diseases such as epilepsy and the design of neural stimulators for their treatment.

Abstract: Systems neuroscience is increasingly able to leverage new recording technologies and statistical analyses to describe the coordinated activity of larger populations of neurons, even entire brains. Combined with new precise stimulation technologies, we can begin to dissect large-scale circuits in vivo, constructing models that causally relate neural activity to behavior. Direct testing of hypothesized brain-behavior links, however, requires statistically efficient methods for both estimating and intervening on population-level neural dynamics in real time. To build neural models online, we describe a new method called Bubblewrap that combines fast, stable dimensionality reduction with a soft tiling of the resulting neural manifold, allowing dynamics to be approximated as a probability flow between tiles. This method can be fit efficiently, scales to large populations, and outperforms existing methods when dynamics are noise-dominated or feature multi-modal transition probabilities. We demonstrate the performance of Bubblewrap on both simulated nonlinear dynamical systems and experimental neural data with up to thousands of recorded units. Our algorithm can learn at kilohertz rates, faster than data acquisition, and generate predictions in less than 1 ms.
To demonstrate how real-time interventions can be tailored to individual or population-level neural activity, we address the optimization problem of finding peak neural responses to multidimensional visual stimuli in larval zebrafish. Here we leverage our adaptive software platform, improv, to construct an experimental pipeline that takes in two-photon calcium images, analyzes the neural responses for each observed neuron, and generates the next visual stimulus to display online. We employ a Bayesian optimization approach for choosing stimuli, which uses Bayesian inference to search for optimal function values, particularly in cases where evaluating the function is costly or time-consuming. Our visual stimuli are presented to the zebrafish as moving sinusoidal gratings from below with varying direction, speed, spatial frequency, and contrast. Even with a modest number of choices for each parameter (5-15 options), this results in nearly 8,000 unique stimuli. By contrast, our adaptive approach with Bayesian optimization allows us to determine optimal stimuli for a neural subpopulation within only a few hours, leaving time for subsequent causal testing. Our efficient and scalable methods for online brain state modeling and closed-loop stimulus optimizations can enable automated, large-scale network dissection infeasible with current methods.

Title: Development of Realistic Simulated EEG Data for Assessing Preprocessing Methods

Authors: *E. AUGER[1], E. BERRY-KRAVIS[2], L. E. ETHRIDGE[1];
[1]Univ. of Oklahoma, Norman, OK; [2]Rush Univ. Med. Col., Chicago, IL

Abstract: Increased objectivity in EEG research via automated methods for artifact rejection in EEG data have been in consistent development and refinement. One major difficulty in developing methods for successfully cleaning EEG data is the inability to know with 100% certainty if the recorded signal is true brain or true artifact. Methods of assessing signal-to-noise ratio (SNR) in real EEG data are only estimates, making quantifiable testing of processing methods using real data challenging. Many researchers use simulated data to assess processing methods. However, current methods of simulating data may not accurately mimic the complexity of real data, which could bias assessments.We created a set of simulated data that more closely resembles real data, which could be used to test data cleaning methods. Data consisted of 56 simulated datasets with 34 components each: 10 brain components, 8 artifact components, and 16 pink noise components to mimic 1/f distributed noise sources. Brain signal was simulated using SimEEG, using a channel waveform from real EEG to estimate power of frequency bands from two components each from delta, theta, alpha, beta, and low gamma frequency bands and mimic dipole topographies. The eight artifact components were derived from real EEG data using independent components analysis and were selected for being stereotypical but appropriately time-varying examples of ocular, cardiac, and muscle artifact. Each artifact was shifted in both time and amplitude to vary the relative timing and variance accounted for by each artifact. Simulated data was tested using an automated EEG processing pipeline that had previously been validated only on real EEG data. This pipeline uses machine learning trained on a large database of EEG data to identify artifact. However, true SNR retention by any pipeline can only be evaluated using simulated signal and noise which can be fully quantified. Given the real EEG training database, realistically modelled EEG artifact in simulated data is necessary to accurately test such a pipeline. Tests of the pipeline via hierarchical linear modeling using approximated SNR from real EEG data and quantified SNR from simulated data confirmed similar loss of signal in both datasets, with quantified simulated signal allowing us to isolate the most significant signal loss to lower frequency bands. Many newly developed automated EEG processing programs utilize machine learning from large databases of real EEG data to identify and remove artifact. This method of simulating data using realistic artifact components allows for quantifiable performance testing on such pipelines to evaluate and optimize SNR retention capabilities.

Title: Aperiodic EEG activity masks the dynamics of neural oscillations during loss of consciousness from propofol

Authors: *N. BRAKE[1], F. DUC[2], A. ROKOS[4], F. ARSENEAU[5], S. SHAHIRI[3], A. KHADRA[1], G. PLOURDE[2];
[1]Dept. of Physiol., [2]Dept. of Anesthesia, [3]McGill Univ., Montreal, QC, Canada; [4]Univ. Col. Cork, Cork, Ireland; [5]Innodem Neurosciences, Montreal, QC, Canada

Abstract: Many states of consciousness can be inferred directly from an electroencephalogram (EEG). Although differences in the EEG are often ascribed to changes in neural synchrony, it is becoming increasingly evident that the aperiodic component of the EEG signal may change as well. The goal of this study was to determine whether the general anesthetic propofol alters the aperiodic component of the EEG, and if so, what implications this may have for interpreting changes in neural synchrony related to loss of consciousness (LOC). To address this question, we recorded the EEG of 14 human subjects undergoing a fixed-rate infusion of propofol. To interpret these data, we derived a biophysical model of the aperiodic component of the EEG which describes the ensemble electric field generated by asynchronous neural activity. This model demonstrated that propofol's known potentiation of $GABA_A$ receptors, in tandem with a suppression of neuronal firing, suffices in explaining over 80% of the observed EEG changes during induction of anesthesia, without requiring any differences in neural synchrony. When accounting for these aperiodic changes, the inferred time course over which propofol-induced rhythms evolved was significantly altered. Whereas a typical spectral analysis of our data indicated that the moment of LOC was correlated with the appearance of both alpha (8-15 Hz) and delta (1-4 Hz) rhythms, consistent with past studies, correcting for changes in the aperiodic component of the EEG produced a clear temporal separation between these rhythms. We concluded that LOC was only correlated with the appearance of delta rhythms, while alpha rhythms emerged and plateaued well beforehand. This study proposes specific physiological parameters that shape the aperiodic component of the EEG signal and provides insight into the mechanisms of propofol-induced LOC.

Title: Automated whole brain reconstruction of serial sections mapped to a brain reference atlas

Authors: N. J. O'CONNOR[1], B. S. EASTWOOD[1], A. D. LEDUC[1], D. HOPPES[1], C. S. GERFEN[1], P. J. ANGSTMAN[1], J. R. GLASER[1], *C. R. GERFEN[2];
[1]MBF Biosci., Williston, VT; [2]NIMH, Bethesda, MD

Abstract: Molecular neuroanatomical methods expand the ability to characterize the connectivity of specific neuron subtypes under varying behavioral or pathological patterns of neuronal activity. Analyses of connectivity and neuronal activity across whole mouse brains that have been registered to a reference atlas reveal details about the functional organization of these brain circuits with the ability to draw comparisons across animals, experiments, and laboratories. Here we present advances to our previous work for automatically aligning and reconstructing images of mouse brain sections labeled with histochemical techniques into whole-brain 3D image volumes, registering these brain image volumes to the Allen Mouse Brain Common Coordinate Framework (CCF), and subsequently automatically mapping neuron populations to regions in experimental brain volumes.
A reference section containing brain regions with well-defined anatomic landmarks is registered to the CCF with a convolutional neural network (CNN)-enhanced transform model that accounts for artifacts due to histological cutting, mounting, and fixation. This reference section's transform is then propagated to other sections with linear and nonlinear refinements to accurately map all sections of the reconstructed whole brain image volume to the CCF.
Examples of whole-brain analysis of connectivity using trans-synaptic rabies labeling of neurons providing inputs to Cre-expressing neuron subtypes, and of behaviorally relevant brain circuits using fos labeling of activity in neurons correlated with specific behaviors, are presented. For analysis, coronal brain sections are reconstructed into a 3D volume, labeled neurons are automatically marked using CNN cell detection classifiers trained for detecting pyramidal neurons and neurons expressing fos, and brain sections and marked neurons are registered to the CCF. The number of labeled neurons in each of the over 830 delineated structures in the CCF are tallied, allowing for comparative quantitative analysis between mice. Fiducial points throughout the brain are used to determine registration accuracy on the order of three to four neuron widths.

Title: A multimodal cortical atlas for clinical decision making and function-structure hypotheses in epilepsy surgery

Authors: *T. JAFAR, H. MCGRATH, A. KSENDZOVSKY, H. ZAVERI, P. FAROOQUE, E. COLLINS, L. LAMSAM, A. SIVARAJU, K. WU, E. DAMISAH, X. PAPADEMETRIS, D. SPENCER; Yale Univ., New Haven, CT

Abstract: Epilepsy surgery evaluation generates significant multimodal data, imaging, and electrophysiology. It is critical to aggregate this data in a common space for research and clinical decision making. Existing brain atlases lack an intuitive naming or parcellation that provides for easy cross referencing. We define an atlas which addresses these issues in epilepsy surgery and test its use as a visual database.

We registered multimodal data from epilepsy patients onto the Yale Atlas; our cortical brain atlas parcellated to reflect standard contact spacing of intracranial electrodes and defined by landmarks on the MNI 152 brain. Structural 3T MRI images underwent linear/nonlinear registration, and 3D electrode coordinates were transformed to the atlas and verified with Yale BioImage Suite. Electrophysiology data of seizure onset and spread and bipolar language stimulation mapping was incorporated.

A total of 3386 intracranial electrode contacts from 20 temporal lobe epilepsy patients were transformed to the atlas. In the mesial temporal group, the most common parcel of onset was H A (pes hippocampus) in 50% and H B (hippocampal body) in 40%. While the neocortical group was TP2.2 A (anterior inferior temporal pole) in 40% and T2.1 C (upper middle temporal gyrus) in 30%. In Figure 1, a patient with H B onset underwent a resection of parcels involved at onset, 1st and 2nd spread, and remained seizure free at 1 year. The 2nd patient had spread outside of the resected neocortical parcels and failed surgery. Figure 2 shows language mapping superimposed on the atlas. Seizure onset was observed in the dominant temporal lobe neocortex. Mapping parcels critical for language function, 2 RNS strips were placed to cover the parcels of onset and spread with an ILAE 2 outcome.

We present an epilepsy surgery atlas for aggregating multimodal data, co-registration of multiple data sources onto one visualization, and exact cross referencing for research and clinical purposes. Mapping patient data onto this atlas allows us to compare PET, fMRI, stimulation mapping and electrophysiology for outcome correlation.

Title: Eeg-mediated real-time continuous-scale emotion assessment for applications in robotics using reinforcement learning

Authors: *L. A. THIERGART[1], R. PALEJA[2], E. SERAJ[2], M. C. GOMBOLAY[2];
[2]Sch. of Interactive Computing, [1]Georgia Inst. of Technol., Atlanta, GA

Abstract: Robot technologies trained by human experts hold great promise to improve daily life. Tasks like autonomous driving, surgical robotics or assistive care may benefit from democratised access to robotic systems for human trainers. To achieve this, it is necessary to remove requirements for programming language knowledge, insight into the robot's training process, and the need for ideal task execution by the human. New communication modalities which are intuitive and accessible to non-technical users are needed. While grounding (or tying) natural language to tasks and commands remains difficult, Brain Computer Interfaces (BCI) can create a more natural, direct and effortless communication between the human teacher and the robot student. BCIs circumvent the step of the teacher needing to articulate themselves verbally or through technology and also enables non-able-bodied users to train robots for specialised tasks. The high temporal resolution and non-invasiveness of EEG makes it a suitable BCI technology.
Prior work includes the framework TAMER (Training an Agent Manually via Evaluative Reinforcement learning) in which a human teacher watches a robot student perform a task and provides positive and negative feedback by pressing buttons on a controller. TAMER requires less data and training time than learning from a demonstration (Knox et al, 2008). However, TAMER remains limited to single, scalar value feedback with inherent communication delay.
We propose to leverage a 16-electrode EEG (EMOTIV EPOC+) to augment TAMER for autonomous driving tasks. We record and extract positive and negative emotion on a continuous scale in real-time from an EEG signal. Our human-subjects experiment (n=20) validates the reliable extraction of the desired signal using signal processing and machine learning methods modified from those proposed by Ramirez et al (2012). We show a reduction in latency of the EEG-interface compared to a baseline of button-clicking. We then demonstrate a human can train an autonomous ground vehicle to navigate an urban environment from start to a goal while avoiding obstacles and taking a user-preferred route. Previous work shows users can experience illness from autonomous vehicles not driving in their style (Iskander et al., 2019). We report the results of subjective Likert-scale surveys regarding user's experience for useability and trust in this mode of interaction relative to our baseline method.
This work opens avenues to help non-technical experts more efficiently train robots in specialist domains. The improved access, user experience, latency and training effort enables cheaper and more effective robotic applications.

Title: Applying Data Science to Addiction Neuroscience: Importance of Collaborations

Authors: *L. FRIEND[1], A. AVILA[1], S. WRIGHT[1], R. LITTLE[1], W. NILSON[2], W. COMPTON[1]; [1]NIDA, Bethesda, MD; [2]NSF, Bethesda, MD

Abstract: Data science is recognized as an increasingly important cross-cutting research approach in neuroscience as data increases exponentially in volume and velocity. Therefore, increasing the capacity of experts in data science for biomedical research of addiction is crucial. The National Institute on Drug Abuse (NIDA) and National Science Foundation (NSF) are working together to increase collaborations between computer scientists and neuroscientists working in the field of substance use disorders. These cross-disciplinary collaborations have a high potential to mine large and rich data sets that have been previously unstudied. To this end, we are interested in implementing proven strategies and models to improve and expand training in this emerging field. NIDA has published a Notice of Scientific Interest in Data Science research in training and other early career awards (NOT-DA-21-013); however, community input and involvement is critical to this effort. We will also report out on issues and ideas raised at a workshop sponsored by NSF and NIDA this past Fall. We will discuss challenges to such collaborations including expanding the early career pipeline, finding partners in research, and understanding unique career paths and terminology for computer scientists and academic researchers.

Title: Preliminary screening of depressive disorders using electroencephalography signals

Authors: *I. INJAR[1,2], O. GHARBI[1], J.-P. MIRON[1], E. BOU ASSI[1];
[1]Neurosci., Univ. of Montreal Hosp. Res. Ctr. (CRCHUM), Montréal, QC, Canada; [2]Med., Univ. of Sherbrooke, Sherbrooke, QC, Canada

Abstract: Rationale: According to the World Health Organization, depression affects 264 million people worldwide[1]. Unfortunately, the screening of major depressive disorders (MDD) remains descriptive relying on subjective questionnaires (symptoms). The development of quantitative tools to accelerate MDD screening could significantly impact patient management. Recently, a growing interest with auspicious findings on the use of electroencephalography (EEG) to complement the diagnosis of MDD has been witnessed.**Objective:** We explored the use of EEG-based features to distinguish between participants with low and high depressive symptomatology.**Methods:** We performed an exploratory analysis using resting-state EEG signals from the publicly available "James F. Cavanagh & John J.B. Allen depression rest database"[2]. The severity of depressive symptomatology was assessed using the Beck Depression Inventory (BDI)[3]. We studied a group of 73 healthy controls (HC: BDI<10) and 44 individuals with high depressive symptomatology (DEP: BDI>10). Band power features were extracted from 2-sec epochs during vigilance-controlled eyes closed resting conditions. More specifically, 50 measures from different lobes, in 5 frequency bands: delta (0.5 – 4 Hz), theta (4 – 8 Hz), alpha (8 – 13 Hz), beta (13 – 30 Hz) and low gamma (30 – 50 Hz) were assessed. A t-test was used to evaluate the existence of significant differences in EEG features between HC and DEP.**Results:** Fourteen features exhibited significant differences between HC and DEP subjects (Bonferroni corrected). The most informative measures were in the beta band (right-central lobe in beta band: p=.0033; right-parietal lobe in beta band: p=.045).**Significance:** Our preliminary findings highlight the possibility of EEG-based screening of DEP. Further analyses in a larger cohort of patients, with a confirmed diagnosis of MDD, are required. **References:**[1] GBD 2017 Disease and Injury Incidence and Prevalence Collaborators. (2018). Title: The FreeMoCap Project: A free-and-open-source, hardware-and-software-agnostic, research-grade, minimal-cost motion capture system and platform for decentralized scientific research, education, and training

Authors: *A. CHERIAN, Y. LU, C. CICALO, J. ALLEX, J. S. MATTHIS;
Northeastern Univ., Boston, MA

Abstract: The computer vision community is making tremendous advances in the field of markerless motion capture software, but because these advances often require a high floor of technical knowledge to be used to their full extent they are of limited utility to the scientific community. We developed the Free Motion Capture (FreeMoCap) system to create a common framework for the recording and analysis of human, animal, and robotic movement in order to advance the scientific frontier while creating a more accessible and equitable approach to research, training, and education. The FreeMoCap system leverages emerging markerless motion capture software (e.g. OpenPose, DeepLabCut, etc) to create a streamlined 'one-click' pipeline for 3D kinematic reconstruction. This system works with arbitrary camera hardware and provides methods for synchronous recording of wired cameras (e.g. USB webcams) as well as the post-hoc synchronization of independent cameras (e.g. GoPros). The FreeMoCap system is developed with the intention of being easily accessible to the scientific community and customizable to research needs. We aim to allow integration of other markerless motion capture methods (e.g. AlphaPose, DAANCE, etc) into the system, as well as reformatting motion capture data from traditional optical (Vicon, Qualisys, etc) and IMU-based (e.g. Rokoko, etc) motion capture systems into a common, human-readable data type to facilitate research collaboration and sharing of analytical methods. Support for eye tracking data (e.g. Pupil Labs) is currently in development. By creating a common framework with shared data types, the FreeMoCap system allows researchers from otherwise disparate fields to combine their findings and methodologies in service of a broad and multi-faceted understanding of human and animal movement in the natural world. The FreeMoCap system allows for the recreation of a research-grade motion capture system for less than 100 US Dollars, which coupled with its ease-of-use, widely expands the accessibility of human and animal movement tracking within the scientific community.

Title: Common spatial pattern detection of concept semantic relatedness using combined ERP and frequency spectrum features

Authors: *M. J. DOYEL, A. W. L. CHIU;
Biol. and Biomed. Engin., Rose-Hulman Inst. of Technol., Terre Haute, IN

Abstract: One of the chief contributing factors to slowing down BCI spellers for users with profound disabilities is backtracking to delete mistakes or correct certain selections. The ability to design an EEG-based strategy to identify the desire to make corrections in the BCI speller would enhance the user experience and bit rate of the device. Past efforts suggested that Common Spatial Patterns (CSP) may show promise in helping detect and classify semantic violations in reading despite CSP not being widely used in event-related potential (ERP) applications. Semantic violations in EEG often exhibit deflections in the N400 and P600 region coinciding with the violation. The purpose of this research is to create a CSP model that can improve the classification accuracy of semantic violations in reading by incorporating neural oscillation information. Visual stimuli consisting of 150 pairs of nouns from Maguire et. al. (2010) and Calvo et. al. (2018) were presented, where the first word served as the Primer and the second word served as the Target. EEG signals from 14 channels were parsed to obtain the average N400 potential, the average P600 potential, and signal power in the alpha and theta bands, creating a 56-dimension (14 channels by 4 feature types) feature space. The CSP algorithm was implemented to improve orthogonality in the feature space, and the feature space dimension was reduced to 2. Three types of classification strategies Linear Discriminant Analysis (LDA), Naïve Bayes (LB), and K-Nearest Neighbor (KNN) were implemented. Graphical analysis by CSP showed that while individual features did not appear separable, a higher dimension dataset including all four feature types does demonstrate separability. The 10-fold validation results showed that two-class models optimized for individual subjects achieved accuracies ranging from 50% to 66% with LDA, 78% to 98% with KNN, and 76% to 100% with NB. Examining the mixing matrices during the dimension reduction step in CSP suggested that alpha frequency band and EEG locations P7, F4, F3, AF4, and FC6 consistently play a critical role in the success of these classifiers across the different subjects.

Title: Sex-specific DNA (hydroxy) methylation in glutamatergic and GABAergic cortical neurons.

Authors: *J. CHIEN[1,2], J. LI[2], A. KOZLENKOV[3,4], S. DRACHEVA[3,4], E. A. MUKAMEL[2];
[1]Dept. Physics, [2]Dept. Cognitive Sci., Univ. of California San Diego, La Jolla, CA; [3]James J. Peters VA Med. Ctr., Bronx, NY; [4]Friedman Brain Inst. and Dept. of Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Covalent modifications of DNA, including methylation and hydroxymethylation of genomic cytosine, transform the neuronal epigenome during brain development and contribute to the diverse identities of neural cell types. DNA methylation could contribute to alterations in neurodevelopment

underlying psychiatric disease such as schizophrenia, yet the cell type-specific distribution of (hydroxy)methylcytosine in health and disease are largely unknown. We recently reported whole-genome, base-resolution DNA (hydroxy)methylation analysis in three major cell types in human prefrontal cortex (PFC)--glutamatergic excitatory neurons (Glu), gamma-aminobutyric acid (GABA)ergic inhibitory neurons, and oligodendrocytes--that were isolated from the autopsied brains of two neuropsychiatrically intact male donors (Kozlenkov et al. 2018). We detected a unique association between hydroxymethylcytosine (hmC) and gene expression in inhibitory neurons that differed from the pattern in excitatory neurons and oligodendrocytes. We also found that risk loci associated with neuropsychiatric diseases, including schizophrenia, were enriched near regions of reduced hmC in excitatory neurons and reduced mC in inhibitory neurons. To address the potential role DNA (hydroxy)methylation in neural cell types in the context of neuropsychiatric disease, we compared the PFC Glu and GABA neurons in schizophrenia patients and matched control individuals (a total of 29 male and female donors, ranging in age from 14 to 60 years old). We confirmed our previous findings that GABA neurons contain a higher level of tmCG, but lower hmCG compared to Glu. Similar patterns were confirmed for non-CG methylation (mCH). We also detected neuron-subtype-specific sex differences for these two major epigenetic marks, as well as systematic variation with age. In summary, this analysis provides a fine-resolution mapping of cell-type- and sex- specific epigenetic marks in control and schizophrenia brains and highlights the important role of hydroxymethylcytosine.

Title: A functional map of subthalamic nucleus oscillations in Parkinson disease

Authors: *N. SALEHI[1], E.-L. BAUER[1], M. H. A. BOPP[2], S. MARURI[1], T. DEMBEK[4], D. PEDROSA[3], C. NIMSKY[2], L. TIMMERMANN[3], I. WEBER[3], C. R. OEHRN[3];

Abstract: Besides beneficial effects on movement, deep brain stimulation (DBS) in the subthalamic nucleus (STN) can have adverse effects on cognition and emotional processing depending on the stimulation site. Parkinson's disease (PD) is associated with functionally distinct changes in subthalamic neural oscillations related to motor, cognitive and limbic functions. However, their spatial distribution within the STN is still unclear. Further, it is unknown, whether the underlying functional signature or lead location is a better predictor for stimulation outcome. Previous studies localizing oscillations used post-

operative instead of intraoperative electrode location, which can be biased e.g., by deviations from the planned trajectory and postoperative lead rotation. Here, we used intraoperative microelectrode local field potentials (MER) and intraoperative computed tomography (iCT) to compute a map of subthalamic oscillations in MNI space. Further, we predict postoperative stimulation outcome including preoperative and intraoperative data. We recorded electrophysiological activity of 43 awake PD patients (32m, age=60±5.5), during bilateral implantation of DBS electrodes in the STN. Location of MER was reconstructed using iCT and preoperative 3T MRI data using DISTAL atlas (Lead-DBS toolbox). Power spectral density was mapped into MNI space with a radius of 1 mm around contact location. We tested spatial power distribution of each frequency against uniform distribution on group level by means of a cluster-based permutation analyses using paired t-tests and localized the of volume of tissue activated based on final lead location and best clinical stimulation settings. We used a linear support vector machine (SVM) incorporating preoperative patient information, structural connectivity and oscillatory activity of the stimulated area, as well as lead location as predictors for the motor, cognitive and limbic outcomes of DBS (UPDRS III, MOCA, BDI-II, Matlab V2016b). Cluster-based permutation analyses indicate largely overlapping local power peaks for alpha and beta oscillations in the dorsolateral STN, which is in accordance with previous studies. Further, theta oscillations were most prominent in the central STN. Gamma activity, on the other hand, was not confined to either portion of STN and appeared as local peaks throughout STN. SVM indicate that stimulating areas with oscillatory signatures has a larger impact on DBS outcome than anatomical location *per se*. Using a combination of iCT and MER, we present a map of subthalamic oscillations and show that the functional subthalamic signature predicts DBS outcome better than structural information.

Title: Toward higher-sensitivity, shorter-interval MRI measures of atrophy in neurodegenerative dementias

Authors: *M. BRICKHOUSE[1], L. HANFORD[2], N. CARVALHO[1], M. ELDAIEF[1], R. MAIR[2], J. NIELSEN[2], A. TOUROUTOGLOU[1], R. BUCKNER[2], B. DICKERSON[1];
[1]Frontotemporal Disorders Unit, Massachusetts Gen. Hosp., Boston, MA; [2]Harvard Univ., Cambridge, MA

Abstract: Background Conventional single acquisition T1w structural MRI can detect significant change in brain structure given ample latency between scans; most contemporary studies of neurodegenerative dementias collect MRI scans at one-year intervals and calculate annualized rates of atrophy. MRI methods to detect atrophy over shorter (3- or 6-month) intervals would be extremely valuable for basic human neuroscience research about neurodegenerative disease mechanisms as well as for translation into clinical trials. Measurement of change over short intervals would allow neurodegeneration to be monitored in smaller, early-phase therapeutic trials—potentially even as a marker of target engagement in trials of disease-modifying interventions.
Method Our pilot cohort consisted of 5 patients: 4 with primary progressive aphasia (2 semantic variant likely due to FTLD, 2 logopenic variant likely due to AD), 1 with posterior cortical atrophy likely due to AD. We collected 32 accelerated 1mm T1w scans in four 30-minute blocks across two days for each of 3 timepoints (baseline, 3 months, 6 months). We used the FreeSurfer longitudinal processing stream to make robust estimates of the cortex and subcortical structures for each T1w volume. For each timepoint, cortical thickness and volume and subcortical volume estimates were derived from all 32 reconstructed scans. Rates of change were calculated from ROI measures. In addition, a cortical atrophy map was calculated for each subject at each timepoint in comparison with a group of age-matched controls (N=32). Between timepoint surface maps were generated for each subject, showing both cortical spread as well as highlighting regions with greatest change in thickness
Results Each of the patients exhibits a typical pattern of atrophy for their clinical syndrome. Cortical atrophy maps are highly reliable between timepoints, and for each subject show visibly apparent but small changes in the magnitude and spread of atrophy. ROI measures demonstrate a slight but observable decrease in the size of many brain structures, even across a 3-month interval. Cortical thickness changes in regions implicated in the patient's individual clinical syndrome show the greatest magnitude of change over time—detectable in each individual at 3-month intervals.
Conclusion This novel approach to MRI acquisition and analysis can sensitively measure neurodegeneration in individuals over shorter intervals of time, which could lead to substantial changes in methods for measuring disease mechanisms and in clinical trial design.

Title: Cortical thickness correlates with cortical morphology

Authors: N. DEMIRCI, *M. HOLLAND;
Univ. of Notre Dame, Notre Dame, IN

Abstract: The cerebral cortex of the human brain has a highly folded structure with consistently thicker outer gyral tops and thinner inner sulcal bottoms. This intriguing form of the cortex has been noted in numerous studies before, and our work (Holland et al. Phys. Rev. Lett. 2018) has suggested that this is the result of the passive physical forces generated during cortical folding. In this study, we explored the systematic patterns of cortical thickness not only among gyral and sulcal folds but also along the bends and intersections of gyri and sulci. For this purpose, we developed an open-source computational pipeline that extracts the local thickness and shape (i.e. sulcal depth and curvature) from reconstructed cortical surfaces. In an analysis of 564 neurotypical human subjects (aged 7-64 years) from the preprocessed Autism Brain Imaging Data Exchange (ABIDE), we found a strong correlation between the macroscopic morphology and thickness of the cortex. Specifically, the cortex is consistently thicker for convex (outward-bending) points, which tend to be gyral folds or the outside of tangential folds, than saddle-shaped points, which are found primarily along inner tangential folds. Concave (inward-bending) points, which are mostly found in sulcal pits, are consistently thinnest. This suggests that the passive physical forces involved in the curving and bending of gyral and sulcal folds also contribute to the characteristic patterns of thickness in the cortex. This relationship is important to understand before making comparisons between the cortical thickness of differently-folded regions. We are currently exploring these patterns of cortical thickness among different species of non-human primates, which have brains of different shapes and sizes. We expect to observe a similar correlation between shape and thickness, although we hypothesize that the differences should be less extreme in less-folded brains and those with thinner cortices. Our findings might offer a new framework into understanding the rationale for variations of thickness in relationship to both shape and size.

Title: Mechanisms of Impaired Consciousness in Medial Temporal Lobe Seizures Investigated with Intracranial EEG

Authors: B. P. LITVINOV, A. KUMAR, **Z. AHMAD**, N. GUNAWARDANE, C. YOTTER, I. QURAISHI, *H. BLUMENFELD;
Yale Univ. Sch. of Med., New Haven, CT

Abstract: Impaired consciousness can have detrimental effects on a patient's quality of life. Our goal was to use intracranial EEG to identify distinct characteristics between medial temporal seizures that either impaired or did not impair consciousness, operationalized by behavioral responses. We hoped to gain mechanistic insights and to also identify signal characteristics that could guide the use of neurostimulation to prevent impaired consciousness. Intracranial EEG of 76 medial temporal lobe onset seizures in 8

patients were analyzed. Behavioral responsiveness was broadly classified into two main categories of either impaired or unimpaired responsiveness to external stimuli based on blinded review of video during seizures. Using the fast Fourier transform (FFT), the EEG signals from each electrode contact were processed to calculate the signal power at different frequencies. Signals were synchronized to the onset time of the seizure and averaged across electrodes in major anatomical regions. The change in power from preictal baseline for seizures with impaired and spared behavioral responsiveness was compared. Group data averages (ictal vs pre-ictal baseline) in various frequency bands (delta, theta, alpha, beta, and gamma) were analyzed for seizures with (n = 18) and without (n = 58) impaired behavioral responsiveness. Seizures with impaired behavioral responsiveness had significantly longer mean duration (99.18 ± 62.07 s) than those without impairment (53.72 ± 33.91 s; $p<0.05$). Additionally, impaired seizures in medial temporal lobe onset contacts had greater EEG signal power across all frequency bands. These findings indicate that broad increases in frequency power in the temporal lobe are associated with impaired consciousness in focal temporal lobe seizures. Our findings suggest that severe local changes in the temporal lobe could trigger impairment in a broad network of cortical and subcortical dysfunction outside the temporal lobe. Additionally, the intracranial signal markers we identified can potentially help develop neurostimulation therapies to restore consciousness in temporal lobe seizures and improve quality of life for people with epilepsy.

Title: Methods to discover symmetry in neural data and impose symmetry constraints for clustering neural response patterns.

Authors: *C. CHUN[1,2], D. D. LEE[1];
[1]Cornell Univ., New York, NY; [2]Tri-Institutional Training Program in Computat. Biol. and Med., Weill Cornell Med., New York, NY

Abstract: Neural responses in the brain exhibit many different kinds of symmetries. For example, there exists rotational symmetry of neural responses to directional visual stimuli in the primary visual cortex (V1) and retinal ganglion cells. Also, due to the bilateral symmetry of the brain, there can be a pair of neurons whose response levels to some left-side and right-side stimuli are permuted. However, there lacks a method to incorporate these symmetries when grouping neurons with similar response patterns to identify functional neuronal units. Finding functional units that represent the population of neurons is crucial for simplifying the brain circuit for understanding a neural mechanism of sensory processing. Here we present efficient methods to discover symmetries of different types in noisy data using linear

programming, along with a modified k-means clustering algorithm that finds symmetric clusters by utilizing the symmetry relationship discovered earlier. We applied these methods to neural activities in transgenic Tg(elavl3:GCaMP5G) zebrafish larvae engaged in optomotor response (OMR; fish n=22). The fish were presented with binocular directional visual stimuli to induce OMR, and neuronal activities (neurons n=22782) in the brain parts involved in OMR, i.e. pretectum and anterior hindbrain, were recorded using 2-photon microscopy. In this dataset, we expect to see pairs of neurons whose responses were permutated with a cycle of 2, largely due to the bilateral symmetry of the brain. We found the symmetry between leftward and rightward stimuli, but also between inward (visual fields converging to the body center) and outward (diverging from the body center) which were unexpected and would have been difficult to find without this method. This finding suggests the neural connections to inward selective units and outward selective units are symmetric. This demonstrates that the symmetric clustering method can provide deeper insights into neural circuitry. The method can also find a permutation symmetry of any number of cycles in polynomial time (O(n^2)), and the method can be applied to continuous data by acting on Fourier components of the signals.

Title: Optimal noise correlations are biologically implausible

Authors: *P. SACHDEVA[1], J. LIVEZEY[2], S. MADHOW[3], M. DOUGHERTY[4], K. E. BOUCHARD[5]; [1]Univ. of California, Berkeley, Oakland, CA; [2]Biol. Systems and Engin., E O Lawrence Berkeley Natl. Lab., Berkeley, CA; [3]UC Berkeley, Berkeley, CA; [4]Lawrence Berkeley Natl. Lab., Berkeley, CA; [5]UCSF, UCSF, San Francisco, CA

Abstract: *Correlated variability across simultaneously recorded neurons (noise correlations) has been observed across a variety of cortical areas and experimental paradigms. In many contexts, this correlated variability has been shown to improve the coding fidelity of experimental stimulus parameters as measured by the linear Fisher information (LFI), compared to a null model with no correlations. However, most existing results do not shed light on whether neural populations achieve optimal coding properties. Assessing optimality in data is conditional on the choice of null model: the null model specifies both the degrees of freedom that we hypothesize a neural system can control as well as constraints that it cannot change. Here, we propose to assess optimality in diverse datasets by comparing observed LFIs to the distribution expected according to a null model where its degrees of freedom are sampled uniformly. In order to accomplish this, we propose two novel null models: a rotation null model*

and factor analysis null model that have alternative degrees of freedom and therefore distinct biophysical interpretations compared to the shuffle null model. We show that across datasets and dimensionalities, neural populations have suboptimal coding performance according to the rotation and factor analysis null models, relative to the shuffle null model. We explain this finding by demonstrating that the optimal neural response distributions violate two measures of biological plausibility. Furthermore, we find that across datasets, the optimality of the observed responses decreases with dimensionality for all null models. Together, these results shed light on the limitations of neural systems in achieving optimal coding of experimental stimulus parameters, and highlights the importance of carefully considering the biological interpretation of null model degrees of freedom.

Title: Characterize laminar-specific features of inter hemispheric functional connectivity with bilateral line-scanning fMRI

Authors: *S. CHOI[1,2], X. YU[3];
[1]Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany; [2]Grad. Training Ctr. of Neurosci., Tuebingen, Germany; [3]Dept. of Radiology, Harvard Med. School, Massachusetts Gen. Hosp., Athinoula A. Martinos Ctr. for Biomed. Imaging, Charlestown, MA

Abstract: Despite extensive efforts to identify corpus callosum (CC) mediated interhemispheric (i-) functional connectivity (FC), several reports have demonstrated nearly intact i-FC in post-callosotomy brains. To relate the controversial studies to dynamic functional changes in the brain, it is plausible to investigate how correlations change in i-FC mediated by callosal projection neurons. Here, we developed a bilateral line-scanning functional magnetic resonance imaging (fMRI) method to detect laminar-specific blood-oxygen-level-dependent (BOLD) fMRI signals from symmetric forepaw somatosensory cortex (FP-S1) regions with spatial and temporal resolution (100 μm, 100 ms) in rodent brains. We investigated laminar-specific correlation features under both evoked and resting-state (rs-) conditions in anesthetized rats (55 trials of 4 rats). In evoked fMRI, we sorted all trials into two groups based on BOLD signals detected in left CC ipsilateral to stimulation. Interestingly, Group 1 showed negative correlations between superficial layers of right FP-S1 and all layers of left FP-S1 (Fig. C), possibly highlighting the

transcallosal postsynaptic inhibitory effect in a delayed time scale negatively coupled to the BOLD signal detected in the draining veins of activated right FP-S1. In contrast, Group 2 only showed positive correlations between infragranular layers of right FP-S1 and all layers of left FP-S1, implying direct neuronal activation coupled BOLD signals across bilateral FP-S1. We also sorted all trials into two clusters based on rs-CC fMRI signals detected at a high frequency band (0.08-0.1 Hz) completely distinguishing from an ultra-slow fluctuation (0.01-0.02 Hz). Notably, Cluster 1 showed positive correlations between Layer 2-6 of right and left FP-S1, but weak or zero correlations of Cluster 2 were observed (Fig. E), possibly indicating brain state-dependent i-FC changes. This work provides a unique laminar-specific i-fMRI mapping scheme to investigate evoked and rs-FC, distinguishing transcallosal-mediated neuronal interactions across two hemispheres.

Abstract: Dopamine (DA) neurons of the VTA and SNc project densely to the ventral (vSTR) and dorsal striatum (dSTR, respectively, and are critical regulators of basal ganglia functions, movement and cognition. The connectivity of the DA system is intriguing due to the dual character of its axonal domain, with terminals that are typically non-synaptic in structure, but with a subset that are synaptic and from which glutamate or GABA can be released. The molecular mechanisms underlying the formation of synaptic and non-synaptic terminals is presently undetermined. However, a growing body of work, mainly performed on neurons that are exclusively synaptic, has highlighted the implication of trans-synaptic cell adhesion molecules such as neurexins (Nrxns) in synapse regulation. In this study, we evaluated the role of Nrxns in the formation and function of axon terminals and synapses established by DA neurons. We crossed a triple conditional Nrxn mouse line (Nrxn123 TKO) with a DAT-Ires-Cre mouse to selectively delete Nrxns in DA neurons. We observed that the density of excitatory and inhibitory synapses established by DA neurons *in vitro* was not affected, and that loss of Nrxns does not impair the basic development and connectivity of DA neurons. However, we found that the loss of Nrxns caused an impairment of DA transmission in striatal brain slices prepared from adult mice, revealed by a reduced rate of DA reuptake after electrically-evoked DA release and with impaired amphetamine-induced locomotion. Interestingly, after deletion of all Nrxns, quantitative immunohistochemistry in striatal sections revealed an adaptation of the DA system, with an increased intensity of vesicular monoamine transporter (VMAT2) immunoreactivity and a decrease of DA transporter immunoreactivity, without any change of tyrosine hydroxylase levels in the ventral striatum. Overall, these results suggest that Nrxns play a key role in regulating neurotransmission by DA neurons.

Title: Gaba co-release by dopamine projections in the striatum is regulated by neurexins.

Authors: G. B. DE CARVALHO[1], C. DUCROT[2], N. GIGUERE[2], L.-E. TRUDEAU[2], ***L. Y. CHEN**[1];
[1]Anat. and Neurobio., Univ. of California, Irvine, Irvine, CA; [2]Univ. of Montreal, Montreal, QC, Canada

Abstract: Dopamine (DA) afferents projecting from the Ventral Tegmental Area (VTA) and Substantia Nigra (SN) regulate striatal synaptic transmission through releasing neurotransmitters such as DA, glutamate, and GABA. However, little is known about the release mechanisms involved and the synapse specificity in different striatal regions. Neurexins (Nrxns) have been identified as major contributors to presynaptic transmission in a synapse-specific manner. They have been shown to regulate various synaptic functions, including neurotransmitter vesicle docking and release. We examined the role of Nrxns in DA-mediated synaptic transmission by creating DA neuron-specific NrxnKO mice using $Nrxn123^{flox}$ mice crossed with DAT-IRES-Cre mice. Synaptic transmission was measured in medium spiny neurons (MSNs) of the dorsal or ventral striatum in acute brain slices prepared from WT, HET and KO mice via whole-cell patch-clamp electrophysiology. Presynaptic DA afferents projecting to striatal regions were selectively stimulated by expressing channelrhodopsin in VTA/SN neurons via stereotaxic viral injections. Optical stimulation, coupled with pharmacology, was used to measure glutamate or GABA synaptic currents in MSNs. DA/NrxnKO mice showed region-specific changes in inhibitory synaptic responses evoked by optical stimulation (oIPSC) of DA neuron axons. An increase of oIPSC amplitude with an increased decay time constant was observed in the ventral, but not the dorsal striatum. The oIPSCs were blocked by the vesicular monoamine active transporter-2 (VMAT2) inhibitor reserpine. Electrical stimulation was used to measure local synaptic changes where we observed similar region-specific alterations. These findings indicate that Nrxns play an active role in regulating VMAT2-dependent GABA co-release from VTA DA neurons.

Title: Probing synaptic $GABA_A$receptor function using Artemisinins

Authors: *N. GUZIKOWSKI[1], E. T. KAVALALI[2];
[2]Vanderbilt Brain Inst., [1]Vanderbilt Univ., Nashville, TN

Abstract: Synapses are the fundamental unit of the nervous system whereby a heterogenous structure and molecular composition facilitate different modes of neurotransmission that ultimately regulate the transfer of information. Extensive work has been conducted at the excitatory synapse delineating the precise arrangement of proteins that drive and facilitate neurotransmitter release and postsynaptic signaling.

However, our knowledge of neurotransmission at the inhibitory synapse is relatively lacking. Recently gephyrin was identified as a primary mammalian target of Artemisinins, a common antimalarial drug. Crystal structures of the gephyrin E domain with Artemisinins demonstrated that Artemisinins target the gephyrin universal binding pocket, which is essential for inhibitory receptor anchoring. However, despite these recent advances in elucidating the interaction of Artemisinins and gephyrin, how Artemisinins modulate synaptic inhibitory neurotransmission at central synapses is not fully known. We used this new family of small molecule compounds to probe the relationship of gamma-aminobutyric acid A receptors ($GABA_A$Rs) and gephyrin. In this study we use Artemisinins as a tool to explore the necessity and utility of gephyrin in mediating inhibitory synaptic transmission. Following the application of Artemisinins to primary hippocampal cultures we investigate neurotransmission using electrophysiology and synaptic proteins using immunocytochemistry. Collectively, our results suggest gephyrin interactions maintain $GABA_A$ receptor organization vital for proper inhibitory neurotransmission.

Title: Neurexin-3 defines synapse- and sex-dependent diversity of GABAergic inhibition in ventral subiculum

Authors: *E. E. BOXER[1], C. SENG[2], D. LUKACSOVICH[2], J. KIM[1], S. SCHWARTZ[1], M. J. KENNEDY[1], C. FOLDY[2], J. AOTO[1];

Abstract: Ventral subiculum (vSUB), the major output structure of ventral hippocampus, regulates stress and reward, and its hyperactivity is implicated in schizophrenia (SCZ), depression, and substance use disorders (SUDs). An understanding of the intrinsic connectivity and synaptic properties of the local vSUB inhibitory circuit, however, is limited. The presynaptic adhesion molecule, Neurexin-3 (Nrxn3), is also associated with SCZ and SUDs and is highly expressed in hippocampal inhibitory neurons, but its function at hippocampal inhibitory synapses has remained elusive. Using slice electrophysiology, imaging and single-cell RNA sequencing in PV-Ai9, PV-Cre, and PV-Nrxn3 KO young adult mice, we investigated the functional role of Nrxn3 at GABAergic parvalbumin (PV) interneuron synapses made onto regular and burst spiking (RS and BS) neurons, the two physiologically distinct classes of vSUB

principle neurons. Surprisingly, we found that intrinsic connectivity of vSUB and synaptic function of Nrxn3 in vSUB are sexually dimorphic. We found that PV inhibitory drive is significantly greater onto RS compared to BS neurons in male vSUB, but greater onto BS compared RS neurons in female vSUB. This synapse-specific circuit organization is facilitated by differences in synapse number in males, but quantal size in females. Furthermore, we found that Nrxn3 KO in PV neurons produced synapse-specific and sex-dependent phenotypes: PV synapse density and inhibitory currents were impaired at male RS synapses, while at female RS synapses, PV release probability and inhibitory currents were enhanced. These effects were specific to PV-RS synapses, as PV inhibitory currents in BS neurons were unaltered. These findings represent the first characterization of vSUB as a sexually-dimorphic region and demonstrate that Nrxn3 can govern distinct aspects of inhibitory synaptic transmission that depend on postsynaptic cell identity and sex. These findings may also provide insight to sex differences observed in neuropsychiatric and mood disorders that involve vSUB dysregulation and Nrxn3 mutations.

Abstract: In vitro modeling of human brain connectomes is key to explore the structure-function relationship of the central nervous system (CNS). The comprehension of this intricate relationship will serve to better study the pathological mechanisms of neurodegeneration, and hence to perform improved drug screenings for complex neurological disorders, such as Alzheimer's and Parkinson's diseases. However, currently used *in vitro* modeling technologies lack potential to mimic physiologically relevant neural structures, because they are unable to represent the concurrent interconnectivity between myriad subtypes of neurons across multiple brain regions. Here, we present an innovative microfluidic design that allows the controlled and uniform deposition of various specialized neuronal populations within unique plating chambers of variable size and shape, used as organ-on-a-chip platforms for neuroscience research. By applying our design, we offer novel neuro-engineered Organ-on-Chip (OoC) microfluidics, also known as neurofluidic devices, which demonstrate the capacity to isolate, control, and manipulate cellular environments, allowing to co-culture different neural cell types while these are fluidly isolated. To mimic their *in vivo* environment, *in vitro* neural networks are composed of connected nodes seeded with

specialized neuronal populations. The next step in the creation of OoC for CNS research is to couple a microfluidic architecture that can reconstruct complex interconnected neuronal networks, with a functional recording using multi electrode arrays (MEA). These advances provide essential enhancements to *in vitro* platforms in the quest accurately model the brain for the investigation of human neurodegenerative diseases. Composed of multi-nodes interconnected with physiologically relevant structural connectivity patterns, we were able to create a models of CNS circuits affected in neurodegenerative diseases as the direct way of the basal ganglia loop of the brain, involved in Parkinson disease and Huntington disease. This loop is composed of five anatomic parts represented by five microfluidic compartments aligned on the device with respect to the converted required surface and linked using several arrays of microchannels. The activity of these networks can be record thanks to an electrophysiological recording system that has been specifically design to fit an even distribution throughout the compartments in 256 electrodes MEA.

Abstract: Osmotic equilibrium and membrane potential in animal cells depend on concentration gradients of sodium (Na^+) and potassium (K^+) ions across the plasma membrane, a function catalyzed by the Na^+,K^+-ATPase alpha (α) subunit. Here, we describe *ATP1A3* variants encoding dysfunctional α3

subunits in children affected by a developmental malformation of the cerebral cortex characterized by abnormal folding and laminar organization. To gain cell-biological insights into the early developmental spatiotemporal dynamics of prenatal *ATP1A3* expression, we built an *ATP1A3* transcriptional atlas of fetal cortical development using mRNA *in situ* hybridization and transcriptomic profiling of ~125,000 individual cells with single-cell RNA sequencing (Drop-Seq) from eleven areas of the midgestational human neocortex. We find that fetal expression of *ATP1A3* is most abundant to a subset of excitatory neurons carrying transcriptional signatures of the developing subplate, yet also maintains expression in non-neuronal cell populations. Moving forward a year in human development, we profiled ~52,000 nuclei from four areas of an infant neocortex and show *ATP1A3* expression persists throughout early postnatal development, most predominantly in inhibitory neurons, including parvalbumin interneurons in the frontal cortex. Finally, we discover the heteromeric Na^+,K^+-ATPase pump complex may form non-redundant cell-type specific α-β isoforms combinations, including α3-β1 in excitatory neurons and α3-β2 in inhibitory neurons. Together, the developmental malformation phenotype of affected individuals and single-cell *ATP1A3* expression patterns point to a key role for α3 in human cortex development, suggesting a similar prenatal ion dysregulation pathway as other known genes (i.e. SCN3A).

Title: Hyperactive ERK/MAPK in glutamatergic neurons alters connectivity in the mouse cortex

Authors: *K. P. REES[1], G. R. BJORKLUND[2], K. RIORDAN[1], J. M. NEWBERN[1];
[1]Sch. of Life Sci., [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Glutamatergic neurons comprise 80% of the total neuron population in the cerebral cortex, however, the function of the RAS/RAF/MEK/ERK (ERK/MAPK) signaling cascade within this subpopulation of cells is not well understood. Clearly defined mutations within this pathway cause syndromes known as the RASopathies. Clinical symptoms include intellectual disability, developmental delay, cardio-facial deficits, and in some cases hypotonia. A majority of RASopathies are attributed to hyperactivation of ERK/MAPK signaling. Individuals with Neurofibromatosis Type 1 (NF1) and Noonan Syndrome (NS), two common RASopathies, exhibit aberrant structural connectivity in diffusion tensor imaging (DTI) studies, however, the contributions of axonal versus oligodendrocyte deficits to this phenotype are not fully understood. Here, we used a conditional genetic approach to delineate the neuron autonomous effects of hyperactive ERK/MAPK in subpopulations of glutamatergic neurons in the mouse

cortex. We have previously found reduced corticospinal tract (CST) axon extension in these mutants. We now show that this defect is layer V neuron autonomous using a Cre-dependent reporter and anterograde viral tracing. We have also implemented retrograde viral tracings to better understand input into primary motor cortex (M1). Analysis of oligodendrocyte markers revealed limited deficits in these neuron directed mutants. The relationship between structural and functional connectivity has not been explored in these mutants, we therefore investigated the expression of activity dependent genes responsive to glutamatergic signaling. Using both pan-glutamatergic and layer V directed approaches, we found that ERK/MAPK hyperactivation led to both cell autonomous and cell non-autonomous alterations in FOS and ARC expression. ERK/MAPK hyperactivation specifically in GABAergic neurons, did not result in significant changes in activity dependent gene expression. Overall, our data shows that glutamatergic neuron ERK/MAPK hyperactivation during embryogenesis is sufficient to alter both structural and functional connectivity in the mature mouse cortex. Future work will be aimed at elucidating the direct ERK1/2 mediated molecular mechanisms important for circuit formation.

Abstract: The remarkable capacity of neurons to reorganize their structure, function, and connections in an activity-dependent manner is supported by an extensive network of molecules and effectors. Among those, the 'hub' protein Activity-regulated cytoskeleton-associated protein (Arc, also known as Arg3.1) can be considered one of the central, as well as most versatile, players. Notably, Arc has been shown to maintain direct interactions with key synaptic factors like PSD95, TARPγ2, and CaMKII, as well as participate in many aspects of neuroplasticity such as trafficking of AMPARs and modeling of dendritic

spines. As a protein with homology to the retroviral Gag protein, a particular characteristic of Arc is its capacity to self-assemble into virus-like capsids that can package mRNAs and transfer those transcripts to other cells. How a single protein like Arc can do all this remains difficult to explain, but a complete answer to that question will certainly include a mix of protein post-translational modifications acting to confer molecular and functional specificity. Recently, proteomics and sequence analysis of Arc protein led us to recognize two candidate phosphorylation sites specific to TRAF2 and NCK-interacting protein kinase (TNIK)—a member of the Germinal Center Kinases (GCK) subfamily that is considered a possible risk factor to different psychiatric disorders, including schizophrenia and bipolar disorder. These two sites of interest were found in structurally distinct locations, S67, located within the coil-coiled region of the nuclear retention domain, and T278D which was located within the flexible hinge region between the N- and C-lobe of the capsid-forming domain. Here, we summarize evidence supporting the interaction between Arc and TNIK using co-immunoprecipitation and kinetic assays. These results support Arc as a substrate for TNIK phosphorylation. Next, we present how site-directed mutagenesis to create Arc S67 and T278 mutant variants reveal that TNIK action at those amino acids can strongly influence Arc's subcellular distribution and self-assembly as capsids. Finally, we highlight how modification of Arc's T278 site can change its interaction with other synaptic protein effectors. In summary, we present biochemical, proteomics, and electron microscopy evidence supporting the influence of TNIK on Arc's neurobiology. Together, our efforts offer exciting new scenarios about the interaction of these two factors in the context of synaptic plasticity and the pathophysiology of certain brain disorders.

Abstract: Recent evidence suggests that nanoorganization of proteins within synapses may control the strength of communication between neurons in the brain. The unique subsynaptic distribution of glutamate receptors, which cluster in nanoalignment with presynaptic sites of glutamate release, supports this idea. However, testing it has been difficult because mechanisms controlling subsynaptic organization remain unknown. Reasoning that transcellular interactions could position AMPA receptors, we targeted a key transsynaptic adhesion molecule implicated in controlling AMPAR number, LRRTM2, using engineered, rapid proteolysis. Severing the LRRTM2 extracellular domain led quickly to nanoscale de-clustering of AMPARs away from release sites, not prompting their escape from synapses until much later. This rapid remodeling of AMPAR position produced significant deficits in evoked, but not spontaneous, postsynaptic receptor activation. These results dissociate receptor numbers from their nanopositioning in determination of synaptic function, and support the novel concept that adhesion molecules acutely position AMPA receptors to dynamically control synaptic strength.

Title: Lipophorin Receptors participate in mushroom bodies development and function

Authors: *F. ROJO-CORTÉS[1], V. TAPIA-VALLADARES[1], N. FUENZALIDA-URIBE[2], S. HIDALGO[1,3], M.-C. GONZÁLEZ-RAMÍREZ[1], C. B. ROA[1], C. OLIVA[1], J. M. CAMPUSANO[1], M.-P. MARZOLO[1];
[1]Cell. and Mol. Biol., Pontificia Univ. Católica de Chile, Santiago, Chile; [2]Biol., Univ. of Puerto Rico, San Juan, Puerto Rico; [3]Dept. of Entomology and Nematology, Univ. of California Davis, Davis, CA

Abstract: The Lipophorin Receptors (LpRs) are members of the Low-density Lipoprotein Receptor family that mediate lipid uptake in insects. In *Drosophila melanogaster* two LpRs have been described,

LpR1 and LpR2, which are orthologs of the Reelin receptors ApoER2 and VLDL-R, present in vertebrates. Reelin is a signaling molecule associated with the correct development of laminated structures like the hippocampus, cerebral cortex and cerebellum. It is currently unknown whether LpRs play similar roles in the fly brain, though Reelin is not present in the Drosophila genome. Herein we show that LpR-deficient flies exhibit impaired olfactory memory and sleep patterns, function that relays on the Mushroom Bodies (MB) in fly brain. These animals also present anatomical defects in this critical association area. Cultured *Drosophila* MB neurons treated with mammalian Reelin increase their neurite complexity, which is similar to what has been observed in hippocampal neurons. This is not observed in neurons from animals bearing mutations in LpRs genes. In vitro experiments showed that the short isoforms of LpRs bind and internalize Reelin. Furthermore, our data suggest that the effect of Reelin on neuron complexity depends on Dab, a protein homologous to vertebrate Dab1, involved in Reelin signaling cascade. These results show for the first time that LpRs have a role beyond lipid metabolism in *Drosophila*, and further support the existence of a Reelin-like molecule in *D. melanogaster*.

Title: Regulation of the excitatory synapse through USP7

Authors: *H. BAKER, R. GU, C. CHANG, V. VO, E. C. OH;
Nevada Inst. of Personalized Med., Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: Regulation of the excitatory synapse through *USP7*
Loss of function lesions in Ubiquitin-specific protease (USP) 7 are associated with intellectual disability with significant speech delay, autism spectrum disorder, and seizures. While the deubiquitinating activity of USP7 has been characterized in P53-dependent apoptosis, a role for cell-growth arrest and distinct neurological conditions seen in patients with mutations in *USP7* has not been established. Here, we show that USP7 can regulate the development of the brain by localizing to synaptosomes in the hippocampus and stabilizing neural-specific substrates. Using mass spectrometry, we identify discrete protein complexes that interact with USP7 and are necessary for functions such as signaling, vesicular trafficking, Golgi assembly, and cell polarity at the synapse. Missense mutations in *USP7* abolish these interactions and haploinsufficiency of *USP7* in induced neurons from induced human pluripotent stem cells (iPSCs) results in the perturbation of neural synchrony and network oscillations. We characterized heterozygous loss of function mice and show that mutant phenotypes can be associated with stability of neural proteins

that are required to form the excitatory synapse. Taken together, our iPSC and mouse models suggest that USP7 is necessary to promote synaptic function and cognition during development.

Title: Proteolytic processing and nuclear function of PCDH19

Authors: *S. NEWBOLD, C. LLINARES-BENADERO, I. W. FOX, I. MARTINEZ-GARAY; Cardiff Univ., Cardiff, United Kingdom

Abstract: Mutations in the X-linked gene Protocadherin-19 (*PCDH19*) lead to epilepsy with cognitive impairment in heterozygous females and post-zygotic mosaic males. The disorder phenotype is currently explained by cellular mosaicism of *PCDH19* expressing and non-expressing cells in the brain, which leads to defective cell-cell communication and circuits. Although the gene codes for a cell adhesion protein of the cadherin superfamily expected to localize at the cell membrane, recent reports have implicated PCDH19 in the regulation of gene expression and have identified the protein in the nucleus. The aim of this study was to determine if PCDH19 could undergo proteolytic cleavage resulting in the generation of an intracellular fragment (PCDH19-ICD) that could translocate to the nucleus in order to regulate gene expression. In addition, we wanted to identify pathways which are regulated by PCDH19 processing in neural progenitors and neurons. To test this hypothesis, we have analysed how the absence or inactivation of specific proteases affects the generation of PCDH19-ICD in heterologous cells and neurons. Our results show that PCDH19 can be processed by ADAM10 and gamma secretase, and that PCDH19 undergoes activity-dependent proteolytic processing in neurons. To determine potential transcriptional targets of PCDH19, we have generated a mouse embryonic stem cell line that overexpresses the cytoplasmic domain of PCDH19 from the Rosa26 locus (CYTO), and an isogenic PCDH19-knockout line (KO). Both lines, together with a control, have been used for RNAseq analysis. RNAseq analysis indicates changes in several synaptic pathways in those neurons overexpressing PCDH19 cytoplasmic domain, suggesting a potential role for PCDH19 processing in the modulation of synaptic function. We are currently complementing our *in vitro* analysis with an *in vivo* overexpression of PCDH19-CYTO in order to assess an effect on dendritic morphology *in vivo*. We believe that PCDH19 is capable of transducing information about events happening at the membrane to the nucleus to elicit appropriate cellular responses and expect that our *in vivo* analysis will provide new mechanistic insights into the function of PCDH19 in post-mitotic neurons.

Title: Placental endocrine function loss may contribute to human preterm cerebellar white matter alterations

Authors: *C.-M. VACHER[1], H. LACAILLE[1], S. SEBAOUI[2], J. SALZBANK[1], J. O'REILLY[1], A. A. PENN[1];
[1]Columbia Univ. Med. Ctr., New York, NY; [2]Ctr. for Neurosci. Res., Children's Natl. Hosp., Washington, DC

Abstract: We have recently reported a novel conditional mouse model that was designed to study the specific contribution of placental endocrine function to normal and pathological fetal brain development (*Nature Neuroscience*, in press). In our model (named plKO), the gene encoding 3alpha-hydroxysteroid dehydrogenase (3α-HSD) is deleted in trophoblasts, resulting in the insufficient production of placental allopregnanolone (ALLO), a progesterone derived neurosteroid, during the second half of mouse gestation. Adult mice that lacked placental ALLO exhibit sex-linked neurodevelopmental and behavioral alterations. The anatomical and molecular alterations included cerebellar white matter (WM) abnormalities that correlated with autistic-like behavior only in male offspring. A single injection of ALLO during late gestation abolished these alterations. To evaluate the translational potential of our findings, we have asked whether human preterm birth, a well-described risk factor for human autism, was associated with similar cerebellar myelin alterations comparable to those seen in the plKO mice. We examined 24 post-mortem cerebellar vermises from term (>37 weeks of gestation) and preterm (<34 weeks of gestation) infants who died at a mean corrected age of 6 weeks. Compelling similarities between our mouse model and human pathology were found. Specifically, cerebellar myelin protein contents were augmented in males and reduced in females born preterm as compared with term counterparts, showing a sex-divergent myelination trajectory in the cerebellum after preterm birth. In addition, the higher levels of *pdgfra*- and *cspg4*-mRNA in the cerebellum of preterm males suggest either delayed progression of the oligodendrocyte lineage or increased proliferation of oligodendrocyte precursor cells, as temporarily seen in the plKO males. This striking correlation between mice exposed to ALLO insufficiency and infants born preterm suggests that altered ALLO exposure may contribute to abnormal preterm brain development. Our study also indicates that placental hormone replacement may offer novel therapeutic opportunities to prevent later neurobehavioral disorders.

Title: P53-mediated rescue of microcephaly caused by Pals1 loss

Authors: *N. STERLING[1,2], S. KIM[1,2];
[1]Shriners Hosp. Pediatric Res. Ctr., [2]Dept. of Neural Sci., Temple Univ., Philadelphia, PA

Abstract: The protein associated with Lin7 (Pals1) is an integral apical polarity complex protein which is necessary for cortical progenitor self-renewal. Previous studies have demonstrated that loss of Pals1 in cortical progenitors nearly abrogates formation of the cerebral cortex resulting in microcephaly in mice. However, the mechanism by which cell reduction occurs in Pals1 mutant cortices is not fully understood. To determine the effects of Pals1 loss on cortical progenitors, we generated Pals1 conditional knockout mice (cKO) using Emx-1 Cre to target cortical progenitors. Using time-lapse experiments and analyses of mitotic phases, we found that Pals1 mutant cortical progenitors display significantly increased time to undergo mitosis with a larger proportion of these cells found in ana/telophase, and observable cytokinesis defects. These findings show that Pals1 is required for normal mitotic progression in cortical progenitors. Mitotic defects resulting from loss of Pals1 may cause the cell death which leads to microcephaly in Pals1 mutants. Previous studies have shown that microcephaly-associated cell death may be caused by activation of the tumor suppressor protein p53. To determine if p53 activation plays a role in the neural progenitor cell death and microcephaly caused by Pals1 deficiency, we have examined whether p53 is activated in Pals1 mutants. In the developing cortices of Pals1 cKO mice, p21, a prime downstream target of p53, is upregulated, suggesting that p53 is activated. To test whether genetic elimination of p53 will prevent cell death and restore cortical size in Pals1 mutants, we have generated a double conditional knockout of p53 and Pals1. To examine the effects of p53 loss in Pals1 reduction, we have analyzed cortical size, cortical layering, and progenitor cell mitosis. Cortical size and cell numbers are significantly increased in the p53 co-deletion compared to Pals1 mutants. Importantly, when p53 is co-deleted, the time to undergo mitosis and cytokinetic defects observed in Pals1 mutants are also significantly rescued. Collectively, these findings indicate that p53 activation plays a critical role in the development of the microcephaly phenotype caused by Pals1 depletion in the mouse cortex, not simply by preventing cells from undergoing apoptotic cell death, but also by rescuing the mitotic defects resulting from Pals1 reduction.

Human cytomegalovirus (HCMV) is a beta herpesvirus that can cause severe congenital birth defects including microcephaly, vision loss, and hearing loss. Currently, no approved treatment options exist for managing in utero infections. Our previous work showed that HCMV infection in undifferentiated human induced pluripotent stem cell (iPSC) derived neural progenitor cells (NPCs) and iPSC derived cortical organoids have reduced baseline calcium levels, were unresponsive when evaluated 5 days post infection, and struggle to generate cortical neurons. To identify underlying mechanisms, we have used RNA sequencing to understand how the infection impacts the transcriptome in infected organoids. We infected cortical organoids using HCMV TB40/E expressing eGFP and cell populations were sorted via FACS and then sequenced. Our studies demonstrate that HCMV infection significantly impairs neural function and several developmental pathways. Further, these transcriptional effects were not limited to cells expressing GFP and instead were found throughout the organoid. We are now using single cell RNA sequencing (scRNAseq) to gain a deeper understanding of specific populations impacted by HCMV infection as we and others have shown that NPCs are more susceptible to HCMV infection than more terminally differentiated cells. One mechanism for this selective preference could be due to the entry receptor profile found on NPCs compared to more terminally differentiated cells. Therefore, we are using flow cytometry and scRNAseq to determine the relative expression of trimeric and pentameric entry receptors to better characterize HCMV infection properties in human NPCs and organoid-derived tissues. Together, these data will further define HCMV infection properties in human neural tissues with the ultimate goal of identifying potential targets of therapeutic intervention.

Title: Characterization of neuronal protein-protein interactions using baits from the 15q11.2 locus

Authors: *N. BASAZINEW, N. GHANI, C. CHANG, R. GU, H. BAKER, M. GHANI, V. VO, E. C. OH;
Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: The 15q11.2 microdeletion syndrome results in neurodevelopmental deficits that include developmental delay and psychiatric conditions. While comprehensive microarray studies have demonstrated that four genes (*NIPA1*, *NIPA2*, *CYFIP1*, and *TUBGCP5*) within the 15q11.2 locus are associated with behavioral and anatomical pathology, a unifying hypothesis to correlate gene function to phenotype has not been established. Copy number variations within chromosome 15 are relatively frequent in approximately 1% of the population. An increasing number of genes are associated with intellectual disability (ID) and autism spectrum disorders (ASDs). Fragile X mental retardation gene 1 (*FMR1*), whose silencing causes the Fragile X syndrome, is the most common form of ID and autism. The precise functional significance of the CYFIP/FMRP interaction is not understood fully; however, among the interactors of FMRP, CYFIP1/2 are good candidates for ID and autism, based on their genetic implication and functional properties. CYFIP1 and CYFIP2 represent a link between Rac1, the WAVE complex, and FMRP, favoring the cross-talk between actin polymerization and translational control. Thus, the role of Cyfip1 in brain connectivity is yet to be explored. Using mass spectrometry, immunoblotting, and immunoprecipitation datasets, we will characterize protein-protein interactions and mechanisms associated with the manifestation of neural disorders linked with the 15q11.2 microdeletion syndrome, and more specifically, with CYFIP1 copy number variation.

Title: Interrogating a centrosomal-specific role for DDX3X during brain development

Authors: *N. GHANI, N. BASAZINEW, C. CHANG, R. GU, H. BAKER, V. VO, E. OH;
Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: DEAD-box proteins are RNA helicases that are characterized by a conserved Asp-Glu-Ala-Asp motif. These proteins are involved in a variety of processes within cells, ranging from cell cycle progression to the innate immune response. DDX3X is a protein-coding gene found on the X chromosome that codes for a DEAD-box RNA helicase and variants in this gene are believed to be involved in 1-3% of unexplained intellectual disabilities in females. The DDX3X protein is vital for cell viability and is found in all tissues within the body. While mutations in the human *DDX3X* gene have been characterized to cause intellectual disabilities, seizures, and autism, the mechanism that associates the genetic lesions to pathology is still under investigation. Here, we use mass spectrometry to characterize a complex interactome of DDX3X in the mouse brain. We also verify the novel interactions using immunoblotting techniques and show that phenotypes associated with loss of function *DDX3X* mutations can be explained through some centrosomal proteins identified in our screen. The data suggest that the loss of DDX3X from the centrosome can perturb neuronal development.

Title: Age, sex, and race impact the expression of coronavirus receptors in the human brain

Authors: *N. HALABIAN[1], K. NAEEM[1], L. MONTEIRO[2], B. KUMAGAI[1], K. M. MURPHY[1,2];
[1]Psychology Neurosci. & Behaviour, [2]Neurosci. Grad. Program, McMaster Univ., Hamilton, ON, Canada

Abstract: The symptoms and severity of COVID-19 can vary based on host factors such as age, sex and race. For example, older adults, males and African Americans who become infected with the SARS-CoV-2 virus are more likely to experience severe outcomes. Those include a range of neurological symptoms, such as stroke, delirium and anxiety. Some of the sequelae might be secondary to the viral infection, but the virus can invade the brain, directly causing cell death and localized inflammation. However, few studies have characterized the expression of coronavirus receptors in the human brain, and none have examined if there are age- sex- or race-related differences that might help understand the host factor

vulnerabilities. Here we used two publicly available transcriptomic databases to assess the impact of age, sex and race on the expression of a network of 29 SARS-CoV-2-related genes, including coronavirus receptors (e.g. ACE2, NRP1, DPP4), proteases (e.g. TMPRSS2, furin), and integrins (e.g. ITGA5) in the human brain. First, we used data from 16 brain areas (n=48, F=21, M=27, age:4 mo-80 yrs) to assess the impact of age by determining the lifespan trajectory (LOESS curves) for each gene in each area. We used PHATE, a dimension-reduction analysis and visualization technique, to reveal the high dimensional development of the 16 brain areas. We found 4 distinct developmental trajectories that clustered the 16 areas into 1 subcortical trajectory and 3 cortical trajectories. Second, we used a larger dataset to assess the impact of age, sex and race (African American & Caucasian) on the developmental profile of the prefrontal cortex (n= 269, F/AA=58, F/CAUC=31, M/AA=89, M/CAUC=89, age:4 mo-80 yrs). Developmental trajectories (LOESS curves) were calculated separately for female and male samples and African American and Caucasian samples for each of the 29 genes. Hierarchical clustering of the female and male trajectories identified 7 clusters. Each cluster had trajectories from male and female samples, but most of the genes differed. Clustering of the trajectories separated by race found 4 clusters. Similar to the analysis of sex differences, most of the genes in a cluster were different for Caucasian and African American samples. This series of studies identified robust age, sex, and race differences in the development of SARS-CoV-2 genes. Furthermore, those differences may influence the brain's vulnerability to SARS-CoV-2 infection.

Title: Plexins Promote Hedgehog Signaling Through Their Cytoplasmic GAP Activity

Authors: *T. M. HOARD[1], J. M. PINSKEY[4], X.-F. F. ZHAO[2], N. E. FRANKS[2], Z. C. FRANK[2], A. N. MCMELLEN[5], R. J. GIGER[3], B. L. ALLEN[1];
[1]Cell and Developmental Biol., [3]Neurology/Cell and Developmental Biol., [2]Univ. of Michigan Sch. of Med., Ann Arbor, MI; [4]Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [5]Univ. of Colorado, Aurora, CO

Abstract: Hedgehog signaling is essential for patterning tissues and organs during embryonic development, including in the developing brain and spinal cord, and continues to play critical roles postnatally and throughout life. Despite the importance of Hedgehog signaling to embryogenesis, tissue homeostasis, and tissue renewal and regeneration, we still lack a complete understanding of the entire

complement of Hedgehog pathway components, and their contributions to the regulation of Hedgehog pathway activity. Previous work has identified Neuropilins, well-characterized components of Semaphorin signaling, as positive regulators of Hedgehog signaling. In the context of Semaphorin signaling, Neuropilins work closely with Plexin coreceptors, but a role for Plexins in Hedgehog signaling has not yet been explored. Here we provide evidence that multiple Plexins promote Hedgehog signaling in NIH/3T3 fibroblasts. Further, we find that the cytoplasmic GAP activity of Plexins is required for Hedgehog signaling promotion, and that constitutive activation of the Plexin GAP domain further amplifies Hedgehog pathway activity, including the stimulation of neural progenitor migration in the developing chicken neural tube. Notably, Plexins regulate Hedgehog signaling at the level of GLI activation and require intact primary cilia to mediate Hedgehog signal promotion. Finally, we demonstrate that Plexin loss-of-function significantly reduces the response to Hedgehog activation in fibroblasts and in the mouse dentate gyrus. Together, these data identify Plexin receptors as novel components of the Hedgehog signaling pathway.

Title: Intense unilateral flash stimulation leads to local signatures of sleep pressure in the contralateral primary visual cortex in laboratory mice

Authors: *J. PRIUS MENGUAL[1], L. B. KRONE[1], A. CHAKRABARTY[1], C. BLANCO DUQUE[2], M. C. KAHN[2], C. J. AKERMAN[1], V. V. VYAZOVSKIY[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]MIT, Cambridge, MA

Abstract: It is established that extended wakefulness leads to a global increase in EEG slow-wave activity (SWA; power density between 0.5-4 Hz) both in the wake EEG and during subsequent sleep. In addition, SWA is regulated at the local level, which led to the hypothesis that sleep is an activity- or use-dependent process. While several molecular, cellular and circuit mechanisms have been proposed to account for the global and local sleep regulation, there is a scarcity of experimental models that afford the opportunity to selectively and physiologically manipulate local sleep need in the neocortex of freely behaving animals. Here we present a new model for investigating the neurobiological mechanisms of local sleep, based on a selective local cortical activation during waking, achieved by sensory stimulation. We adopted a paradigm previously established in rats for investigating mechanisms of enduring neuroplastic changes in the visual cortex as a result of sensory experience. To induce sustained synaptic activity unilaterally in the visual cortex, we built removable devices that enabled us to position light-emitting diodes (LEDs) in front of one of the eyes of a freely behaving mouse. EEG and/or 16-channel

laminar electrodes were used to record cortical activity and animals were kept awake for 4 hours starting at light onset, during which LED stimulation was performed by delivering trains of 8 Hz light pulses (pulse duration 10 ms, train duration 2 s), every 30 s. The LED device was subsequently removed, and animals were allowed to sleep undisturbed for the remainder of the 24 hours. In all animals with laminar probes and EEG recordings, visual stimulation reliably evoked responses in the contralateral visual cortex that were visible in the local field potentials and/or neuronal spiking activity. As expected, EEG spectral analysis revealed an elevated power at 8 Hz, which exceeded the non-stimulated side. No discernible responses were detected in the ipsilateral EEG or frontal cortex.
Having established that visual stimulation induces local neuronal responses, we asked whether the paradigm leads to signatures of high sleep pressure in the wake EEG. We observed that in all animals, the occipital EEG spectral power density in the SWA frequency range was consistently higher in the stimulated hemisphere, compared to the non-stimulated side (mean values, SEM: 132.8±12.8% and 107.2±5.7% respectively). These preliminary results establish a new model for local manipulations of neural activity in freely behaving mice using a physiologically relevant frequency. This paradigm will be useful for investigating the neurobiological mechanisms of homeostatic sleep need.

Title: The human iEEG exhibits long-range temporal correlations which follow a hierarchical organization, decline under antiepileptic drug action and break down during slow wave sleep

Authors: *C. MEISEL[1], P. MUELLER[2];
[1]Charité Berlin, Berlin, Germany; [2]Charité, Berlin, Germany

Abstract: Cortical network function in general, and information integration specifically, are believed to benefit from a network's ability to integrate inputs over long timescales. Such long-range temporal correlations (LRTCs) generically arise when networks are poised at or near a critical point. Monitoring LRTCs in cortical networks therefore provides a measure of information integration capabilities and, more generally, about the dynamical state of these networks. Previous research in non-human primates has indicated the existence of a gradient in LRTCs aligned with functional hierarchy, which may explain how inputs are integrated over increasingly longer timescales as a signal progresses higher along the hierarchical axis. However, whether LRTCs follow such a hierarchical gradient in the human brain also is still unclear. Further, whether LRTCs are impacted by different vigilance states, e.g., to provide a functional analog to the breakdown of information integration during slow wave sleep, is currently unknown. Lastly, the effect of antiepileptic drugs (AEDs), many of which impact network information processing, on these timescales remains to be determined. Here, we assessed LRTCs in human invasive EEG (iEEG) across different states of vigilance, as a function of AED load and across the hierarchical

organization in cortical networks. We assessed LRTCs in iEEG data from 17 patients with epilepsy undergoing presurgical monitoring (9 female, mean age = 27 ± 14 years, total duration 756.3 hours). LRTCs were determined at the individual channel level of power band fluctuation in the high gamma band (log power 56-96 Hz, 0.125 sec binning). LRTCs were calculated from the decay of power band autocorrelation functions (2 min segments, half-width at half maximum). Vigilance and slow wave sleep (SWS) states were classified as in Reed et al. 2017. Anatomical channel locations were determined from MNI coordinates. Evaluations included high and low AED drug days (24 h each). First, LRTCs were found to align along a functional hierarchy across different anatomical areas, thus electrophysiologically confirming similar findings from non-human primates in humans for the first time (Fig. 1). Second, LRTCs were found to break down during SWS compared to non-SWS ($p<0.02$, two-sample ttest). Third, LRTCs decreased under AED administration ($p<0.02$, two-sample ttest). Our results provide mechanistic and functional links between specific measurable changes in cortical network dynamics relevant for characterizing the brain's changing information processing capabilities along a hierarchical cortical gradient, across vigilance states and during antiepileptic drug action.

Title: Characterising sleep spindles in human anterior thalamic nuclei and thalamocortical spindle propagation

Authors: *H. BERNHARD[1], J. REITHLER[1], B. JANSMA[1], R. P. W. ROUHL[2], V. H. J. M. VAN KRANEN-MASTENBROEK[3], E. GOMMER[3], P. DE WEERD[1], M. J. ROBERTS[1];
[1]Dept. of Cognitive Neurosci., Maastricht Univ., Maastricht, Netherlands; [2]Dept. of Neurol., [3]Dept. of Clin. Neurophysiol., Maastricht Univ. Med. Ctr., Maastricht, Netherlands

Abstract: Sleep spindles are thought to be an important mechanism for memory consolidation during NREM sleep, potentially allowing windows of communication in thalamocortical circuits. However, research into thalamocortical interaction during spindles in human brains has been sparse. Spindles are transient (0.3 - 2 s) oscillatory patterns of 8 to 16 Hz originating in the reticular nucleus of the thalamus (RN). Cortical slow oscillations lead to inhibition of the thalamus through the RN, followed by rebound spikes which form the spindle. Through thalamocortical connections, these thalamic spindles may then propagate to the cortex. Spindles can be categorized into slow spindles (8-12Hz) that tend to occur in frontal cortical areas, and fast spindles (12-16Hz) at centro-parietal sites, as has been shown both in EEG and iEEG. Most spindles tend to occur at one electrode only (local spindles), but there can also be global spindle events spanning larger parts of the cortex. Spindle frequency might be determined by the underlying thalamic nuclei, with more anterior nuclei oscillating at slower frequencies (although this has only been shown in posterior parts of the thalamus). Cortical globality of spindles might be related to the spread of spindles within the thalamus.

In this study, we investigated spindles in human anterior thalamic nuclei. We recorded one night of sleep in 7 individuals with epilepsy (2 female, mean 35 years, range: 17 - 59 years) undergoing implantation of deep brain stimulation electrodes targeting the anterior nucleus of the thalamus. Anterior thalamic nuclei showed both slow and fast spindle activity during NREM sleep. When assessing their spread to the cortex, we found that predominantly frontal EEG spindles tended to co-occur with thalamic slow spindles. For fast spindles, we observed two opposing scenarios: Some thalamic electrodes showed overlap with fronto-central EEG electrodes, whereas others showed de-coupling from the cortex, i.e. fast spindles occurring at this thalamic site lowered the probability of a spindle occurring in the cortex.Characterising the anterior thalamic involvement underlying spindle activity in EEG may elucidate the involvement of the different thalamic nuclei in sleep spindle modulation, and thus serve as a bridge between previous iEEG studies and the vast EEG literature on sleep spindles and their functional role in e.g. memory consolidation.

Title: Distinctive response of sleep slow oscillations to acoustic stimulation is determined by different underlying synchronization processes

Authors: M. NAVARRETE[1], D. HENAO[1], M. LE VAN QUYEN[2], ***M. VALDERRAMA**[3]; [1]Dept. of Biomed. Engin., Univ. of los Andes, Bogotá, Colombia; [2]Lab. d´Imagerie Biomédicale (LIB), U1146 INSERM- SU – CNRS 7371, Paris, France; [3]Dept. of Biomed. Engin., Univ. of Los Andes, Bogotá, Colombia

Abstract: Slow oscillations (SO) during sleep are large amplitude waves with frequencies between 0.5-2Hz and thought to be crucial for cognitive and physiological processes. Closed loop acoustic stimulation (CLAS) has shown to boost SO amplitude, spindle power (11-16Hz) and related functional activities1. However, the neural mechanisms causing this boost are not understood. Recently, it was suggested that the SO response to the stimuli may be linked to their underlying cortical synchronization2. Also, it has been proposed that spontaneous SO are determined by two different synchronization processes: generalized thalamocortical Type I and the localized corticocortical Type II waves. These processes are thought to have different functional roles and be differentially affected by external stimuli3. We hypothesized that SO response to CLAS depends on these underlying synchronization dynamics. Hence, we applied CLAS during NREM sleep of healthy subjects (n=10) during one control (CNT, when sounds were muted) and one stimulation night (STM). Then, we identified tree main clusters using a k-means algorithm according to their synchronisation attributes (SO relative scalp involvement and mean slope). These clusters denoted (C1) steep slope SO with global spread (Type I like), (C2) localized flat slope SO

(Type II like) and (C3) flat slope SO with global spread (sharing features of Type I and Type II waves). Two-way ANOVAs examining stimulation and cluster conditions showed a significant interaction between these effects and spindle coupling ($P < 0.001$), while post-hoc analyses indicated that most spindles were coupled with C1 clusters ($P < 0.001$). Then, the proportion of SO events by cluster showed a significant interaction between the effects of stimulation (CNT vs STM) and cluster type (C1, C2, C3) ($P < 0.001$). Post-hoc analyses showed that the proportion of C3 and C2 events decreased (both $P<0.01$) while the proportion of C1 events increased ($P < 0.001$) as response to CLAS. Finally, evaluating the mean SO amplitudes for spontaneous (CNT) and stimulated (STM) SO clusters, we found a significant amplitude enhancement for all of them in STM (all $P<0.05$). The stimuli then promoted C1 waves by enhancing C2 and C3 waves, while spindle coupling mainly increased for C1 waves. Our findings support the hypothesis of distinctive SO response to CLAS depending on different synchronization processes during NREM sleep. Because the response of C1 clusters to CLAS, our results suggest that acoustic stimulation enhances SO by boosting thalamocortical synchronization during NREM sleep. 1. Ngo et al. Neuron 78, 2013. 2. Title: Probing cortical excitability using 40 Hz auditory stimuli during NREM sleep

Authors: *D. HENAO[1], M. NAVARRETE[1], J. NIETO[1], M. VALDERRAMA[1], M. LE VAN QUYEN[2]; [1]Univ. De Los Andes, Bogotá, Colombia; [2]Lab. d'Imagerie Biomédicale INSERM U1146, Sorbonne Univ. UMCR2 UMR7371 CNRS, PARIS, France

Abstract: Neocortical excitability can be studied by assessing the response to a stimulation as a function of ongoing brain activity [1]. Especially during non-rapid eye movement (NREM) sleep, auditory stimuli lead to a series of state-dependent evoked potentials (ERP) [2]. Specifically, an attenuation of the early N100 component has been observed while P200 is enhanced [3]. In addition, sleep specific late ERP components such as the N350, P450, N550 and P900 responses arise (all substantially larger when K-complexes are present in the average). From these observations, it has been suggested that these evoked responses during NREM reflect a decreased cortical excitability and increased inhibitory processes [4].In our work, we investigated how 40 Hz Auditory Steady State Responses (ASSR) can directly test the excitability of neocortical networks during NREM sleep. For this, we performed polysomnographic recordings (10-20 international EEG system, 2 EOG and 1 EMG) and stimulated 12 healthy subjects (mean age 22.16 ± 3.06) during one complete night. Trials consisted of a 400 ms train of white noise clicks of 1.5 ms duration applied at 40 Hz and with a maximum intensity of 15 dB. Stimulation was applied in blocks of 30 trials during NREM sleep (mean 200 events/night) using earbuds. We compared the corresponding ERP and the 40 Hz Inter Trial Coherence (ITC) response, depending on electrode locations and sleep stages N2 and N3. We report strong ITC responses in both sleep stages and resulting

ERPs with major components at P200, N550 and P900. Specifically, the 40 Hz ITC response was significantly stronger in frontal electrodes during N2, while in N3 this was higher in parietal and occipital electrodes. Comparing ERP components, P200 and N550 amplitudes were larger in frontal areas for N2 but higher for central and posterior regions and with shorter latencies for N3. Finally, P900 amplitudes were larger and latencies shorter for most of the channels in N3 compared to N2.
Our results suggest that 40 Hz ASSR is a powerful tool to study state-dependent shifts in neocortical excitability during NREM sleep. In particular, changes in ERP components and ASSR responses between N2 and N3 within NREM sleep might be related to increased inhibitory processes and different hyperpolarization levels of the thalamo-cortical system.

Title: Correlation structure of cortical activity at slow-wave timescales across sleep states and wakes.

Authors: *T.-Y. LIU, B. WATSON;
Dept. of Psychiatry, Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: Interaction between a pair of neurons is the fundamental building block to construct a complex neural network. These interactions can be inspected by cross-correlations. Much research is focused on short-time scale (<4 msec) correlations to examine the functional connectivity between neurons, while less is known about interactions at longer time scale (hundreds of msec). We examined cross-correlations between cortical neurons in a longer time scale across sleep states and wake. We expected that at ~1 Hz timescales we would see synchronization between neurons during non-rapid eye movement (NREM) sleep, given the UP/DOWN fluctuations of neuronal membrane potentials during this state. Surprisingly, in addition to synchronized pairs, we found anti-synchronized pairs and the effects are augmented during the most NREM or high deltas. In particular, this correlation structure is preserved during the course of sleep and wake. The degree of correlation or anticorrelation is modulated by the local field potential (LFP) in the delta frequency range during NREM and in the gamma frequency range during wake. These anticorrelations persist across 24 hour recordings and are consistent between given pairs of cells. Furthermore, removing the spikes with lower interspike interval (ISI) reduces the degree of the anticorrelation.

Title: Modulation of network excitability by sleep oscillation phase

Authors: *D. KLORIG, A. O'DELL, T. SMITH, D. GODWIN;
Neurobio. and Anat., Wake Forest Univ., Winston Salem, NC

Abstract: We have observed a strong association between behavioral state (wake, REM, and NREM) and network excitability using active optogenetic probing of hippocampal circuitry. In order to understand the mechanisms responsible for this association and determine the influence of the sleep rhythms, we examined the effect of state specific pre-stimulus oscillatory phase on population discharge (PD) probability. We measured population discharge probability in chronically implanted transgenic mice using optogenetic dose-response curves (Klorig et. al. eNeuro 2019). Our chronic preparation consists of an optrode above area CA1 of Thy1-ChR2 (line 18) mice and 7 individually placed microwires in hippocampal and peri-hippocampal structures to monitor the network wide propagation of optogenetic stimulation. A range of light intensities was presented in randomized order, occasionally producing all-or-none high amplitude optogenetic PDs (oPD). The conditional probability of oPD given each light intensity was calculated and fit with the Boltzmann equation to determine an I50, or the light intensity at which oPDs occur 50% of the time. This metric, the I50, can be used to precisely track network excitability in freely moving mice. Using long-term oPDT recordings, we segmented the data by behavioral state using a convolutional neural network to automate sleep scoring. Pre-stimulus oscillation phase was determined using generalized phase (Davis et. al. Nature 2020). Phases were binned and the conditional probability of an oPD was calculated for each bin. In addition, an unbiased estimate of the influence of the pre-stimulus period was generated by averaging the pre-stimulus period of stimuli near the I50 (where the P(oPD) ~ 0.5) separated by outcome (oPD and non-oPD) and by behavioral state (wake, NREM, and REM). Separating the pre-stimulus period by sub- or supra-threshold responses reveals a detectable but relatively weak effect of ongoing phase on PD probability that varies by behavioral state (wake, REM, NREM). During wake periods and REM periods, probability was modulated by the phase of hippocampal theta with the highest probability of oPD on the peak and lowest probability during the trough. During NREM, slow-wave activity modulates the oPDT with oPDs more likely during the peak. The greatest differences in the average pre-stimulus period for oPD vs. non-oPD outcomes were observed in PFC, CA1, CA3, and subiculum. Although phase dependent modulation was detected, the magnitude of the effect was not sufficient to explain the large behavioral state dependent shifts in network excitability observed.

Title: Role of hippocampal sharp-wave ripples in motor memory consolidation during sleep

Authors: *J. KIM[1,3], A. JOSHI[2], L. FRANK[2], K. GANGULY[1,3];
[1]Neurol. department, [2]HHMI and Departments of Physiol. and Psychiatry, Univ. of California San Francisco, San Francisco, CA; [3]Neurol. and Rehabil. Service, San Francisco Veterans Affairs Med. Ctr., San Francisco, CA

Abstract: Sleep appears to play an essential role in driving brain plasticity and the consolidation of both declarative and procedural memories. A growing number of studies have now found evidence for the important role of the hippocampal formation, in general, and hippocampal sharp-wave ripples (SWRs), in specific, during the sleep-dependent consolidation of declarative memories. Interestingly, while initially it was thought that procedural/motor memories were consolidated through a separate non-hippocampal process, recent functional neuroimaging studies have suggested a role of the hippocampus in early motor skill learning. However, little is known about the precise neurophysiological mechanisms that might allow for the hippocampus to contribute to motor memory consolidation. In this study, we tested the hypothesis that hippocampal SWRs during sleep may play a role in motor memory consolidation by transiently supporting cross-area communications between prefrontal cortex (PFC) and primary motor cortex (M1) during NREM sleep. Using a reach-to-grasp skill learning task in rats and multi-area recordings from the hippocampus, PFC, and M1, we specifically found that hippocampal SWRs during the post-training sleep were linked, in a temporally precise manner, to globally coordinated slow oscillations (SO) in PFC and M1 in the early phase of skill learning. Strikingly, we observed a sharp drop in SWR activity during the transition to a slow/later phase of skill learning, where there were only slow improvements in performance across days. Across animals, we observed that increases in SWRs in the post-training sleep were most correlated with practice sessions with marked changes in task success within a session; increases were also closely linked to task sessions with elevated neural variability. Thus, our results suggest a salient role for hippocampal SWRs in the early phase of skill learning through large-scale coordination of cortical regions during NREM sleep. Our results further suggest a universal role for hippocampal SWRs in sleep-dependent memory consolidation.

Title: Genistein, a dietary isoflavone, prevents seizure-induced respiratory arrest in DBA/1 mice

Authors: J. GUO[1,2], D. MIN[1], ***H.-J. FENG**[1];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Neurol., Xiangya Hospital, Central South Univ., Changsha, China

Abstract: Background: Sudden unexpected death in epilepsy (SUDEP) is a fatal event that ranks second in years of potential life lost among neurological disorders. Both clinical and animal studies demonstrate that seizure-induced respiratory arrest (S-IRA) is the primary instigator leading to death in many SUDEP cases. However, there are currently no effective pharmacological interventions to prevent S-IRA. In the present study, we examined the effect of genistein, a naturally occurring isoflavone found in a variety of dietary vegetables such as soybeans, on the incidence of S-IRA in DBA/1 mice. **Methods:** DBA/1 mice, after priming (3-4 daily acoustic stimulation at 96 dB SPL), exhibit generalized tonic-clonic seizures and S-IRA evoked by acoustic stimulation. The susceptibility to S-IRA in primed DBA/1 mice of both sexes was confirmed 24 hr prior to experiments. Genistein, dissolved in 60% DMSO and 40% saline, or vehicle was intraperitoneally (i.p.) administered, and the effect of genistein or vehicle control on the incidence of S-IRA and seizure behaviors was examined 2 hr after injection. Videos were digitally recorded for off-line analysis. The comparison of S-IRA incidence between the treatment and the control was performed using Chi-square test. **Results:** Acoustic stimulation evoked generalized tonic-clonic seizures in primed DBA/1 mice, which were composed of wild running and clonic/tonic seizures followed by S-IRA. The incidence of S-IRA in DBA/1 mice was significantly reduced 2 hr after i.p. administration of genistein at 1 mg/kg (12.5%, $n = 8$; $p < 0.01$), 10 mg/kg (25%, $n = 8$; $p < 0.05$), 30 mg/kg (23.1%, $n = 13$; $p < 0.01$), 60 mg/kg (41.2%, $n = 17$; $p < 0.05$) and 90 mg/kg (22.2%, $n = 9$; $p < 0.01$) as compared with that in the vehicle control (87.5%, $n = 8$). Compared with that in the vehicle control, the incidence of S-IRA was not significantly suppressed by genistein at 0.2 mg/kg (50%, $n = 8$). Among those DBA/1 mice whose S-IRA was blocked by genistein, genistein at 1 mg/kg blocked S-IRA without interfering with any component of seizures in 100% of mice, suggesting that genistein specifically blocks S-IRA in these mice. Genistein specifically blocked S-IRA in 100% of mice at 10 mg/kg, 90% at 30 mg/kg, 80% at 60 mg/kg and 42.9% at 90 mg/kg. **Conclusions:** Our data show that genistein, a natural isoflavone, reduces the incidence of S-IRA in DBA/1 mice. Genistein can specifically block S-IRA, especially at relatively lower doses. These data suggest that genistein can be potentially used to prevent SUDEP in at-risk patients.

Title: Brain extracellular matrix alters local ion concentrations and responses to injury

Authors: *K. NORMOYLE[1,2], V. DZHALA[1,2], K. LILLIS[1,2], K. EGAWA[3], J. C. GLYKYS[4], N. RAHMATI[1,2], K. STALEY[1,2];

Abstract: The reversal potential of $GABA_A$ receptors (E_{GABA}) is dependent upon the chloride concentrations on both sides of the neuronal membrane. The chloride on the extracellular aspect of the membrane ($[Cl^-]_o$) is canonically considered to equal the chloride in the bulk cerebrospinal fluid. However, neurons are surrounded by an extracellular matrix (ECM) comprised of variably sulfated glycosaminoglycans that can alter local $[Cl^-]_o$ and can be hydrolyzed by active matrix metalloproteinases released by tissue injury. Having synthesized a single-wavelength, pH-insensitive chloride-sensitive fluorophore and constrained it to the extracellular space by conjugation with 10 kilodalton dextran, we used 2-photon Fluorescence Lifetime IMaging (FLIM) to measure extracellular chloride in acute and organotypic cultures of hippocampal slices. We first tested whether the extracellular sulfate moieties change the baseline local chloride concentration. We found that $[Cl^-]_o$ between neurons in the depths of acute hippocampal slices and at all depths of organotypic hippocampal slice cultures was only half of the bulk CSF chloride. We next measured $[Cl^-]_o$ after the sulfate moieties in the matrix were freed by endogenous matrix metalloproteinases (MMPs) after brain injury. We found a strong dependence of $[Cl^-]_o$ vs distance from injury, with chloride concentration increasing to the ACSF levels near the injured surface of acute slices or proximity to photolysed neurons in organotypic slices, respectively. These changes in $[Cl^-]_o$ should also alter the neuronal intracellular chloride ($[Cl^-]_i$) via the activity of the high-velocity equilibrative membrane chloride transporters. We have previously reported such changes in slices and confirmed them in both injury models here, in addition to an *in vivo* piglet model for which preliminary data is presented. If the injury-induced increases in $[Cl^-]_o$ and $[Cl^-]_i$ were due to release of extracellular sulfates and replacement by chloride, these sulfates should be released to the perfusate, and we confirmed this using colorimetric assays of chondroitin sulfate. Finally, the release of sulfates should be inhibited by MMP antagonists, which we confirmed with both broad-spectrum and more specific inhibition (ZX-1 or SB3CT, respectively) each of which reduced $[Cl^-]_o$ and $[Cl^-]_i$ and neuronal volume at the surface of cut slices and in proximity to photolysed neurons. We conclude that $[Cl^-]_o$ is partially displaced by sulfates in the ECM and that damage to ECM following brain injury alters the transmembrane chloride distribution. These findings have immediate implications for the treatment of cytotoxic edema and seizures after acute brain injury.

Title: Developmental exposure to seizures perturbs the functional integration of newly born neurons into the Xenopus optic tectum and promotes seizures in later life

Authors: *A. C. THOMPSON, C. A. VADUVA, D. R. MENDOZA, C. D. AIZENMAN;
Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Neurogenesis begins in development, continues after birth and persists into old age. Neurogenesis is a tightly regulated process involving proliferation and survival of neural precursor cells, before the specification, migration and functional integration of newly born neurons into the established circuitry. As newborn neurons have a high propensity to undergo synaptic modification, they are uniquely placed to contribute to experience-dependent modification of circuit function. In disease states, including epilepsies, newly born neurons have been found to both protect cognitive function and cause abnormal neural activity following their integration into the circuitry. While it has been well characterized that epilepsies can result from prior seizure activity, a cellular level understanding of the mechanisms and principles by which prior seizures affect the functional integration of later born neurons, and whether this is causative for epileptogenesis, is incomplete.
To characterise how seizure activity impacts the development and functional integration of newly born neurons as they become integrated into the established, functioning circuitry of *Xenopus laevis* optic tectum, we used photoconversion of Kaede protein to fluorescently-tag neurons that were born later in development. Whole-cell patch clamp electrophysiology was used to measure the biophysical and synaptic properties of later-born neurons. We show that neurons born in later development mature and become integrated into the tectal circuitry over a period of 5-7 days. When we recorded from newly born neurons that were exposed to chemically-induced seizures following their birth, we observed that seizure-exposed newly born neurons were more excitable and received less inhibitory transmission compared to naïve newly born neurons. This observation correlated with an increased seizure susceptibility in tadpoles exposed to seizures during development. We also describe how seizure activity during development effects the morphology of newly born neurons as they mature. Finally, we explore the contribution of seizure-exposed newly born neurons to later seizure behavior.

Title: Nrf2 activation is neuroprotective and suppresses the development of epilepsy

Authors: *T. SHEKH-AHMAD;
Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Many epilepsies are acquired conditions following a brain insult such as a prolonged seizure, traumatic brain injury or stroke. Following such brain insults, excessive generation of reactive oxygen species (ROS) and induction of oxidative stress has been proposed to contribute to neuronal death and the development of epilepsy. Here we use a combinational strategy of 1) increasing the endogenous antioxidant defences by upregulating the Nrf2 transcription factor via Omaveloxolone, and 2) inhibiting NADPH oxidase (NOX) enzyme, found as a major source of ROS in epilepsy, using AEBSF. We first show that the combination of both drugs had a greater effect (versus each drug alone) on reducing ROS generation as well as on low Mg^{2+} induced cell death. We next determined the effect of this combination antioxidant therapy on Total Antioxidant Capacity (TAC) following kainic acid (KA) induced status epilepticus (SE) in rats. Following 2 h of SE, Omaveloxolone completely restored TAC in both plasma and hippocampus. In rats treated with the combination of Omaveloxolone and AEBSF, TAC was increased to supranormal levels, and was 2-3 times higher in plasma and hippocampus compared to the vehicle group. We next asked if the combination therapy can suppress the development of epilepsy following SE. Vehicle treated animals developed a progressive increase in seizure frequency over time. Rats treated with a single administration of either AEBSF or Omaveloxolone had a decrease in seizure frequency at 10-12 weeks after the first spontaneous seizure. Importantly, seizure frequency in rats treated with both drugs was dramatically decreased from 2 to 12 weeks after the first seizure. From weeks 8-12, 7 of 10 animals treated with combination therapy were seizure-free, compared to only 1 of 10 animals treated with vehicle. For the combination therapy, the odds ratio for being seizure-free (weeks 8-12) compared to vehicle treatment was 21. Thus, a combination of Nrf2 activation and NOX inhibition following SE exerts a neuroprotective and disease-modifying effect and can prevent the development of epilepsy.

Abstract: Effect of type-2 diabetes mellitus on neurodegeneration and oxidative stress induced by *status epilepticus* in adult rats.
Evidence shows that type-2 diabetes mellitus (DM2) facilitates status epilepticus (SE) incidence. SE characterizes by continuous epileptic activity associated with neurodegeneration and high mortality. The main goal of this study was to analyze the effect of DM2 on the severity of SE and the subsequent neurodegeneration and brain oxidative stress (OE) in adult rats. DM2 was produced in male Wistar rats with streptozocin (STZ 100 mg/kg, s.c., n= 18) on postnatal day (P)3; control rats (CTRL, n = 19) were administered with the vehicle (0.1 M citrate buffer, pH 4.5). Glycemic levels were analyzed at P30, P60, and P90. At P90, SE was induced in both groups with the lithium-pilocarpine model (LiCl 3 mEq/kg, i.p.; pilocarpine hydrochloride 30 mg/kg, s.c). Seizure severity was evaluated with Racine´s scale (1972). To stop the seizures, rats were injected with diazepam (10 mg/kg, i.p) 1 h after SE onset. Neurodegeneration was evaluated 24 h after SE with fluoro-Jade B (F-JB) staining. Brain OE was determined 6 and 24 h after SE, through the analysis of lipid peroxidation and the formation of reactive oxygen species (ROS). Neurodegeneration and OE were evaluated in the hippocampus, the piriform cortex, the thalamus, and the amygdala.At P90, STZ rats showed augmented blood glucose levels compared with CTRL rats. We found that STZ rats showed increased latency to the first generalized seizure and SE, and a higher number of generalized seizures of longer duration when compared with CTRL rats. STZ rats also showed an increased number of F-JB positive cells in CA3 and CA1 fields, dentate gyrus, and the hilus of the hippocampus, the piriform cortex, the dorsomedial nucleus of the thalamus, as well as in the medial and cortical amygdala nuclei, in comparison with CTRL rats. Lipid peroxidation and ROS levels were similar in both experimental groups for all the analyzed brain regions.Our results suggest that DM2 increases SE severity and neurodegeneration, but it does not modify brain OE in adult rats.

Title: Tracking the evolution of synaptic dysplasticity after early life seizures

Authors: *B. XING[1], A. BARBOUR[2], B. BABROWICZ[1], Y. SONG[1], M. HANDY[1], F. E. JENSEN[1]; [1]Univ. of Pennsylvania, Philadelphia, PA; [2]Univ. of Pennsylvania, Neurology, PA

Abstract: Rationale: Multiple lines of clinical and experimental evidence suggest that seizures in early life can be associated with long lasting cognitive and behavioral deficits. Despite the evidence for ELS being associated with long lasting behavioral changes and impaired plasticity at a network level, far less is known about the evolution of changes at a single neuron level that occur following a seizure through the lifespan. **Methods:** Using activity-dependent genetic labeling (TRAP, which relies upon the detection of Cre-induced permanent tdTomato expression, which is driven by the immediate early gene Fos, a widely used marker of activated neurons), we identified and characterized a specific subgroup of neurons activated by ELS in the hippocampus. **Results:** The mice with tonic-clonic seizure induced by postnatal day 10 (P10) intraperitoneal injection of chemoconvulsant kainate (KA) showed a robust neuronal activation in CA1 region. The TRAPed cells in CA1 included mainly glutamatergic neurons (93.517± 8.9, $p < 0.0001$ vs. saline) with little astrocytes (6.9% ± 2.1%). Whole-cell patch clamp recording revealed that the ELS-activated CA1 neurons (tdtomato+, td+) during early development have persistent increases of postsynaptic AMPAR function (spontaneous EPSC amplitude at P30 38.6 ± 8.9, $p < 0.05$ vs. saline and Td- cells, Kruskal-Wallis test) and rapid diminishment of NMDAR-only silent synapses (fraction of silent synapse at P15 of td+ cells was 25.5%, much less than Td- 63.8% and saline 73.8%; the fraction of silent synapse were comparable among groups at P30, $p > 0.05$, one-way ANOVA), a process that involved synaptic insertion of calcium-permeable AMPARs (CP-AMPARs) (rectification index at P30 td+: 3.58 vs td-: 1.84 and saline: 1.64, $p < 0.05$, one-way ANOVA). *In vivo* pharmacological treatment following the ELS with a selective GluA2-lacking receptor blocker specifically reversed the long lasting deficits in the subsets of neurons initially recruited by the ELS (rectification index at P30 IEM: 1.31 vs saline 2.34, $p < 0.01$, unpaired t test). **Conclusion:** Our findings indicate that AMPAR-mediated synaptic dysplasticity is critical for persistent developmental dysregulation induced by ELS, and this mechanism may facilitate a more comprehensive understanding of ELS-induced long-term epileptogenesis and cognitive impairment, shedding light on the new therapeutic strategies in this clinical space where no current cure exists.**SOURCES OF FUNDING:** This work was supported by the National Institutes of Health (1R37NS115439-01A1 to F.E.J.)

Title: Augmented adult neurogenesis in the dentate gyrus of naïve and epileptic mice following transplantation and integration of medial ganglionic eminence-derived GABAergic progenitors

Authors: *M. ARSHAD, S. OPPENHEIMER, J. JEONG, J. R. NAEGELE;
Dept. of Biol., Wesleyan Univ. Neurosci. and Behavior Program, MIDDLETOWN, CT

Abstract: GABAergic interneurons are vulnerable to seizures in the pilocarpine model of temporal lobe epilepsy (TLE). Subtypes of GABAergic interneurons located in or near the neurogenic niche of the adult hippocampus also influence stages of adult-neurogenesis in rodents including proliferation and migration of newborn granule cells (GCs) into the granule cell layer (GCL) of the dentate gyrus. In TLE, neurogenesis is severely altered, resulting in an increased number of abnormally-positioned GCs in the hilus, which form hyperexcitable hubs and contribute to seizures. These observations led us to ask in the mouse pilocarpine model of TLE whether replacing GABAergic interneurons via transplantation would restore normal patterns of adult neurogenesis. To address this question, we transplanted fetal medial ganglionic eminence (MGE)-derived GABAergic progenitors into the hilus of the DG in TLE mice and quantified Type 1 and Type 2 progenitors as well as doublecortin+ immature adult-born GCs, focusing on the different stages of adult neurogenesis. We found that MGE transplants reduced the number of Type 1 and Type 2 progenitors in the subgranular zone (SGZ) of the DG in TLE mice. As previously reported, doublecortin (DCX)-positive immature adult-born GCs in ectopic positions in the hilus were significantly increased in TLE mice, and MGE-derived GABAergic transplants significantly reduced the number of ectopic cells, while concomitantly increasing normotopic GCs in the GCL. These results are consistent with the hypothesis that hilar transplants of MGE-derived GABAergic cells normalize the migration of DCX+ adult-born GCs in TLE mice. Prior work showed that pilocarpine-induced TLE in mice is associated with spontaneous seizures that are suppressed by transplants of MGE-derived GABAergic cells (Hunt et al., 2013; Henderson et al., 2014; Arshad MN and Naegele JR 2020). The underlying mechanisms for seizure suppression include increased inhibitory synaptic currents in adult-born GCs (Gupta et al., 2019; Arshad MN et al., 2021). Furthermore, transplant-mediated innervation of adult-born GCs in TLE mice restricts the growth of GC dendritic arbors (Gupta et al., 2019). Our new findings demonstrate that in addition to providing enhanced synaptic inhibition of dentate gyrus GCs, the mechanisms for seizure suppression by GABA transplants may include a reduction in ectopic adult-born GCs.

Title: Stimulation of DRN serotonergic terminals within the PPT decreases PGES duration in amygdala-kindled mice

Authors: *A. PETRUCCI, A. R. JONES, R. LI, G. F. BUCHANAN;
Univ. of Iowa, Iowa City, IA

Abstract: The leading cause of death in patients with refractory epilepsy is sudden unexpected death in epilepsy (SUDEP). A risk factor for SUDEP may be post-ictal generalized EEG suppression (PGES), a period of reduced EEG amplitude following some seizures. The networks comprising PGES are unknown. Our prior work indicates that increased serotonergic (5-HT) signaling and stimulation of dorsal raphe nucleus (DRN) 5-HT neurons prior to and during a seizure reduces PGES duration. A downstream intermediary may be the pedunculopontine tegmental (PPT) nucleus, a largely cholinergic region associated with arousal and sleep-wake regulation. We hypothesized that excitation of DRN 5-HT terminals in the PPT will reduce PGES duration, whereas inhibition will increase PGES duration. Pet1-Cre (8-16 wks, express Cre recombinase in 5-HT neurons) and WT (n = 8 per sex/genotype/condition) mice were implanted with EEG/EMG and a bipolar stimulating/recording electrode in the right basolateral amygdala (in mm from bregma: AP: -1.3; ML: -2.8; DV: -4.7), and received an AAV injection of Cre-mediated Channelrhodopsin2-mCherry, Archaerhodopsin-YFP, mCherry, or YFP into the DRN (AP: -4.6; ML: 0; DV: -3.0, coupled with an optical fiber in the PPT (AP: -4.46; ML: ± 1.12; DV: -3.5). After 4 weeks, mice underwent afterdischarge threshold determination and were kindled with their threshold current (2x/day, 80-540 μA, 1 s train of 1 ms biphasic square wave pulses at 60 Hz) until stimulation evoked consistent generalized tonic-clonic seizures. During trials, DRN 5-HT terminals in the PPT were stimulated (473 nm, 4 Hz, 10 mW) or inhibited (593 nm, constant, 10 mW) by laser light prior to and during a seizure induced in wake or NREM or at seizure termination. Analysis included seizure and PGES duration and the latency of the EEG (delta, 1-4 Hz; theta, 4-8 Hz; alpha, 8-12 Hz; beta, 12-30 Hz) to recover from PGES. Trials in female mice were conducted in met/diestrus. Viral transfection and implant locations were verified post-hoc. PGES duration was decreased by excitation of DRN 5-HT terminals in the PPT. Inhibition of DRN 5-HT terminals delayed recovery of EEG to baseline from PGES. Seizure duration was unaffected by laser treatment. No significant sex differences were identified or differences among mice that received AAV mCherry or YFP. These results indicate that PGES may be influenced by a DRN to PPT network. However, the PPT neurons and 5-HT receptors mediating our findings are unknown. Future experiments aim to identify these mechanisms utilizing pharmacology and immunohistochemical assays. Elucidating this network could have important implications for developing prophylactic strategies for SUDEP.

Title: Lateral fluid percussion injury and dysbiosis: implications for post-traumatic epilepsy

Authors: *A. MAZARATI, J.-S. MEDEL-MATUS, V. LAGISHETTY, C. SANTANA-GOMEZ, D. SHIN, J. JACOBS, R. STABA, R. SANKAR;
Univ. of California Los Angeles David Geffen Sch. of Med., Los Angeles, CA

Abstract: Changes in gut microbial composition and function have been documented after traumatic brain injury (TBI). In turn, TBI is a major cause of epilepsy. Using an animal model of the TBI - posttraumatic epilepsy (PTE) continuum, lateral fluid percussion injury (LFPI) in the rat, we examined whether (a) TBI produced changes in microbial composition and (b) whether fecal microbiome transfer (FMT) from post-LFPI animals altered the susceptibility to post-traumatic epilepsy (PTE) in recipients. Microbial composition was analyzed by 16S ribosomal RNA gene sequencing in 60 LFPI and 21 sham LFPI rats prior to, 1 week, 1 month and 6 months after the injury. Time-dependent changes in both alpha diversity (Chao1 and Faith's index) and beta diversity (robust Aitchison distance) were observed in both LFPI and sham-LFPI subjects. Prior to the LFPI/sham LFPI, beta diversity was similar between the animals of the two groups (Adonis p=0.08). One week after LFPI, beta diversity was significantly different between LFPI and sham LFPI rats (Adonis p=0.02), and the difference further increased at 1 month (p=0.0001). For FMT, the following donors were used: naïve; 1 week after LFPI, with subsequent development of PTE; 7 months after LFPI with confirmed PTE; 7 months after LFPI without PTE. Samples from 3-4 donors of each category were combined and administered to recipients (7 per group), 3 weeks after LFPI, and after 2-week treatment with oral antibiotics to suppress commensal microbiota. PTE was examined 7-9 months after LFPI first by monitoring of spontaneous seizures, followed by kindling of amygdala. There were no statistically significant differences in the incidence and frequency of spontaneous seizures between untreated and FMT rats, for any of the donor type. After LFPI, 10 out of 26 rats kindled faster, 8 out of 26 rats kindled slower, and 8 out of 26 rats kindled at a rate similar to sham and naive subjects. After FMT, notwithstanding the type of the donor, no animals had accelerated kindling rate, with 4-6 rats per group having normal, and the remaining- slow kindling. Antibiotics alone had no effects. The observed differences in kindling were statistically significant as compared to untreated rats, but similar among the different types of recipients (Kruskal Wallis + Dunn's). In conclusion, our data show that both LFPI and sham LFPI alter gut microbiome; however, LFPI-specific changes are also present. Judging by the results of FMT on kindling, these changes may counteract the increased susceptibility to epilepsy after TBI.

Title: Characterization of interactions between seizures and cortical spreading depression using calcium imaging and multisite DC-coupled electrographic recordings in vivo.

Authors: *D. RATHORE[1], A. SMITH[2], E. MASVIDAL-CODINA[4], L. F. ROSSI[5], A. GUIMERÀ-BRUNET[4], Y. TIMOFEEVA[1,3], R. C. WYKES[1,6], K. E. VOLYNSKI[1];

Abstract: Cortical seizures are often accompanied by cortical spreading depression (CSD), but the relationship between these two phenomena remains enigmatic. CSD, the physiological correlate of migraine aura, arises from a propagating destabilization of ion homeostasis, resulting in prolonged suppression of subsequent neuronal activity. While this suppression of activity has been linked to the termination of epileptic paroxysms, many reports also indicate increased excitability and epileptiform discharges immediately after a CSD. However, most experimental studies to date have been limited to recording from single, or few, cortical sites with DC-coupled electrodes, failing to capture the circuit relationship between CSD and seizures.

To capture the interactions between ictal discharges, seizures and CSD waves, we developed a method to characterise the spatial propagation and interaction of these events in the cortex of awake mice. We expressed the calcium indicator GCaMP7a in both cortical hemispheres, and recorded the propagation of picrotoxin-induced seizures and associated CSDs across different cortical regions using wide-field imaging. Moreover, we placed transparent, 16-channel graphene solution-gated field effect transistor (gSGFET) arrays on the dura, which allowed simultaneous recording of full-bandwidth electrophysiological signals.

To examine the temporal relationship between seizures and CSD, we developed an automated analysis pipeline to classify and characterize events based on cortical origin and propagation properties. For each CSD event, we extract multiple properties (such as amplitude, waveform, co-occurring hyperpolarization, duration and laterality) and perform unbiased statistical testing with seizure-relevant parameters. Using gSGFET-acquired data, we resolve the full-bandwidth electrophysiology signals into physiologically-relevant frequency components and compare the power of each during different events. This allows us to correlate cortical oscillations with the activity throughout both hemispheres. Using these methods, we are able to perform high-throughput event analyses to examine the diversity of ictal-associated infraslow events and resolve these based on the role they play in epileptic paroxysms.

Altogether, the methodology presented in this study provides a previously unseen view into the relationship between CSD and cortical seizures. We envision that combined application of calcium imaging and gSGFET recordings will provide unparalleled insights into the understanding of seizure initiation and termination, and will facilitate the development of novel therapeutic avenues.

Title: Novel mechanism of hypoxic injury mediated by non-excitatory amino acids

Authors: *I. ÁLVAREZ-MERZ[1,2,3], J. SWORD[3], J. M. HERNÁNDEZ-GUIJO[1], J. M. SOLÍS[2], S. A. KIROV[3];

Abstract: One of the major pathogenic events causing acute brain damage during head trauma and hemorrhagic stroke is bleeding and release of plasmatic content, including amino acids (AA), into cerebral parenchyma. Consequently to the decrease in blood flow, abrupt tissue hypoxia-anoxia develops. However, little is known about non-excitotoxic AA contribution to hypoxic cellular injury. Recently we have shown in hippocampal slices that hypoxia-induced synaptic depression becomes irreversible in the presence of non-excitatory AA, coinciding with their intracellular accumulation and increased tissue electrical resistance (Álvarez-Merz *et al.*, 2021). Here, we hypothesize that transporters-mediated uptake of non-excitatory AA promotes cell swelling and exacerbates hypoxia-induced neuronal injury by releasing excitotoxins through volume-regulated anion channels (VRAC). A combination of four AAs (AGQS: L-alanine, glycine, L-glutamine, and L-serine) at plasmatic concentrations were applied to brain slices from 42 male and female adult mice expressing EGFP in pyramidal neurons (Thy1/EGFP) or astrocytes (GFAP/EGFP). Simultaneous high-resolution 2-photon imaging and field electrophysiological recordings in hippocampal CA1 *st. radiatum* were used to monitor astroglial and neuronal swelling concurrently with signs of injury to synaptic circuitry signified by dendritic beading and loss of synaptic transmission. Imaging changes in light transmittance (LT) were used for global monitoring of tissue swelling and shrinking. Data were analyzed blind to conditions. We find that during normoxia, AGQS-induced increase in LT is due to astroglial but not neuronal swelling (n=13 slices). In contrast, an increase in LT during 30-min hypoxia and AGQS manifests irreversible neuronal and astroglial swelling. AGQS-induced permanent loss of synaptic transmission during hypoxia develops alongside dendritic beading, indicating structural damage (n=15). Interestingly neuronal damage is not caused by spreading depolarization, which does not occur in our experiments. Blockade of NMDA receptors prevents neuronal damage and irreversible loss of field potentials (n=10). Control 30-min hypoxia without AA does not cause changes in cell volume, leaving dendrites intact (n=19). Deleterious effects of AGQS during

hypoxia are avoided by alanine-serine-cysteine transporter 2 (ASCT2) and VRAC blockers (n=7 and 8). Our results suggest that extracellular volume reduction induced by intracellular accumulation of non-excitotoxic AA through neutral AA transporters and the resulting glutamate release through swelling activated VRAC aggravate deleterious hypoxia outcomes.

Title: Glucose and oxidative stress as modulators of retinal Müller cells pluripotency capacity. Involvement of histone deacetylase SIRT6.

Authors: F. SANHUEZA SALAS[1], A. GARCÍA VENZOR[2], N. BELTRAMONE[3], C. CAPURRO[3], D. TOIBER[4], ***D. SILBERMAN**[1];
[1]CEFYBO-UBA-CONICET, Buenos Aires, Argentina; [2]Dept. of Life Sciences, The Zlotowski Ctr. for Neuroscience, Ben-Gurion Univ. of the Negev, Beer Sheva, Israel; [3]IFIBIO-CONICET, Buenos Aires, Argentina; [4]Dept. of Life Sciences, The Zlotowski Ctr. for Neurosci., Ben Gurion Univ., Beer Sheva, Israel

Abstract: Müller glial cells (MGs) play a critical role in retinal metabolism and are among the first cells to demonstrate metabolic changes in retinal stress or disease. In response to a harmful stimulus they can rapidly dedifferentiate acquiring neural stem cells properties, proliferate and migrate to the damaged retinal layer and differentiate into lost neurons making them candidates as a potential source of regenerative cells in this tissue. However, how this process is regulated in mammals remains unknown.Somatic reprogramming and pluripotency are characterized by a transition from oxidative metabolism into anaerobic glycolysis. Interestingly, the NAD+ dependent histone deacetylase SIRT6 has been shown to act as a key modulator of glucose homeostasis, to be a direct regulator of the expression of core pluripotent genes and to play a role in retinal function. In this work we aimed to study the effect of glucose variations in MGs reprogramming capacity and analyze the participation of SIRT6 as a potential epigenetic modulator of this process. The retinal Müller glial derived cell line MIO-M1 was cultured with different glucose concentrations and under oxidative stress conditions. We found that glucose variations do not exert an effect in the glial cell marker glutamine synthetase (GS) levels nor in the migration capacity of MGs but the combination of high glucose concentrations and oxidative stress induced a decrease in GS levels ($p<0.05$) as well as an increase in the migration capacity ($p<0.05$) suggesting that these experimental conditions could induce some degree of dedifferentiation and favor the migration ability. High glucose also induced an increase in the levels of pluripotent factor SOX9 ($p<0.05$) and a decrease in SIRT6 ($p<0.05$) levels accompanied by the increase in the acetylation levels of one of its

substrates (H3K9) ($p<0.001$). Notably, inhibiting SIRT6 expression by siRNA rendered an increase in SOX9 levels. A moderate increment of SOX9 levels was also observed in retinas from mice with a conditional deletion of SIRT6 in the CNS (Nes-Cre) suggesting that this enzyme, as shown for other reprogramming factors, may be a modulator of this transcription factor. Further studies will help us to understand the mechanisms that regulate MGs response under metabolic impaired conditions.

Title: Astrocyte secreted factors drive microglial activation in SMA patient iPSC cultures

Authors: *R. L. ALLISON[1], G. KHAYRULLINA[2], B. G. BURNETT[2], A. D. EBERT[1];
[1]Cell Biology, Neurobiology, and Anat., Med. Col. of Wisconsin, Milwaukee, WI; [2]Anatomy, Physiol. and Genet., Uniformed Services Univ., Bethesda, MD

Abstract: Spinal muscular atrophy (SMA) is the leading genetic cause of infant mortality and is caused by a mutation or deletion of the survival of motor neuron 1 (SMN1) gene, resulting in reduced expression of the ubiquitous SMN protein. Motor neurons are particularly impacted by decreased SMN protein levels, and motor neuron loss is the primary phenotypic outcome in SMA patients. SMN deficient motor neurons show intrinsic deficits in splicing and electrophysiological function, but these defects alone are not sufficient to induce overt motor neuron loss. Data from us and others indicate that there are significant non-cell autonomous astrocyte and microglia influences on motor neuron health and survival, raising the possibility that glia directly contribute to the vulnerability of neurons in SMA.
Our lab has previously found that astrocytes in SMA undergo morphological and functional changes early in the disease and are capable of inducing motor neuron pathology. Additionally, others have shown that microglia in SMA exhibit activation later in the disease process and are involved in synapse engulfment. However, the mechanisms of glia-mediated neuron dysfunction and the temporal contributions of astrocyte-microglia crosstalk to SMA pathology have not been elucidated.
We hypothesize that early SMA astrocyte dysfunction induces motor neuron pathology and simultaneously drives microglial activation. In support of this, we found that astrocytes differentiated from SMA patient-derived induced pluripotent stem cells (iPSCs) express high levels of pro-inflammatory cytokines IL1β and IL6 as well as complement factors C1q and C3 compared to healthy (unaffected) astrocytes. Moreover, we found that SMA iPSC-derived microglia upregulate the receptors for these ligands, suggesting several avenues of glial crosstalk. Exposure of SMA microglia to SMA astrocyte conditioned medium (ACM) increased reactive morphology and phagocytic ability compared to

control ACM. Interestingly, lentiviral knockdown of the upregulated transcription factor GATA6 in SMA astrocytes abrogated these effects. No differences in astrocyte activation were found after exposure to SMA microglia conditioned media.
These data indicate the significant role of astrocyte secreted factors in contributing to disease phenotypes and suggest an astrocyte-to-microglia timeline of glial activation in SMA. Gaining a better understanding of glial contributions to SMA pathology can help identify additional SMN-independent targets for therapeutic intervention.

Abstract: Aβ40 and Aβ42 adopt distinct fibril structures that differentially stimulate astrocytes and microglia
Xiaoyue Zhu[1,2], Joseph M. Schrader[1,2], Brandon Irizarry[3], Steven O. Smith[3], and William E. Van Nostrand[1,2]*
[1]George and Anne Ryan Institute for Neuroscience, [2]Department of Biomedical and Pharmaceutical Sciences, University of Rhode Island, Kingston, RI, United States[3]Department of Biochemistry and Cell Biology, Stony Brook University, Stony Brook, NY 11794-5115
Fibrillar amyloid β-protein (Aβ) deposits in brain, which are primarily composed of Aβ40 or Aβ42 peptides, are key pathological features of Alzheimer's disease and related disorders. Structural studies on mature Aβ40 fibrils formed in solution have suggested they adopt a two stranded (U-shaped) structure whereas studies on Aβ42 fibrils typically show a three-stranded structure. Fibrillar amyloid deposits in brain promote activation of astrocytes and microglia although the underlying mechanisms are still not clear. Here, we prepared Aβ40 and Aβ42 fibrils and NMR analysis confirmed the distinct two-stranded structure of Aβ40 fibrils and three-stranded structure of Aβ42 fibrils. Primary astrocytes and microglia were isolated from neonatal rat brains and treated with Aβ40 or Aβ42 fibrils. RNA sequencing was performed on cells treated with the different amyloid fibril preparations. The expression data were analyzed and set with limits of ≥5-fold increase in expression and $p < 0.05$. Results show that Aβ40 fibrils stimulated the expression of 180 genes in microglia but >1700 genes under Aβ42 fibrils stimulation. In contrast, Aβ40 fibrils only stimulated 35 genes in astrocytes and 38 genes under Aβ42 fibrils treatment.

Immunohistochemical analysis was performed in an AD rat model with parenchymal fibrillar Aβ42 deposits confirming the expression of MMP9, MMP12, PAI-1 and C1r in plaque-associated microglia supporting the RNAseq results in the treated cultured glial cells. Together, these studies show that the distinct structures of Aβ40 and Aβ42 fibrils differentially stimulate the gene expression profile of astrocytes and microglia and that Aβ42 fibrils are more potent stimulators. These findings indicate that different types of amyloid fibrils can promote distinct gene expression signatures in glial cells that may participate in the pathogenesis of AD and related amyloid-depositing disorders. Work was supported by NIH grant AG061775.

Abstract: Neurofibromatosis type 1 (NF1) is a genetic disorder characterized by tumors in peripheral nerves called neurofibromas. We found that the purinergic receptor P2RY14 is expressed in human and mouse neurofibroma Schwann cell precursor-like cells (SCPs) and in Schwann cells (SCs). Neurofibroma $P2RY14^{+}$ SCP-like cells were enriched in cells with the potential to self-renew. Conversely, SCP self-renewal was blocked by pharmacologic or genetic targeting of P2RY14 in mouse *Nf1* mutants. Downstream of P2RY14, G_{i}-mediated cAMP signaling contributed to these effects. *In vivo,* in a mouse model of NF1, P2RY14 loss delayed neurofibroma initiation, normalized nerve architecture, rescued the reduced cAMP characteristic of neurofibromas and normalized neurofibroma cell proliferation. Thus, the purinergic receptor P2RY14 regulates SCP self-renewal and neurofibroma initiation, and to a lesser

extent, contributes to later stages of tumorigenesis. These gain and loss of function experiments suggest roles for P2RY14 signaling in peripheral nerve that are perturbed by loss of the NF1 tumor suppressor.

Title: Critical role of Hv1 and zinc in microglial inflammatory neurotoxicity

Authors: *D. HERNÁNDEZ ESPINOSA, E. AIZENMAN;
Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Although an inflammatory response is necessary for moderating injurious processes, the dysregulation of microglial activation can directly cause neuronal death, a term we define as inflammatory neurotoxicity. The Hv1 (HVCN1) proton channel participates in the regulation of microglia activation, although its precise roles are not completely defined. In the CNS, this channel is expressed exclusively in microglia, and its activity is strongly regulated by zinc. The present work focuses on defining the widespread consequences of the pharmacological inhibition of Hv1 during microglial activation, as well as the effect of zinc in this process. We used a model of chronic activation in a rat microglia cell line (HAPI cells) as well as in a primary cortical neuronal-microglial coculture. Microglia were treated with LPS/IFNγ for 24 h in the presence or absence of 2-Guanidinobenzimidazole (2GBI), an Hv1 inhibitor, as well as under conditions that increase (ZnPyR) or decrease (TPEN) intracellular zinc. To confirm microglial activation, we quantified phagocytic activity, ROS, NOX and iNOS activity, as well as cytokine production. We also quantify microglial intracellular pH (ipH) changes and neuronal viability in our coculture preparation. During microglia activation, 2GBI causes a dramatic fall in microglial ipH, decreased phagocytic activity, and stunted reactive species production. Hv1 inhibition also reduces NOX and iNOS activity as well as reactive species production by nearly 50%. LPS/IFNγ treatment normally produces a 10-fold increase in IL-6, also partially blocked by Hv1 inhibition. Interestingly, microglial activation produced a discrete increase in IL-10, which is totally blocked by Hv1 inhibition. Regarding inflammatory neurotoxicity, the viability of cortical neurons decreases approximately 40% when cocultured for 24h with activated microglia, while if activation occurs during Hv1 inhibition the neuronal viability only decreases by 15%. When we added ZnPyR during microglia activation, IL-6 production and neurotoxicity increases by 20%, an effect absents in 2GBI-treated cells. In contrast, administration of TPEN increases IL-10 production and decreases neurotoxicity, but only during Hv1 inhibition. In summary, activation of the Hv1 proton channel is necessary for microglial activation and resulting inflammatory neurotoxicity, while zinc chelation during Hv1 inhibition can further restrict

microglial neurotoxicity. These results suggests that the inhibition of Hv1 together with the administration of intracellular zinc chelators could represent a therapeutic option for the control of inflammation-associated neurotoxicity

Abstract: The c-fos gene was first described as a proto-oncogene responsible for the induction of bone tumours. In brain sciences, the protein product c-Fos has been studied as an activity marker restricted to neuronal cells. However, according to reports of c-fos expression in astrocytes, microglia, and oligodendrocytes, it is necessary to reconsider this specificity in order to generate a wider vision of c-fos utility in cellular studies. Here, we show that intense stress induces a robust c-Fos protein expression in most of the glial phenotypes residing in brain. We used the immunohistochemical approach to evidence that c-Fos marker may colocalize with other phenotypical markers such as GFAP, Iba1, Olig2 or NG2 proteoglycan. Then, we believe that c-Fos expression may also be useful to evidence activation changes involving glial cells.

Title: Primary cilia regulate and stabilize neuronal positioning in compact neural structures

Authors: *J. YANG[1], L. QIU[1], X. CHEN[2];
[2]Dept. of Molecular, Cell. and Biomed. Sci., [1]Univ. of New Hampshire, Durham, NH

Abstract: Primary cilia are rigid, centriole-derived, surface protrusion present in most mammalian cells including neurons. It is known that primary cilia regulate early neurodevelopment such as neural tube patterning. Nevertheless, it is not clear how primary cilia are engaged in neuronal positioning. We compared the morphological dynamics of neuronal primary cilia in the hippocampus, cortex and adrenal medulla during development. Here we show that neuronal primary cilia emerge only after hippocampal pyramidal neurons have migrated to reach the pyramidal cell layer, but before the final neuronal positioning. Primary cilia in the pyramidal cell layer undergo marked changes in morphology and orientation postnatally, which coincide with pyramidal neuronal positioning to the deep and superficial sublayers. Moreover, primary cilia of deep-sublayer neurons mostly point to the ventricle zone, whereas those of superficial-layer neurons point to the opposite direction. Calbindin staining show the opposing cilia pointing in the deep and superficial sublayers is in line with the inside-out lamination pattern. Surprisingly, we also found that the centriole/cilia movement during neuronal positioning is different from that of saltatory migration. Overexpression of Arl13B not only elongates primary cilia length, but also promotes earlier cilia emergence, slightly changing the ratio of the opposing cilia pointing in the pyramidal cell layer. Similarly, primary cilia of cortical pyramidal neurons emerge after the completion of migration, and their cilia orientation aligns with the migration direction and inside-out lamination. In contrast, chromaffin cells in the adrenal medulla, which migrate collectively, have different timing of ciliation. Their primary cilia are prominent at embryonic stage and during neuronal migration, and apparently well-positioned to stabilize the functional unit, but do not point to the migration direction. Together, these data suggest that neuronal primary cilia may function like “mechanical anchors” to regulate and stabilize neuronal positioning in compact neural units.

Title: Aged-dependent microbiome dysbiosis and BBB dysfuction in postoperative delirium pathogenesis

Authors: Z. ZHAO, *L. LIU, Z. XIE, ***Y. ZHANG**;
Anesthesia, Critical Care and Pain Med., Massachusetts Gen. Hosp. and Harvard Med. Sch., Charlestown, MA

Abstract: Introduction: Delirium, a syndrome of confusion and inattention, is the most common postoperative complication in senior patients and is associated with accelerated cognitive decline, such as Alzheimer's disease. Senior patients are more likely than younger ones to develop postoperative delirium (POD). However, the neuropathogenesis of POD remains mostly unknown. Gut microbiota dysbiosis, a condition of microbiota imbalance or maladaptation inside the gut, which could lead to altered immune functions and associated with disorders of the immune, endocrine, and central nervous systems, including with POD. Aging is associated with changes in the gut microbiota and microbiota dysbiosis. Our previous studies demonstrated that anesthesia/surgery causes age-dependent gut microbiota dysbiosis and the POD-like behavior in mice. Meanwhile, anesthesia/surgery induce blood-brain barrier(BBB) dysfunction and cognitive impairment in mice. We hypothesized that the aged-dependent gut microbiota dysbiosis associated with the BBB permeability changes lead to POD-like behavior in mice. Therefore, our hypothesis that anesthesia/surgery causes age-dependent changes in the BBB permeability dysfunctions and POD-like behavior in mice that is attenuated by probiotics. Methods: Female 3 or 18 months old mice received abdominal surgery under 1.4% isoflurane for two hours. We employed a battery of natural and learned behavioral tests to determine the POD-like behavior, assessed BBB permeability by tail vein injection with dextran and levels of brain IL-6. For intervention, intragastric administration of probiotic was used to mitigate the anesthesia/surgery-induced above changes. Results: Firstly, we found that anesthesia/surgery induces age-dependent POD-like behaviors and cognitive impairment between the 18 and 3 months old mice.The anesthesia/surgery-induced greater POD-like behavior, increased brain IL-6 levels, and significant BBB permeability dysfunction in 18 than 3 months old mice. Treatments with probiotics mitigated the anesthesia/surgery-induced above changes. Conclusion: We demonstrated that anesthesia/surgery induces age-dependent changes in BBB permeability dysfunction, increases brain levels of IL-6, while also promoting the development of POD-like behaviors in the mice. Treatment with probiotics prior to anesthesia/surgery mitigated these detrimental effects, strongly suggesting that abnormalities in the gut microbiota contribute to the development of postoperative delirium.

Title: Longitudinal assessment of structural brain alterations following short-term, Gulf War-related chemical exposure

Authors: J. M. CARPENTER[1], S. H. NGUYEN[2], K. M. MASON[2], N. M. FILIPOV[1];
[1]Physiol. and Pharmacol., [2]Univ. of Georgia, Athens, GA

Abstract: Gulf War Illness (GWI) affects nearly 30% of veterans from the 1990-1991 Gulf War as a multi-symptom illness characterized by neurological and immunological effects that are attributed to in theatre war-time chemical overexposures. Numerous imaging studies have revealed structural and functional neurological alterations in GWI veterans, such as reduced hippocampal and cerebellar volumes, connectivity, and signaling that highly correlate to poor performance in tasks evaluating cognition and motor function. Symptomology has been recapitulated in GWI rodent models as aberrations in behavioral performance (i.e. cognition/memory, motor, and mood) and biological parameters (i.e. neuroinflammation). While these models produce similar GWI behavioral and biological phenotypes, structural imaging studies remain limited. Thus, this study aimed to longitudinally characterize the progression of brain structural alterations over the course of 9 months following GW chemical exposure to a nerve agent prophylactic (pyridostigmine bromide; PB) and pyrethroid insecticide (permethrin; PM). Male C57BL/6J mice (8-9 weeks) were co-administered PB/PM (0.7/200 mg/kg IP, respectively) or DMSO control daily for 10 days. Using a Varian 7T Bore MRI System, structural (coronal T1- and sagittal T2-weighted) scans were performed at 3, 6, and 9 months post chemical exposure. Regions of interest (ROIs) including the cortex, hippocampus, cerebellum, lateral ventricle, and third ventricle were delineated in the open source Aedes Toolbox in MATLAB, followed by volumetric analysis in ImageJ. Of the data analyzed to date, there were no observed treatment effects on ROIs within 3 or 6 months. However, hippocampal volume was decreased in PB/PM mice from 3 to 6 months; ventricular volumes remained unaffected, suggesting the hippocampal volume decreases precede and/or are independent of ventricular volume changes at this state. In the cerebellum, significant decreases in cerebellar volume were present within both groups from 3 to 6 months, suggesting age related rather than treatment related effects within this region. The observed alterations in brain structures thus far align with GWI clinical reports and neurobehavioral deficits previously characterized in this model; the cerebellar data hints that this brain region may be amongst the earliest affected by age. Overall, the effects seen here further add translational validity to this model for future GWI therapeutic interventions. This research was supported by the University of Georgia Franklin Foundation Imaging grant awarded to JMC, DoD grant number W81XWH-16-1-0586 awarded to NMF, and NIH grant number T35OD010433-14.

Title: The effect of manganese on synaptic transmission and its impact on various physiological processes

Authors: *C. L. PANKAU[1], J. NADOLSKI[2], H. TANNER[3], C. CRYER[1], J. DI GIROLAMO[1], C. N. HADDAD[1], R. E. WILSON[1], D. M. NEELY[1], M. MILLER[1], M. J. LANNING[1], B. WHITTINGHILL[1], R. L. COOPER[1];
[1]Dept. of Biol., Univ. of Kentucky, Lexington, KY; [2]Dept. of Mathematical and Computat. Sci., Benedictine Univ., Lisle, IL; [3]Dept. of Biol., Eastern Kentucky Univ., Richmond, KY

Abstract: Manganese (Mn^{2+} as present within $MnSO_4$ and/or $MnCl_2$) is an element that is essential to various cellular processes, for example, the functioning of essential enzymes such as superoxide dismutase (SOD). Manganese is present within soil, fresh waters, and marine waters; however, overexposure to manganese can be toxic and is often associated with a variety of neurological issues. Overexposure to manganese is often attributed to working within the mining or metal processing industry, being exposed to $MnSO_4$ that had been added to soil for agricultural purposes, or being exposed through other food sources such as infant formula. Research has demonstrated that hypermagnesemia can be associated with the onset of Parkinson's disease-like symptoms and acute cardiovascular disorders in mammals. This impact seems to occur as a result of the blockage of dopaminergic neural circuits by manganese. In order to investigate these effects further, this study was intended to examine the effect of hypermagnesemia on not only dopaminergic synapses, but also on development, behavior, survival, cardiac function, and glutamatergic synaptic transmission through experimentation with *Drosophila melanogaster*. In addition, the effect of manganese on sensory neurons in marine and freshwater crustaceans, glutamatergic neuromuscular junctions in freshwater crayfish, and the shape of neuronal action potentials in freshwater crayfish was also examined. The results from this study indicated a dose-response effect where higher Mn^{2+} has an adverse effect on development, survival, and cardiac function in *D. melanogaster* larvae and survival in adults. It was also shown that $MnSO_4$ and $MnCl_2$ block stretch-activated responses in primary proprioceptive neurons in a dose-response manner. Glutamatergic synaptic transmission at the neuromuscular junction of both crayfish and *D. melanogaster* indicate that Mn^{2+} blocks evoked responses but not glutamate receptors, which suggests that these effects may result from a presynaptic block of voltage-gated Ca^{2+} channels. The effects of manganese on glutamatergic synaptic transmission and the shape of action potentials in axons will also be reported on. The effect of Mn^{2+} is multi-faceted, so learning about its impact on various physiological functions is relevant in order to gain a better understanding about the acute and long-term consequences of overexposure.

Title: Chronic methamphetamine administration induces degeneration of locus coeruleus neurons and monoamine oxidase inhibition is neuroprotective

Authors: *Y. DU, A. PILSKI, S. CHOI, Y. LEE, S. M. GRAVES;
Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Methamphetamine (meth) is an addictive psychostimulant with the capacity to induce neurodegeneration. Meth causes dysfunction of vesicular monoamine transporter 2 proteins resulting in increased cytosolic monoamine concentrations. In substantia nigra pars compacta (SNc) dopamine neurons this leads to increased axonal mitochondrial stress due to monoamine oxidase (MAO) metabolism (Graves *et al., Nat Neurosci*, 23:15 2020). Chronic administration of meth results in SNc degeneration which is prevented by MAO inhibition, suggesting that meth-induced MAO-dependent mitochondrial stress is a causal factor (Graves *et al., Neurobiol Dis*, 156:105409 2021). Meth also targets noradrenergic systems and MAO enzymes metabolize norepinephrine. To determine whether locus coeruleus (LC) norepinephrine neurons are also vulnerable to chronic meth-induced degeneration we first assessed mitochondrial stress in these neurons. The redox biosensor roGFP was expressed in the mitochondrial matrix of LC neurons; both somatic and axonal mitochondrial stress was measured in *ex vivo* mouse brain slices as previously described (Graves *et al., Nat Neurosci* 23:15 2020). Similar to that observed in SNc neurons (Graves *et al., Nat Neurosci* 23:15 2020), meth (10 μM) had no effect on somatic but increased axonal mitochondrial stress in LC neurons. The increase in axonal mitochondrial stress was attenuated by MAO inhibition (1 μM rasagiline). To ascertain whether chronic meth was neurotoxic to LC neurons mice were administered saline or meth (5 mg/kg; i.p.) for 28 days, sacrificed, and tissue collected for immunohistochemistry. LC axons in the motor cortex were stained for the norepinephrine transporter (NET); cells in the LC were stained for tyrosine hydroxylase (TH) and counterstained for NeuN, a non-specific neuronal marker. Stereological quantification indicated that chronic meth decreased the length of NET^+ axons in the motor cortex and number of TH^+ cells in the LC. To confirm that these findings reflected degeneration and not phenotypic suppression, NeuN stained cells in the LC were also counted; meth similarly decreased the number of NeuN stained cells in the LC confirming degeneration. Lastly, to determine whether MAO activity contributes to LC degeneration as it does in the SNc (Graves *et al., Neurobiol Dis*, 156:105409 2021), mice were administered the MAO inhibitor rasagiline (1 mg/kg; i.p.) 30 min prior to meth for 28 days. Consistent with the SNc, MAO inhibition also prevented chronic meth-induced LC degeneration. These results suggest that meth-induced MAO-dependent mitochondrial stress is necessary for chronic meth-induced LC degeneration.

Title: Ethanol exaggerates cell death at high but not low impact force in an organotypic hippocampal slice culture mechanical distension model of traumatic brain injury

Authors: *J. JAGIELO-MILLER[1], S. P. PATEL[2], C. S. BAILEY[1], C. COUNT[1], A. G. RABCHEVSKY[3], M. A. PRENDERGAST[1];
[1]Psychology, [2]Spinal Cord & Brain Injury research Center, Dept. of Physiol., [3]Spinal Cord & Brain Injury Res. Ctr. (SCoBIRC) & Dept. of Physiol., Univ. of Kentucky, Lexington, KY

Abstract: Every year more than 2.8 million people sustain a traumatic brain injury (TBI) in the United States. A large percent (25-50%) of individuals of are intoxicated at the time of their injuries. Despite the prevalence of TBIs that occur under the influence of alcohol (EtOH), it is not well understood how EtOH impacts the cellular cascades of secondary injury which are triggered by the initial injury, or how EtOH impacts patient outcomes. Research on TBI patients has shown a mixture of findings from EtOH improving, worsening and not changing TBI outcomes. This prompts further investigation into the effects of EtOH on these secondary injury mechanisms. Organotypic slice cultures serve as a useful tool to study these biochemical phenomena in a tightly controlled manner while minimizing the number of animals used. Hippocampal tissue was taken from 8-day old Sprague Dawley pups (n=12) and cultured for five days prior to treatment on culture inserts. Culture inserts were then transferred into new culture media (+/- 50 millimolar ethanol) for an additional 2 days. Following the 2 days of EtOH exposure, tissue in the injury groups were subjected to an indirect stretch injury used to model axonal damage associated with TBIs. Infinite Horizon Impactor was used at two different forces (50 kilodyne (kD) or 100kD) for two different dwell times (0 seconds or 5 seconds) to stretch the culture membranes (4 slice cultures per membrane) which in turn stretched the tissue, causing injury. All tissue inserts were then transferred to new culture media containing propidium iodide (PI), a crude fluorescent marker of cell death in which more PI uptake indicates higher levels of cell death. Tissue was imaged 24 hours post injury for PI uptake. Tissue in all the injury groups showed an increase in PI uptake compared to tissue in the control condition. The EtOH group did not show an increase in PI uptake compared to the Control group. Following lower impact (50kD), there was no effect of EtOH on PI uptake at either dwell times. However, tissues in higher impact (100kD) groups that were exposed to EtOH showed an increase in PI uptake compared to their control injury counterparts at both the 0 second and 5 second dwell times. There was a sex difference (n= 186, 97 females) in both the cornu ammonis 1 (CA1) and cornu ammonis 3 (CA3) regions of the hippocampus, such that male tissue showed an increase in PI uptake compared to female tissue, but this was not found in the dentate gyrus. The findings of this study are preliminary and require future replication with the addition of immunohistochemical staining; however, they indicate that the models used offer a promising paradigm for further understanding of how EtOH use impact TBIs.

Title: Hippocampal vulnerability to hyperhomocysteinemia worsens mild traumatic brain injury pathological outcomes in rats

Authors: *F. TCHANTCHOU[1], C. MILLER[2], G. FISKUM[1];
[1]Anesthesiol., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]U.S Air Force Sch. of Aerospace Med., Wright-Patterson, OH

Abstract: Mild traumatic brain injury (mTBI) interpatient pathological variability hinders our ability to develop effective therapeutic agents. The accumulation of the non-proteinogenic amino acid homocysteine called hyperhomocysteinemia (HHCY) has substantial neurotoxic properties. HHCY can be caused by stress, aging, lifestyle, or genetic predisposition and is implicated in the pathogenesis or influence the pathological progression of several neurological disorders, including stroke. We recently reported on the detrimental impact of HHCY on mTBI cortical pathological outcomes. Here, we investigated the effects of pre-existing HHCY on TBI-associated hippocampal neuropathology and related behavioral deficits in rats. Hyperhomocysteinemic male Sprague Dawley rats (250-300g) were subjected to mTBI by controlled cortical impact (CCI) method under anesthesia with 3.5% isoflurane and body temperature maintained at 37°C. CCI was performed over the left parietal cortex with a 4 mm diameter piston, a magnetic impact of 5 m/s, and a penetration depth of 1.5 mm. Rats were assessed for working memory, euthanized on days 1, 7, or 30 post-surgery, and brain collected for histological and biochemical analyses. Statistical analysis was performed by one-way or repeated ANOVA with Tukey-Kramer post-test. There were 5-12 rats/group, and UMB IACUC approved the study. The assessment of the effect of HHCY on the oxidative stress marker nitrotyrosine found an 11-fold increase in nitrotyrosine positive cells in the dentate gyrus (DG) of HHCY-shams compared to normohomocysteinemic (NHCY)-shams ($p < 0.01$). Furthermore, there was also a 2.5-fold increase in nitrotyrosine positive cells in HHCY-CCI rats versus NHCY-CCI rats ($p < 0.01$). HHCY also caused a 35% reduction of occludin expression in the hippocampus of HHCY-CCI rats versus NHCY-CCI rats ($p < 0.05$). Changes in occludin expression were associated with Electron microscopy determined significant elongation and enlargement of the endothelial cell nucleus in HHCY-CCI rats. Significant neuronal cell loss was found in the ipsilateral and contralateral DG of HHCY-shams and HHCY-CCI rats compared to NHCY-CCI. There was also an increased expression or proteolysis of pro-apoptotic proteins BAX and α-ii spectrin parallel with decreased phosphorylation of cell survival-promoting proteins ERK and AKT in HHCY-CCI rats. These mTBI hippocampal pathological alterations were associated with significant deficits in working memory in HHCY-CCI versus NHCY-shams ($p < 0.01$). In summary, HHCY exacerbated working memory deficits in mTBI rats associated with HHCY-induced oxidative stress, BBB disruption, and neuronal cell loss.

Title: Death of hippocampal neurons after acute injury to the developing brain: neurotoxicity, neuroprotection, and delayed neuronal death

Authors: *T. BALENA[1], L. A. LAU[4], K. P. LILLIS[2], N. RAHMATI[5], K. J. STALEY[3];
[2]Neurol., [1]Massachusetts Gen. Hosp., Charlestown, MA; [3]Massachusetts Gen. Hosp., Boston, MA;
[4]Neurol. Res., MGH, Boston, MA; [5]Harvard Med. School/Massachusetts Gen. Hos, Boston, MA

Abstract: Neuronal death terminates with microglial engulfment of apoptotic neurons or necrotic neuronal debris. Many studies of neurotoxicity and neuroprotection are predicated on changes in the number of visibly dying neurons or their effluent cytoplasmic enzymes. This number is a function of three variables: the rate at which neurons enter the death process; the visibility of neurons during the process (which depends largely on the membrane permeability delimiting the rate of biomarker uptake); and the rate at which they exit the process via microglial engulfment. We describe our initial findings in an in vitro preparation in which this process can be studied.
We evaluated the death of neurons in a chronically epileptic in vitro preparation in which multiphoton microscopy could be performed over a period of several days. Organotypic hippocampal slice cultures were made from wild-type C57BL/6J mice on P6, incubated in vitro, and imaged serially.
We report the following sequence of events in delayed neuronal death following the substantial trauma involved in brain slice preparation. Neurons entering the death process quenched fluorescent proteins concurrent with elevated caspase activity. Due to their increased membrane permeability these neurons rapidly took up AM ester dyes, shrank, and exhibited evidence of DNA degradation. The membrane transporters of dying neurons remained active for as long as two weeks after entering this pathway. Throughout this period, the permeability of the neuronal membranes gradually increased, as evidenced by a progressive increase in $[Na^+]_i$, and eventually reached the point where polar dyes entered the nucleus. The death process ended with microglial engulfment. Neurons were also exposed to conditions in the developing nervous system considered to be neurotoxic (ethanol) or neuroprotective (kynurenate). Ethanol did not affect fluorescent protein quenching or PI positivity but did alter $[Na^+]_i$, whereas kynurenate did not affect $[Na^+]_i$ but did alter PI positivity and microglial engulfment.
Using serially imaged organotypic hippocampal slice cultures we found that the effects of widely accepted neurotoxic maneuvers such as perinatal ethanol exposure, as well as neuroprotective strategies such as seizure blockade, were primarily mediated by confounding effects on microglial activity and membrane permeability, with either no or opposing effects on healthy neurons identified by ongoing fluorescence emission of transgenic proteins. Accordingly, longitudinal assessment of neuronal health is an important additional assay for the assessment of acute neurotoxic and neuroprotective effects.

Title: Rna sequencing documents polyethylene glycol induced gene expression changes that accompany inhibition of Wallerian degeneration in a rat sciatic nerve injury model.

Authors: *S. N. WEISS[1], J. M. LEGATO[2], Y. LIU[3], C. N. VACCARO[3], H. HAKONARSON[3], R. J. BUONO[1], D. A. FULLER[2];
[1]Cooper Med. Sch. of Rowan Univ., Camden, NJ; [2]Bone and Joint Inst., Cooper Univ. Hosp., Camden, NJ; [3]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Application of polyethylene glycol (PEG) to a peripheral nerve injury at the time of primary neurorrhaphy is thought to prevent Wallerian degeneration via direct axolemma fusion. The exact mechanism of nerve fusion is unclear. This study aims to investigate the molecular basis of the protective effect of PEG during primary neurorrhaphy in traumatic peripheral nerve injuries via analysis of differential gene regulation in both the neural and muscular environments. Lewis rats underwent unilateral sciatic nerve transection with immediate primary repair. Subjects were randomly assigned to receive either PEG treatment or standard repair at the time of neurorrhaphy. Samples of the sciatic nerve and tibialis muscle were harvested at 24 hours and 4 weeks postoperatively. Total RNA was extracted and depleted of rRNA with subsequent preparation and sequencing of cDNA libraries using Illumina technology. Three tissue samples were used from separate animals per cohort (N=3). Differential gene expression was defined as a two-fold increase or decrease in PEG-treated subjects compared to controls. Correction for multiple testing was performed by the Benjamini method and p-values lower than 0.05 were considered significant. Gene Ontology (GO) Ingenuity Pathway Analysis (IPA) and the Kyoto Encyclopedia of Genes and Genomes (KEGG) were used for bioinformatics analyses. Our results demonstrate an inverse relationship in differential gene expression among tibialis muscle and sciatic nerve at both time points. At 24 hours, 1,480 genes pertaining mainly to inflammation are differentially regulated within the PEG-treated tibialis muscle compared to control, whereas no genes are differentially regulated within the PEG-treated sciatic nerve compared to control. Conversely, at 4 weeks, only 3 genes continue to be differentially regulated within the PEG-treated tibialis muscle compared to control, whereas 918 genes are differentially regulated within the PEG-treated sciatic nerve compared to control. These genes lead to the differential regulation of pathways supporting peripheral nervous system embryogenesis only expressed during fetal development. Our findings indicate that PEG application during primary neurorrhaphy leads to differential gene regulation in both the neural and muscular environment associated with inhibition of Wallerian degeneration. A more complete understanding of PEG activity may facilitate amplification of its effect through either systemic or focal treatments at the time of neurotmesis. A closer examination of these data is underway to identify key molecules or pathways that could be targeted to accelerate recovery after nerve damage.

Title: Implantation and control of wireless, battery free systems for peripheral nerve interfacing

Authors: *H. WANG[1,2], D. D'ANDREA[2], Y. CHOI[3], Y. BOURICHA[2], G. WICKERSON[3], H.-Y. AHN[3], H. GUO[3], Y. HUANG[3], M. S. SANDHU[2], S. W. JORDAN[1], J. A. ROGERS[3], C. K. FRANZ[2]; [1]NORTHWESTERN UNIVERSITY, Chicago, IL; [2]Shirley Ryan AbilityLab, Chicago, IL; [3]Northwestern Univ., Evanston, IL

Abstract: Peripheral nerve interfaces are frequently used in experimental neuroscience and regenerative medicine for a wide variety of applications. Such interfaces can be sensors, actuators, or both. Traditional methods of peripheral nerve interfacing must either tether to an external system, or rely on battery-power that limits the time frame for operation. With recent developments of wireless, battery-free and fully implantable peripheral nerve interfaces, a new class of devices can offer capabilities that match or exceed those of their wired or battery-powered precursors. Here we demonstrate methods to (i) surgically implant, and (ii) wirelessly power and control this system in adult rats. To highlight the versatility of our approach, we select as examples the sciatic and phrenic nerve models. We show how the peripheral nerve interface can evoke compound muscle action potentials, deliver a therapeutic electrical stimulation protocol, and incorporate a conduit for the repair of peripheral nerve injury.

Title: Intraneural topography of rat sciatic axons: Implications for polyethylene glycol fusion peripheral nerve repair.

Authors: *E. HIBBARD[1], D. R. SENGELAUB[2];
[1]Indiana Univ. Program in Neurosci., Bloomington, IN; [2]Indiana Univ. Bloomington, Bloomington, IN

Abstract: Peripheral nerve injuries are the most common type of nerve trauma, and results in the rapid degeneration of the distal nerve segment and immediate loss of motor and sensory function. Behavioral recovery is typically poor. We have been working with a novel repair technique using a plasmalemmal fusogen, polyethylene glycol (PEG), to re-fuse the membranes of severed axons. PEG-fusion repair allows for immediate re-innervation of distal targets, prevents axonal degeneration, and improves behavioral recovery. PEG-fusion of severed axons is non-specific, and we have previously reported that following injury and PEG-fusion in either single-cut or allograft repairs of the sciatic nerve, misconnections between spinal motoneurons and their distal targets were present, and more common in animals with allograft repairs. Surprisingly, appropriately paired proximal and distal motor axons were observed in all PEG-fused animals, regardless of repair type. We hypothesized that a topographic organization of axons contributing to the sciatic nerve could explain the incidence of appropriate connections. In this study, we traced the course of specific axon populations contributing to the sciatic nerve in young adult rats. Following intraneural injection of Fast Blue (2 µl; 2.5%) into the tibial branch, labeled axons were confined to a centralized location along the course of the sciatic nerve from the distal trifurcation to the proximal sciatic notch, and occupied approximately 53% of the transverse area of the nerve. Following intramuscular injection of cholera toxin-conjugated horseradish peroxidase (2 µl; 0.2%) into the anterior tibialis, labeled axons were confined to a discrete lateral position throughout the nerve, and occupied approximately 12% of the transverse area. In both cases, the relative locations of labeled axons were consistent bilaterally within animals, as well as across animals and sexes. Thus, the presence of specific axon populations that occupy a relatively consistent location throughout the nerve could underlie the appropriate re-established connectivity previously seen in PEG-fused animals. Misalignment of these axon populations through rotations of the original nerve stumps during repair, or sizing differences in allograft repairs, could account for the pattern of misconnection observed after PEG-fusion repair. Knowing the organization of axons within the sciatic nerve promotes accurate territory realignment during repair, therefore aiding in recovery outcomes.

Title: Biomechanical validation of a novel nerve coaptation device

Authors: *G. S. BENDALE[1], M. SONNTAG[2], I. P. CLEMENTS[2], J. E. ISAACS[1];
[1]Orthopedic Surgery, Virginia Commonwealth Univ., Richmond, VA; [2]Biocircuit Technologies, Atlanta, GA

Abstract: Despite decades of research, the functional outcomes of peripheral nerve repairs remain suboptimal. While significant focus has been placed on enhancing axon regeneration, the technical quality of the coaptation has received less attention. Although microsuture neurorrhaphy is the clinical standard, repair quality varies based on microsurgeon training and frequently suffers from poor alignment. Nerve Tape is a novel nerve coaptation device designed to precisely align and entubulate nerve ends for a mechanically secure repair. Epineurium-grabbing nitinol microhook arrays arranged in multiple rows are integrated within a thin and flexible biologic substrate. The resulting construct quickly and easily wraps around severed nerve ends for a mechanically precise and stable repair. Groups of small (1.5 to 2mm) and large (6.5 to 8mm) diameter cadaveric nerves were transected and repaired utilizing either microsutures or appropriately sized Nerve Tape devices. Free ends of the nerves were clamped onto a custom testing stage consisting of metal clamps, a force gauge and a motorized actuator. The repairs were distracted at a set rate of 40mm/min until failure while measuring and recording load forces. Both Nerve Tape groups exhibited markedly higher repairs strengths vs. the microsuture repair groups with significant difference ($p<.05$) observed in the small size nerve groups. Microsuture repairs tended to fail by rupture of the nerve while Nerve Tape failures resulted from microhook pull-out, without apparent damage to internal fascicles. Our novel coaptation device, Nerve Tape, provides mechanical repair strength comparable or superior to the clinical standard of microsuture neurorrhaphy.

Title: Design and development of a novel microhook-based device for suture-free repair of peripheral nerves

Authors: *M. SONNTAG[1], G. S. BENDALE[2], J. MCNEICE[1], J. ISAACS[2], I. CLEMENTS[1];
[1]BioCircuit Technologies, Atlanta, GA; [2]Sch. of Med., Virginia Commonwealth Univ., Richmond, VA

Abstract: Although microsuturing is the current clinical standard practice for coapting the ends of a transected nerve in direct repairs, it is fundamentally flawed due to the inherent complexity to control the depth of penetration and tension of microsutures. Even with specialized microsurgical training, this method remains challenging to perform, frequently resulting in lengthy operating times and suboptimal repair outcomes. Further drawbacks of suturing include induced focal tension and persistent tissue

reactivity. Entubulation strategies, including wraps and cuffs, offer technical and biological advantages over microsuturing alone, but conduit-assisted repairs are still limited by the need for microsuturing to mechanically fixate the device to the transected nerve. Here, we describe the engineering design, development, and optimization of a biologic wrap with integrated microhooks for suture-free coaptation of peripheral nerves. Microhook geometries and densities were varied to accommodate multiple size ranges of nerves. Materials were selected to closely match the native tissue to create a composite structure with floating microhook columns which by design provide radial conformability and axial strength. Handling experiments and biomechanical testing on cadaver nerves demonstrated excellent handling properties, ease of use, and coaptation strength while significantly reducing the complexity and repair time. Microhooks were demonstrated to bind firmly, safely, and reversibly to the superficial nerve tissue, providing a means to distribute tension evenly across an array of hooks while also controlling the penetration depth. These results demonstrate the promise of a mechanical, suture-free means of nerve coaptation, for quick, consistent, repairs of high technical quality.

Abstract: Exosomes possess therapeutic potential in various diseases including nerve injury. Exosomes are nanoscale vesicles released by many kinds of cells that contain a variety of RNAs and proteins to change the extracellular milieu and impact the functions of adjacent cells. We tested the effects of exosomes secreted by human bone marrow-derived mesenchymal stem cells on neuroregeneration of sciatic nerve after crush injury. TEMPO cellulose film, an oxidized form of micron cellulose with enhanced stability, was used to constrain exosomes at the injury site. Adult female rats received left sciatic nerve crush for 30 s. TEMPO cellulose film and/or exosomes were grafted directly onto the injured nerve segment. Locomotion and tactile allodynia were assessed at various days post-injury. Animals in the film+exosome and film only groups showed accelerated recovery of the ipsilateral hindlimb

locomotion and deterred development of tactile allodynia compared to the injury control group. Immunohistochemical studies showed better regeneration of axons in the film+exosome-treated group as well. No observable side effects were noticed. These results suggest that the combination of TEMPO cellulose and exosomes could be very useful to promote neuroregeneration induced by peripheral nerve trauma.

Abstract: The loss of a lower limb is accompanied by an increased difficulty to maintain balance and posture during walking. Gait instability caused by the lack of sensory feedback from the amputated limb and by neuromuscular adaptations to the use of the prosthesis leads to altered muscle synergies, gait asymmetry, and increased energy consumption during walking. To improve post-amputation therapies that restore sensory feedback, it is crucial to understand the neuromuscular mechanisms behind these motor output adaptations. The aim of this study was to investigate gait stability and dynamics in unilateral lower limb amputees. We focused on two aspects of postural control during gait, the stability of the pelvis and the dynamics of its stride-to-stride variability. Five unilateral transfemoral amputees and five age-matched able-bodied controls were recruited. Participants were instructed to walk for two minutes on a treadmill at 1, 2, and 3 km/h. Three-dimensional angular velocity and acceleration of the pelvis and of the upper and lower legs were recorded using a motion capture system based on inertial measurement units. Stride times were calculated by computing the time between peaks in the vertical acceleration of the intact/dominant foot. To assess pelvis stability, we computed the short-term (SLE) and long-term (LLE) Lyapunov exponents of its angular velocity, which quantifies the rate of divergence of neighboring trajectories in the state space, providing a measure of the stability of the postural system. The Entropic Half-Life (EnHL) method was used to measure the dynamics of the stride-to-stride fluctuations of the angular velocity of the pelvis. To avoid the influence of the periodicity of the gait cycle in the estimation of the stride-to-stride dynamics, a high-pass filter at the maximum frequency content of the angular velocity was applied previous to computing the EnHL. We compare outcomes of the SLE, LLE and the

EnHL between amputees and controls to explain how motor output adaptations caused by the amputation influence the complexity and stability of gait.

Title: The Role of Cerebrovascular Reactivity in Maintaining Cerebral Oxygenation during Hemodialysis

Authors: *W. T. RICHERSON[1], B. D. SCHMIT[2], D. F. WOLFGRAM[3];
[1]Biomed. Engin. Dept., Marquette Univ. Med. Col. of Wisconsin, Milwaukee, WI; [2]Dept. of Biomed. Engin., Marquette Univ. Dept. of Biomed. Engin., Milwaukee, WI; [3]Dept. of Med., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Background: Hemodialysis (HD) patients demonstrate significant white matter hyperintensity burden on neuroimaging which is thought to be a byproduct of cerebral ischemia. During hemodialysis treatments, patients are at risk for cerebral hypoperfusion due to rapid and large declines in systemic blood pressure. The risk for cerebral hypoperfusion may be greater if cerebrovascular reactivity is impaired. A recent study showed that HD patients have a decreased cerebrovascular reactivity (CVR) when measured by transcranial doppler ultrasound, even when compared to chronic kidney disease patients not receiving HD. We hypothesized that CVR combined with intradialytic blood pressure changes are associated with declines in cerebral oxygen saturation during HD. Study Methods: We collected demographic data, comorbidities, intradialytic measurements of blood pressure and cerebral oximetry, as well as resting state fMRI and anatomical MRI for participants on HD. CVR was determined using a resting state CVR pipeline developed to calculate regional CVR without a gas challenge. Regression analysis was used to examine the relationship between intradialytic oxygenation, intradialytic blood pressure changes and resting state CVR in different gray matter regions in the Harvard Oxford Brain Atlas.Results: MRIs were collected from 26 HD patients, mean age of 65.3 years old. CVR in the Anterior Cingulate Gyrus ($p=.0278$, $r^2=.186$) and Insular Cortex ($p=.026$, $r^2=.191$) regions negatively correlated with decline in intradialytic cerebral oxygenation. Multiple linear regression models using CVR and blood pressure as predictors of oxygenation drops demonstrated that the Anterior Cingulate Gyrus CVR and intradialytic systolic blood pressure changes were associated with oxygenation drops during HD ($p=.0075$, $r^2=0.346$). The Insular Cortex CVR and intradialytic systolic blood pressure changes were also associated with oxygenation decreases ($p=.0319$, $r^2=.259$). No other gray matter regions tested were significant and models using diastolic blood pressure changes and CVR were not

significant.Conclusions: We found significant relationships between resting state CVR measured in several different regions of the brain and decline in intradialytic cerebral oxygenation. In particular, CVR in the Anterior Cingulate Gyrus and systolic blood pressure changes explained about 35% of the variance in cerebral oxygenation deficits. This analysis shows that there is a relationship between the cerebral small vessels' ability to increase blood flow and cerebral oxygenation desaturation during HD.

Title: Improvements in flexion reflex modulation in complete SCI after combined transspinal stimulation and step training

Authors: M. O. ZAAYA[1], *T. S. PULVERENTI[1], **M. KNIKOU**[2];
[1]Dept. of Physical Therapy, CUNY Col. of Staten Island, Staten Island, NY; [2]The Grad. Ctr., City Univ. of New York, Staten Island, NY

Abstract: Spinal cord injury (SCI) severely impairs coordinated spinal reflex modulation and locomotor muscle activity and thus compromises walking ability and mobility. Locomotor training is a potent rehabilitation tool for stepping recovery that restores spinal reflex modulation and coordinated locomotor muscle activity. Excitingly, non-invasive spinal (termed here transspinal) stimulation may augment locomotor training benefits by enhancing the responsiveness of spinal locomotor networks to descending and sensory inputs that contribute to neurorecovery. Recent work has highlighted that higher frequency (e.g. > 100 Hz) spinal stimulation may be more advantageous than conventional spinal stimulation frequencies (5 to 40 Hz). Despite the therapeutic potential of interventions combining high-frequency transspinal stimulation and locomotor training little is known about the neurophysiological effects. Therefore, in this study we aimed to establish neurophysiological changes of spinal flexion reflexes following high frequency transspinal stimulation during robot assisted step training in individuals with chronic motor complete SCI. Four individuals with motor complete SCI received an average of 18 sessions of transspinal stimulation over the thoracolumbar region with a pulse train at 333 Hz during robotic assisted step training. Each session consisted of 60 min of walking, with an average of 240 stimulations delivered during each training session. Before and after the combined intervention, we measured the phase-dependent modulation of the long-latency tibialis anterior (TA) flexion reflex and transspinal evoked potentials(TEP) recorded from flexors and extensors during assisted stepping, and the TEP input-output recruitment curves at rest. The long-latency TA flexion reflex was depressed in all phases of the step cycle and the phase-dependent amplitude modulation of TEPs was altered during

assisted stepping, while spinal motor output based on TEP recruitment curves was increased after the combined intervention. This study shows that non-invasive high-frequency transspinal stimulation coupled with locomotor training depresses flexion reflex excitability and concomitantly increases motoneuron output over multiple spinal segments for both flexors and extensors in people with motor complete SCI. Our current findings support the use of transspinal stimulation to augment locomotor training induced neuroplasticity. However, combined interventions, such as transspinal stimulation and locomotor training, for rehabilitation of neurological disorders need to be systematically assessed.

Title: Inflammatory predictors of functional improvement following acute intermittent hypoxia in individuals with incomplete spinal cord injury

Authors: A. BARRY, R. BIBI, L. SIBLEY, W. Z. RYMER, A. DOMENIGHETTI, *M. SANDHU; Shirley Ryan AbilityLab, Chicago, IL

Abstract: An injury to the spinal cord (SCI) impairs motor control and mobility by disrupting the pathways between the brain and spinal cord. Current therapeutic strategies are mainly focused on improving preserved motor function, but they are ineffective. Acute intermittent hypoxia (AIH) is an emerging strategy to enhance neuroplasticity and recovery in SCI patients. It involves exposure to moderate levels of hypoxia (9% O_2), which has been shown to increase synaptic strength and motor neuron excitability in the animal models. AIH has been shown to be safe and effective for enhancing voluntary lower limb function in people with an incomplete SCI. In most published studies, about a third of individuals with SCI do not respond to AIH therapy. An increase in systemic inflammation, common among SCI patients, may be linked to some individuals not responding to AIH therapy. This study aimed to identify inflammatory or neuroplasticity biomarkers associated with responsiveness to AIH in individuals with chronic, incomplete SCI. In a randomized, double-blinded, placebo controlled study, ten subjects with incomplete SCI (ASIA C or D) visited the laboratory twice, at least a week apart, and received both AIH and sham AIH in a randomized manner. During AIH, the subjects were exposed to 15 60-second periods of hypoxia (9% O2) alternating with 60 seconds of normoxia (21% O2), for a total of 30 minutes. Sham AIH consisted of alternating exposures to normoxia. Maximal voluntary torque at the ankle joint was assessed prior to, and at 60 minutes post-AIH. We found 8 out of 10 patients responded to AIH as demonstrated by at least 10% increase in plantarflexion ankle strength. Ankle plantarflexion torque increased by 37.2 ± 11.1% following AIH, compared to 6.9 ± 3.8% change after sham AIH ($p < 0.05$ vs sham AIH). We measured plasma levels of pro-inflammatory markers IL-1β, IL-10, and TNF-α before and after AIH using enzyme-linked immunosorbent assays. In addition, plasma BDNF

concentrations were quantified. The levels of IL-1β and IL-10 were too low to be detected. Our preliminary data suggest a moderate association ($R^2 = 0.57$) between TNF-α levels and responsiveness to AIH therapy (i.e. change in plantarflexion strength after AIH). The relationship between baseline levels of plasma BDNF and strength change after AIH was weak ($R^2 = 0.15$). Consistent with previously published literature, our study found that a single session of AIH significantly improved a participant's ability to generate strength. Further, ongoing experiments indicate that inflammatory biomarker analyses may be used to target SCI patients who are most likely to respond to AIH therapies.

Title: Assessment of rat lower limb responses to combined epidural spinal cord and neuromuscular electrical stimulation for movement control

Authors: *D. SONG[1], M. C. TRESCH[1,3,2];
[1]Biomed. Engin., [2]Physiol., Northwestern Univ., Chicago, IL; [3]ShirleyRyan Ability Lab., Chicago, IL

Abstract: Electrical stimulation techniques such as epidural spinal cord stimulation (ESS) or neuromuscular electrical stimulation (NMES) are two commonly used approaches to restore lower limb movements after paralysis from spinal cord injury (SCI). However, using both techniques simultaneously has not been explored. A combined approach could potentially generate several complementary benefits. ESS can produce generic extension or flexion type movements, but granular control of these actions is difficult. Neuromuscular stimulation (NMES), on the other hand, can evoke more fine-tuned movements by selective muscle stimulation. Additionally, the fast fatigue motor units that are typically recruited by NMES may complement the more fatigue resistant motor units recruited by ESS potentially producing more energetically efficient movements. To develop control schemes using a combined ESS and NMES approach, we need to understand whether simultaneous stimulation produces predictable responses. One common assumption of NMES controllers is that forces produced by simultaneous stimulation of multiple muscles can be predicted by the forces produced by each muscle individually. Whether this holds true for combined ESS and NMES stimulation is unknown. To assess this, we evoked various hindlimb forces in anesthetized rats (n = 4) using different pairs of ESS and NMES inputs. A variety of current amplitudes as well as spinal cord and muscle stimulation sites were tested. We found that the average relative force prediction errors for combined ESS and NMES trials was higher than force prediction errors for muscle costimulation trials (paired t test, p = .013). This suggests that ESS and NMES, unlike muscle costimulation, interacts nonlinearly and may produce larger or smaller than expected forces.

Characterizing these interactions will be necessary to develop movement control schemes in spinal cord injured rats.

Abstract: As an alternative to traditional exercise, passive leg cycling (PLC) is often utilized with human patients with limited lower-limb function. Despite its widespread application, cardiovascular benefits of PLC reported in the literature are inconsistent. Passive hindlimb cycling (PHLC) in rodent models of SCI, however, has been shown to dramatically improve multiple indices of cardiac function, revealing an obvious and interesting discrepancy between the effects of PLC in humans and PHLC in rats. The mechanisms underlying the robust post-cycling improvements seen in rats are poorly understood. One potential mechanism is increased return of peripheral blood to the heart through spinal reflex activation of hindlimb muscles and the resulting effects of the skeletal muscle pump. Movement frequency directly influences the rate of muscle length change, which in turn may alter muscle activation through spinal reflexes and ultimately the force applied to the pedals. We hypothesized that stretch reflex pathways will be activated during PHLC causing activation of the muscles during their lengthening phase and resulting in pedal forces of detectable magnitude. To validate these hypotheses, we have developed a motorized rodent cycling ergometer that incorporates an embedded uniaxial force sensor in one pedal and a corresponding instrumentation system that allows the synchronization of recorded hindlimb kinematics and pedal reaction forces. Previous studies in our lab investigating rats with contusion and transection injuries demonstrated that a low frequency component of the pedal forces was associated with the motion of the pedal, while a high frequency component was presumably associated to spasticity. To differentiate between the low and high components of pedal forces, we created a frequency-domain method for separating forces developed with the motion of the pedal and the remaining high-frequency forces. Preliminary results from rats withT2-35 g-cm contusion injuries (n=5) cycled at cadences of 5, 10, 15, 30, 45, and 60 RPM suggest that low frequency component of the pedal forces increases for movement frequencies ranging from 30 RPM to 60 RPM, with the magnitude of this component typically ranging from10 to 30 percent body weight. Conversely, high frequency component of the pedal force was larger for movement frequencies below 30 RPM while the limb is in extension, with the magnitude of this component can range from 20 to over 100 percent body weight. Additionally, we are currently investigating how both components of this force influence instantaneous blood pressure and heart rate responses during PHLC using implantable telemetry devices.

Title: Respiratory Training with Intermittent Hypercapnia to Enhances Supraspinal and Interneuronal Plasticity After Cervical Spinal Cord Injury

Authors: M. L. RANDELMAN[1], L. ZHOLUDEVA[2], T. FORTINO[1], H. KING[1], D. BILAS[1], M. LANE[1];

Abstract: Cervical spinal cord injury (SCI) frequently leads to severe respiratory dysfunction due to damage of the phrenic circuit responsible for diaphragm innervation - the primary muscle of respiration. While some spontaneous functional plasticity occurs following cervical SCI, the extent is limited, and respiratory deficits persist. The goal of this ongoing research is to test whether a novel activity-based therapy – daily acute intermittent hypercapnia (IHc) – can enhance respiratory plasticity and diaphragm recovery sub-acutely (1wk) after mid-cervical contusion injury in the adult female rat. We hypothesized that rehabilitation with this respiratory-specific therapy will stimulate anatomical and functional phrenic plasticity and improve diaphragm function post-SCI. Anatomical plasticity following injury and treatment was investigated using anterograde tracing of descending respiratory axons with biotin dextran amine (BDA) and transsynaptic retrograde tracing with pseudorabies virus (PRV) to label phrenic circuitry within the cervical spinal cord. Immunohistochemistry was used to assess changes in phrenic interneuron integration and supraspinal (serotonergic and bulbospinal respiratory axons) onto phrenic circuitry. Functional plasticity and respiratory recovery following IHc training were assessed with terminal diaphragm electromyography (dEMG). Hypercapnia trained animals showed a greater density of serotonergic and bulbospinal respiratory axons within denervated phrenic circuitry below the lesion epicenter compared with air-treated control animals. It was also found that four weeks of IHc training resulted in a greater recruitment of interneurons - including cholinergic interneurons - into ipsilateral and contralateral phrenic circuitry when compared to controls. Diaphragm EMGs of the IHc trained animals resulted in a significant improvement in diaphragm inspiratory amplitude and response to a respiratory challenge. Correlating anatomy and function changes revealed a significant, positive correlation between the number of phrenic interneurons that were connected to the phrenic network and recovered diaphragm function. These results, therefore, suggest that IHc can promote plasticity within the phrenic network and improve breathing following cervical SCI.

Title: Acute Intermittent Hypoxia and Respiratory Strength Training to Improve Respiratory Function in Individuals with Chronic Spinal Cord Injury: Preliminary Outcomes

Authors: *A. K. VOSE[1], J. WELCH[1], J. NAIR[1], K. CAVKA[2], L. DEMARK[2], G. BRUNETTI[2], C. WAUNEKA[2], H. SNYDER[2], G. MITCHELL[1], E. FOX[1];
[1]Univ. of Florida, Gainesville, FL; [2]Brooks Rehabil., Jacksonville, FL

Abstract: Background: Spinal cord injury (SCI) disrupts neural pathways to respiratory motor neurons, causing paralysis and decreased breathing capacity. Since respiratory impairment is a major cause of illness and death in SCI, it is critical to devise new strategies to restore breathing function. Acute intermittent hypoxia (AIH) is a promising therapeutic modality that elicits spinal synaptic plasticity, improving breathing in animal models of SCI. AIH also elicits plasticity in limb motor systems in both rodent models and humans with chronic SCI, where functional gains are greatest when paired with task specific training. The impact of similar combinatorial treatments on breathing ability is unknown. Here, we report breathing outcomes in four adults with chronic SCI who received AIH and task specific training (respiratory strength training; RST).
Subjects: Four males with chronic SCI (36.3 ± 18.5 yrs of age; 1.5-15 yrs post-SCI; 3 cervical, 1 thoracic injury; C4-T6 AIS A-D). Respiratory function was 39% ± 10% of the age predicted normative function for expiratory pressure generation and 88% ± 23% of normative values for inspiratory function.
Methods: Participants completed two random ordered 5-day protocols AIH+RST and Sham, 3+ weeks apart. AIH consisted of 15, 1-minute episodes of breathing a hypoxic gas mixture (9% oxygen), interspersed with 1.5-minute episodes breathing room air (21% oxygen). Thirty minutes after AIH, RST involved both inspiratory and expiratory training; 4 sets of 6-12 breaths with the pressure threshold device set to 80% of each individual's maximum. Sham treatments replicated AIH but used room air. Maximal inspiratory pressure (MIP), maximal expiratory pressure (MEP), and forced vital capacity (FVC) were assessed prior to and 1-day post-intervention.
Results: MIP increased 9% and MEP increased 5% 1 day after AIH+RST but not after Sham. MIP (AIH+RST: pre 118 ± 24 cmH20, post 129 ± 27 cmH20; Sham: pre 123 ± 36 cmH20, post 123 ± 36 cmH20). MEP (AIH+RST: pre 77 ± 18 cmH20, post 81 ± 21 cmH20; Sham: pre 74 ± 23 cmH20, post 74 ± 17 cmH20). No changes in FVC were evident (AIH+RST: pre 4.1 ± 1.0L, post 4.1 ± 1.1L; Sham: pre 4.15 ± 1.1L, post 4.2 ± 1.2L) given ≤1% change pre/post. Following AIH+RST, MIP increased 6-21% in 3/4 participants with a 1% decrease in 1 participant, and MEP increased 1-11% in 3/4 participants with a 6% decrease in 1 participant.
Conclusions: Preliminary outcomes suggest AIH+RST may improve respiratory function in adults with SCI. Next steps will be to test in more individuals and compare this combinatorial treatment to AIH and RST alone to determine if effects are synergistic. Research examining individual response variations is also warranted.

Neurosciences, Ctr. Hospitalier Universitaire Vaudois (CHUV), Lausanne, Switzerland; [6]Univ. of Bordeaux, Bordeaux, Bordeaux, France

Abstract: We aim to establish a neuroprosthetic bridge between the sensorimotor cortex and the dormant neurons located in the spinal cord that are deprived of brain inputs due to a spinal cord injury (SCI). These dormant neurons located in the lumbosacral spinal cord can be reactivated by electrical epidural stimulation (EES) of the spinal cord. This digital bridge, also called a brain-spine interface, aims to restore mobility and promote neurological recovery in people who are chronically paralyzed.
We determined the potential and limitations of electroencephalography (EEG) and electrocorticography (ECoG) signals to control a brain-spine interface. We developed a computational framework for decoding gait events from features using high-density EEG or ECoG recordings. Our EEG framework is based on the accurate source localization to extract time-frequency features from sensorimotor cortical areas. This analysis was conducted on signals recorded from 6 healthy participants, 6 participants with SCI with different injury classification (ASI A-D) and two participants with chronic pain who were implanted with ECoG electrodes over the sensorimotor cortex as part of paint treatment. The people with SCI were implanted with neurostimulation system to reactivate the lumbar spinal cord (EES) as part of an ongoing "STIMO" clinical trial.
In EEG signals, we identified beta band modulations time-locked with gait events during different walking tasks. The average decoding accuracy between right and left stepping achieved using these features in healthy volunteers was 64% SD 7.3. In people with SCI this performance was reduced despite state-of-the-art denoising methods. However, decoding performance was significantly higher (90% SD12.2) in a more controlled, single-joint movement task. Therefore we enabled 4 people with SCI to control their EES spinal stimulation using these EEG features while seated. The output probability of the decoder was mapped to the EES amplitude. This brain-spine interface allowed all people with SCI to regain graded control over single joint movements. Our analysis of ECoG signals reaffirmed the beta band modulations previously found in EEG signals, additionally we identified features in the gamma band

which substantially increased the accuracy of decoding of gait events rising to 90% on average. We demonstrated the feasibility of EEG-based decoders for lower-limb neurorehabilitation therapies in a controlled environment but also highlighted the limitations of this approach to operate a gait prosthesis. Our results indicate that epidural ECoG may provide a good trade-off in between invasiveness and efficacy when controlling gait prostheses.

Title: Impacts of epidural spatial stimulation effects on recovery and spasticity in combined bionic and biological SCI therapies

Authors: *A. P. BORISYUK, K. J. DOUGHERTY, S. F. GISZTER;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Spinal cord injury (SCI) is a debilitating condition without a cure. Our lab has previously demonstrated enhanced locomotor outcomes in rats with complete T9/10 SCI after combining viral BDNF treatment and pelvis-based robot training. Combining epidural stimulation (ES) with viral BDNF and pelvis-based rehabilitation further enhanced these outcomes. Interestingly, a combined treatment with robot rehabilitation at the ankle and ES didn't result in outcomes to levels as high as viral BDNF treatment with pelvic-based robot weight-supported treadmill training alone (no ES). Relative to the viral BDNF effects, our prior work has demonstrated the possibility of a critical period during the initial two weeks of training where ES likely helps prevent development of some spasticity side effects of the viral BDNF treatment on motor function, in the experiments using pelvic centered rehab. These cumulative side effects can result in the eventual collapse of gained motor function in ~40% of rats. This collapse was completely prevented when broad current spread ES centered at L2 and S1 was combined with viral BDNF and pelvic-based robot training. We hypothesized that the combined treatment of viral BDNF with localized ES and pelvic based robot training would result in improvement in weight-supported stepping throughout therapy due to the better selectivity. The current study aims to measure the changes in modularity and compare the improvement in functional outcomes in rats with complete SCI through rehab combining viral BDNF, pelvic-based training, and (a) broad versus (b) local ES. Our data so far show that the more focused local ES does not prevent spastic collapse later in BDNF treated rats if used alone. In

contrast to the broad current spread ES, more focused current delivery at L2 and S1 did not mitigate spastic collapse. While our best combination treatment utilized broad ES (broad ES centered on L2 and S1 spinal segments), we next aim to improve the therapy with the combined use of intense but more local ES in parallel to the broad ES current delivery, most intensely stimulating only segments containing central pattern generators for locomotion and extensor support by (focusing intense current locally to L2 and S1, in parallel with a broader delivery to avoid the spastic effects). We hypothesize that modularity analysis of the hindlimb muscles will help reveal the patterns of change during an initial period of reorganization of spinal circuit and then a subsequent stabilization in the different ES and rehabilitation treatments.

Title: Electrical stimulation of intact spinal cord activates broader range of muscles than anatomical motor pool

Authors: *J. PATTERSON[1], A. A. MAHROUS[2], M. K. CHARDON[2], M. D. JOHNSON[4], J. MILLER[1], C. HECKMAN[3];
[2]Physiol., [3]Dept. of Physiol., [1]Northwestern Univ., Chicago, IL; [4]Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Background: Direct electrical spinal cord stimulation shows promise as a therapy for patients with motor impairments after spinal cord injury. The anatomical location of the motor pools for muscles used in locomotion has been identified. However, the map of surface electrical stimulation of the spinal cord and its functional output to different muscles is still relatively unknown and represents a significant gap in knowledge in spinal cord injury rehabilitation. Objective: Our goal was to determine what hindlimb muscles are activated by surface electrical stimulation of the lumbar spinal cord of the cat. Methods: In 8 decerebrate cats with intact spinal cords, eleven locations were stimulated starting from the caudal portion of lumbar segment L3 to the border of sacral segments S1 and S2. Stimulation was done 15 times at each location at 1 Hz with stimulation amplitudes high enough to evoke muscle responses without causing tissue injury. EMG was measured in 9 hindlimb muscles: soleus, tibialis anterior, lateral gastrocnemius, sartorius, medial gastrocnemius, vastus lateralis, biceps femoris posterior, gluteus medius, and pectineus. EMG peak to peak amplitude of the short-latency response (presumably monosynaptic) was used to assess muscle response. Results: For most muscles, the most effective stimulus was at or near the center of the anatomical location of the motor pool. However, some muscles, including the sartorius, and medial and lateral gastrocnemius, were strongly activated outside of their motor pools. Additionally, stimulation at most locations activated multiple muscles with diverse, even antagonistic functions.

Conclusion: These results suggest that surface electrical stimulation of the spinal cord can activate some muscles outside the anatomical location of their motor pools. This broader range of muscles activated by stimulation likely further expands following spinal cord injury. This indicates that surface spinal stimulation used for treatment of spinal cord injury is unlikely to generate specific movement patterns, and thus must be approached with a more holistic understanding of the broad array of muscles and even their antagonists that may be activated by specific stimulation.

Title: Spinal stimulation for motor rehabilitation differentially modulates nociceptive and non-nociceptive sensory transmission

Authors: *M. F. BANDRES[1,2], J. L. GOMES[2], J. G. MCPHERSON[2,3,4,5,1];
[1]Biomed. Engin., Washington Univ. in St. Louis, St. Louis, MO; [2]Program in Physical Therapy, [3]Dept. of Anesthesiol., [4]Washington Univ. Pain Ctr., [5]Program in Neurosciences, Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Spinal cord injury (SCI) leads to radical physiological changes at and below the lesion. SCI usually results in dysregulation of spinal reflexes, reduction of voluntary motor output below the lesion, and neuropathic pain. Spinal stimulation-based therapies intended to enhance motor rehabilitation after SCI often fail to consider modulation of neural transmission in spinal sensory pathways, including pathways integral to SCI-related neuropathic pain. Here, we used spike train analyses to characterize the effects of intraspinal microstimulation of the ventral horn (vISMS) on the firing dynamics of sensory neurons (e.g., nociceptive specific, NS; and wide dynamic range, WDR) in the dorsal horns *in vivo*. All experiments were approved by the Institutional Animal Care and Usage Committees of Florida International University and Washington University in St. Louis and were conducted in adult male Sprague-Dawley rats under urethane anesthesia (n=6). After T13-L2 laminectomy, microelectrode arrays were implanted at the L5 dorsal root entry zone. Electrode locations for spinal stimulation targeted the ventral horn region, whereas their locations for quantifying neural transmission in sensory pathways spanned the superficial and deep dorsal horns. Prior to, during, and after vISMS, we mechanically stimulated the L5 dermatome by applying controlled forces ranging from non-painful to painful. Primary outcome measures included the number of sensory neurons in the dorsal horns, changes in the temporal profile of their neural activity (assessed via peristimulus time histograms of single-neuron spike times), and changes in their temporal features (e.g., mean frequency, and mean intra-burst frequency). The

threshold for detecting a change after vISMS was ≥20% difference in a given parameter.
We found that even short periods of vISMS (≤10min) could modulate neural transmission in pain and non-pain-related pathways of the dorsal horn. Our results showed that 45% of NS (n=60) and 29% of WDR (n=452) neurons reduced their mean intra-burst frequency (number of spikes during painful mechanical stimulation of the dermatome over the duration of the stimulus) after vISMS, whereas 18% of NS and 23% of WDR neurons increased their mean intra-burst frequency after vISMS.
Our results suggest that vISMS paradigms may reduce transmission in spinal pain pathways while continuing to enhance spinal motor output. Future work is required to elucidate potential mechanisms behind the modulation of spinal pain transmission by vISMS, and to optimize the therapeutic effects of vISMS in motor output and pain transmission.

Title: Assessment of spinal cord stimulation-based modulation in the spontaneous hyperexcitability model of neuropathic pain

Authors: *S. IDLETT-ALI[1], M. SAWCHUK[2], S. HOCHMAN[2];
[1]Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [2]Physiol., Emory Univ., Atlanta, GA

Abstract: Spinal cord stimulation (SCS) is used clinically for relief of chronic neuropathic pain. The gate control theory presents a theoretical framework of the therapy's mechanism of action associated with Aβ sensory afferent recruitment, but the true mechanisms remain unclear. Preclinical studies frequently investigate mechanisms leading to modulation of stimulus-evoked pain, despite the primary function of therapeutic SCS being modulation of chronic, stimulus-independent pain. Here, we utilized an *ex vivo* spinal cord-dorsal root ganglia preparation to generate a model of spontaneous hyperexcitability in sensory nociceptive circuits using 4-aminopyridine (4-AP). Applied 4-AP selectively increased Fos immunolabeling in superficial dorsal horn neurons - consistent with selective recruitment of pain circuitry (n=2). We characterized spontaneous activity by recording from sensory afferents in lumbar dorsal roots (DR), Lissauer's tract (LT), and neurons in the superficial dorsal horn (DH). 4-AP led to the emergence of spontaneous activity manifesting as rhythmic dorsal root potentials with superimposed burst firing, and coincident rhythmic field potentials with superimposed spikes in LT and the subjacent DH (n=4). To investigate modulation of spontaneous nociceptive activity by gate control theory mechanisms we assessed the effects of clinically analogous SCS at dorsal column (DC) and dorsal root (DR) recruitment threshold intensities. We observed that 50 Hz SCS at DC threshold intensity depressed spiking activity in LT/DH during SCS, but it could not modulate field potentials or produce prolonged modulation following cessation of stimulation (n=4). These results demonstrate the utility of a 4-AP model of spontaneous

hyperexcitability and the limitations of presumed selective Aβ recruitment as underlying SCS modulation of spontaneous nociceptive activity.

Title: Spinal cord stimulation (SCS) evokes irregular activity from dorsal column (DC) axons

Authors: *N. D. TITUS[1], T. C. ZHANG[2], R. ESTELLER[2], W. M. GRILL[1];
[1]Duke Univ., Durham, NC; [2]Boston Scientific, Valencia, CA

Abstract: Conventional tonic SCS generates pain relief by activating DC axons but also generates concomitant paresthesias. Recent SCS paradigms reduce the amplitude of stimulation to subperception amplitudes to avoid these uncomfortable paresthesias, but the mechanisms underlying pain relief with these approaches remains unclear. We hypothesized that low-amplitude, low-frequency SCS activates DC axons at frequencies less than the SCS frequency, thereby producing asynchronous spiking. We tested this hypothesis *in vivo* by placing a bipolar electrode paddle under the T10-T11 vertebrae and recording from single DC axons underneath the T12-L1 vertebrae in urethane anaesthetized male rats. We recorded the responses of 24 axons across 8 rats to symmetric biphasic 90 Hz SCS at amplitudes just above each axon's activation threshold (AT). Stimulation amplitudes from 1-1.4x AT resulted in axonal spiking at frequencies <90 Hz. Stimulation at 1-1.1x AT evoked spikes from approximately 25-65% of axons per pulse, and stimulation at 1.1-1.2x AT evoked spikes from approximately 65-90% of axons per pulse. On average, full axon entrainment to the stimulation frequency, i.e., following at 90 Hz, occurred at 1.21x AT, and no axons were entrained by stimulation <1.1x AT. Additionally, we found that axonal spiking at <90 Hz generally consisted of "bursts" of spikes at 90 Hz interspersed with short gaps of quiescence with varying length, in contrast to our expectation that responses would be regular firing at some divisor of 90 Hz (e.g. 10, 30, or 45 Hz). The "bursting" responses were generally characterized by two dominant frequencies: the intraburst frequency equal to the stimulation frequency and the gap frequency, which defined the interval between bursts (typically 1-8 stimulation pulses). The number of spikes per burst varied greatly from a few spikes to hundreds. Increasing or decreasing the SCS amplitude increased or decreased, respectively, both the burst length and gap frequency, but did not affect the intraburst frequency. These results demonstrate that amplitudes of SCS just above AT can generate axon spiking at frequencies less than the stimulation frequency and confirmed that low-amplitude, low-frequency stimulation produced asynchronous axonal responses. Additionally, low-amplitude, tonic SCS can evoke "bursting" patterns from DC axons. The asynchronous and bursting nature of axonal responses to low-amplitude, low-frequency SCS may help to determine the mechanism through which sub-perception SCS paradigms produce analgesia without generating paresthesia.

Title: Antiallodynic effect of α-lipoic acid is associated with the reduction of the integrated stress response in a model of neuropathic pain in mice.

Authors: *S. MUÑOZ-LOMBARDINI[1], P. BARRAGAN-IGLESIAS[2], V. GRANADOS-SOTO[1]; [1]Dept. De Farmacobiología, CINVESTAV, Mexico City, Mexico; [2]Dept. of Physiol. and Pharmacol., Univ. Autónoma de Aguascalientes, Aguascalientes, Mexico

Abstract: Painful diabetic neuropathy is a complication generated by chronic hyperglycemia, a condition of patients with Diabetes mellitus. Diabetic patients with pain have elevated concentrations of plasma methylglyoxal (≥600 nM). By itself, methylglyoxal (MGO) generates mechanical hypersensitivity by the activation of the integrated stress response (ISR) in mouse dorsal root ganglion (DRG) neurons. Preclinical pain models and clinical trials have shown that α-lipoic acid (ALA) reduces mechanical hypersensitivity in diabetic rodents and humans, respectively. Interestingly, ALA reduces the phosphorylation of eukaryotic initiation factor 2α (eIF2α) (main marker of ISR activation) in cell cultures pretreated with high doses of glutamate or other drugs that activate ISR. However, the effect of ALA on the ISR in tissues involved in pain transmission is unknown. The purpose of this study was to investigate the effects of ALA on tactile hypersensitivity and phosphorylation of eIF2α in DRG and spinal cord in MGO-induced model of neuropathic pain in mice. Tactile allodynia was assessed with Von Frey filaments and phosphorylation of eIF2α was determined by western blotting. Intraplantar (0.72 [0.4], 7.2 [4], 72 [40], and 720 [400] ng (μM) or intraperitoneal injection (2 mg/kg) of MGO induced tactile allodynia in female and male Swiss Webster mice. MGO generated tactile hypersensitivity in female mice starting the first hour post-administration and returning to baseline on different days depending on the dose. Oral (100-300 mg/kg) and intraperitoneal (5.6-30 mg/kg) administration of ALA, but not vehicle,

partially reversed MGO-induced tactile allodynia in female mice. Intraperitoneal administration of ALA (10 mg/kg) produced a similar effect in male and female mice on MGO-induced neuropathy. ALA (10 mg/kg) had no effect *per se.* These results suggest that the antiallodynic effect of ALA is associated with the mechanisms that generate the pronociceptive effects of MGO in mice. Accordingly, MGO enhanced phosphorylation of eIF2α, while ALA blocked MGO-induced effects on eIF2α at DRG but not spinal cord. Data suggest that antiallodynic effect of ALA is associated with a reduced phosphorylation of eIF2α in peripheral sensory neurons.

Title: Electrophysiological effects of dorsal root ganglion stimulation on C-type neurons

Authors: *A. S. JHAND[1,3], R. D. GRAHAM[1,3], S. F. LEMPKA[1,3,2];
[1]Dept. of Biomed. Engin., [2]Dept. of Anesthesiol., Univ. of Michigan, Ann Arbor, MI; [3]Biointerfaces institute, Ann Arbor, MI

Abstract: Dorsal root ganglion stimulation (DRGS) has shown promise for managing chronic pain, but fails to provide pain relief in some patients. We do not understand the mechanisms of action of DRGS, preventing us from optimizing the outcomes of this therapy. Low-pass filtering has been observed at the bifurcation (T-junction) of C-type dorsal root ganglion (DRG) neurons, preventing some action potentials (APs) in high frequency trains from propagating into the central axon from the periphery. Animal models have shown that this filtering ability is diminished in chronic pain states. It has been hypothesized that DRGS may restore this low-pass filtering ability by modulating C-type neuron activity, but computational and experimental studies have reported conflicting findings on the activation of C-neurons during DRGS. Therefore, we developed a computer model to investigate the possible biophysical mechanisms of DRGS-induced C-neuron activation and low-pass filtering at the T-junction.
We constructed a three-dimensional finite element method (FEM) model of a human L5 DRG using published data from experimental and cadaver studies. We developed a multi-compartment model of a nonmyelinated C-type neuron. The model included Hodgkin-Huxley style representations of voltage-gated sodium (Nav1.7, Nav1.8, Nav.19), potassium (KDR, KA, KCNQ), and calcium (L-type) channels. We also included a small-conductance calcium-dependent potassium channel.
The C-type neuron model reproduced previously published *in vitro* somatic calcium traces (amplitude and decay time). The model also produced following frequencies (i.e., the maximal frequency at which all pulses in an afferent train propagate into the central axon) in the range observed experimentally. We then

coupled the multi-compartment C-type neuron model to the FEM model of DRGS to simulate the effect of DRGS on unmyelinated C-type neurons. Activation thresholds (i.e., the stimulation amplitude needed to induce an AP) of this novel C-type neuron model were in the range observed in previous computer modeling studies.
We are currently investigating the mechanisms by which DRGS may augment the low-pass filtering behavior at the T-junction and the effects of cell morphology and stimulation parameters on C-type neuron dynamics during DRGS. These results may provide further insights into the mechanisms by which DRGS produces pain relief. A clear understanding of the mechanisms of action of DRGS will help to optimize the therapy to improve patient outcomes.

Title: Multidimensional chronic neuropathic pain phenotypes after traumatic brain injury

Authors: *L. E. ROBAYO RIOFRIO[1,2], V. GOVIND[3], E. R. FELIX[4], L. FLEMING[5], R. VASTANO[5], E. WIDERSTROM-NOGA[5,1,2];
[1]Neurosci. Grad. Program, [2]The Miami Project to Cure Paralysis, [3]Dept. of Radiology, [4]Dept. of Physical Med. and Rehabil., [5]Dept. of Neurolog. Surgery, Univ. of Miami, Miami, FL

Abstract: Chronic pain is a debilitating condition that affects more than 50% of people following traumatic brain injury (TBI), yet effective treatment is still lacking. Characterizing pain phenotypes may lead to a better understanding of underlying pain mechanisms and contribute to developing effective treatment approaches for TBI-related chronic pain. Thus, in the present study, we 1) evaluated up to three different pains in individuals with TBI-related chronic pain (N = 25, males = 14, females = 11), 2) identified neuropathic pain phenotypes in nineteen (N = 19) of these participants, based on neuropathic pain symptom inventory (NPSI) scores, and 3) compared the phenotypes on somatosensory and psychological function, and psychosocial impact of pain. Our results showed that individuals with TBI-related chronic pain experienced multiple simultaneous pains characterized by nociceptive and neuropathic pain symptoms. A two-step cluster analysis indicated two pain phenotypes: high neuropathic

pain symptom severity (HNP, N = 11) and low neuropathic pain symptom severity (LNP, N = 8). The HNP phenotype experienced significantly more severe pressing, paroxysmal, evoked pain, and paresthesia/dysesthesia than the LNP phenotype. Regarding somatosensory function, assessed by quantitative sensory testing (QST), the HNP phenotype exhibited cold hyperalgesia and vibration hypoesthesia on the forehead, possibly due to spinal or supraspinal sensitization, reduced inhibition, or deafferentation. In contrast, the LNP phenotype exhibited pressure hypoalgesia on the right medial calf suggesting neuronal dysfunction. These findings indicate an altered somatosensory function in both phenotypes compared to healthy, pain-free individuals. In addition, the HNP phenotype scored significantly higher on overall pain severity ($t(1,17) = 4.14$; $p = 0.001$), post-traumatic stress disorder ($t(1,17) = 3.66$; $p = 0.002$), anxiety ($t(1,17) = 4.28$; $p = 0.001$), depression ($t(1,17) = 4.01$; $p = 0.001$), and affective distress ($t(1,17) = 4.14$; $p = 0.001$) than the LNP phenotype. These results indicate that more severe neuropathic pain symptoms are associated with greater somatosensory alteration, psychological dysfunction, and affective distress that negatively impact the quality of life after TBI. Collectively, our findings further the understanding of pain phenotypes associated with TBI-related chronic pain. Future work is required to fully characterize the underlying mechanisms of this condition and ultimately develop phenotype-based treatment approaches.

Title: Disrupted population coding in the prefrontal cortex underlies pain aversion

Authors: A. LI[1,5], Y. LIU[1], Q. ZHANG[1,5], I. FRIESNER[1,5], ***H. JEE**[1], Z. S. CHEN[5,2,3,4], J. WANG[1,5,2,4]; [1]Dept. of Anesthesiology, Perioperative Care, and Pain Med., [2]Dept. of Neurosci. and Physiol., [3]Dept. of Psychiatry, [4]Neurosci. Inst., New York Univ. Grossman Sch. of Med., New York, NY; [5]Interdisciplinary Pain Res. Program, New York Univ. Langone Hlth., New York, NY

Abstract: The prefrontal cortex (PFC) regulates a wide range of sensory experiences, and recent studies indicate that neurons in the PFC can increase their firing rates in response to noxious stimuli. Chronic pain is known to impair the endogenous neural response to these noxious inputs, leading to enhanced pain aversion. However, it remains unknown how nociceptive responses in the cortex are processed at the population level, and whether such processes are disrupted by chronic pain. We, therefore, sought to investigate whether the PFC utilizes population coding to process pain information, and if so, how chronic pain affects this coding scheme. Using *in vivo* endoscopic calcium imaging, we tracked calcium activity in the prelimbic PFC (PL-PFC) of freely-behaving rats before and after delivering a noxious mechanical stimulus or a control, non-noxious stimulus. We identified increased population activity in

response to noxious stimuli, and using the graph-theoretic functional connectivity analysis, found stable patterns of functional connectivity among neurons in the PL-PFC. We also discovered that persistent inflammatory pain, modeled by injecting Complete Freud's Adjuvant (CFA) to the rat's hind paw, disrupts PL-PFC neurons' functional connectivity and reduces the overall nociceptive response. Interestingly, a single sub-anesthetic dose of ketamine, a neuromodulator used to treat a number of neuropsychiatric diseases including chronic pain, restores the functional connectivity among PL-PFC neurons in the chronic pain state to produce anti-aversive effects. These results suggest a dynamic resource allocation mechanism in the prefrontal representations of pain, and indicate that population activity in the PFC critically regulates pain and may serve as an important therapeutic target in chronic pain management.

Title: Blocking peripheral drive from colorectal afferents by sub-kilohertz DRG stimulation

Authors: *B. FENG[1], L. CHEN[1], T. GUO[1], S. ZHANG[1], P. P. SMITH[2];
[1]Univ. of Connecticut, Storrs, CT; [2]Univ. of Connecticut Hlth. Ctr., Famington, CT

Abstract: Clinical evidence indicates dorsal root ganglion (DRG) stimulation effectively reduces pain without the need to evoke paresthesia. This paresthesia-free anesthesia by DRG stimulation can be promising to treat pain from the viscera, where paresthesia usually cannot be produced. Here, we explored the mechanisms and parameters for DRG stimulation using an *ex vivo* preparation with mouse distal colon and rectum (colorectum), pelvic nerve, L6 DRG, and dorsal root in continuity. We conducted single-fiber recordings from split dorsal root and assessed the effect of DRG stimulation on afferent neural transmission. We determined the optimal stimulus pulse width by measuring the chronaxies of DRG stimulation to be below 216 μsec, indicating spike initiation likely at attached axons rather than somata. Sub-kilohertz DRG stimulation significantly attenuates colorectal afferent transmission (10, 50, 100, 500 and 1000 Hz), of which 50 and 100 Hz show superior blocking effects. Synchronized spinal nerve and DRG stimulation reveals a progressive increase in conduction delay by DRG stimulation, suggesting activity-dependent slowing in blocked fibers. Afferents blocked by DRG stimulation show a greater increase in conduction delay than unblocked counterparts. Mid-range frequencies (50-500 Hz) are more efficient at blocking transmission than lower or higher frequencies. In addition, DRG stimulation at 50 and 100 Hz significantly attenuates *in vivo* visceromotor responses to noxious colorectal balloon

distension. This reversible conduction block in C- and Aδ-type afferents by sub-kilohertz DRG stimulation likely underlies the paresthesia-free anesthesia by DRG stimulation, thereby offering a promising new approach for managing chronic visceral pain.

Title: Assessing synergistic pain-reducing potential of cannabis components cannabidiol and β-caryophyllene using a rat SCI pain model

Authors: *A. PACHECO-SPIEWAK, A. EESWARA, S. GROSS, S. JERGOVA, J. SAGEN; Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Medical marijuana is most frequently reported to be used for pain relief, however there is a paucity of preclinical studies evaluating the effects of cannabis components in chronic pain models. Anecdotal observations show patients with spinal cord injuries (SCI) experience significant pain relief using marijuana and its medicinal extracts. Thus, the goal of this study was to evaluate the effects of two cannabis components, cannabidiol (CBD) and β-caryophyllene (BCP), and their potentially synergistic pain-relieving combination. Male and female Sprague-Dawley rats received spinal cord injuries using a clip compression model at mid-thoracic levels. First, we conducted dose-response analyses for both CBD and BCP using a battery of behavioral tests including the Von Frey test, the acetone evaporation test, and the Hargreaves test. Animals were evaluated for the presence of tactile and cold hypersensitivity every 30 mins up to 2 hours, at 5 hours and 24 hours post drug administration, starting at 4 weeks post SCI. Drugs were administered by i.p injection (CBD, saline) or oral gavage (BCP). Dose response analyses were conducted to determine A50 doses for individual drugs to be used in the combination. Possible synergism between drugs was evaluated by isobologram. Both males and females developed hypersensitivity to tactile and cold stimuli by week 4 post SCI. Injection of CBD at dose 0.1-1-3-5 mg/kg showed dose-dependent effect with A50 determined for males as 3.02 for tactile and 1.23 for cold, for females as 7.5 for tactile and 1.8 for cold. BCP was injected at doses 10-20-50 mg/kg with A50 values for males as 22.6 for tactile and 19.03 for cold, for females as 35.2 for tactile and 20.7 for cold. For the assessment of the combined effect, drugs were administered at the A50 values as a starting dose, with 50% reduction for the other 2 doses in dose-response experiment. Data from this experiment were used to create isobolograms to evaluate possible synergism. Data shows a synergistic effect of the drugs for reducing cold allodynia in males and females. Additive effects were observed for tactile allodynia. The effects of both compounds and the combination appeared less potent in females compared to males, suggesting that sex differences will need to be considered when developing cannabinoid pain-reducing strategies. We observed no overt

side effects from combining CBD and BCP. These findings support the further development of cannabis extracts as potentially safe and effective therapeutics in the management of chronic SCI pain.

Title: Evaluation of recombinant gene therapy with serine-histogranin and endomorphin-1 in a model of phantom limb pain in male and female rats

Authors: *S. GROSS, A. EESWARA, A. PACHECO-SPIEWAK, K. LIEBMANN, S. JERGOVA, J. SAGEN;
Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Limb amputation, either from direct traumatic injury or medically indicated due to injury severity and inability to adequately repair extremities, often results in the emergence of phantom limb pains (PLP). Local targeting of pain processing centers using gene therapy can provide analgesic substances directly where they are needed and avoid the off-target effects of systemically administered drugs. A key mechanism thought to underlie nerve injury pain is enhanced excitatory N-methyl-D-aspartate (NMDA)-mediated signaling in the spinal dorsal horn. The naturally-derived NMDA antagonist peptide, [Ser^{1}]histogranin (SHG), demonstrates inhibitory properties at the NMDA receptor and can reduce pain in other models. Recent studies in our lab using male rats have shown that injection of viral vectors producing SHG can reduce pain symptoms following peripheral and CNS injury. The addition of a potent mu-opioid peptide, endomorphin-1 (EM-1), provided additional synergistic antinociception. Since pain responses can differ between sexes, both female and male Sprague-Dawley rats were evaluated for PLP using a pre-injury complete nerve transection model. AAV_SHG, AAV_SHG/EM1 or AAV_GFP constructs were administered via dorsal root ganglion injection, intrathecally, or intraspinally either on the same day as transection or a week later, with pre-amputation nerve injury induced at 1 to 14 days prior to transection. Animals were scored daily for PLP autotomy behaviors including onset, severity and location. Several pain-related biomarkers were evaluated using CSF and tissue to discover possible underlying pathological changes. Our data shows slightly reduced severity of PLP-like behavior in females compared to males. In both groups, significant attenuation in the severity and onset of PLP-like behavior was observed in animals treated with SHG and SHG/EM1 compared to GFP. SHG and SHG-EM1 outcomes showed that animals treated with SHG/EM1 presented lower autotomy scores, indicating that simultaneous activation of mu-opioid receptor by EM1 may generate more potent PLP alleviation than inhibition of glutamate signaling by SHG alone. The most potent effect of both constructs was observed after intraganglionic injection when conducted on the same day as transection, with intrathecal

delivery yielding the most consistent results across all time points. CSF samples and immunocytochemistry showed downregulation of inflammatory mediators IL-1β and TNF-α and reduction in reactive glial markers GFAP and Iba-1 in correlation with the severity of the behavior. These findings suggest that combination gene therapy strategies can attenuate chronic PLP in both sexes.

Title: Inhibitory interneuron activity is increased during combined 10 kHz and low frequency spinal cord stimulation

Authors: K. LEE, D. C. LEE, D. WANG, ***Z. B. KAGAN**, K. BRADLEY;
Nevro Corp., Redwood City, CA

Abstract: 10 kHz spinal cord stimulation (SCS) is believed to operate by causing inhibitory interneurons in the superficial dorsal horn (SDH) to substantially increase their action potential firing rate, while only minimally changing the firing rate of excitatory interneurons in the same area, without activation of dorsal column fibers. In contrast, low frequency (LF) SCS (40-60 Hz) is believed to operate by generating action potentials in large diameter dorsal column fibers. Based on this difference, these types of SCS are often applied at different locations along the spinal cord, with 10 kHz SCS applied more caudally and LF SCS applied more rostrally. We hypothesized that simultaneously applying 10 kHz SCS more caudally and low frequency SCS more rostrally would produce synergistic effects as measured by the relative firing activity of interneurons in the SDH.
Adult male Sprague-Dawley rats (n=7) were anesthetized with urethane and a spinal-segmental (ss) L1-L4 laminectomy was performed. A 4-shank, 16-channel microelectrode was implanted at the L5 level to record from neurons in the SDH with a receptive field of the left hind paw. All recordings were digitized at 40 kHz before band-pass filtering between 500 and 10k Hz. Individually identified unit firings were categorized as belonging to either inhibitory or excitatory interneurons on the basis of their response (non-adapting or adapting, respectively) to mechanical stimulus to the left hind paw. SCS was applied caudally (ss L5-L6) and rostrally (ss L1-L2) with two inline tripolar isodiametric electrodes. SCS strategies included (a) 10 kHz applied at 30% of motor threshold (MT) alone or LF stimulation at 70% MT alone through either the rostral or caudal electrode, (b) applying an interleaved 10 kHz SCS and LF SCS to either electrode, or (c) simultaneously applying 10 kHz SCS to the caudal electrode and LF SCS to the rostral electrode. Firing rates of each neuron type in response to stimulation was used to determine whether a given strategy had a significant effect.
In total, 25 inhibitory and 30 excitatory neurons were identified. Simultaneously delivering 10 kHz

caudally and 40 Hz rostrally increased the activity of inhibitory interneurons by 26 Hz, while increasing excitatory interneurons by 4 Hz. The next largest difference between inhibitory and excitatory interneurons was observed when 10 kHz alone was applied caudally, with inhibitory and excitatory neurons increasing their activity by 4.7 and 0.7 Hz, respectively. These results suggest that this approach of combining 10 kHz and low frequency SCS at different stimulation locations may be a method of further reducing patients pain compared with current available.

Title: Neurophysiological and behavioral correlates of auditory contextual emotional processing in healthy adult women: description of the loudness dependence auditory evoked potential and its role in the description of affective processing

Authors: *R. GAJARDO[1], R. A. HENRIQUEZ[2], F. J. ABOITIZ[2];
[1]Dept. of Psychiatry, Pontificia Univ. Catolica de Chile, Santiago, Chile; [2]Dept. of Psychiatry, Pontificia Univ. Católica de Chile, Santiago, Chile

Abstract: Major depression disorder (MDD) is described as a dysfunction of serotonergic system. Studies have correlated serotonergic activity, psychophysical performance and emotional sensitivity with the modulation of an event-related potential component called Loudness Dependence of the Auditory Evoked Potential (LDAEP), evoked by tonal auditory stimuli.
In this pilot study, we evaluate whether the LDEAP is elicited by a novel version of auditory oddball paradigm using stimuli with emotional valence and if it is correlated with psychophysical indicators and the emotional sensitivity scale of the Inventory of Beck (BDI) in 10 healthy female subject. We sought to describe and explore changes in LDAEP component as well as in psychophysical indicators in a task of detection and recognition of emotional auditory stimuli.Behavioral and electroencephalographic (EEG) data were obtained using a modified auditory oddball paradigm. We used audios (300 ms) with emotional valence (positive-laughs, negative-cries, neutral-vowel) obtained from The Montreal Affective Voices. There were 3 conditions: (1) standard:negative/ distractor:positive (PD); (2) standard:neutral/distractor:positive-negative (OD); (3) standard:positive/distractor:negative (ND). EEG was recorded from 64 non-polarizable Ag/AgCl active electrodes. In addition, the BDI was conducted to assess the emotional sensitivity of the participants.
Behavioral analysis indicates that false alarm percentage presented a statistical difference between PD

and OD condition ($p < 0.001$, one-way ANOVA;bonf. correction). In reaction times and total accuracy, percentage of correct responses between standards and distractors have a significant difference ($p < 0.0001$, Wicoxon test) within their same category. This demonstrates that emotional processing is an early phenomenon that depends on physical properties of the stimuli -intensity/ duration/ emotional information- affecting their behavioral response. EEG analysis describe that LDAEP is elicited with auditory stimuli with emotional valence. The grand average in each condition shows a greater amplitude -not significative- in increasing order in the conditions ND < PD < OD. Sperman correlation between the LDAEP component and BDI scale values show a trend with a $r \geq 0.8$ in the 3 conditions.
This pilot study is the first evidence to date that shows the appearance of the LDAEP component against auditory stimuli of contextual human vocalization with emotional valence. Also suggest that the LDAEP presented with an emotional paradigm is a useful tool for assessing emotional regulation, as well as a tool that can be used for the clinical diagnosis of MDD.

Title: Distinct representations of tonotopy and pitch in human auditory cortex

Authors: *E. J. ALLEN[1], J. MESIK[1], K. N. KAY[2], A. J. OXENHAM[1];
[1]Psychology, [2]Radiology, Univ. of Minnesota, Minneapolis, MN

Abstract: Tonotopy is a fundamental organizing principle present at numerous stages throughout the auditory system, from the cochlea of the ear up through the brain. However, it is unclear whether tonotopic maps in cortex reflect physical frequency, inherited from the cochlea, a computation of pitch (reflecting fundamental frequency, F0), or a combination of such features. We used high-resolution, ultra-high field (7T) fMRI to measure BOLD responses in the auditory cortices of 10 normal hearing participants as they listened to sequences of tones in three different conditions: 1) pure tones, traditionally used to estimate tonotopy, that vary in both F0 and spectral content (frequency); 2) complex harmonic tones with a fixed spectral envelope peak but varying F0; and 3) complex harmonic tones with a fixed F0 but varying spectral envelope peak. Encoding models were used to compare representations of pure tones to the representation of tones varying in F0 or spectral envelope. Traditional tonotopic maps were found to be maps of spectral tuning, and bilateral representations of pitch selectivity were found to partially overlap these tonotopic maps, with distinct regions tuned to low, medium, and high F0s distributed

throughout auditory cortex. The data suggest the existence of two cortical representations: one based on spectral tuning (i.e., tonotopy), and the other based on pitch or F0 tuning. Consistent with hierarchical organization, more primary regions (i.e., Heschl's gyri) appear to predominantly exhibit tuning to spectral content, whereas surrounding regions bilaterally exhibit more tuning to pitch. Follow-up work is underway exploring whether and how relative changes in frequency (i.e., musical interval size and direction, irrespective of absolute frequency) are represented in human auditory cortex, as another way to determine the extent to which cochlear tonotopy is simply reflected or reshaped in different regions of the auditory cortex.

Title: Neural representations of temporal and spectral regularities of reverberant environments

Authors: *H. GARCIA-LAZARO, Y. ALWIS, S. TENG;
Smith Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Auditory scene analysis perceptually segregates complex acoustic inputs into multiple auditory perceptual objects. Among these is reverberation, the aggregate acoustic reflections from multiple nearby surfaces, which both distorts source signals and carries information about the local space. Human listeners are perceptually sensitive to temporal and spectral regularities of reverberation (Traer & McDermott 2016), which facilitates perceptual segregation and enables a separable neural code for sound sources and reverberant spaces (Teng et al., 2017). However, it remains unclear how neural responses represent reverberant acoustic statistics and, importantly, how the neural representations index perception of those acoustics.

To address these questions, we conducted an EEG experiment in which participants (N=14) listened to a 2s excerpt of spoken sentences, unique to each trial and convolved with a reverberant impulse response (IR). The IRs were either "Real" (R), recorded in a real-world environment, or "Fake" (F), synthesized in one of five ways matching or deviating from various statistical features of real environments (Traer & McDermott 2016). On each trial, subjects heard the 2000ms stimulus, followed by a 500ms delay and a visual cue commencing an untimed response period; the task was to ignore the speech signal and judge the reverberant space as R or F.

Perception of R and F IRs was reliably above chance, varying across synthetic conditions consistent with previous findings (Traer & McDermott 2016). Multivariate Pattern Analysis of EEG trials showed reliable decoding between R and F IRs starting at ~500 ms, suggesting that despite irrelevant speech signal information, the neural response reliably captures statistical regularities of physically realistic reverberation across multiple IRs. Classification accuracy increased when trials were filtered for correct

responses, indicating that stimulus representations were enhanced with improved task performance. Subject-wise behavioral performance across conditions correlated significantly with decoding accuracy starting at ~800 ms. Our results suggest that subtle statistics of complex acoustic environments are captured by early cortical responses, and that perception is driven by later responses.

Title: Investigating the neural correlates of harmonicity in auditory cortex in humans

Authors: *A. H. MEHTA[1], E. J. ALLEN[1], J. MESIK[1], K. N. KAY[2], A. J. OXENHAM[1];
[1]Psychology, [2]Radiology, Univ. of Minnesota, Minneapolis, MN

Abstract: Pitch and harmonicity are central perceptual properties of real-world sounds, including speech and music, and are crucial for the perceptual organization of sounds in an auditory scene. Despite advances in our understanding of how pitch is perceived and coded in the human auditory system, there are still significant gaps in our basic understanding of how pitch is represented in auditory cortex. Regions anterolateral to Heschl's gyrus have been identified as potentially pitch sensitive. However, it is not yet clear whether the activation truly reflects the pitch elicited by harmonically related tones, or whether these cortical regions are sensitive to other spectro-temporal differences between pitch-evoking complex tones and frequency-matched broadband noise. Previous work has suggested that resolved harmonic complex tones have stronger representations in the putative pitch sensitive regions of auditory cortex compared to unresolved harmonic complex tones and frequency matched noise. However, these stimuli differ significantly, not only in their pitch salience but also in other spectro-temporal properties. In this study, we compare 3T fMRI responses for harmonic complex tones (resolved and unresolved) to inharmonic complex tones, which were matched to the harmonic tones in terms of spectral density and frequency range but do not elicit a clear unambiguous pitch. Additionally, we measure responses to frequency matched broadband noise which has traditionally been used as a reference condition for localizing pitch sensitive regions. We also examine the effect of phase manipulation in the unresolved harmonics in order to investigate the responses driven by envelope fluctuations. We observed robust, bilateral, stimulus-driven activity in Heschl's gyrus and surrounding auditory regions for all stimuli. While data collection is ongoing, preliminary data shows minimal differential activation in previously reported pitch sensitive regions for stimuli with and without salient pitch percepts, when controlling for spectral density and bandwidth. We will also investigate whether any harmonicity-driven differences exist outside of primary auditory cortex. This work will help determine which properties inherent to pitch stimuli are represented in the putative pitch center.

Title: Frequency-based attention reduces auditory cortical responses to relevant sounds

Authors: A. LAGE-CASTELLANOS[1], F. DE MARTINO[2], O. GULBAN[3], ***M. MOEREL**[4];
[1]Cuban Ctr. for Neurosci., Havana, Cuba; [2]Fac. of Psychology, Maastricht Univ., Maastricht, Netherlands; [3]Brain Innovation B.V., Maastricht, Netherlands; [4]Maastricht Ctr. for Systems Biol., Maastricht Univ., Maastricht, Netherlands

Abstract: Auditory attention enables prioritizing currently relevant information. Results from animal electrophysiological studies suggest that attention induces rapid changes in auditory neuronal feature preference and selectivity [1]. Functional magnetic resonance imaging (fMRI) studies of human auditory cortex have revealed an increase in BOLD response in neuronal populations tuned to attended sound features [2]. However, as fMRI studies could typically not characterize the influence of attention on neuronal population receptive field properties, it is still largely unclear how the results obtained with fMRI in humans relate to the electrophysiological findings in animal models.We used ultra-high field fMRI to examine auditory processing while participants (N = 10) listen to ripple sounds and natural sounds. Participants performed a detection task on the ripple sounds. By manipulating the chance of target occurrence, participants alternatively attended to low frequency (300 Hz) or high frequency (4 kHz) ripple sounds. Instead, responses to natural sounds were used to compute neuronal population receptive fields (PRFs).In the behavioral data, we observed a faster reaction time to noise bursts in attended compared to unattended ripples indicating a beneficial influence of attention on task performance. In contrast with previous fMRI studies, the auditory cortical response to attended ripple sounds was *lower* than when the same sounds were not attended. This difference decreased with increasing distance between the voxels' best frequency (BF) and the attended sound frequency. Maps of frequency preference (BF) and selectivity (tuning width; TW) were similar across attentional conditions, with the exception of a narrower TW with attention in parabelt locations with a BF close to the attended frequency.Our results suggest that frequency-based attention results in narrower tuning width in voxels whose preferred frequency matches the attended one. This could underlie the observed lower response to attended, compared to non-attended, ripple sounds. The difference between our results and previous fMRI studies [2] may be explained by the difference in experimental design. Previous studies simultaneously presented attended and reference non-attended sounds, while our presentation was sequential. This suggests that fundamentally different mechanisms may underlie these different attentional settings. [1] Fritz et al. R. Nat. Abstract: Predictive coding postulates that our brains build an internal representation of the sensory world through the comparison of predictions casted by an internal model and the sensory input. Such a process takes place throughout the (sub-) cortical hierarchy attributing a specific role to the different cortical layers in the information flow between top-down predictions and bottom-up sensory evidence [1, 2]. However, in the auditory cortex, the particular role of cortical layers is still debated [3]. We use ultra-high field fMRI (7T) to investigate the role of cortical layers in response to tones that either respect or deviate from contextual cues. In addition, we evaluate the impact of fMRI (thermal noise) denoising using Noise Reduction with Distribution Corrected (NORDIC) PCA [4] for the investigation of submillimeter fMRI responses in temporal regions.We acquired anatomical (0.75 mm iso) and functional (0.8 mm iso) data, while volunteers (N = 8) listened to tone sequences. The sequences consisted of four tones. The last tone was either presented in a predictable context (e.g. a high frequency tone preceded by three ascending ones) or an unpredictable context (e.g. a high frequency tone preceded by three tones whose frequency was not ordered). In the predictable context, in a small proportion of the trials, the last tone could be an oddball (e.g. a low frequency tone following three ascending ones). Preliminary analyses revealed that, in the Heshl's gyrus, a high-low-high frequency gradient [5] is present in the tonotopic maps of all conditions. The tonotopy appears similar between sequences with a predictable and unpredictable context, but slightly altered in response to sequences ending with an oddball. The same gradient was visible in both the original data and the data processed with NORDIC. As expected, NORDIC resulted in clearer responses to sound presentation due to the thermal noise suppression [3]. This preliminary result suggests that NORDIC offers a comparative advantage to the standard reconstruction, while also suggesting that oddball responses are differently represented than the predictable and unpredictable ones.In follow-up analyses we will quantify the spatial correlation between the tonotopic maps of different sequence types. Additionally, we will investigate the (cortical depth dependent) responses to predictable, unpredictable and oddball stimuli and their relationship to the tonotopic representation [6].

Title: Rhythmic priming results in neural entrainment and persistent effects on sensorimotor synchronization

Authors: *M. A. VELASQUEZ[1], K. A. YURGIL[3], L. DOMENECH[2], C. PEARSON[2], J. L. WINSTON[1], P. J. COLOMBO[1];
[1]Psychology, [2]Neurosci., Tulane Univ., New Orleans, LA; [3]Psychological Sci., Loyola Univ., New Orleans, LA

Abstract: Rhythm is an important component in music, and neural entrainment has been proposed as a key mechanism for its perception. Neural entrainment occurs when the frequency of neural oscillations synchronizes to a rhythmic stimulus and reports indicate a positive relationship between rhythm entrainment and sensorimotor synchronization (SMS). The present study examined the role of neural entrainment on SMS and whether the effects of neural entrainment on behavioral and neural responses persist after termination of auditory stimulation. Electrical brain activity was recorded from participants (N=30) while they listened to either a synchronous (2.5 Hz) or asynchronous auditory stimulus for 6 minutes (10 trials of 33s each with 3s intertrial intervals). After presentation of the stimuli, participants in both conditions were instructed to tap their index finger in time with the synchronous stimulus (2.5 Hz) for 33s. After a 15 min delay, all participants listened to the synchronous stimulus for 6 min then completed the finger-tapping task a second time. Participants receiving the initial synchronous stimulus showed higher amplitudes at the beat frequency, indicating neural entrainment, and better tapping accuracy, indicating better sensorimotor synchronization, compared to participants who heard the asynchronous stimulus. Among those who received the synchronous stimulus, there was a correlation between the amplitude at the beat frequency and tapping accuracy, indicating that stronger neural entrainment was related to better sensorimotor synchronization. During the post-delay synchronous stimulation, there was no group difference in amplitude at the beat frequency. However, the synchronous group showed better accuracy and less variability than the asynchronous group, indicating that the effect of either synchronous or asynchronous stimulation was persistent. In both groups, there was a correlation between tapping variability and amplitude at the beat frequency, indicating that the differences in behavioral performance post-delay were most likely influenced by the synchronous stimulus and not the

asynchronous stimulus. Lastly, while there was a difference in tapping performance between groups after the delay, there was no difference in amplitude at the beat frequency, suggesting that this difference was due to a mechanism other than neural entrainment. Overall, the current results show that sensorimotor synchronization can be influenced by the rhythmicity of an auditory prime, and these effects can persist after a delay.

Title: Naturalistic Stimulation Reveals the Tonotopic Structure of Human Auditory Cortex

Authors: *N. HEDGER[1], T. KNAPEN[2];
[1]Univ. of Reading, Reading, United Kingdom; [2]Cognitive Psychology, Vrije Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Despite the importance of audition in spatial, semantic, and social function, there is no consensus regarding the detailed organisation of human auditory cortex. Using a novel computational model to analyse a high-powered naturalistic audiovisual movie-watching dataset, we simultaneously estimate spectral tuning properties and category selectivity to reveal the modes of organisation and computational motifs that characterise human auditory cortex. We find that regions more remote from the auditory core exhibit more compressive, non-linear response properties and finely-tuned, speech-selective receptive fields in low frequency portions of the tonotopic map. These patterns of organisation mirror aspects of the visual cortical hierarchy, wherein tuning properties progress from a stimulus category-agnostic 'front end' towards more advanced regions increasingly optimised for behaviorally relevant stimulus categories.

Title: Neurofunctional differences when processing subsecond and suprasecond auditory time intervals.

Authors: *N. THIBAULT[1], P. ALBOUY[1], S. GRONDIN[2];
[1]CERVO, Québec, QC, Canada; [2]Univ. Laval, Québec, QC, Canada

Abstract: How does the human brain process time intervals? The perception of subsecond intervals (below 1 sec) is thought to be supported by automatic sensory circuits. In contrast, it has been proposed that suprasecond intervals (above 1 sec) are processed by high-order cortical network such as the central executive network. However, some inconsistencies have emerged in the recent neuroimaging literature when trying to identify the brain networks responsible for the perception of time intervals. In the present study, we investigate whether distinct or common neural resources support the perception of sub and supra second time interval using electroencephalography (EEG) and an auditory oddball paradigm. Twenty participants underwent 12 blocks of 8 minutes of an oddball paradigm on time intervals. In each block, 40 trials of 10 sounds were presented for each condition (subsecond, suprasecond). For each trial, one deviant inter-sound-onset-interval was randomly presented through the standard intervals (800ms for the subsecond condition, and 1600ms for the suprasecond condition). These deviant intervals were either shorter than the standard interval (early condition: 700, 750; 1400, 1500ms) or longer than the standard interval (late condition: 850, 900; 1700, 1800ms). Auditory evoked potentials were studied for each condition at both the sensor and source level. We first show that different event related responses and neural resources support the perception of duration of intervals (suprasecond, subsecond). A positive frontocentral peak at 190ms after stimulus onset, with generators in the right primary auditory cortex, was associated with the detection of subsecond deviants. For the suprasecond condition, a biphasic response was associated with deviance detection. First, a negative peak at 170ms with generators in the right inferior frontal gyrus and right precentral gyrus was observed. This peak was followed by a frontocentral positivity at 350ms with generators in the dorsal pathway including the premotor cortex and the supplementary motor area. Finally, similar brain activity in the central executive network were observed for the processing of late deviants (that occurs after the after the expected timing) as compared to early deviants in both sub and supra second condition. Activity in this fronto-parietal network for detection of late deviants might represent top down and prediction error mechanisms. These results suggest that distinct neural mechanisms support the perception of sub and supra second time intervals in the human brain.

Title: Spatial summation for motion detection

Authors: *J. A. SOLOMON[1], C. W. TYLER[2];
[1]Ctr. for Applied Vision Res., [2]City, Univ. of London, London, United Kingdom

Abstract: We used the psychophysical "summation" paradigm to reveal some spatial characteristics of the mechanism responsible for detecting a motion-defined visual target. All stimuli were composed of 256 x 256 pixels, subtending 1.5 degrees of visual angle, with randomly selected graylevels. Graylevels within each 16 (horizontal) x 1 (vertical) group of pixels shifted rightwards with a velocity defined by a noisy, two-dimensional Gaussian function of space. Independent variables were the Gaussian target's space constant and the variance of the velocity noise. The dependent variable was the target's threshold amplitude for (81%-correct, two-alternative forced-choice) detection. To a first approximation, all thresholds were observed to decrease with the square-root of the target's space constant (i.e., the fourth-root of its area). Similarly satisfactory, quantitative fits to the data were obtained with two styles of model: an "uncertainty" model, in which decisions are based on the maximum of many independent signals, and an otherwise-ideal-observer model, subject to intrinsic noise and inefficient sampling, as though a random grid of small elements comprised each receptive field. Both styles of model fit best when the maximum area for any individual receptive field contained between 50 and 100 pixels. Thus, regardless of whether the mechanisms for motion detection integrate information over locally contiguous or sparsely distributed regions of the visual field, it is clear from our results that these regions contain little area. In other words, there is surprisingly little spatial summation for human motion detection.

Title: Causal inference in hierarchical motion perception

Authors: *S. SHIVKUMAR[1,2], G. C. DEANGELIS[3,2], R. M. HAEFNER[4,2];
[1]Brain and Cognitive Sci., [2]Ctr. for Visual Sci., [3]Brain Cognitive Sci., [4]Brain & Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Our subjective percept of an object's motion has been shown to differ dramatically from its retinal velocity in the presence of other moving objects (Johansson 1950). In particular, when an object is part of a larger object, then the perceived motion of the part corresponds most closely to the part's motion relative to the whole. This observation holds even for impoverished visual scenes consisting only of dots, with no semantic information about objects and their relationships, raising the question of how the brain parses and segments such a scene and correctly infers relative motion in a hierarchical fashion. Inspired by recent computational work (Gershman et al. 2016), we have developed a hierarchical Bayesian causal

inference model that can qualitatively account for the findings of prior studies on motion perception (Shivkumar et al. 2020). Our hierarchical model consists of a single recurring motif in which the velocity of each visual element is decomposed into the velocity of the "group" that it belongs to and a velocity relative to the group. Importantly, the prior over the relative velocity is a mixture of a delta function at zero velocity and a Gaussian distribution centered at zero. This modification of the classic slow-speed prior (Stocker et al. 2006) effectively performs causal inference (Kording et al. 2007) over whether the object is stationary or moving and leads to a hierarchical segmentation of the visual scene into groups and supergroups (of groups) when applied to multiple visual elements.Here, we report the results of new psychophysical experiments that quantitatively probe both the hallmark of causal inference in our model, and the hallmark of hierarchical motion perception: the probabilistic transition from cue-integrating dots of sufficiently similar motion to segmenting them into different but connected objects, and perceiving them relative to each other in a hierarchical fashion. Fixating human observers report the perceived direction of a coherently moving "center" group of dots using a dial. This patch of dots is surrounded by coherently moving dots in two concentric annuli of surrounding dots ("S1" and "S2"). Our model predicts that when the motion of the center group is close to that of the motion of S1, then the center and S1 are perceived as one group and its motion is perceived as relative to S2. On the other hand, when the center motion is very different from S1, then the center is segmented from S1 and the center motion is perceived relative to S1, with a probabilistic transition in between both scenarios. Our behavioral data clearly show this transition, allowing us to constrain the parameters of our model in future work.

Title: Design and implementation of an at-home treatment regimen for visual motion hypersensitivity

Authors: *Ó. RÚNARSSON, T. WIBBLE;
Karolinska Institutet, Stockholm, Sweden

Abstract: Patients who suffer from motion-sickness, visual vertigo and other conditions relating to *visual motion hypersensitivity* (VMH) will often feel dizzy when exposed to rapid visual motion or cluttered fields-of-view. Previous studies indicate that attentiveness to these stimuli influence the intensity of discomfort for these individuals. Allowing patients to visualize their attentional levels or cognitive involvement may therefore aid in suppressing VMH.
This study aims to develop a visual biofeedback system for use with a commercial *electroencephalographic* (EEG) headset and a personal computer which may be used for treating motion-sickness and VMH. A neurofeedback program was constructed using MATLAB and a Muse 2 Meditation Device (InteraXon Inc., Toronto, Canada), which functions as a commercial EEG. The program projected a spinning maze-like pattern on a monitor where increase in velocity was proportional to increase in theta wave activity (3.5-6.5 Hz) detected by the Muse. Five test subjects (3M, 2F, avg. age 31) were recruited.

They filled out a *Short-form Motion Sickness Susceptibility Questionnaire* (MSSQ-Short) and were subjected to a proficiency test, where balance and EEG data was collected in a controlled environment while they used the program for the first time. They received a copy of the program and a Muse, and instructed to practice reducing their EEG activity, reflected in the program as a slower spin velocity of the maze. These practice sessions took place daily for seven days. They then returned to the lab for another proficiency test.
Mean spectral power data from the training regimen shows a 23.7% drop in theta wave activity from first session to last ($p = 0.005$). Using Pearson's correlation, no significant results were obtained while comparing training improvements and proficiency test improvements ($r = -0.22$, $p = 0.72$) or reduction in body sway ($r = 0.78$, $p = 0.12$). MSSQ-Short scores correlated significantly with body sway before training ($r = 0.93$, $p = 0.02$) but not after training ($r = 0.68$, $p = 0.21$).
For every subject there was a clear drop in spectral power over the course of the training, indicating that the neurofeedback system works as intended. The high correlation between MSSQ-short scores and body sway during the initial proficiency testing session indicates that the program evokes a balance response. This correlation disappears after the training sessions, however the person who got the highest MSSQ-Short score by far (49.5/54, high susceptibility) was also the one who improved the most. This indicates that the program may be more effective on those who are already susceptible, though a greater sample size is required for validation.

Title: Biological Motion Perception in Perceptual Decision Making Framework

Authors: *B. AYDIN, B. A. URGEN;
Bilkent Univ., Ankara, Turkey

Abstract: Neurophysiological studies with non-human primates characterize perceptual decision-making with a two-step process: 1) sensory evidence accumulation, 2) decision that leads to response selection (Gold and Shadlen, 2007). These studies commonly use random dot motion stimuli (RDM) and show that the firing rate of the neurons in LIP increases and the behavioral response time decreases as the coherence of the motion stimuli increases. Recently, EEG studies in humans have revealed the CPP component, which shows similar functional properties as LIP neurons, and is associated with the sensory evidence accumulation process (Kelly and O'Connell, 2013). Furthermore, it is distinguished from the LRP component which is associated with response selection. The aim of the present study is to investigate whether these processes would generalize to more complex and socially meaningful stimuli such as biological motion. Sixteen participants did a direction discrimination task with biological motion stimuli as 64-channel EEG was recorded. The coherence of the stimuli was manipulated by embedding noise dots at four different levels. The task was to indicate whether the noise-embedded biological motion walker

moved towards left or right. Our behavioral results show that the reaction times and miss rate decrease as the coherence is increased. Furthermore, we found that the peak rate of the CPP component tracks the coherence of the biological motion stimuli and is distinguished from the LRP component. However, CPP has a later onset compared to the RDM task, probably due to further processing needed for biological motion stimuli. In sum, our results suggest that perceptual decision-making processes can be generalized to more complex and socially important stimuli with some delays in timing.

Title: Distinct neural dynamics underlie the encoding of visual speed in stationary and running mice

Authors: *E. A. B. HORROCKS, A. B. SALEEM;
Univ. Col. London, London, United Kingdom

Abstract: Sensory experiences are often driven by an animal's self-motion. For example, an animal's movement through an environment can drive rapid changes to visual inputs in the form of visual flow. Real-time encoding of visual motion during locomotion is therefore critical for an animal to understand and control its interaction with an environment. Whilst locomotion has been shown to modulate visual responses in the mouse brain, little is known about how it modulates the temporal dynamics (time courses) of these responses. In this study, we compared the temporal dynamics of single neuron and population responses, in stationary and running sessions (n=17 mice), from eight mouse visual areas to dot field stimuli moving at a range of visual speeds using the Visual Coding dataset from the Allen Institute for Brain Science. We found a diverse range of reliable trial-averaged temporal response dynamics, and responses in stationary and running sessions had distinct temporal dynamics - responses recorded during running had less transient stimulus onset and offset response features. We therefore investigated the functional encoding of visual speed by assessing tuning strength over the response period. In running sessions, a combination of increased dynamic range and more reliable temporal response dynamics enabled visual speed tuning to emerge faster (-67ms, $p<0.001$) and persist for longer (+93ms, $p=0.014$). As a result, visual speed could be decoded above chance more quickly (-53ms, $p=0.030$) and until later (+114ms, $p<0.001$). Population activity reflected the temporal dynamics of single neuron responses, including their modulation by locomotor state. We used factor analysis to obtain neural trajectories which evolved over time. Using a geometric measure (the Distance Ratio) we found that neural trajectories in running sessions made more direct transitions between baseline and stimulus steady

states during the stimulus onset and offset periods ($p<0.001$ for both periods). This enabled faster and more persistent encoding of visual speed from population activity. Interestingly, the structure of population coding for visual speed also differed between locomotor states - population activity prioritised the encoding of visual speed in running, but not stationary sessions. Our results reveal a profound influence of locomotion on the temporal dynamics of neural responses. We find that during running, mouse visual areas prioritise the encoding of potentially fast-changing, behaviourally relevant features such as visual speed.

Title: State and stimulus dependence reconcile motion computation and the Drosophila connectome

Authors: *J. P. PORTES, J. R. KOHN, M. P. CHRISTENSON, L. F. ABBOTT, R. BEHNIA; Columbia Univ., New York, NY

Abstract: Sensory neurons dynamically optimize their tuning to encode stimuli across a wide range of environmental and behavioral conditions. Although such adaptation has been widely studied, its impact on the computations performed by neural circuits is not understood. The well-described and anatomically characterized *Drosophila* motion detection circuit provides a prime opportunity to address this issue. We measured the filtering properties of neural inputs to the OFF motion-detecting T5 cell in *Drosophila* and report state- and stimulus-dependent changes in the shape of temporal responses which, importantly, become more biphasic under specific conditions. Summing these inputs within the framework of a connectome-constrained model of the visual-motion circuit demonstrates that the observed shape changes are necessary and sufficient to explain T5 responses to a variety of motion stimuli. These findings provide a clear example of how a neural circuit can dynamically optimize an important sensory computation.

Title: Heterogeneity of direction selectivity and receptive field profile in randomly-wired models of component and pattern cells in visual cortical area MT

Authors: *Z. YAO[1], W. BAIR[2];
[1]Bioengineering, [2]Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Visual receptive fields (RFs) in cortical area MT are conventionally conceptualized and modeled to be homogeneous such that MT neurons prefer the same direction throughout the spatial RF and that sensitivity is relatively even but drops off toward the edge. However, a recent study found that

nearly 50% of macaque MT neurons had multi-peaked RFs with heterogeneous direction preference (Richert et al., 2013, Front Syst Neurosci). This raises basic questions about the spatial structure of MT RFs. To test under what conditions such heterogeneity can arise from simple random connectivity models that achieve realistic spatial integration of V1 inputs, we extended a previous MT model (Baker & Bair, 2016, J Neurosci) and simulated a population of units having architectures that accounted for both component (CDS) and pattern direction selective (PDS) neurons. The spatial structure of the V1-MT connections in the models was controlled by variation of four major factors: (1) the density of V1 connections to the MT unit, (2) the spatial uniformity vs. randomness of the locations of those inputs, (3) the organization of V1 direction channel inputs into coherent local spatial subunits, and (4) the direction bandwidth of the distribution of weights on the V1 inputs (PDS units have wider bandwidth than do CDS units). For comparison to Richert et al., we applied reverse correlation using random dot stimuli like theirs to map the sensitivity profile and direction preference of our model RFs. We found that manipulation of the above model parameters could achieve RF heterogeneity to a limited extent. When V1 inputs of different direction channels were spatially aligned, forming local subunits, both CDS and PDS models with sparse and randomly positioned subunits tended to have heterogeneous sensitivity profiles. Spatially staggering the direction channels did not affect the level of RF heterogeneity for CDS models, but such a configuration significantly reduced the heterogeneity of the sensitivity profile and increased the direction heterogeneity for PDS models. Overall, we observed minimal RF direction heterogeneity in our models: while we were able to simulate irregular RFs with multiple subregions fragmented by low sensitivity gaps, these subfields shared similar preferred directions. Our results suggest that spatial randomness in the wiring of V1 inputs would not be sufficient to produce RF subregions in MT neurons with substantially different direction tuning to the degree reported by Richert et al. Thus, the existence of direction heterogeneity in the RFs of single MT neurons most likely arises from concerted, non-random developmental processes.

Title: ICMS-evoked touch sensations are enhanced during attempted grasp

Authors: *T. CALLIER[1], J. E. DOWNEY[2], A. SOBINOV[2], V. KARAPETYAN[4], R. A. GAUNT[4,5,6,7], S. J. BENSMAIA[1,2,3];

Labs, [5]Dept. of Physical Med. and Rehabil., [6]Dept. of Bioengineering, [7]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Electrical stimulation of somatosensory cortex (SC) elicits artificial touch sensations and can be used to deliver sensory feedback from prosthetic limbs. This feedback improves prosthetic control, underscoring the importance of closing the sensorimotor loop. The perceptual correlates of intracortical stimulation (ICMS) of SC are necessary to determine object properties in real-time, but have almost exclusively been studied under open-loop conditions, in which stimulation is delivered to participants, who then make reports of the perceptual experience. In the present study, we wished to examine the degree to which ICMS-evoked touch sensations are modulated by the behavioral state of the participant. Specifically, we asked whether the sensations would differ if they were paired with a motor act. First, we had participants perform a detection task under two conditions. In one condition ('active'), peri-threshold ICMS pulse trains were synchronized with a hand grasping an object in virtual reality (VR) and participants were instructed to attempt to mimic the observed grasp. In the other condition ('passive'), the same ICMS pulse trains were presented without the VR context. In both conditions, ICMS trials were randomly interleaved with catch trials with no stimulation. We found that participants were better able to detect peri-threshold ICMS pulse trains in the attempted grasp condition compared to the passive condition. Next, we had the participants report the intensity of the sensations evoked by suprathreshold ICMS in the attempted grasp condition and in the passive condition. We found that the evoked sensations were systematically more intense when ICMS was paired with attempted grasp. We conclude that sensations are enhanced when the ICMS-based feedback is congruent with an attempted motor act.

Abstract: High-resolution neuroprosthetic decoding of finger movements and hand gestures could greatly improve the usability of robotic limbs and enable new communication methods such as ten finger typing. Here, we aimed to better understand the geometry of motor cortical neural activity during naturalistic hand gestures, to guide the design of hand motion neuroprostheses.
Simultaneous neural population activity was recorded from two intracortical Utah arrays (192 channels) in the 'hand knob' area of premotor cortex of a human participant with tetraplegia while they attempted different hand gestures. Each trial was cued with an animated hand, with a 1 second preparatory period followed by a 2 second movement period. Trials varied across laterality (left/right hand) and palm position (up/down/sideways). Trials started from a neutral resting position to one of 81 different gestures consisting of an exhaustive combination of three targets (flexion/extension/no movement) for four finger groups (ring and little fingers had the same movement). For the same single finger movement (flexion/extension), changing the hand laterality (left/right), the hand pose (up/down/sideways) or the identity of the finger was largely captured by a uniform, time-independent shift in neural activity for the entire duration of the trial. However, for multi-finger gestures, a decoding analysis revealed a more complex structure. First, a linear classifier was able to distinguish between 81 gestures on four finger groups with 40% accuracy (chance accuracy <2%), confirming that the neural activity was modulated by the movement of each finger. Second, for the same movement of the other fingers (condition), decoding the movement of a particular finger using training data from the same condition had high accuracy (>88% accuracy across all fingers). Third, a classifier trained on one condition had low accuracy when tested on other conditions (varied between 78% for thumb and 57% for middle finger; chance accuracy 50%).
In conclusion, using neural recordings from the hand knob area of the motor cortex, accurate decoding of single finger movements, across hands lateralities and poses, could be achieved using standard linear methods but simultaneous movement of all fingers would likely require non-linear methods.

Title: Real-time linear prediction of simultaneous and independent movements of two finger groups using an intracortical brain-machine interface

Authors: *S. R. NASON[1], M. J. MENDER[1], A. K. VASKOV[2], M. S. WILLSEY[3], N. GANESH KUMAR[4], T. A. KUNG[4], P. G. PATIL[3], C. A. CHESTEK[1];

Abstract: Current brain-machine interfaces (BMIs) can return mobility to cervical level spinal cord injury patients (BrainGate), where upper-limb function is of utmost importance (Anderson 2004). A major roadblock to their clinical use is their inability to restore the functionality and naturalism of the native hand. Here, we present a low-power intracortical BMI capable of predicting the simultaneous and independent movements of two finger groups to help close that gap. We implanted two nonhuman primates (N and W) with Utah microelectrode arrays in the hand area of primary motor cortex. We trained them to perform a behavioral task in which they controlled a virtual hand by moving their physical hand or using the BMI. The index finger and the middle-ring-small (MRS) fingers as one group were each presented with their own virtual targets, for two targets total. During the task, we recorded spiking band power (SBP), which is a low-bandwidth signal that accurately captures the firing rate of the highest amplitude unit on each electrode (Nason *et al.*, 2020), and trained ReFIT Kalman filters to predict the simultaneous and independent movements of both finger groups in real-time using their thoughts. We analyzed cortical tuning to these movements in a 2D space made by plotting the 1D index finger movements against the 1D MRS group movements. The ReFIT Kalman filter enabled the nonhuman primates to acquire targets in 1.01s (N) and 2.4s (W) on average. When investigating the cortical activations for these movements, we found that the SBP activity for a given movement could be linearly predicted by the activity for related movements. This enabled us to predict combined finger movements using a decoder model that was trained only on individuated movements, and vice versa, with a 0.04 (N) and 0.08 (W) loss in correlation. Finally, we investigated the tuning of SBP channels to both position and velocity of the fingers across a wide variety of behaviors and found that a channel's preferred position rarely aligns with that channel's preferred velocity. Our results suggest linear models can sufficiently predict complex finger movements during tasks involving two targets. Further, training and testing on mutually exclusive behaviors suggests cortical activity related to fingers is consistent between independent and combined movements, at least up to 2 degrees of freedom. Finally, misalignment in the preferred positions and velocities of cortical units related to finger movements suggests simultaneous encoding of multiple kinematic parameters within individual units. Future work will use this multi-dimensional finger BMI to control an implantable functional electrical stimulation system.

Title: How similar are representations of observed and executed grasps in the frontoparietal cortical grasping network?

Authors: *J. M. GOODMAN, Jr.[1], S. SCHAFFELHOFER[2], H. SCHERBERGER[1];
[1]German Primate Ctr., Goettingen, Germany; [2]cortEXplore GmbH, Linz, Austria

Abstract: Neurons in the frontoparietal cortical grasping network respond during both the execution and observation of an action. This has been used to support theories that link motor control and cognition and has offered the tantalizing promise of straightforward observation-based training of decoders for brain-computer interfaces (BCIs). Such observation-related signals have often been described as grasping-related phenomena, further pointing to their potential utility for training grasp decoders. However, the precise link between execution and observation activity remains elusive, specifically the granularity of information shared between both contexts. To address this, chronic multi-electrode arrays were used to record simultaneously from neuronal populations in parietal (AIP), premotor (F5), and primary motor (M1) nodes of the cortical grasping network as animals either grasped a variety of different objects or observed a human subject doing the same. From these data, no distinct class of neuron emerges which is particularly responsive during observed grasps. Instead, neurons in the grasping network span a continuum of relative preference for execution and observation, although on average, AIP or F5 neurons exhibit more activity during observation than M1 neurons. Absent a particular class of neuron to study, targeted dimensionality reduction identifies linear combinations of these neurons that capture shared neuronal activity patterns, some of them being nearly identical during execution and observation. These shared activity patterns are more prominent in AIP and F5 than they are in M1. Linear classifiers and decoders were then used to determine whether this shared activity is sensitive or invariant to object identity and hand kinematics. Initial results suggest that this common activity pattern, reduced to its transient movement-specific component, is largely invariant to both object identity and grip kinematics. Thus, while observation-related signals serve well to localize nodes of the cortical grasping network, they may not be suitable for effective BCI training.

Title: Effects of intracortical microstimulation in somatosensory cortex across multiple human participants

Authors: *C. HUGHES[1], T. CALLIER[4], V. KARAPETYAN[1], C. VERBAARSCHOT[1], N. BRANTLY[2], E. OKOROKOVA[4], J. E. DOWNEY[5], N. G. HATSOPOULOS[4], M. BONINGER[1], J. L. COLLINGER[1], S. J. BENSMAIA[5], R. A. GAUNT[3];

Abstract: Intracortical microstimulation (ICMS) of the human somatosensory cortex can evoke sensations from the hands of paralyzed individuals and can improve control of prosthetic arms. While these observations demonstrate proof-of-principle, the real potential of this approach remains uncertain as most of the work on the stability of these devices, as well as the perceptual and functional effects of stimulation, has been conducted in single participants at different study locations. The observed effects, however, can be dependent on the implanted devices, implant location, time since injury, and many other factors that are likely to vary across participants. In Pittsburgh and Chicago, we have implanted multiple participants to begin addressing multi-subject and multi-site factors related to ICMS. One participant has been implanted for over 6 years (P2) and two participants have been implanted for approximately one year (P3 and C1), enabling us to examine the recording quality on stimulated electrodes and the perceptual effects of stimulation across three participants. Although P3 and C1 have been implanted for much less time than P2, we have already observed several differences. First, the signal quality increased initially in all participants as assessed with peak-to-peak voltages and the number of high-amplitude waveforms. Signal quality then declined slowly, but there has been variability in how individual electrode arrays behave over time across participants. Some stimulation arrays have outperformed recording-only arrays in motor cortex, while others have not. Second, we have seen the effect of frequency on evoked sensation is dependent on the stimulated electrode, and the presence and spatial distribution of these relationships are dependent on the participant. Finally, survey data collected in all participants showed evoked sensations that followed an expected somatotopy, but the location of the sensations, distribution of evoked qualities, and reported naturalness of the sensations were different across participants. These effects, particularly on recording and stimulation stability, will need to be observed for longer periods of time in both P3 and C1 for a more direct comparison with data from P2. These results demonstrate the importance of repeating studies in multiple participants As sensory restoration through ICMS becomes more common, establishing standardized or comparable assessment and reporting guidelines will be important to enable multi-site replication across multiple participants to understand the true potential of ICMS to restore somatosensation.

Title: Studying the consistency of neural and muscular representation of stereotypical grasps

Authors: *F. RIZZOGLIO[1,4], K. L. BODKIN[1], X. MA[1], E. ALTAN[1,2], E. J. PERREAULT[2,3,4], L. E. MILLER[1,2,3,4];

Abstract: Primates can perform a rich repertoire of arm and hand movements with remarkable consistency. Recent studies have hypothesized that the fundamental building blocks underlying this consistent behavioral execution are stable latent cortical dynamics within a low-dimensional manifold of neurons controlling motor activity. The stability of these latent representations over time has been established, but little is known about the consistency of representations across individuals. Such consistency would suggest that behaviors could be inferred from neural activity in a robust manner and that such inference could form the basis of brain machine interfaces that generalize even across individuals. The purpose of this study was to explore the consistency of motor behaviors and their neural representation across animals by assessing the similarity of neural and muscular recordings across monkeys performing a variety of grasping tasks.
We trained three monkeys to perform two types of grasps and recorded neural signals from the hand area of primary motor cortex (M1) and intramuscular electromyographic (EMG) signals from several arm, forearm, and hand muscles. We assessed similarity in both the high-dimensional domain of these signals and in their lower dimensional representations. Results show that the high-dimensional neural recordings of different monkeys are largely uncorrelated but that the similarity increases when these recordings are projected into a low-dimensional space. In contrast, EMG signals from the muscles controlling movement were similar in both the recording space and the lower dimensional latent space. In an attempt to extract a single latent space that represented the activity recorded across monkeys, we implemented Canonical Correlation Analysis (CCA) to align the latent dynamics of M1 signals and the EMG signals from each animal. The similarity between the low dimensional manifolds for both M1 signals and EMG signals increased further after CCA alignment. Consequently, we asked how accurately a decoder trained to predict EMG based on aligned latent dynamics from one monkey would perform on aligned latent dynamics from a different monkey. The across-monkey accuracy of this decoder was higher than that of decoders based on both the recorded neural activity and the unaligned latent dynamics.
Our findings suggest that consistent representations of motor activity exist across animals. Discovering this common representation is a crucial first step in designing generalizable BMI decoders that perform well even in the absence of subject-specific tuning.

Abstract: Closed-loop control of a prosthetic limb involves decoding motor intent from motor cortex (M1) while conveying somatosensory feedback via intracortical microstimulation (ICMS) delivered to somatosensory cortex (SC). Decoders are often trained with the assumption that ICMS to SC evokes only negligible activity in M1. However, the known functional connectivity between M1 and SC implies that some activity in the former may be synaptically transmitted to the latter. To test this possibility, we delivered ICMS pulse trains at varying frequencies and amplitudes to SC while measuring the neuronal activity evoked in M1 in human participants implanted with electrode arrays in both SC and M1. First, we found that individual ICMS pulses delivered to SC could evoke action potentials in M1 with latencies as short as 2 ms. Second, the spatial pattern of activation in M1 depended on the location of the stimulating electrode in SC. Third, multi-channel ICMS evoked stronger and more widespread activity than would be predicted from the linear sum of its single-channel counterparts. We propose that closed-loop control may improve if ICMS-induced activation of M1 is taken into consideration in building decoders.

Surgery, [5]Univ. of Chicago, Chicago, IL; [9]Dept. of Neurosurg., Univ. of Texas at Austin, Austin, TX

Abstract: Intracortical brain-computer interfaces (iBCIs) are a promising approach to restore arm and hand function for people with tetraplegia. Here we report the signal quality recorded from Utah Electrode Arrays (UEAs) implanted in motor cortex and the progress toward restoring arm and hand function across four study participants (ages 52, 28, 28, and 57 at time of implant) at two sites: the Universities of Pittsburgh and Chicago. Three participants are currently active, including one participant who has contributed for more than six years. Neural data recorded at the start of each test session were used to quantify signal quality. Active motor array channels were defined as those recording threshold crossings with firing rates >0.7Hz and peak-to-peak voltage (Vpp) >30uV. In all participants, the number of active channels in motor cortex increased over the first ~100 days post-implant before slowly declining. To assess longevity, we report active channels for the most recent session. P1 was implanted for ~32 months and had 48% active channels at the time of explant (due almost entirely to low firing rates, though the signals were sufficient for BCI control of a robotic arm). P2 had 73% active channels at 74 months post-implant, P3 had 97% active channels at 11 months post-implant, and C1 had 72% active channels at 8 months post-implant. These longitudinal neural recordings enabled all participants to achieve kinematic control of a robotic or virtual arm, including endpoint velocity and hand grasp. All participants achieved at least 90% success in a 4D grasp and carry target acquisition task within six months of training, showing improvements in performance over time. Additionally, participants P1, P2, and P3 were able to control a robotic arm to complete an object transfer task that involved picking up and transporting an object as many times as possible with performance ranging from at least 6 to a maximum of 24 transfers in two minutes. Participant C1 has completed this task in a virtual environment. In addition to kinematic control, all active participants (P2, P3, C1) have successfully controlled grasp force of a virtual hand model to interact with objects. The ability to chronically record neural activity from motor cortex has enabled high-dimensional control of arm and hand movements across four participants indicating that these technologies can work consistently for long periods of time, which is promising for future clinical applications. Future work will focus on robust grasp force decoding for dexterous hand control, generalizability of control across task contexts, and integration of touch feedback via intracortical microstimulation of somatosensory cortex.

Abstract: Brain-controlled prosthetic arms can be used by people with tetraplegia to complete functional reach and grasp tasks. To date, this prosthetic control has almost exclusively involved decoding movement kinematics from motor signals. While this strategy has achieved a good measure of success, it does not allow for the straightforward, graded application of isometric forces, critical when grasping objects. Furthermore, during natural interactions with objects, force variation results in continuously varying somatosensory feedback, without which force control is compromised. Previous work has shown that, during imagined grasps, force signals in motor cortex are transient, fading during sustained grasp. We hypothesized that this transience of force-related signals in motor cortex stems from the lack of somatosensory feedback.To investigate this possibility, we monitored the activity evoked in the motor cortex of a human participant during 3 closely related conditions: During the first condition the subject attempted to grasp an object with a consistent amount of force for every trial, but received one of 10 possible stimulation amplitudes during the grasp. During the second condition he attempted to grasp with a specified amount of force and received no ICMS feedback. During the final condition, he attempted to grasp with a specified amount of force and received ICMS feedback with an amplitude proportional to that force. Using these three conditions, we identified separate neuronal subspaces related to ICMS and grasp force. Activity that is directly related to the ICMS is not useful for decoding, because the BCI user does not have direct volitional control of the ICMS. Therefore, in an offline analysis, we used neuronal activity exclusively from the force subspace to decode intended grasp force during ICMS and found that the resulting force predictions were both stronger and longer lasting than their counterpart without ICMS. Applying these findings to online control should result in more dexterous and precise control of grasp force, increasing the number of tasks that a BCI user can complete independently.

Title: Statistical Measures of Nonstationarity in Simulated Neural Data During BCI 2D Control

Authors: *T. K. PUN[1,2], M. KHOSHNEVIS[3], M. T. HARRISON[3], L. R. HOCHBERG[4,1,5,6,2];

Abstract: Intracortical brain-computer interfaces (iBCIs) are designed to bypass damaged motor pathways and provide new links to assistive technologies for people with neuromotor deficits from conditions such as amyotrophic lateral sclerosis, brainstem stroke, and spinal cord injury. The ongoing BrainGate clinical trials of iBCIs have demonstrated impressive progress of enabling rapid point-and-click control over external devices and reach-and-grasp actions with prosthetic arms. However, in order to translate iBCIs for 24/7 practical use, researchers have to design a stable and reliable iBCI system that is effective for supporting continuous, independent use without the oversight of a technician. One challenge is to maintain stable cursor control for long-term use, especially when the decoder becomes ineffective in handling a large degree of within- and across-day nonstationarity in the relationship between neural activity and intended movements. Neural activity underlying consistent behaviors can vary over time due to changes in recording conditions and individuals' cognitive states.

It is important to systematically investigate how different types of nonstationarity can lead to a drop in decoder performance on cursor control. We first simulated neural data during a center-out-and-back task using a feedback control model described in Willett et al. (2017). We perturbed the neural encoding model to simulate various types and severity of nonstationarity, while not updating the decoder trained on the unperturbed model. By looking at the neural-kinematic pair, we then proposed using the hypothesis test offered by Toyoda and Ohtani (1986) to detect a change in our probabilistic encoding model compared to the unperturbed model. However, in general it is not possible to obtain the true intended movement data in clinical settings with tetraplegic participants, especially during independent personal use of the BrainGate system where targets are not instructed. With only neural data available, we found that Wasserstein distance can be a useful metric to measure change in the neural data resulting from a perturbed model. It correlates nicely with the amount of perturbation introduced in our model as well as the mismatch decoder performance on simulated cursor control.

To summarize, we found that the associated p-values from hypothesis test and Wasserstein distance are

both sensitive to different kinds of perturbation.
Next, we will evaluate these methods for detecting nonstationarity in neural activities in real time, and for quantifying the need for decoder recalibration to maintain steady iBCI performance for reliable continuous use.

Abstract: Intracortical brain-computer interfaces (iBCIs) aim to restore movement and communication to people with paralysis by decoding movement signals from the brain via microelectrodes implanted in the cortex. To date, most iBCI studies have been limited to the control of a single effector for point-and-click typing (e.g., one cursor) and reaching/grasping (e.g., one arm). Recent work has shown that “arm/hand” area of motor cortex represents all body parts, not just the contralateral arm. This opens the door to creating iBCIs that restore the motion of multiple effectors at the same time. However, it may be more challenging to decode the simultaneous motion of multiple effectors, as recent work has also shown that the neural tuning changes nonlinearly during dual-effector motion (i.e., neural tuning during bimanual movement is not simply the linear sum of neural tuning during unimanual movement). We addressed this problem by designing and developing recurrent neural network decoders (RNNs) to enable real-time continuous bimanual control of two cursors on a computer monitor.

Our research participant (T5) has tetraplegia due to spinal cord injury (C4 AIS-C) and is enrolled in the BrainGate2 clinical trial. He underwent implantation of two 96-channel microelectrode arrays (implanted in the dorsal "hand knob" area of motor cortex) approximately 6 years ago. To train the RNNs, our participant first performed an "open-loop" delayed-movement task in which he attempted to move both of his hands in correspondence with two cursors on a screen that traveled at random speeds to targets at random locations. Trials were interleaved with bimanual movements (both hands) and unimanual movements (either the left or right hand by itself). We found changes in neural tuning depending on the movement type, including changes in preferred direction between bimanual and unimanual movements and tuning suppression during bimanual movement. After training and optimizing RNNs with data collected from multiple session days, we demonstrated online continuous control of two cursors via RNN decoders. Future work will assess performance of these RNN decoders against linear decoders and expand to include additional effectors.

Title: Enabling a high quality user experience during independent home use of an iBCI by an individual with tetraplegia

Authors: *T. SINGER-CLARK[1], R. GROSS[2], T. HOSMAN[4,2,3], A. KAPITONAVA[1], J. D. SIMERAL[4,2,3], L. R. HOCHBERG[4,2,1,5,3];

and Neurotechnology, Dept. of VA Med. Ctr., Providence, RI; [5]Dept. of Neurol., Harvard Med. Sch., Boston, MA

Abstract: Intracortical brain-computer interfaces (iBCIs) have the potential to improve independence for individuals with tetraplegia resulting from injury or neurological disorders such as spinal cord injury or ALS. Using the BrainGate iBCI, paralyzed individuals have displayed general-purpose point-and-click control of an unmodified consumer tablet computer to, among other things, send and receive email and browse the web. However, for iBCI systems to reach their full potential in positively impacting the lives of users with paralysis and achieve widespread adoption, they will need to be usable independently in the home without expert supervision, be enabled and disabled at the user's discretion, and require minimal recalibration - all while providing high performance control of enabling devices. Such features of the iBCI, although potentially quite technically complex, must be readily accessible to users through an intuitive, unintimidating user interface. Here, we describe an iBCI user interface, called BG Home, that was developed to satisfy many of these requirements and to support consistent, long-term independent use of an iBCI by individuals with tetraplegia at home. Versions of BG Home have been in use at home by a clinical trial participant for over a year, typically 2-3 days per week.

The iBCI system processes neural data transmitted wirelessly from the user's head. Caregivers were trained to don and doff the transmitters so the participant could use the system without research staff present which, critically, enabled usage to continue during the COVID-19 pandemic. Through a remote connection, research staff could power the system on, after which the user was free to use the system independently. The iBCI system performs 2D kinematic decoding and discrete multi-gesture decoding to provide mouse cursor control and actions such as click and scroll, all on the participant's own Windows 10 PC, enabling iBCI control of all their familiar applications. The user could pause and resume control of their device by imagining a sequence of gestures. The system detects when the user moves into or out of range of the wireless receiver system and pauses or resumes decoding and neural control appropriately. The GUI component of BG Home, which appears as a small, relocatable, floating button on the user's screen, allows the user to recalibrate neural decoders, see feedback messages from the system, adjust mouse speed, and more.

These innovations supplement the technical capabilities of the iBCI with user-centered features designed to prioritize user satisfaction and usability of iBCI technology in the home setting.

Title: How many people would benefit from an intracortical brain-computer interface?

Authors: *A. DUFFY[1], D. B. RUBIN[1], R. MARUJO[1], D. A. SCHOENFELD[2], L. R. HOCHBERG[1,3,4,5,6]; [1]Dept. of Neurol., [2]Dept. Biostatistics, Massachusetts Gen. Hosp., Boston, MA; [3]Sch. of Engin., [4]Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [5]Dept. of Neurol., Harvard Med. Sch., Boston, MA; [6]Dept. of VA Med. Ctr., VA RR&D Ctr. for Neurorestoration and Neurotechnology, Providence, RI

Abstract: Intracortical brain-computer interfaces (iBCIs) have the potential to restore motor function and communication in individuals with severe brain and spinal cord damage/disease. The BrainGate system uses an intracortical microelectrode array implanted in the arm/hand region of the motor cortex to record, decode and translate neural activity to an effector (e.g. robotic arm, computer cursor) during motor imagery. Quantifying the number of people who would benefit from an iBCI would demonstrate to payors, investors, and government and foundation-based agencies the vast unmet need to expand current iBCI research and treatments. We queried the Massachusetts General Brigham (MGB) Research Patient Data Registry (RPDR) (data from 6.5 million patients: 2 billion medical records) to quantify those who would benefit from an iBCI for upper extremity use and/or communication. Querying 170 relevant diagnosis codes resulted in >190,000 cases. We developed a protocol to review records of the 131 individuals with locked-in state (LIS) to characterize these cases as 1.) Likely to benefit from an iBCI 2.) Unlikely to benefit 3.) Severely dysarthric (only symptom) 4.) Withdrawal of life-sustaining therapy (WLST) within 1-year 5.) Death <1-yr from precipitating event (not due to WLST) 6.) Cognitive impairment 7.) Unable to undergo iBCI surgery or 8.) Uncertain due to lack of data. We established a team of 3 clinicians and one neuroscientist to independently characterize the LIS patients to ensure inter-rater reliability. To characterize iBCI benefit across all 170 diagnoses, we pursued a sampling methodology. We grouped diagnoses by modality (upper extremity/communication), and clustered diagnoses with the same estimated proportion of iBCI benefit (e.g. 2.5%, 50%, 90% etc.). We defined any diagnosis with >10,000 cases as its own cluster, resulting in 14 diagnosis clusters. We used a sampling equation that incorporates the variances of these estimated proportions of people who would benefit from an iBCI. This study provides the methodology to characterize iBCI benefit of a subset of people with locked-in state within the MGB system as well as a sampling methodology to perform a more efficient but still statistically valid review of cases across all 170 chosen diagnoses. Extrapolating these proportions to larger national databases (i.e. private insurance, Medicare and the VA) will demonstrate the importance of developing and financing novel iBCI technologies and resources.The MGH Translational Research Center has a clinical research support agreement with Neuralink, Paradromics, and Synchron, for which LRH provides consultative input.

Title: Relative timing of vibration and electrically-evoked tactile stimuli

Authors: B. CHRISTIE[1], L. OSBORN[1], D. MCMULLEN[2], A. S. PAWAR[3], S. J. BENSMAIA[4], P. A. CELNIK[3], M. S. FIFER[1], *F. TENORE[1];
[1]Res. and Exploratory Develop., Johns Hopkins Univ. APL, Laurel, MD; [2]NIMH, NIH, Bethesda, MD; [3]Physical Med. & Rehab, Neurol, Johns Hopkins Univ., Baltimore, MD; [4]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Electrical stimulation of the primary somatosensory cortex (S1) can elicit feelings of touch, which can be used as feedback for people with sensorimotor deficits. Characterizing the timing of this artificial touch feedback is critical for predicting how beneficial sensory neuroprostheses will be, as noticeable lags will impede usability. Previous studies have compared the reaction time (RxT) of artificial touch to cutaneous vibration in humans and monkeys [Caldwell et al. 2019; Godlove et al. 2014; Sombeck & Miller 2019]. Even though cortical stimulation bypasses a great deal of neural circuitry, artificial touch was perceived more slowly than vibration. However, prior studies did not closely match the perceived intensity between stimuli, which can strongly influence RxT. Therefore, one goal of this study was to further characterize the RxT of artificial touch. We also sought to measure the perception of simultaneous artificial and natural touch, which informs how cortical stimulation interacts with existing somatosensory circuits. We worked with a human subject who has microelectrode arrays implanted in S1 and retained tactile sensation. In a RxT task, the subject received vibration or artificial touch and responded when he felt the stimulus onset. In a temporal order judgement (TOJ) task, we sequentially delivered vibration and artificial touch and the subject answered which stimulus came first. Vibration and artificial touch were offset by 0, 50, 100, 200, 300, or 500 ms, with 20 trials per offset. In both tasks, we adjusted stimulation levels until the subject reported that vibration and artificial touch felt equal in intensity. The RxT was 352 $\pm$ 10 ms (mean $\pm$ std error) for vibration and 400 $\pm$ 13 ms for artificial touch. Sigmoidal curves were fit to raw TOJ data to extract the point of subjective simultaneity (PSS), representing the time at which two stimuli are maximally simultaneous. When vibration and artificial touch occurred in the same region of the hand, the PSS was -18 ± 16 ms, meaning that vibration must occur before artificial touch in order for the stimuli to be perceived as maximally simultaneous. In summary, our RxT results agree with prior findings: the RxT to vibration is faster than artificial touch. Interestingly, the PSS was close to zero, implying a dissociation between processing time and tactile event sequencing. Nevertheless, even though artificial touch takes ~50 ms longer to perceive than natural touch, the stimuli can be simultaneously delivered to the same hand region and be perceived as simultaneous. This indicates that somatosensory neuroprostheses have the potential to be used without noticeable lag in sensorimotor rehabilitation.

Title: A glia-derived antimicrobial peptide mediates a brain-gut-brain axis to sustain lifespan

Authors: *W. XU, J. RUSTENHOVEN, A. FERREIRO, C.-A. BURNHAM, Z. PAPADOPOULOS, G. DANTAS, J. KIPNIS;
Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: As a hallmark protein of Alzheimer's disease (AD), amyloid beta was proposed to be an antimicrobial peptide (AMP), which is involved in AD pathogenesis. However, whether and how other brain-derived antimicrobial peptides regulate aging is largely unknown. Here, we used *Drosophila* and identified an evolutionally conserved AMP as a key modulator of aging. This aging-induced AMP is glia-derived and required to sustain life span via the regulation of sleep quanlity. Furthermore, we found that the sleep modulation by the glial AMP was microbiota-dependent. Glial knockdown of the AMP alters the composition of gut microbiota, and microbiota transfer to germ-free flies phenocopies the sleep deficits. Hence, our study identified a glia-derived immune molecule confers a brain-gut crosstalk, and links neuroinflammation with sleep decline during aging.

Title: Deletion of the N/OFQ peptide or its receptor NOP alters the effects of inflammatory endotoxin LPS on the exploratory response to a novel object and open field

Authors: *M. NISSENBAUM[1], P. PAYNE[1], C. CARDINALE[1], J. E. PINTAR[2], A. W. KUSNECOV[1];
[1]Behavioral and Systems Neuroscience, Dept. of Psychology, Rutgers Univ., Piscataway, NJ; [2]Neurosci. and Cell Biol., Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: The precursor propeptide for Nociceptin/Orphanin FQ (ppN/OFQ) and the nociceptin receptor (NOP) are widely distributed in the brain, particularly limbic regions like the hippocampus, amygdala, and hypothalamus. The N/OFQ peptide has been linked to a variety of behavioral changes, including nociception, reward, and anxiety regulation. Activation of NOP often acts in opposition to a variety of actions including stress, inflammation and mu-opioid receptor stimulation. Here we examined in

C57BL/6 background NOP-deficient [NOP KO] (16F; 20M) or ppN/OFQ-deficient mice [ppN/OFQ KO] (8F; 11M) and their littermate WT controls (8F; 11M) the behavioral and neural response to an inflammatory stimulus, LPS (200μg/kg IP), which reliably elicits systemic IL-1β, TNFα and IL-6. Mice of each genotype were given Saline (13/genotype) or LPS (11/genotype) and subjected to open field (OF)/novel object behavioral testing after 90 mins. A subset of mice per group remained in the home cage. All mice were killed 90 mins after behavioral testing or home cage for spleen cytokine measures and brain c-Fos IHC (quantification in progress). The OF/novel object test assesses anxiety-like responses to contextual and object novelty and consisted of 5 mins of exploration in an empty OF (Phase 1) followed by 5 mins with a novel object placed in the center of the OF (Phase 2). Object introduction reduced exploration for all parameters (distance travelled in inner and border zones, entries into the inner zone, time spent in each zone, latency to enter the inner zone, and latency to approach the object; $p<0.05$). Compared to WT controls, ppN/OFQ KO mice travelled less total distance ($p<0.05$) in both sexes. For both phases, an interaction effect between treatment and genotype was present in which LPS caused reduced total distance travelled in NOP and ppN/OFQ KO mice, but increased distance travelled in WT mice ($p<0.05$). Across sex, LPS-treated NOP KO mice also spent less time in the inner zone during Phase 2, while LPS female NOP KO mice entered the inner zone less than LPS females of other genotypes ($p<0.03$). WT animals interacted with the object more than NOP KO mice. These data suggest that the NOP/OFQ system may counteract the proinflammatory effects of LPS in anxiogenic/exploratory environments. Limbic brain regions are being analyzed to determine if in NOP or ppN/OFQ KO mice c-Fos expression is enhanced in response to behavioral and/or inflammatory stimulation.

Title: Neuroinflammation and its association with cognition, neuronal markers and peripheral inflammation after chemotherapy for breast cancer

Authors: *G. SCHROYEN[1], J. BLOMMAERT[2], D. VAN WEEHAEGHE[3], C. SLEURS[2], M. VANDENBULCKE[4], N. DEDONCKER[4], S. HATSE[2], A. GORIS[4], M. KOOLE[3], A. SMEETS[2], K. VAN LAERE[3], S. SUNAERT[1], S. DEPREZ[1];

[1]Imaging and Pathology, [2]Oncology, [3]Nuclear Med. and Mol. Imaging, [4]Neurosciences, KU Leuven, Leuven, Belgium

Abstract: Background: To uncover mechanisms underlying chemotherapy-induced cognitive impairment in breast cancer, we studied new biomarkers of neuroinflammation and neuronal survival. **Methods:** This cohort study included 74 women (47±10 years) from September 22, 2017, until August 20, 2020. Nineteen chemotherapy-treated and 18 chemotherapy-naïve patients with breast cancer were assessed one month after completion of surgery and/or chemotherapy, and 37 healthy controls were included. Assessments included neuropsychological testing, questionnaires, blood sampling for 17 inflammatory and 2 neuronal survival markers (neurofilament light-chain (NfL) and brain-derived neurotrophic factor (BDNF) and PET-MR neuroimaging. To investigate neuroinflammation, translocator protein (TSPO) [^{18}F]DPA714-PET-MR was acquired for 15 participants per group, and evaluated by volume of distribution normalized to the cerebellum. **Results:** Chemotherapy-treated patients showed higher TSPO expression, indicative for neuroinflammation, in the occipital- and parietal lobe when compared to healthy controls or chemotherapy-naïve patients. After partial-volume correction, differences with healthy controls persisted (p_{FWE}<.05). Additionally, compared to healthy- or chemotherapy-naïve controls, cognitive impairment (17-22%) and altered levels in blood markers (F≥3.7, p≤.031) were found in chemotherapy-treated patients. NfL, an axonal damage marker, was particularly sensitive in differentiating groups (F=105, p=4.2E-21), with levels 20-fold higher in chemotherapy-treated patients. Lastly, in chemotherapy-treated patients alone, higher local TSPO expression was associated with worse cognitive performance, higher blood levels of BDNF/NfL and decreased fiber cross-section in the corpus callosum (p_{FWE}<.05). **Conclusion:** These findings suggest increased neuroinflammation is associated with chemotherapy-related cognitive impairment in breast cancer. Additionally, NfL could be a useful biomarker to assess neurotoxic effects of anticancer chemotherapies.

Title: Ptsd and airway inflammation: a role of t helper 17/il-17a in fear-memory regulation

Authors: *E. ALLGIRE[1], R. AHLBRAND[2], J. MCALEES[3], I. LEWKOWICH[3], R. SAH[1,2];
[1]Univ. of Cincinnati, Cincinnati, OH; [2]VA, Cincinnati, OH; [3]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Posttraumatic stress disorder (PTSD), a trauma associated disorder, is facilitated by maladaptive fear responses that persist beyond typical trauma response. Investigating mechanisms that facilitate persistence of traumatic fear memories will lead to effective screening and treatment regimen for individuals at risk for PTSD. Our lab focuses on the role of asthma-associated airway inflammation (AI) in fear regulation. Of interest, recent evidence supports a synergistic effect of T helper 2 (Th2)/T helper 17 (Th17) mixed response in severe asthma. Higher asthma severity has a greater association with PTSD; thus we have chosen to directly target Th17 signaling. Our recent studies highlight a role of AI and Th17 signaling in regulation of fear extinction, a PTSD relevant behavior. These findings are consistent with strong epidemiological links between severe asthma and PTSD. Using genetic and immunological interventions the current study examined the necessity and sufficiency of IL-17 in regulating extinction. A pilot RNAseq run was conducted to map AI-induced changes in brain transcriptomic signatures. We hypothesized that Th17/IL17A expansion and elevated CNS IL17A will lead to increased fear related behaviors, as well as significant alterations in immune-associated transcripts. Methods: 1) For Th17/Il17A expansion, intratracheal allergen (house dust mite (HDM)) was administered to BALB/c mice with a control antibody (mild) or a C5a receptor-blocking antibody that has been shown to shift the immune response to a mixed Th2/Th17 phenotype. 2) severe asthma prone A/J mice, or A/J mice lacking IL-17 receptor A (IL-17RA KO) were generated. 3) To test sufficiency, recombinant IL17A was administered intracerebroventricularly (ICV) to BALB/c mice prior to behavior. Fear conditioning and extinction was performed in all three manipulations. Consistent with our hypothesis, we found increased extinction freezing in BALBc-C5 mice expressing a mixed Th2/Th17 phenotype, and reduced extinction freezing in IL-17RA knockout mice. Direct administration of lL17A promoted anxiogenic (reduced open arm time) behavior, however, no significant effects on fear extinction were observed. Collectively, these data suggest that Th17A/IL17A expansion and IL17A signaling is necessary for fear extinction deficits associated with airway inflammation, however, indirect mechanisms or other secondary mediators are required for IL17A-mediated fear regulation. Overall, our work provides novel mechanistic information on how airway inflammatory mediators can modulate PTSD-relevant fear behavior and is highly relevant for understanding PTSD association with asthma.

Title: Investigating the persistent impact of developing germ free on reward learning and motivation in adult male and female mice after conventionalization

Authors: *S. L. THOMPSON[1], S. M. GROMAN[1,2], N. W. PALM[1], J. R. TAYLOR[1];
[1]Yale Univ., New Haven, CT; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: The gut microbiome is a critical factor in the developmental and behavioral mechanisms underlying psychiatric disorders. Mounting evidence indicates that the gut microbiome influences reward-based behavior, but the extent and mechanisms are not fully understood. Here, we assessed the effects of germ free status during development on aspects of instrumental reward learning and motivation for food reward in adult mice after conventionalization (i.e., ex-germ free). C57BL/6 mice were conventional (n = 12 female/11 male) or ex-germ free (n = 12 female/11 male). Ex-germ free mice were bred in sterile isolators and then conventionalized at eight weeks old with stool from their conventional counterparts. In adulthood, mice were food-restricted to 85% of free-feeding weight. Hedonic value was assessed by measuring free-access intake of three concentrations of sweetened condensed milk. Mice were trained in an instrumental task to respond for 10% sweetened condensed milk on a fixed ratio-1 reinforcement schedule to assess reward learning. Next, mice were tested on a progressive ratio schedule and on an effort discounting task to measure aspects of effortful motivation. Data were analyzed with change point analyses, cox proportional hazard models, demand functions, factor analyses, and generalized estimating equations, with alpha = 0.05 and p-values corrected for multiple comparisons. Sweetened condensed milk consumption was unaffected by ex-germ free status. Ex-germ free mice acquired the instrumental response slower than conventional mice ($p<.0001$), and this effect was larger in females. However, all groups ultimately achieved equivalent performance. Ex-germ free mice consistently reached lower breakpoints on the progressive ratio schedule ($p<.01$). In the effort discounting task, ex-germ free mice disproportionately discounted the higher effort, larger reward option in an effort-dependent manner ($p<.0001$) and exhibited a larger global effort discounting parameter than conventional mice ($p<.05$). Overall, females learned faster and exerted more effort to acquire rewards compared to males ($p's<.05$). A factor analysis revealed multiple dissociable aspects of motivation and learning, where the learning factor best predicted group assignment. Together, absence of a microbiome during development caused persistent changes in instrumental reward learning and motivation in adult conventionalized mice, particularly in females, but without disruption of basic hedonic drive for a palatable liquid food reward. These results suggest a critical role for the microbiota in the neurodevelopmental mechanisms that underlie reward learning and motivation.

Title: Chronic neuroinflammation and behavior changes with continuous allergen exposure in a mouse model of cow's milk allergy

Authors: *A. BRISHTI, D. GERMUNDSON, N. SMITH, K. NAGAMOTO-COMBS;
Univ. of North Dakota, Grand Forks, ND

Abstract: Cognitive and behavioral changes are often observed in food allergic individuals. Although the mechanism by which food allergy influences cognition and behavior has not been defined, exposure to an allergen is likely the trigger since the removal of suspected food from their diet reportedly improves the associated symptoms. Importantly, these individuals seem capable of consuming offending foods without severe discomfort or anaphylaxis. Consequently, they may not be aware of their food hypersensitivity or necessarily concerned with allergen avoidance, repeatedly placing themselves at risk of allergen exposure and its sequelae. Previously, we demonstrated that inducing cow's milk allergy (CMA) in C57BL/6J mice via sensitization to bovine β-lactoglobulin (BLG) resulted in neuroinflammation with associated anxiety- and depression-like behavior, even though the mice did not display anaphylaxis upon acute allergen challenge. We hypothesized that these allergen-induced peripheral and central inflammatory effects would be prolonged or exacerbated when allergen exposure is recurrent for an extended period. To test this hypothesis, we developed a chronic allergen exposure paradigm by placing BLG-sensitized mice on a whey-containing diet for 3 months to simulate continued dairy consumption by individuals with non-anaphylactic CMA. At the completion of a 5-week sensitization procedure, BLG-sensitized mice showed elevated plasma levels of BLG-specific IgE and IgG1 despite the lack of overt allergic reactions as reported previously, indicating CMA development. After 3 months of whey diet consumption, the allergen-specific immunoglobulin levels and depression-like behavior were comparable in all groups. However, BLG-sensitized mice performed the elevated zero maze test with increased latency to enter the open zones and the cross maze test with decreased number of successful arm alternations, exhibiting anxiety-like behavior and spatial-memory impairment, respectively. In addition, several inflammatory cytokines were elevated in the brains of BLG-sensitized mice on the whey diet, particularly in the hippocampus, compared to respective sham mice or BLG mice placed on a whey-free diet after sensitization. Moreover, BLG-sensitized mouse brains showed increased glial fibrillary acidic protein immunoreactivity. Our results indicated that peripheral and central inflammation and behavioral changes were differentially affected in BLG-sensitized mice by the presence of allergens in their diet and the duration of consumption.

Title: Early life cancer and chemotherapy exposure results in cognitive deficits: a potential role for brain and gut cytokine responses

Authors: J. P. KONSMAN[1], C. J. LAAKER[2], K. R. LLOYD[3], B. L. SMITH[4], M. A. SMAIL[5], ***T. M. REYES**[6];
[1]CNRS UMR 5287 INCIA / Univ. Bordeaux, Bordeaux, France; [3]Pharmacol. & Systems Physiol., [4]Dept. of Psychiatry and Behavioral Neurosci., [5]Pharmacol. and Systems Physiol., [2]Univ. of Cincinnati, Cincinnati, OH; [6]Univ. of Cincinnati, Col. of Med., Cincinnati, OH

Abstract: Survival rates for acute lymphoblastic leukemia (ALL), the most common childhood cancer, are now close to 90%, but survivors of childhood cancer are at an increased risk for long term cognitive deficits, particularly affecting executive function (e.g., attention, planning, inhibitory control, cognitive flexibility). The chemotherapeutic agent methotrexate (MTX) is used to treat most ALL patients, and is closely associated with executive function deficits. Thus a pressing need exists to define the mechanisms that link MTX exposure to cognitive dysfunction.
To that end, we have developed a translationally relevant mouse model of leukemia survival that combines cancer exposure (mouse leukemic cell line (L1210 cells) with contemporary chemotherapeutic drugs (vincristine and MTX, with leucovorin rescue) administered during early life. Male and female mice were tested several weeks later using novel object recognition (recognition memory) and 5-choice serial reaction time task (executive function). Gene expression of proinflammatory, white matter and synapse-associated molecules was assessed in the prefrontal cortex and gut both acutely after chemotherapy and chronically after cognitive testing. Early life cancer-chemotherapy exposure resulted in recognition memory and executive function deficits in adult male mice. Prefrontal cortex expression of the chemokine Ccl2 was increased acutely, while gut expression of the proinflammatory cytokine tumor necrosis factor-alpha was elevated both acutely (both sexes) and chronically (males only). Inflammation in the gut was related to prefrontal cortical proinflammatory and synaptic gene expression changes, as well as to executive function deficits. Collectively, these data indicate that the current protocol results in a robust mouse model in which to study cognitive deficits in leukemia survivors, and suggest that gut inflammation may represent a novel contributor to adverse CNS consequences of early life chemotherapy.

Title: Microglia Depletion in Adult Female Rats Promotes the Display of Maternal Behavior

Authors: *C. DYE[1], D. FRANCESCHELLI[2], B. LEUNER[1], K. LENZ[1];
[1]Psychology, Neurosci., [2]The Ohio State Univ., Columbus, OH

Abstract: The peripartum period is a time of dramatic shifts in the peripheral immune system, particularly significant immunosuppression which allows the fetus to be carried to term. Interestingly, we

and others have also demonstrated significant neuroimmune changes that occur during pregnancy, most prominently a decreased number of microglia across limbic brain regions (Haim, et al., 2017; Posillico & Schwarz, 2016). However, the functional significance of peripartum microglial alterations remains unclear. Given that these microglial decreases emerge in late pregnancy, we hypothesize that they are important for the coordinated onset and display of maternal behavior. To test this, we recapitulated the peripartum neuroimmune profile by depleting microglia in non-mother rats. Adult female virgin rats are typically not maternal but can be induced to behave maternally towards foster pups following repeated exposure, a process called maternal sensitization. BLZ945, a selective colony-stimulating factor 1 receptor (CSF1R) inhibitor, was administered systemically to virgin rats 2 times 48 hours apart, which led to ~75% decreases in microglia number in the brain within 24 hours of the last injection. BLZ- and vehicle-treated females then underwent maternal sensitization via daily exposure to foster pups. We found that BLZ-treated females met criteria for displaying maternal behavior significantly sooner than vehicle-treated females. Moreover, BLZ-treated animals displayed increased pup-directed behaviors including licking and sniffing. BLZ-treated animals also displayed reduced anxiety-like behaviors as measured by increased entries and time in the center of an open field. Ongoing work examining factors that facilitate experience-dependent plasticity, such as perineuronal nets, that are typically upregulated in the absence of microglia, show promise as mediators of the changes we report here. Though previous work suggested that microglial depletion does not significantly affect behavior in adult males (Elmore et al., 2014; Dagher, et al., 2015), our results demonstrate for the first time that microglia are crucial regulators of behavior in the adult female brain, and might be particularly important in the context of maternal care.

Abstract: Mechanisms governing how immune cells and their derived molecules impact homeostatic brain function are still poorly understood. Here, we elucidate neuronal mechanisms underlying effects of T cells on synaptic function and episodic memory. Depletion of CD4 T cells led to memory deficits and impaired long-term potentiation. In addition, severe combined immune-deficient (SCID) mice exhibited amnesia, which was reversible by repopulation with T cells from wild-type but not from IL-4-knockout mice. We further demonstrated that the impaired cognition was mediated via IL-4 receptors (IL-4R) expressed on neurons but not myeloid cells in the healthy brain. To study the effect T cells are playing on cognition in depth, exploration of neurons participating in memory processing by single-nuclei RNAseq, provided insights into synaptic organization, plasticity-associated pathways and genes regulated by T cells and IL-4. IL-4Rα knockout in inhibitory neurons impaired contextual fear memory, suggesting participation of an IL-4-associated switch in regulating synaptic function and promoting contextual fear memory. These findings provide insights into immune dysfunction seen in neurological and psychiatric conditions. They also indicate that certain T cell subsets drive processing steps in the brain and potentially relay information to modulate mammalian behavior.

Title: Use of foods of varying palatability to induce binge-like eating behavior in male and female rats: Effects of lisdexamfetamine administration alone and in combination with dopamine antagonists with varying receptor selectivity profiles

Authors: *R. E. PRESBY[1], J. C. MASTHAY[1], M. SHEKAR[1], A. MEMON[1], M. BRAUN[1], R. A. ROTOLO[1], A. ECEVITOGLU[1], E. M. ZORDA[1], C. CARRATALÁ-ROS[2], E. ARIAS-SANDOVAL[2], N. M. MEKA[1], S. M. SRINATH[1], M. CORREA[2], J. D. SALAMONE[1];
[1]Psychological Sci., Univ. of Connecticut, Storrs, CT; [2]Psicobiologia. Univ. Jaume I, Castello, Spain

Abstract: Binge Eating Disorder (BED) is characterized by feelings of a lack of control in food consumption causing an individual to consume large amounts of food in a short period of time, leading directly to an array of physical and mental health sequelae. Animal models of binge-like eating behavior are essential for interrogating the brain systems underlying binge eating. Extensive work has demonstrated that intermittent and restricted access to highly palatable food in rats promotes an escalation of food intake. The only medication currently FDA approved for the treatment of BED, lisdexamfetamine (LDX; *Vyvanse*), acts as a d-amphetamine pro-drug (i.e., slow-release formulation) to facilitate dopamine (DA) transmission via inhibition of DA transport and stimulation of release. The focus of the present work is on the development of binge-like eating behavior in male and female rats involving food types with varying palatability, the manipulation of this behavior through administration of LDX, and the role

that DA receptors may be playing in the regulation of binge-like eating behavior through co-administration of various selective and non-selective DA receptor subtypes. Results indicate that the degree of induced binge-like eating behavior differed across food-type (chocolate > high-carbohydrate pellets > grain pellets) but LDX administration significantly reduced intake of all foods. A partial reversal of this LDX-induced reduction in binge-like eating of chocolate was seen after co-administration of selective antagonists for D1 and D2 DA receptors, as well as the non-selective DA antagonist flupenthixol. This indicates a role for both DA D1 and D2 receptor subtypes in the suppression of binge-like eating induced by LDX, but the partial nature of the reversal also leaves open the possibility of involvement from other neurotransmitters such as norepinephrine.

Title: Characterization of the catecholamine uptake inhibitor bupropion and the opioid antagonist naltrexone on binge-like eating behavior

Authors: *J. C. MASTHAY[1], R. E. PRESBY[1], R. A. ROTOLO[1], A. ECEVITOGLU[1], E. M. ZORDA[1], C. CARRATALÁ-ROS[2], E. ARIAS-SANDOVAL[2], N. M. MEKA[1], S. M. SRINATH[1], M. CORREA[2], J. D. SALAMONE[1];
[1]Psychological Sci., Univ. of Connecticut, Storrs, CT; [2]Psicobiologia Univ. Jaume I, Castello, Spain

Abstract: The overconsumption of highly palatable foods, as seen in Binge Eating Disorder (BED), represents a substantial risk for both physical and mental health. Currently, the only medication FDA approved for the treatment of BED is lisdexamfetamine (LDX; *Vyvanse*) a d-amphetamine pro-drug (i.e., slow-release formulation) that acts to facilitate dopamine (DA) transmission. Development of novel therapies that will lead to more robust treatment options for patients diagnosed with BED is imperative, and animal models of binge-like eating behavior play an integral role in treatment development. An animal model of binge-like eating in which rats are given intermittent, short access to a highly palatable food (Cadbury's Milk Chocolate) was used in the present experiments. This research aimed to characterize the effects of two commonly prescribed drugs for weight-loss that have been suggested as novel treatment options for BED: the catecholamine uptake inhibitor bupropion (BUP; 10.0-40.0 mg/kg IP) and the opioid antagonist naltrexone (NTX; 0.1-3.0 mg/kg IP) on binge-like eating behavior in male and female rats. A significant reduction in binge-like eating was found at the highest dose of BUP and all doses of NTX in male rats. Female rats also showed suppression of chocolate intake after 40.0 mg/kg

BUP. These results are similar to what has been reported in humans, and give credence to the use of these drugs as treatment options for BED. Additional studies should examine the effects of bupropion administered in combination with naltrexone, which is an effective combined treatment for people with obesity. Furthermore, future research should determine the specific brain mechanisms through which these drugs act to suppress intake of palatable foods.

Title: Knockout of MeCP2 in POMC neurons increases preference for high fat diet but does not alter motivation for food reward

Authors: P. FRAYRE[1], **A. BAIRD**[1], J. FRAYRE[1], K.-P. RUBIO[1], M. J. MORRIS[1], E. S. NA[2]; [1]Texas Woman's Univ., Denton, TX; [2]Texas Woman's Univerisity, Denton, TX

Abstract: The obesity epidemic has afflicted 42% of adults in the United States with obesity rates increasing at alarming rates worldwide. Monogenic causes of obesity are extremely rare thus there must other contributing factors to obesity. Disruptions in Methyl-CP-G binding Protein 2 (MeCP2) gene function have been associated with the etiology of Prader Willi Syndrome, a neurodevelopmental disorder characterized by hyperphagia and obesity. MeCP2 is a neuroepigenetic factor that activates or represses specific genes and when knocked out in mice produces obesity and hyperphagia. Given that MeCP2 knockout (KO) mice are hyperphagic, it is not clear if MeCP2 KO mice find food more rewarding or are more motivated to acquire food reward. Using transgenic mice in which MeCP2 is knocked out specifically in pro-opiomelanocortin neurons of the arcuate nucleus of the hypothalamus, POMC-MeCP2 KO mice were subjected to a conditioned place preference test and operant conditioning to assess food preference and motivation to acquire food reward. Body weight and high fat (HF) diet intakes were also recorded to examine the effects of POMC specific knockout of MeCP2 on body weight homeostasis after exposure to an obesogenic diet. Our current data suggest that POMC-MeCP2 KO mice have an increased preference for HF diet as demonstrated by increased time spent in the chamber paired with HF diet (conditioned place preference) but showed less motivation to work for food reward as evidenced by decreased breakpoint in a progressive ratio operant conditioning task. POMC-MeCP2 KO mice also displayed higher body weight relative to WT control mice. Taken together, these data indicate that POMC-specific MeCP2 disruption may cause KO mice to be more sensitive to obesogenic diets and increase preference for high fat food.

Title: Altered hedgehog signaling in adult neurons results in obesity

Authors: *S. E. ENGLE, P. J. ANTONELLIS, K. M. BREWER, R. BANSAL, N. F. BERBARI; IUPUI, Indianapolis, IN

Abstract: Primary cilia are important signaling centers found on nearly every cell type, including neurons throughout the brain. Their dysfunction leads to several different disease phenotypes including neurocognitive deficits. In ciliopathies such as Bardet-Biedl and Alström syndromes, patients present with hyperphagia associated obesity. Additionally, conditional cilia loss in adult mice leads to hyperphagia and obesity, yet how cilia dysfunction contributes to feeding behavior is complex and remains controversial and unclear. One well known pathway coordinated by cilia in mammals is the hedgehog pathway. While crucial for embryonic development, little is known about its role in terminally differentiated neurons. Here we show components of the hedgehog pathway are expressed in the feeding centers of the hypothalamus of adult mice. Furthermore, *in situ* hybridization has revealed hedgehog pathway expression in specific neuronal populations involved in feeding behavior. We also demonstrate by qPCR that hedgehog pathway activity appears responsive to nutritional status and is altered upon obesity. We next explored how body weight is impacted by altering the hedgehog pathway *in vivo.* Using a genetic approach, we constitutively activated hedgehog signaling specifically in adult melanin concentrating hormone receptor 1 (MCHR1) expressing neurons. MCHR1 is a ciliary GPCR with well-recognized roles in energy homeostasis. Hedgehog pathway activation in MCHR1 neurons in adult mice resulted in hyperphagia and obesity. These findings suggest a novel role for ciliary hedgehog signaling in the regulation of feeding behavior and adult energy homeostasis. Current studies are focused on understanding interactions between the hedgehog and MCH signaling pathways in adult neurons. Understanding how the hedgehog pathway influences ciliary GPCR signaling in terminally differentiated neurons could reveal molecular mechanisms associated with clinical features of ciliopathies, such as hyperphagia-associated obesity.

Abstract: Orexins (hypocretins) are neuropeptides expressed by distinct neurons in the lateral hypothalamic area (LHA) and adjacent regions, including the perifornical area and dorsomedial and posterior hypothalamus in humans and rodents. The orexin system consists of the two distinct neuropeptides, orexin-A and orexin-B (hypocretin-1 and -2), which are both derived from a common precursor peptide, and they act on two G-protein coupled receptors, orexin receptor type 1 (Ox1R) and type 2 (Ox2R). The wake-active orexin system plays a key role in maintaining dynamic regulation and daily rhythm of peripheral glucose homeostasis. It has been described to have dual roles in regulating blood glucose, possibly through the autonomic nervous system. Here, we systematically investigated the expression and distribution of orexin receptors in serotonergic neurons in raphe nucleus, and the impact of optogenetic activation of orexin signaling and specific inactivation of Ox1R or Ox2R signaling in serotonin transporter (Sert)-expressing cells on glucose metabolism and energy homeostasis. We show that Ox1R and Ox2R are predominantly expressed in dorsal raphe nucleus-dorsal and -ventral, respectively. Serotonergic neurons in ventral median raphe nucleus and raphe pallidus selectively express Ox1R. Inactivation of Ox1R in serotonin transporter-expressing cells of mice reduced insulin sensitivity in diet-induced obesity, mainly by decreasing glucose utilization in brown adipose tissue and skeletal muscle. Selective inactivation of Ox2R improved glucose tolerance and insulin sensitivity in obese mice, mainly through a decrease in hepatic gluconeogenesis. Optogenetic activation of orexin neurons in the lateral hypothalamus or orexinergic fibers innervating the raphe pallidus impaired or improved glucose tolerance, respectively. Collectively, the present study assigns orexin signaling in serotonergic neurons critical yet differential orexin Ox1R- and Ox2R-dependent functions in the regulation of systemic glucose homeostasis.

Orexin A and orexin B effect on $[Ca^{2+}]_i$ of serotonergic neurons in DRV measured with GCaMP6. Recordings were performed in brain slices from control, Ox1R$^{\Delta SERT}$, and Ox2R$^{\Delta SERT}$ male mice, with GCaMP6 expression in serotonergic neurons. (A) Original recordings (top) and heat maps of 5 individual neurons for each set of experiments (bottom). The recordings show the responses to the orexins and high K^+ saline. Dashed lines indicate the range where the responses were quantified. (B) Calcium responses upon 100 nM orexin A and orexin B. Data are shown as the percentage of the maximal response to high K^+ saline.

Title: Novel molecular profiling based pharmacological strategy leads to the identification of a preclinical compound for weight management.

Authors: *M. SCHNEEBERGER PANE[1], N. L. BRICE[2], K. PELLEGRINO[1], L. PAROLARI[1], J. SHAKED[1], T. TOLPIKO[3], K. PAGE[2], D. BARROWS[1], M. ORTUNO[4], T. CARROLL[1], N. RENIER[3], A. R. NECTOW[4], M. CARLTON[2], N. HEINTZ[5], J. FRIEDMAN[1];

Abstract: Distinct neural subpopulations in the Dorsal Raphe Nucleus (DRN) of the brainstem have recently been shown to acutely regulate food intake, energy expenditure and body weight[1,2]. Intriguingly, in the DRN, excitatory Vglut3- expressing glutamatergic neurons (DRN^{Vglut3}) induce satiety and increase locomotion. Thus, chronically activating DRN^{Vglut3} neurons could induce sustained feeding suppression and in principle be used to manage weight upon obesity.Here, we report that indeed chronic activation of DRN^{Vglut3} neurons using DREADDs stably reduces food intake and body weight in both genetic and diet induced obese (DIO) mice models, bypassing leptin resistance. Given those effects, we next designed a molecular profiling based pharmacological strategy to identify specific therapeutic targets in those neurons. By means of a three-tiered approach combining Translational Affinity Purification (TRAP) of DRN^{Vglut3} neurons with bioinformatic enrichment comparison to the Gene Expression Nervous System Atlas (GENSAT) database and Gene Ontology enrichment for signaling receptors in the plasma membrane, we narrowed down potential targets in DRN^{Vglut3} neurons to 3 highly selective and enriched targets for drug discovery: calcitonin receptor (Gs coupled), orexin 1 receptor (Gi coupled) and G-protein coupled receptor 4 (orphan). Importantly, we demonstrate through pre-clinical pharmacological studies that a new orally distributed and brain penetrant selective antagonist (CVN45502) of Orexin 1 receptor (Hcrt1) was capable of reducing food intake and ultimately body weight upon DIO[3].Together, these studies provide a general approach for the treatment of neuronally driven disorders by identifying drug targets in specific neuronal populations using a molecular profiling-based strategy. Such strategy is thus proven effective for preclinical drug screening and targeting in central populations of neurons, avoiding unspecific bindings and effectively speeding lead molecule identification for clinical trials.[1]Nectow A.R.[*], **Schneeberger M**.[*], ([*]co-first author) et al. Title: Agrp neurons coordinate the mitigation of activity-based anorexia

Authors: *A. K. SUTTON, S. C. DUANE, A. M. SHAMMA, A. SKILLINGS, M. J. KRASHES;
NIH, Bethesda, MD

Abstract: Anorexia nervosa (AN) is a debilitating and deadly disease characterized by low body mass index due to diminished food intake, and oftentimes concurrent hyperactivity. A high percentage of AN behavioral and metabolic phenotypes can be replicated in rodents given access to a voluntary running wheel and subject to food restriction, termed activity-based anorexia (ABA). Despite the well-documented body weight loss observed in AN human patients and ABA rodents, much less is understood regarding the neurobiological underpinnings of these maladaptive behaviors. Here, feeding microstructure analysis revealed ABA mice decreased food intake due to increased interpellet interval retrieval and diminished meal number. Longitudinal activity recordings of hypothalamic agouti-related peptide (AgRP) neurons in ABA animals revealed a maladaptive inhibitory response to food. We then demonstrated that ABA development or progression can be mitigated by chemogenetic AgRP activation through the reprioritization of food intake (increased meal number) over hyperactivity. These results elucidate a potential neural target for the amelioration of behavioral maladaptations present in AN patients.

Title: Characterization of lateral hypothalamic area cells projecting to the dorsal vagal complex

Authors: *J. LEE[1], N. PENCE[1], L. RAYCRAFT[1], A. CALDWELL[1], A. JOHNSON[2];
[1]Michigan State Univ., Lansing, MI; [2]Dept of Neurosci., Michigan State Univ., East Lansing, MI

Abstract: The lateral hypothalamic area (LHA) is a large diencephalic structure that spans the entire rostral-caudal axis of the hypothalamus. The LHA houses a wide variety of molecularly distinct neuronal populations that play a critical role in a range of processes related to metabolic function and ingestive behavior. LHA descending projections to regions with parasympathetic innervation may serve a critical

role in mediating neuronal control of metabolism. Thus, in this study we used a dual-viral tracing approach to determine the nature of projections from the LHA to the dorsal vagal complex (DVC) a region implicated in integrating parasympathetic information to the periphery. Female Sprague Dawley rats received injections of retrograde AAV2 (rAAV2-Cre) containing Cre recombinase transgene into the DVC. When injected into axonal terminals, rAAV2-Cre is retrogradely transported to cell bodies and induces the expression of Cre-recombinase in these cells. In addition, a Cre-dependent virus expressing mCherry was then administered throughout the rostral-caudal axis of the LHA. This approach permits the identification and quantification of LHA cells that monosynaptically project to the DVC. Projections from the LHA to the DVC displayed a rostral-caudal gradient where cell bodies were seen more extensively in posterior sections of the LHA. Next, we examined overlap between LHA - DVC projecting cells and those expressing Melanin Concentrating Hormone (MCH)—an orexigenic neuropeptide implicated in glucoregulation and metabolism. Only a sparse number of LHA MCH expressing cells were found to project to the DVC. Overall, these findings provide insight into the location and properties of LHA projections to the DVC, laying the foundation to explore the function of this circuitry for feeding behavior and metabolism.

Title: Characterizing D1 and D2 receptor-mediated changes in palatable food intake in binge eating prone female rats.

Authors: *M. REES[1], N. FOWLER[2], N. PENCE[2], A. PATARO[3], J. LEE[2], K. KLUMP[2], C. SISK[2], A. JOHNSON[2];

Abstract: Binge eating is a pathological eating behavior that can manifest in several eating disorders in humans. The dopamine system contributes to the regulation of eating behavior, therefore in this study we examined whether differential palatable food (PF) consumption was associated with stimulation and blockade of dopamine receptors in an animal model of individual differences in binge eating behavior. Sixty adult female Sprague Dawley rats were given intermittent access to PF 3x/week for 2 weeks to identify binge eating prone (BEP; consistently high levels of PF intake) and non-BEP rats (all other rats). Next, all rats received intraperitoneal injections of either vehicle, low, or high doses of the dopamine D1R agonist SKF 38393, D1R antagonist SCH 23390, D2R agonist quinpirole, and the D2R antagonist raclopride followed by PF and chow intake tests. Stimulation of D1R had minimal effect over PF or chow

intake in BEP or non-BEP rats, whereas relative to vehicle, high-dose blockade of the D1R led to a reduction in PF intake in BEP and non-BEP rats, with no effect on chow intake. BEP's were also more responsive to the hypophagic effect of D2R stimulation, and the hyperphagic effect of D2R blockade for PF but not chow intake. To examine whether this enhanced responsivity to pharmacological manipulations of dopamine receptors reflected individual differences in receptor expression, D1R and D2R mRNA in the nucleus accumbens was quantified in a subset of BEP and non-BEP rats. Collectively, our findings suggest that alterations in dopaminergic reward circuitry may underlie increased PF intake in BEPs.

Title: Chemogenetic excitation of melanin concentrating hormone neurons produces unique effects on interval timing and motivation depending on sex, estrous cycle stage, and neuron location

Authors: *L. M. RAYCRAFT[1], M. BUNNEY[2], A. NALLA[2], A. PATARO[2], D. A. KASHY[1], E. NOBLE[3], S. E. KANOSKI[4], A. W. JOHNSON[1];

Abstract: In terms of timing, feeding behaviors have typically been studied from a circadian perspective. However, multiple timescales exist that likely inform feeding behaviors. Interval timing is a unique form of timing that refers to the ability to tell time in the seconds-to-minutes range. Importantly, interval timing enables the temporal contiguity that supports learning and decision-making. Notably, no studies have yet examined whether feeding peptides important for food-related learning and decision making can also influence interval timing. In the present study, we examined whether chemogenetic excitation of cells expressing the orexigenic neuropeptide melanin concentrating hormone (MCH) would influence responding in the peak interval task. Male and female Sprague Dawley rats first learned to lever press for sucrose reinforcement, where delivery was contingent on the response occurring after a 20 s criterion duration. Subsequently, non-reinforced probe trials were intermixed, where the lever remained available for ≥ 60 s period. During these trials, responding forms a normal distribution which peaks around the criterion duration (i.e., 20 s). Using a custom AAV to drive excitatory hM3Dq expression under the control of the MCH gene promoter, pMCH, we selectively excited MCH neurons throughout the rostrocaudal extent of the lateral hypothalamic area (LHA) during the peak interval task. Following MCH neuron excitation, we observed significant differences in peak interval responding during probe trials that depended on (1) the location of MCH neuronal excitation within the LHA, (2) sex, and (3) estrous cycle

stage. Furthermore, we used multi-level modeling to confirm effects of MCH neuronal excitation. Altogether, these results indicate that subpopulations of MCH neurons uniquely modulate interval timing and food-seeking depending on sex and estrous cycle stage. Moreover, these findings are the first to identify an influence of orexigenic neuropeptides on interval timing.

Title: Circuit-specific inhibition of dopaminergic signaling associated with phantom gustatory sensations in Disrupted-in-Schizophrenia-1 mice

Authors: *B. R. FRY[1], V. FEX[2], F. SOTOMAYORREINAT[2], M. NIWA[4], A. SAWA[5], A. W. JOHNSON[3];

Abstract: Disrupted-in-Schizophrenia-1 (DISC-1) is a gene which encodes a protein involved in a number of intracellular processes, particularly those critical for early neural development. In mice, perturbations of the DISC-1 genetic locus lead to a syndrome which mimics many of the core endophenotypes associated with schizophrenia. These mice have been shown to display impaired reality testing as revealed by heightened perceptual processing of an absent sucrose solution in the presence of an auditory conditioned stimulus (CS). These impairments were dopamine-dependent and associated with elevated insular cortex (IC) activity. In the current study, we examined whether these effects required activity of ventral tegmental area (VTA) dopamine cells projecting to the IC. To achieve this we bred DISC-1 mice to mice selectively expressing Cre-recombinase within cells expressing the dopamine transporter (DAT-Cre). These DISC-1 x DAT-Cre mice received bilateral infusions of a retrograde Cre-dependent Flp-O recombinase virus in IC, followed by bilateral VTA injections of a Flp-dependent hM4Di inhibitory DREADD virus. Through this approach, intraperitoneal (IP) injections of clozapine-N-oxide (CNO) allows for circuit-specific inhibition of dopamine cells projecting to IC. Following surgery, mice underwent Pavlovian conditioning in order to learn an association between a white-noise CS and delivery of sucrose solution. Subsequently, mice received IP injections of vehicle or CNO on separate test days, at which point the capacity of the CS to transfer sensory responses typically evoked by the sucrose was examined by presenting the CS alone with water. Our findings will offer insight into the genetic and neurobiological mechanisms underlying dopamine-mediated reality testing.

Title: Chemogenetic stimulation of telencephalic and mesencephalic GHSR-expressing cells differentially affects feeding behavior and stimulus palatability.

Authors: *A. KONDILIS[1], A. W. JOHNSON[2];
[1]Cell and Mol. Biol., [2]Dept. of Psychology, Michigan State Univ., East Lansing, MI

Abstract: The gastric hunger signal, ghrelin, influences feeding behavior via activation of the growth hormone secretagogue receptor (GHSR). GHSR's are expressed in multiple brain regions including the basolateral amygdala (BLA), ventral hippocampus (VHPC) and ventral tegmental area (VTA). These regions play a critical role in integrating motivational and reward signals to influence feeding behavior. In this study, we used a GHSR-IRES-Cre mouse line that expresses Cre directed by the GHSR promoter. Mice received Cre-dependent excitatory DREADD into either the BLA, VHPC, or VTA to examine whether chemogenetic stimulation of GHSR-expressing cells within these regions would influence consumption of lab chow or a palatable high fat diet (HFD). On test days, mice were injected with clozapine-N-oxide (CNO) or vehicle solution prior to the onset of the dark cycle and given portioned access to either lab chow or HFD. CNO-evoked DREADD stimulation of BLA or VHPC GHSR-expressing cells significantly enhanced lab chow but not HFD intake. Conversely, stimulation in the VTA attenuated lab chow consumption. To examine intake of specific macronutrients and the nature of any changes in ingestive behavior, we separately investigated fluid intake of lipid (45% corn oil), sugar (20% sucrose), and starch (20% maltodextrin) through an analysis of licking microstructure. This quantitative approach is capable of dissociating overall intake into individual components of pre-ingestive (e.g., orosensory, palatability; via burst size) and post-ingestive (e.g., negative feedback; via burst number) variables that regulate meal intake. The chemogenetic manipulations mainly influenced short-term solution intake in VHPC mice, such that excitation of GHSR-expressing cells in this region surprisingly inhibited sucrose intake through a decrease in burst number. Conversely, DREADD activation of these cells increased the palatability of corn oil. These data provide insight into the differential role of central nervous system GHSR-expressing cells on ingestive behavior that is in part dependent on the neuronal loci in which they are expressed and the nature of the tastant being consumed.

Title: Central Amygdala Htr2a neurons are required for ghrelin-induced hedonic feeding

Authors: *C. PETERS, H. LIM, R. KLEIN;
Molecules - Signaling - Develop., Max Planck Inst. of Neurobio., Planegg, Germany

Abstract: Ghrelin, a gastric-derived small peptide, influences the activities of hypothalamic circuits to promote homeostatic feeding and extra-hypothalamic areas to regulate hedonic feeding. The latter behavior may involve the amygdala, a highly conserved brain region important for the expression of defensive and appetitive behaviors, including feeding. Previous work from our lab showed that the activation of Htr2a+ neurons in central amygdala (CeA) increases food intake through a positive valence signal (Douglass et al, 2017). We hypothesized that part of the rewarding mechanism induced by ghrelin to increase appetite occurs through CeA^{Htr2a} neurons. Our results show that ghrelin increases c-Fos staining and excitatory neurotransmission in CeA^{Htr2a} , but not $CeA^{PKC\delta}$ neurons, a major anorexigenic subpopulation. Chemogenetic inhibition of CeA^{Htr2a} neurons completely blocked the effects of systemic application of ghrelin. Importantly, direct infusion of ghrelin into the CeA increased food consumption of satiated mice, an effect that was dependent on ghrelin (GHSR) and opioid receptors. Our findings also indicate that the neurons activated by ghrelin in CeA project to the parabrachial nucleus (PBN), inhibiting PBN neurons and thereby promoting feeding. This conclusion is consistent with our previous observations that at least part of the orexigenic activities of CeA^{Htr2a} neurons are mediated by projections to the PBN. These findings suggest that ghrelin activates a specific CeA-to-PBN circuit to induce hedonic feeding.

Title: The cholinergic basal forebrain and its imapct on the basolateral amygdala and feeding behavior

Authors: *J. ORTIZ-GUZMAN[1], J. SWANSON[1], M. KUCHOKOV[1], E. HANSON[1], K. UNG[1], E. TANTRY[1], A. ADDISON[1], S. DOOLING[1], Q. TONG[3], B. ARENKIEL[2];
[1]Mol. and Human Genet., [2]Mol. Med., Baylor Col. of Med., Houston, TX; [3]Mol. Med., Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Body weight homeostasis is regulated by balancing energy expenditure with caloric intake. Obesity, a major public health concern, is often the result of excessive caloric intake without reciprocal caloric expenditure. The hypothalamus is considered the master regulator of energy homeostasis and has garnered significant attention towards understanding the neural circuits that govern feeding behavior and body weight homeostasis. However, the hypothalamus does not act independently; extra-hypothalamic circuits throughout the brain perceive, anticipate, and adapt to the availability of food. We recently discovered a population of basal forebrain cholinergic neurons that govern aspects of appetite suppression. Through viral tracing methods, we found that basal forebrain cholinergic neurons densely innervate the basolateral amygdala (BLA). The BLA has known connections to the hypothalamus and reward centers, and is implicated in affecting appetitive behavior. However, the circuit mechanisms that govern BLA-driven feeding behaviors remain largely unknown. Here, using Channelrhodopsin-assisted circuit mapping, we identified muscarinic and nicotinic responses in BLA excitatory principal neurons following cholinergic basal forebrain terminal axon stimulation. Additionally, we found that BLA neurons signal to the nucleus accumbens via differential muscarinic or nicotinic responses. Through in vivo optogenetic manipulations, we show that increased cholinergic signaling from the basal forebrain to the BLA results in reduced food intake in fasted animals with no major effects on stress and/or anxiety. Together, these data support a model in which cholinergic signaling from the basal forebrain onto projection-defined neurons within the basolateral amygdala leads to appetite suppression.

Title: Dopamine projections to the basolateral amygdala mediate the encoding of outcome-specific reward memories

Authors: *A. SIAS[1], K. WASSUM[1,2];
[1]Psychology, UCLA, Los Angeles, CA; [2]Brain Res. Insitute, Univ. of California Los Angeles, Los Angeles, CA

Abstract: Adaptive decision making requires one to accurately anticipate specific rewarding events. When not readily observable, environmental stimuli enable us to mentally simulate the likelihood of particular rewarding outcomes and choose accordingly. Dopamine is known to be critical for reward learning and more recently has been implicated in learning the associative structure between cues and the specific rewards they predict, i.e., model-based learning. But the projections through which dopamine facilitates detailed stimulus-reward learning is unknown. One likely candidate is the basolateral amygdala (BLA). The basolateral amygdala is a hub for emotional learning, and we recently demonstrated it to be critical for encoding detailed, sensory-specific stimulus-reward memories. To investigate whether dopaminergic inputs support the BLA in forming these sensory-specific, appetitive associations, we combined optogenetics with a translationally-relevant behavioral task that assesses the use of unique stimulus-reward memories to inform decision making. Using optical inhibition, we found dopamine projections from the ventral tegmental area (VTA) to the BLA are necessary for encoding detailed stimulus-reward memories. Inhibiting dopaminergic VTA-->BLA projections upon reward experience during Pavlovian stimulus-reward conditioning did not disrupt acquisition or expression of a Pavlovian conditional goal-approach response but did prevent encoding of the sensory-specific stimulus-reward relationships, as evidenced by an inability to subsequently use this information to guide selective choice in a Pavlovian-to-instrumental transfer test. These data reveal that midbrain dopamine projections to the BLA are not needed to develop a Pavlovian response policy but are essential for encoding rich associative memories that link stimuli to the unique rewards they predict.

Title: Cell type characterization of the lateral septum during morphine dependence and withdrawal

Authors: *R. SIMON[1], A. D. SANDERS[2], M. A. ROSSI[3], G. D. STUBER[1];
[1]Dept. of Anesthesiol. and Pain Med., Univ. of Washington, Seattle, WA; [2]Univ. of California San Francisco, San Francisco, CA; [3]Child Hlth. Inst. of New Jersey, Rutgers Univ., New Brunswick, NJ

Abstract: Neuropsychiatric disorders such as addiction and anxiety stem from dysregulation of neural substrates that govern motivated behaviors. Developing therapeutic strategies for individuals suffering from these conditions therefore requires further study of brain areas underlying reward- and anxiety-related behaviors. The lateral septum (LS) has been recognized as both a site of reinforcement and as a regulator of fear expression. Its connectivity with key brain structures in reward learning and in fear and anxiety gives rise to the LS's involvement in diverse behaviors, including locomotion, feeding, mating,

avoidance, and even addiction. Although the LS has genetically defined neuronal subtypes, it is unclear how various populations within the LS respond to positive and negative-valent stimuli. To evaluate how discrete LS cell types respond to divergent stimuli, we used a morphine administration and withdrawal model in which male and female mice received an escalating dose of morphine to cause drug dependence. A separate group of mice received naloxone (NAL) to facilitate withdrawal, an aversive state during which we predict LS cell types to be selectively activated. Mice were then sacrificed for their septal tissue, which next underwent single-nucleus RNA sequencing. This approach allowed us to profile LS cell types and their responsivity to both positive (morphine) and negative (withdrawal) experiences. To ensure rigor and reproducibility of our results, we used litter- and age-matched male and female mice (8 weeks old WT C57/b6) were combined into 3 samples (saline control, morphine dependence and NAL withdrawal). We identified at least 19 septal neuron clusters, including 2 GLUergic and 17 GABAergic types. Our data captured canonical LS types, such as neurotensin+ (*Nts*) and somatostatin+ (*Sst*) cells, and revealed previously unidentified neuron types. Immediate early gene expression not only varied across cell types, but they also highlighted cells that respond differentially to morphine dependence and NAL precipitated withdrawal. Further, morphine substantially altered gene expression across most LS cell types, but we have also identified cell clusters that are preferentially perturbed by drug dependence. For example, neurons co-expressing *Nts* and *Sst* appear especially sensitive to both morphine action and drug withdrawal. While *Nts* and *Sst* cells have been implicated in fear and avoidance behaviors, there is currently little known about their role in drug dependence and withdrawal. These data will provide an atlas for septal gene expression and supply insight into LS cell types that are involved in opioid dependence and affective behaviors.

Abstract: RhoA is a GTPase involved in the regulation cytoskeletal, neuronal morphology, and dendritic arborization. Previous research from our lab has demonstrated that enhanced RhoA in nucleus accumbens (NAc) D1-dopamine receptor expressing medium spiny neurons (D1-MSNs) leads to enhanced dendritic atrophy in promotes depressive-like behaviors. However, whether RhoA impairs or enhances natural

reward seeking behavior has been left unexplored. Here, we infused a retrograde transsynaptic vector expressing Cre recombinase into the ventral tegmental area (VTA) and Cre-dependent viral vectors to overexpress RhoA or control EYFP in NAc-to-VTA projection neurons, and examined whether RhoA regulation affects impacts affects reward learning or motivation in operant tasks for sucrose. *Ad lib* fed mice were able to choose between 1) a nose poke port producing a light cue or 2) a second nose poke port producing a light cue and delivering sucrose into an adjacent food cup. Both RhoA and EYFP control mice showed similar acquisition in our sucrose operant task. However, we found RhoA overexpression decreased operant responding and breakpoint during progressive ratio testing. Interestingly, in sucrose seeking tests, where operant responding produces light cues but no sucrose delivery, RhoA overexpression decreased persistent seeking for sucrose reward relative to EYFP controls. Collectively, our data demonstrate that the overexpression of RhoA in NAc-VTA (putative D1-MSNs) impairs motivation for sucrose.

Title: The neuronal glutamate transporter EAAC1 controls reward-based behaviors

Authors: *B. BENNINK, A. SCIMEMI;
State Univ. of New York, Univ. of Albany, Albany, NY

Abstract: Genetic association studies in humans identify the Slc1a1 gene, encoding the neuronal glutamate transporter EAAT3 (EAAC1 in mice), as a candidate gene for Obsessive Compulsive Disorder (OCD). Patients affected by OCD display structural and functional connectivity changes in cortico-striatal circuits, but the relationship between disrupted basal ganglia activity and OCD remains incompletely understood. Mice represent valuable species for studying the molecular mechanisms underlying complex behaviors in the context of neuropsychiatric disease. In mice, EAAC1 is expressed at relatively high concentrations in the basal ganglia nucleus of the striatum, where it serves to limit the activation of metabotropic glutamate receptors. Here we use a battery of behavioral tests to determine how loss of glutamate uptake via EAAC1 alters the execution of striatal-dependent behaviors. We assessed the acquisition of a simple continuous reinforcement (FR1), operant conditioning task, where a reward was delivered in response to individual lever presses, in C57BL/6J (wild type, WT) and EAAC1$^{-/-}$ mice. Active responses and reward consumption were reduced in EAAC1$^{-/-}$ compared to WT mice, suggesting that EAAC1 enhances the ability to perform instrumental learning tasks. When we switched to a different reinforcement regime (FR8), however, EAAC1$^{-/-}$ mice outperformed WT mice by collecting more rewards, due to their ability to perform the sequence lever presses faster and more frequently than WT

mice. This behavior, which was indicative of increased impulsivity, was associated with changes in immediate early gene expression not only in the striatum but mostly in cortical areas. Similar findings were obtained when constraining the timing of the sequence lever presses. Together, these findings suggest that EAAC1 specifically controls the timing for repeated execution of reward-based behaviors, and point to a novel understanding of how this transporter may contribute to the execution of behaviors implicated with OCD.

Title: Dopamine release and behavior are patterned by the action potential

Authors: *B. JUAREZ[1], M.-S. KONG[1], Y. JO[2], J. ELUM[1], J. X. YEE[1], S. EVANS[1], M. M. CLINE[1], A. C. HUNKER[4], M. A. BAIRD[5], M. A. QUINLAN[1], A. MENDEZ[6], N. L. GOODWIN[1], M. E. SODEN[1], L. S. ZWEIFEL[3];

Abstract: Reinforcement learning is an essential process by which an organism links environmental stimuli and actions with desired outcomes. Dopamine producing neurons within the ventral tegmental area (VTA) modulate information processing in the forebrain, most notably in the nucleus accumbens (NAc) region of the striatum, to facilitate reinforcement learning and to promote goal-oriented behavior. Precise shifts in patterns of dopamine activity in the VTA and dopamine release in the NAc have been associated with distinct phases of reinforcement learning including learning acquisition, invigoration during goal oriented responses, and extinction. However, whether regulators of intrinsic firing properties of dopamine neurons influence patterned dopamine release and reinforcement learning has not been fully established. Here, we used cell-type specific, viral mediated CRISPR/Cas9 gene editing technology to interrogate how two potassium channel subunits that mediate distinct parts of the action potential contribute to dopamine release during reinforcement learning. We found that genetic disruption of Kv4.3 (Kv4.3 LOF) subunits in VTA dopamine neurons caused an increase in the action potential width, an increase in spontaneous activity and increase in intrinsic excitability. Genetic disruption of BKCa1.1

(BKCa1.1 LOF) subunits, however, induced a more depolarized afterhyperpolarization and increased dopamine neuron burst activity. To determine if these distinct effects on the action potential shape, intrinsic excitability and spontaneous activity effected reinforcement learning, we combined a fixed ratio 1 (FR1) operant reinforcement learning task for sucrose with fiber photometry of dopamine release in the NAc using the dopamine sensor dLight1.3b. We found that BKCa1.1 LOF in VTA dopamine neurons, and not Kv4.3 LOF, caused an increase in learning acquisition on the first day of the task and increased phasic-like dopamine release events in the NAc. Interestingly, after learning of the reinforced task had been acquired, mice with Kv4.3 LOF, and not BKCa1.1 KOF mice, displayed robust performance of the task and had an associated increased ramp of dopamine activity during the performance of the goal-oriented lever press response. During extinction training, we found that Kv4.3 LOF mice learned to extinguish their behaviors faster on the first day while BKCa1.1 LOF mice had slower extinction learning. These results demonstrate that potassium channels that contribute to the generation of the action potential regulate the patterns of dopamine release to influence reinforcement learning, performance, and extinction.

Title: Variation in cue-evoked motivation and dendritic spine dynamics in the nucleus accumbens

Authors: *M. COLOM[1], I. KRAEV[1], A. K. STRAMEK[1], I. B. LOZA[1], C. L. ROSTRON[1], C. J. HEATH[1], E. J. DOMMETT[2], B. F. SINGER[3];

Abstract: *Introduction*
Environmental stimuli associated with rewards can acquire motivational properties and influence behaviour. There is considerable variation in their ability to do so, and some individuals are particularly prone to attribute incentive salience to discrete Pavlovian cues. Much research has focused on pre-synaptic characteristics underlying this phenotype, revealing that differences in motivation are related to dopamine neurotransmission in areas involved in reward learning, including in the nucleus accumbens (NAc). However, post-synaptic characteristics, although crucial for learning and plasticity, have not yet been explored. Here, we assessed whether individual variation in motivation in male and female rats is associated with specific spine properties in the NAc core.

Materials and Methods
A first group (n = 45) of male and female Lister Hooded rats was trained on a Pavlovian conditioning procedure. For 5 consecutive days, a lever was repeatedly paired with the delivery of food pellets. Animals were re-exposed to the lever-cue in the absence of reward during a final test session. A 'no learning' control group (n = 12) underwent a similar procedure during which the lever and the reward were temporally dissociated to prevent the lever from becoming a predictive cue. A third cohort (n = 36) was tested under the same paired conditions than the first group, however during the test session rats were subjected to the reward as well. Brains were removed 6h after the final session and prepared for neuroanatomical analysis (Golgi-impregnation technique). Stained NAc dendrites were reconstructed with Neurolucida and dendritic spine density, length and size were examined.
Results
Conditioned animals were found to have lower spine density than control rats in the NAc core. Within this paired group, individuals who approached the lever faster - and therefore attributed more incentive salience to the reward cue - had greater density of spines and longer spines in the NAc core. We did not observe differences in spine properties between males and females.
Conclusion
The lower density of spines found in trained rats might be explained by the omission of the reward on test day, which could have caused a 'negative prediction error' characterised by a decrease in dopamine signalling. The analysis of the third group will allow to explore this hypothesis. Changes in spine length linked to the attribution of incentive value to the cue may be related to the growth of spines and, thus, density measurements. This study offers the possibility of further understanding individual variation in spine dynamics and relate these novel neurobiological findings to prediction errors.

Abstract: Addiction vulnerability is associated with non-drug traits such as the tendency to attribute incentive salience to reward cues and is influenced by environmental and genetic factors. To characterize the genomic regions associated with these behaviors, we performed a genome-wide association study (GWAS) in two cohorts of phenotypically and genetically diverse N/NIH Heterogeneous Stock (HS) rats at two institutions. We first tested HS rats in a Pavlovian Conditioned Approach task, in which we characterized the individual responses to food-associated stimuli ("cues"), and report two general categories of Pavlovian conditioned responses: cue-directed "sign-tracking" behavior, and food-cup directed "goal-tracking" behavior. We then used the conditioned reinforcement procedure to examine whether rats would perform a novel operant response for presentations of the food cue alone, and demonstrate that sign-tracking was associated with heightened cue-directed responding. Finally, we identified genetic loci associated with multiple measures across both tasks in HS rats at each institution. We identified several loci across a number of measures during Pavlovian conditioned approach, with each measure associated with 1-8 loci. Many loci associated with sign-tracking reflected measures that showed the largest heritability values (h^2 = .189-.215) and were identified on chromosome 1. Interval sizes of loci varied, although some of the strongest associations for sign-tracking contained few genes (e.g. *Tenm4*, *Mir708*). During conditioned reinforcement, we also detected multiple loci on chromosome 1, many containing genes identified for the Pavlovian conditioned approach phenotype. We demonstrate that HS rats are useful for investigating the genetic variants underlying complex behavior and may be useful for identifying candidate genes for future testing.

Abstract: Learned associations are thought to be encoded by sparse populations of strongly activated neurons called neuronal ensembles, commonly identified using the immediate early gene *Fos*. Our lab and others previously identified unique transcriptional changes within ensemble neurons following drug-related behaviors. However, these studies used pooled samples (Fos-positive vs Fos-negative) and measured a panel of candidate genes from brain areas of interest. Therefore, the complete transcriptional signature and corresponding cell types within these regions is currently unknown.
Here we use single nuclei RNA sequencing (snRNAseq) and a Fos-based transgenic rat (Fos-mRFP rat) to characterize cocaine relapse ensemble neurons in the infralimbic cortex (IL). We trained rats to self-administer cocaine during twice daily 3 h sessions. Following training and 21 days of abstinence, we tested rats for cocaine-seeking (30 min, extinction conditions) and collected brains 3 h after test (peak Fos driven mRFP expression). We used fluorescence activated cell sorting (FACS) to isolate mRFP-positive (ensemble) and mRFP-negative (non-ensemble) nuclei from IL and will perform snRNA-seq analyses on these isolated nuclei.
Using this unbiased approach, we will determine cell types that comprise cocaine-memory ensemble neurons and identify ensemble-specific differentially expressed genes within specific cell types. In future experiments, we will use CRISPR-based transcriptional modulators to assess causal roles for these cocaine memory-specific genes in relapse. This work was supported by NIDA/NIH.

Title: Long-lasting changes in corticolimbic structures following exposure to intermittent physical stress in mid-adolescence.

Authors: *M. M. WILKIN[1], J. L. MENARD[2];
[1]Psychology, [2]Psychology/Centre for Neurosci., Queen's Univ., Kingston, ON, Canada

Abstract: Exposure to stress during mid-adolescence increases rats' risk-taking behaviour in adulthood, as indexed by their greater willingness to explore the normally avoided open arms of the elevated plus maze. While this outcome is consistent across several studies in our lab and others, the potential underlying neural mechanisms for this behavioural change remain largely unknown. We aimed to extend our behavioural findings by examining the lasting impact of intermittent physical stress (IPS) in mid-adolescence on neuronal arborization and dendritic spine density in three corticolimbic regions of interest: the medial prefrontal cortex (mPFC), the hippocampus, and the basolateral amygdala (BLA). Male and

female Long-Evans rats were exposed to our IPS protocol (i.e., foot-shock, water immersion, and elevated platform; two times each, randomly across mid-adolescence; postnatal day [PD] 35-46). In adulthood (PD 73), rats were tested in the elevated plus maze and 48-72hrs after behavioural testing, their whole-brain tissue was harvested. As expected, exposure to IPS in mid-adolescence increased open-arm exploration. This treatment produced regionally specific changes in neuronal architecture. There was no evidence of stress-induced changes in dendritic arborization or synaptic spine density in the mPFC. Within the hippocampus, exposure to IPS in mid-adolescence reduced dendritic arborization of pyramidal neurons in male rats but produced modest increases in arborization in female rats. The most pronounced stress-induced changes, however, occurred in the BLA as IPS in mid-adolescence produced long-lasting reductions in the complexity of dendritic arborization and spine density within this region. It is possible that the IPS-induced changes in open-arm exploration are due, at least in part, to these structural changes in the BLA, which, in turn, could promote reward-centric, as opposed to security-centric, behaviour.

Abstract: Obesity is characterized by a dysregulation to range of motivated behaviors, including homeostatic and hedonic feeding patterns, ultimately leading to caloric intake that far supersedes energy demands. Furthermore, successful body weight management is confounded by the fact that individuals will continue to overeat despite the well-known negative health and social consequences. Thus, in obesity chronic hyperphagia is accompanied by consummatory patterns that becomes compulsive in nature, failing to respond to internal and external stimuli that typically result in suppression of food intake. We know little about the obesity induced remodeling of brain function that precipitates the emergence of such inflexible feeding patterns. We hypothesized that obesity is accompanied by changes to a complex neuronal network leading to obesity associated behavioral abnormalities that drive compulsive addiction-like eating. Single cell sequencing of RNA transcripts from mouse revealed excitatory neurons in the lateral hypothalamus (LH) show marked obesity-associated alterations in gene expression. Specifically,

transcripts from genes associated with glutamatergic neurotransmission were significantly lower in tissue harvested from obese mice. Using electrophysiology and whole brain clearing with automated quantification of synaptic contacts, we found this transcriptional plasticity accompanied the emergence of LH glutamatergic hypofunction and a profound restructuring of hypothalamic output to a range of brain loci including the lateral habenula, periaqueductal gray and dorsal raphe nucleus. Finally, using transgenic mice and viral manipulation of neuronal function in vivo we linked this LH glutamatergic hypofunction in individual circuits led to the emergence of discrete obesity associated behaviors such as hyperphagia, rejection of less palatable food items and compulsive feeding. Our data indicated obesity induced remodeling of LH activity leads to a wide-ranging functional reorganization of a broad network of brain sites controlled by LH glutamatergic neurons. The consequences of which are the emergence of discrete complex shifts to food motivated behaviors which together amount to an obesity associated behavioral syndrome primed to maintain excessive levels of energy harvesting in our modern food environment. Our research posits rescuing excitatory hypothalamic output as a novel therapeutic strategy for reversing the hyperphagia and motivational shifts associated with obesity and thus correcting caloric intake to match energy expenditure.

Title: Increased synaptic excitability in mouse hippocampus and prefrontal cortex following psychedelic administration

Authors: *Z. ZAHID[1], Z. SULTAN[2], S. M. GRADY[2], C. J. WENTHUR[3], R. A. PEARCE[2], M. I. BANKS[2];
[1]Neurosci. Training Program, [2]Dept. of Anesthesiol., [3]Dept. of Pharm., Univ. of Wisconsin Madison, Madison, WI

Abstract: Introduction: Classical psychedelics (i.e. psychoactive agonists at 5-HT2A receptors) and ketamine demonstrate rapid and long-lasting efficacy in the treatment of psychiatric disorders, yet the underlying mechanisms remain unknown. The pro-neuroplastic effects of psychedelics likely play a role in their therapeutic effects, but it is unclear whether psychedelics acutely induce plasticity, or whether they do so post-acutely. Using *in vivo* and *in vitro* electrophysiology in mice, we explored the effects of psychedelic and ketamine administration on synaptic excitability and plasticity in hippocampus and along the ventral hippocampus - medial prefrontal cortex (mPFC) pathway, areas which are dysregulated in

psychiatric illness. **Methods:** Experiments were conducted on male and female C57BL/6J mice (3-5 mo). For *in vivo* experiments, a stimulating electrode was placed in CA1 of ipsilateral ventral hippocampus (vCA1), and recording electrodes in mPFC and contralateral vCA1. Recordings of evoked responses were obtained at baseline, 4hr, 1, 3, and 7d after IP injection of DOI (1 mg/kg) or 4-AcO-DMT (1 mg/kg). Long term potentiation and depression (LTP/D) were induced using standard protocols. For *in vitro* experiments, transverse hippocampal slices were obtained 1 day after injection of DOI (1 mg/kg; n=21 slices), ketamine (10 mg/kg; n=20), or saline (n=20). After obtaining baseline stimulus-response curves, field EPSPs were recorded from *s. radiatum* of CA1 for 30 min before and 60 min following LTP induction. One-way ANOVA with Tukey post-hoc tests were conducted to compare effects of drug treatment on LTP and sigmoidal stimulus-response model fit coefficients, with $p<0.05$. **Results:** Increased maximal evoked responses were observed 24h after psychedelic administration *in vivo* in ipsilateral mPFC. Fractional change for DOI was 0.50 +/- 0.33 (mn +/- SD, n=3) and for 4-AcO-DMT was 0.37 +/- 0.15 (n=3). In slices, DOI, but not ketamine, enhanced excitability, as measured by increased slope coefficients of stimulus-response curves (DOI: 0.019 +/- 0.012; ketamine: 0.013 +/- 0.002; saline: 0.013 +/- 0.004) and large but variable increases in maximal evoked responses (DOI: 3.24 mV +/- 1.48; ketamine: 2.52 mV +/- 0.67; saline: 2.47 mV +/- 1.04). LTP and LTD were unaffected *in vivo*, and there was no significant effect of drug on LTP *in vitro* ($p = 0.39$). **Conclusions:** We observed evidence for increased excitability but not synaptic plasticity in CA1 and mPFC synapses during an acute window after psychedelic administration. This increase in excitability in limbic regions may underlie the observed therapeutic benefit shown in clinical trials.

Title: Ketamine and psilocybin on fear acquisition and extinction in mice

Authors: *J. A. RAZIDLO[1], J. R. NERAD[2], N. T. JONES[3], M. I. BANKS[4], C. J. WENTHUR[5]; [1]Neurosci. Training Program, [2]Sch. of Pharm., [3]Mol. and Cell. Pharmacol. Program, Univ. of Wisconsin - Madison, Madison, WI; [4]Dept. of Anesthesiol., Univ. of Wisconsin, Madison, WI; [5]Pharm., Univ. of Wisconsin Madison, Madison, WI

Abstract: Major depressive disorder (MDD) has become an increasingly prevalent issue and is compounded by the limited efficacy of current treatment options. To combat this disorder, researchers

have focused their attention on novel therapeutic approaches. Two promising treatments are the N-methyl-D-aspartate receptor (NMDAR) antagonist, ketamine, and the serotonergic $5HT_{2A}$ agonist and classical psychedelic, psilocybin. These compounds have been shown to exert rapid antidepressant effects through mechanisms that have yet to be fully understood. Both of these rapidly-acting antidepressants have been observed to induce an acute stress response, as measured by elevated glucocorticoid release after administration. We propose that the therapeutic effects of these drugs are due to a transient enhancement of neural plasticity in the ventral hippocampal medial-prefrontal-cortex (HPC-mPFC) pathway and subsequent memory formation produced by this acute stress. Impaired plasticity in the HPC-mPFC pathway is observed in patients with MDD, and individuals have reported decreased depressive symptoms after taking either psilocybin or ketamine. These improvements have been reported to last hours or even weeks, with psilocybin typically having longer lasting increases in mood. Despite this, there are no studies to date that assess the duration of this critical window. To study this window of plasticity at the behavioral level, we used C57BL/6J (male and female) mice and the associative learning task of fear conditioning. Mice were administered a single intraperitoneal (IP) injection of saline, ketamine (10-30 mg/kg), or psilocybin (3 mg/kg) at 4 or 24h prior to fear conditioning. Here we found that mice that received ketamine (30 mg/kg) 4h prior to initial testing showed enhanced fear acquisition compared to those that received ketamine 24h prior, psilocybin, or saline ($p<0.05$). This effect was even more pronounced in animals that received a lower dose of ketamine (10 mg/kg, $p<0.05$). Interestingly, psilocybin did not alter fear acquisition from saline controls when administered at either time point. Animals that received ketamine or psilocybin also displayed enhanced fear extinction, although these trends were non-significant. Our results suggest ketamine's enhancement of fear acquisition is negatively correlated with both dose and latency to initial testing after administration. Psilocybin's ability to modulate fear acquisition may be blunted by the acute stress induced by the foot shocks during the fear conditioning trials. Our future studies will continue to evaluate the effects these compounds have on fear memory and their possible interaction with stress.

Title: Role of HPA axis activation in psilocybin's effects in rodent models of anxious behaviors

Authors: *N. JONES[1], Z. ZAHID[2], J. RAZIDLO[2], C. WENTHUR[3];
[1]Mol. and Cell. Pharmacol., [2]Neurosci., [3]Sch. of Pharm., Univ. of Wisconsin, Madison, WI

Abstract: Research into classical psychedelics as potential therapeutics has increased after demonstrating therapeutic efficacy in small-scale clinical studies. Among these compounds, psilocybin, a serotonin receptor (5-HT_{2A}) agonist, has shown positive results when administered to individuals with major depressive disorder (MDD) or end-of-life anxiety. Despite these long-term anxiolytic effects, psychedelics induce an acute stress response. This leads to an increase in glucocorticoid levels, particularly that of corticosterone (CORT). Clinical protocols for administering psilocybin-assisted therapy have noted a correlation between anxious responding and therapeutic outcomes for patients with MDD. Despite this, few studies have directly assessed the role that these drug-induced changes in CORT release have in altering psilocybin's anxiolytic effects. To determine the effect of psilocybin (3 mg/kg) on CORT release, we injected male C57BL/6J mice and collected retro-orbital blood samples at 15 min, 4 h, and 7 d post-injection. When measured, psilocybin induced significantly higher levels of plasma CORT than saline at 15 min but had returned to baseline at 4 h. We then tested an acute and chronic oral CORT protocol to suppress the hypothalamic-pituitary-adrenal-axis (HPA-axis), which controls CORT release. In our preliminary data, as validation for the model, mice that were exposed to oral CORT (80 μg/mL) for 21 d spent significantly less time in the center of an open field apparatus than vehicle-treated mice. We used the novelty suppressed feeding test (NSF) to test the post-acute (4 h) anxiolytic effects, we used the novelty suppressed feeding test (NSF). We found psilocybin significantly reduced the latency to feed, however, this effect was lost following exposure to chronic CORT. When tested in the open field test (OFT) 7 d following administration, mice that received [vehicle + psilocybin] spent significantly more time in the center than those that received [psilocybin + CORT]. To further investigate this interaction, we then administered the glucocorticoid antagonist, mifepristone (10 mg/kg), and saw psilocybin's effects were blunted in both the NSF and OFT. These results suggest that suppression of the HPA-axis via exposure to chronic exogenous CORT not only critically impacts psilocybin's efficacy, but that the acute stress response may have an important role in the mechanism of action. An important goal moving forward is to identify the method by which increased CORT levels alter psilocybin's behavioral effects, which will contribute to the application and development of this breakthrough treatment.

Abstract: Introduction: Classical psychedelics (i.e., psychoactive agonists at 5-HT2A receptors) produce rapid and long-lasting therapeutic benefit for diverse psychological disorders. These agents induce a constellation of acute behavioral, physiological, and biochemical effects, but the intersection of these effects and psychedelics' post-acute effects and therapeutic mechanisms remains unclear. The acute stress response induced by psychedelics has been postulated to play a role in these agents' pro-neuroplastic effects, which likely contribute to their therapeutic effects. We characterized the magnitude and duration of the acute behavioral, biochemical, and neural effects of these drugs in mice **Methods:** Three sets of experiments were conducted on male and female C57BL/6J mice (3-5 mo). Behavioral effects were assayed using induced head twitch responses (HTRs) quantified via magnetometry pre/post intraperitoneal (IP) injection of DOI and various DMT analogues (1 mg/kg), and psilocybin (3 mg/kg), with saline and ketamine (30 mg/kg) for comparison. Endocrinological effects were assayed by measuring plasma corticosterone (CORT) concentrations at various time points (t = 5 min, 15 min, 30 min, 60 min, 4 hr, 24 hr) after IP injection of DOI or saline, and at 15 min & 4 hr after psilocybin and ketamine. Neural effects were assayed by measuring changes in delta and alpha band power via skull screw electroencephalographic (EEG) recordings pre/post injection of psilocybin. **Results:** Administration of DOI, psilocybin, and some analogs, but not ketamine or saline, elevated HTRs by 0.4-0.7/min, with variable duration: DOI, >4 hrs; 4-AcO-DMT, 28 min; 5-MeO-MiPT, 19 min; psilocybin, 17 min. Smaller and shorter effects were observed for 5,6-DiMeO-MiPT (0.21/min, 14 min) and 5-MeO-pyrT (0.37/min, 23 min). No change in HTRs was observed for Pyr-T, 5-MeO-DET and 6-F-DET. CORT was elevated 5 - 60 mins following administration of DOI, with return to baseline at 4 hours. Both psilocybin and ketamine caused an increase of CORT at 15 min with a return to baseline at 4 hours. Finally, psilocybin induced changes in posterior EEG delta and alpha band power that lasted >180 mins and >65 mins, respectively. **Conclusions:** The acute stress response to DOI and psilocybin tracks the duration of behavioral effects, and thus may be causally related. Neural effects of psilocybin in mice are similar to those reported in human subjects and appear to outlast both the acute stress response and behavioral effects. Taken together, these data provide evidence for a role of stress glucocorticoids in changes in neural activity and behavior affected by psychedelic administration.

Title: Psilocybin selectively suppresses REM sleep in the Wistar Kyoto rat model of treatment-resistant depression

Authors: *S. KANTOR, L. GIGGINS, N. UPTON, M. DUXON;
Transpharmation Ltd., London, United Kingdom

Abstract: Introduction: Wistar–Kyoto (WKY) rats show depression-like neurochemical and behavioural characteristics and have been suggested to serve as a model for treatment-resistant depression (TRD). Compared to other rat strains, WKY rats have increased baseline REM sleep amounts that is less sensitive to the suppression by conventional monoamine-based antidepressants. We have shown previously that WKY rats are also more susceptible to the modulation of cortical activity by ketamine, a novel rapid-acting antidepressant with high efficacy in TRD patients. Although the psychedelic drug psilocybin has been shown to be effective in TRD, but its effect on REM sleep in TRD has not been studied yet. The aim of this study was to determine whether psilocybin has differential effects on sleep-wake behaviour and EEG in WKY rats in comparison with an outbred rat strain. **Methods**: 8 Sprague-Dawley (SD) and 8 WKY adult (200-250 g) male rats were surgically implanted with telemetry transmitters (HD-S02; DSI, USA) for EEG, EMG and locomotor activity recordings. Following post-surgical recovery, we treated the rats with different (1, 3 and 10 mg/kg i.p.) doses of psilocybin or its vehicle and monitored the changes in their sleep-wake behaviour for 22h. Vigilance states were automatically scored using a customized algorithm (SleepSign, Kissei Comtec, Japan). EEG power spectra were computed for 2 s epochs (FFT routine, Hanning window) between 0.5-100 Hz per each vigilance state. **Results**: Psilocybin supressed REM sleep in both SD and WKY rats in a dose-dependent manner, but it had no significant effect on the amount of NREM sleep or wakefulness. The differential effect of psilocybin on REM sleep was further evident by a dose-dependent decrease in the REM/NREM sleep ratio seen in both strains. Furthermore, psilocybin also suppressed high-frequency gamma oscillations in the EEG. **Conclusions**: Since early suppression of REM sleep by antidepressants is one of the most consistent findings in patients with depression, suppression of REM sleep after psilocybin treatment could potentially indicate antidepressant-like properties of the drug in WKY rats. Thus suppression of REM sleep in WKY rats may serve as a key translational tool in an effort to discover novel therapeutics against TRD.

Title: Naltrexone blocks the acute and sustained antidepressant-like effects of ketamine, but not it's locomotor effects in mice

Authors: F. ZHANG[1], P. M. ANDERSON[2], P. O. KOPPENHAVER[2], T. N. KEGEN[2], S. G. MANIKA[1], J. T. LANE[1], E. POTTANAT[1], M. VAN FOSSEN[1], E. CELIK[1], R. RICE[1], T. M. HILLHOUSE[2], ***J. H. PORTER**[1];

Abstract: Ketamine has acute and sustained antidepressant effects in both depressed and treatment-resistant depressed patients. However, the neuropharmacological mechanisms responsible for ketamine's antidepressant effects remain unclear as other NMDA antagonists have failed to produce similar effects in the clinical population. As more patients turn to ketamine for treatment, it is important to understand the mechanisms underlying its therapeutic effects. Recent clinical studies have reported that pretreatment with the nonselective opioid antagonist naltrexone attenuated both the rapid antidepressant and antisuicidal effects of ketamine (but not its dissociative effects), suggesting that activation of the opioid system may be involved in ketamine's antidepressant effects. The current study investigated the opioid system's role in ketamine's antidepressant-like effects by testing ketamine with the nonselective opioid antagonist naltrexone in the tail suspension test (TST) and differential-reinforcement-of-low-rate responding (DRL) 72 s task. In addition, open field locomotor activity also was measured. Ketamine at 10 mg/kg produced acute and sustained antidepressant-like effects in TST, which were blocked by pretreatment of 2 mg/kg naltrexone. Ketamine at 32 mg/kg produced an acute antidepressant-like effect in the DRL 72 sec task that was blocked by pretreatment of 2 mg/kg naltrexone (no sustained ketamine effects of ketamine were found in DRL). Both 10 and 32 mg/kg ketamine produced significant increases in locomotor activity; however, pretreatment with 2 mg/kg naltrexone failed to block ketamine's hyperactivity effects. Results from the TST and the DRL 72 s task confirm recent clinical findings suggesting that ketamine's antidepressant effects involve activation of the opioid system. However, opioid systems do not appear to be involved in ketamine's motor effects, thus showing a separation forf the role of opioid systems in the antidepressant and side effects of ketamine.

Title: Central metabolism as a potential origin of sex differences in morphine analgesia but not in the induction of analgesic tolerance in mice

Authors: *F. GABEL[1], V. HOVHANNISYAN[1], V. ANDRY[1,2], Y. GOUMON[1,2];
[1]CNRS UPR3212, Strasbourg, France; [2]Mass Spectrometry facilities of the CNRS UPR3212, Strasbourg, France

Abstract: Sex differences in morphine analgesia and side effects, particularly in the analgesic tolerance to morphine, have been described in both humans and rodents. In mice, morphine is metabolized in the liver in morphine-3-glucuronide (M3G), reported to have pronociceptive effects. Therefore, the metabolic M3G/morphine ratio found in the periphery and in the brain, especially in brain regions related to pain,

might modulate morphine analgesia. We have studied whether the metabolism of morphine is impacted during analgesic tolerance in male and female mice. The tail-immersion test was used to determine the analgesic effect of morphine and LC-MS/MS was used to quantify morphine and M3G in the blood and pain-related brain regions. First, we have observed that morphine has a weaker analgesic effect in females compared to males. In addition, in female mice, we have found higher levels of M3G in the periphery as well as lower amounts of morphine and higher levels of M3G in several pain-related brain regions. These last differences were related to sex differences in central metabolism of morphine. Secondly, we have determined that females become tolerant to the analgesic effect of morphine earlier than males. Moreover, we have found less morphine in the blood and several pain-related brain regions of tolerant mice than control mice. However, central metabolism did not seem to be implicated in these differences. In conclusion, the sex differences observed in the central metabolism of morphine are consistent with the lower potency of morphine in female than in male mice. However, morphine metabolism does not seem to be involved in the induction of morphine analgesic tolerance. **ACKNOWLEDGMENTS AND GRANT SPONSOR -** This work was funded by CNRS, University of Strasbourg (Unistra), French Ministère Délégué à la Recherche et à l'Enseignement Supérieur and FHU Neurogenycs, French National Research Agency (ANR; contract ANR-17-EURE-0022, EURIDOL graduate school of pain).

Title: Use of stable isotope-labelled morphine to investigate in vivo morphine metabolism and brain transport in tolerant mice

Authors: *Y. GOUMON[1,2], I. WEINSANTO[1], A. LAUX-BIEHLMANN[1], J. MOUHEICHE[1], T. MADUNA[1], V. ANDRY[1,2], F. GABEL[1];
[1]CNRS UPR3212, Strasbourg, France; [2]Mass Spectrometry facilities of the CNRS UPR3212, Strasbourg, France

Abstract: ***Context*-** In mice, morphine is mainly metabolized in morphine-3-glucuronide (M3G) in the liver. However, the metabolism of morphine in the brain is poorly characterized. Chronic morphine treatments induce analgesic tolerance, resulting in a decrease in analgesia. No data is available on the potential implication of central metabolism of morphine on analgesic tolerance and the impact on blood-brain barrier (BBB) permeability. Thus, we have characterized *in vivo* the morphine metabolism at central and peripheral levels and its BBB permeability after chronic treatment. ***Methods*-** morphine or NaCl solutions were injected into male mice for eight days to induce analgesic tolerance. On the last day, both groups were injected with a solution of 85% (w/w) of morphine and 15% of d3-morphine (morphine bearing three 2H) to get rid of the remaining morphine and M3G. 90min after the injection, mice were killed, and blood, urine, brain and liver samples were recovered. The levels of morphine, M3G and their d3-labelled counterparts were quantified by LC-MS/MS. ***Results & conclusions*-** We didn’t observe a

significant change in morphine metabolism within the central nervous system (CNS) and BBB permeability between control and tolerant mice [1]. However, we observed that d3-morphine metabolism was reduced by one third compared to morphine without any interference with our study. Thus, our results indicate that analgesic tolerance seems not linked to increased morphine metabolism or a modification of the BBB permeability. Nevertheless, as we have used the whole brain for our analysis and only a 90min time point, it can not be ruled out that either local CNS alterations or a difference in morphine metabolism and uptake occur ([2] and the poster by Gabel et al.). Additional studies at different time points and focusing on discrete brain areas (*e.g.* PAG) are needed to clarify if M3G is involved in morphine analgesic tolerance [2]. [1] Weinsanto I et al. Title: Rescue and prolonged protection from fentanyl overdose with novel bioorthogonal covalent mu opioid receptor antagonists

Authors: *J. P. MCLAUGHLIN[1], S. O. EANS[1], J. THOMAS[2], S. A. ZAIDI[2], T. CHE[4], B. L. ROTH[5], J. REICH[6], S. MAJUMDAR[4], V. V. FOKIN[2], V. KATRITCH[3];
[1]Pharmacodynamics, Univ. of Florida, Gainesville, FL; [2]Quantitative and Computat. Biol. and Chem., [3]Michelson Ctr. for Convergent Biosci., USC, Los Angeles, CA; [4]Ctr. for Clin. Pharmacol., Univ. of Hlth. Sci. & Pharm., St. Louis, MO; [5]Pharmacol., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [6]Sparian Biosci., New York, NY

Abstract: Respiratory depression mediated by mu-opioid receptor (MOR) agonists is life-threatening, with overdose from synthetic opioids such as fentanyl responsible for 36,359 deaths in the U.S. in 2019. While naloxone can reverse these effects, its short duration of MOR antagonist activity limits therapeutic efficacy, particularly against high doses of fentanyl. To generate a longer-lasting treatment against MOR agonist overdose, we synthesized and characterized a series of 12 novel covalent MOR antagonists capable of highly selective irreversible binding to MOR via a recently developed bioorthogonal proximity-guided Sulfur (VI) Fluoride Exchange (SuFEx) reaction. Computational design guided the synthesis of a series of naloxone derivatives functionalized with a weak electrophilic SuFEx “warhead”, SO_2F, that by itself is not reactive in human cells. However, when selectively guided into the MOR pocket by naloxone, and properly oriented in close proximity to nucleophilic tyrosine-150 of the MOR, the SO_2F moiety covalently attaches to the receptor via a SuFEx reaction. In radioligand competition binding experiments, the initial racemic compound TJ-345 displayed high affinity (K_i=5 nM) and selectivity for the MOR with only trace partial agonism (<10% E_{max}) in G-protein or arrestin recruitment assays. Moreover, TJ-345 demonstrated irreversible binding and potent antagonism at MOR, with a wash-

resistant inhibition of binding >48 h after initial incubation. In mice tested with the 55ºC warm-water tail-withdrawal assay *in vivo*, TJ-345 produced brief antinociception (<40 min), but dose-dependently antagonized morphine antinociception after i.c.v. (>3 nmol) or s.c. pretreatment (3-60 mg/kg). TJ-345 (3 nmol, i.c.v.) significantly antagonized morphine up to 48 h, but showed only partial blockade of morphine at 24 h after a 30 mg/kg s.c. treatment. In contrast, the stereoisomer TJ-171 showed no antinociception on its own, and fully antagonized morphine for 24 h after a 30 mg/kg s.c. treatment, consistent with the reported turnover time of the MOR in mice. Prophylactic administration of TJ-345 or TJ-171 (30 mg/kg, s.c., each) to mice further protected against fentanyl-induced respiratory depression and hyperlocomotion in the CLAMS assay, lasting up to 48 h with TJ-171. Moreover, acute administration of TJ-171 to mice 21 minutes after exposure to fentanyl dose-dependently and swiftly reversed MOR agonist-induced respiratory depression and hyperlocomotion, maintaining that protection against additional doses of fentanyl 12 hours later. These results validate the development of selective bio-orthogonal covalent MOR antagonists against fentanyl overdose.

Title: Discriminative stimulus effects of gabapentin in rats

Authors: *A. PRUS, A. N. IANNUCCI, J. N. PRETE, C. E. CLIFTON, B. E. BEAVERS, T. S. BOHINSKI;
Northern Michigan Univ., Marquette, MI

Abstract: Gabapentin is a blocker for Ca2+ channels that contain an $\alpha_2\delta$-1 or $\alpha_2\delta$-2 subunit and is prescribed for neuropathic pain, anxiety, fibromyalgia, and epilepsy. There are increasing reports of abuse with gabapentin, along with its analog pregabalin, suggesting that gabapentin may elicit positive subjective effects. Further, concomitant use occurs with opioids and other substances of abuse. In order to examine the subjective effects of gabapentin, the present study utilized a drug discrimination procedure in 12 male adult Sprague Dawley rats trained to discriminate a 30.0 mg/kg dose of gabapentin versus saline in a two choice operant task for food reinforcement. All 12 of the rats met the training criteria, consisting of 5 out 6 consecutive sessions of at least 80% condition-appropriate responding. Gabapentin (3.75 - 240 mg/kg) produced full-substitution (>80% gabapentin-lever responding; ED_{50}=7.2 mg/kg, 95% confidence interval [CI] = 5.3 to 9.7 mg/kg), with full substitution occurring for all doses at 15.0 mg/kg and higher. Pregabalin (3.75 to 15.0 mg/kg) also produced full substitution (ED_{50}=7.1 mg/kg, 95% CI=4.9 to 10.2 mg/kg), which occurred for a 15.0 mg/kg dose. Partial substitution (> 20% gabapentin-lever responding) was observed for the opioid agonist fentanyl, with the highest percentage of gabapentin lever responding (58.3%) found for a 0.04 mg/kg dose. The present findings indicate that gabapentin elicits subjective effects that can be readily established as a discriminative cue. Further, full substitution by pregabalin

indicates that this compound also produces subjective effects and that these effects are likely mediated by similar pharmacological actions. Similarly, partial substitution observed with fentanyl also suggests some degree of similarity across the subjective effects of these compounds, potentially generated through a shared pharmacological mechanism of action. Overall, the demonstration that gabapentin produces discriminative stimulus effects in rats, which carry a degree of similarity to fentanyl, implies that positive subjective effects may account for increasing trends of gabapentin abuse.

Vienna, Vienna, Austria

Abstract: The pharmacology of different compounds is normally assessed under thermodynamic equilibrium, however, in the human body, the drug-target interaction is influenced by the constant flux of fluids and a variety of physiological processes. Hence, the in vivo properties of a drug differ from the in vitro thermodynamic equilibrium. α-Pyrrolidinovalerophenone (αPVP) is a psychostimulant and drug of abuse associated with severe intoxications in humans. αPVP exerts long-lasting psychostimulant effects, when compared to the classical dopamine transporter (DAT) inhibitor cocaine. We used radiotracer assays, computational approaches, transporter electrophysiology and behavioural assays in mice to investigate the role of binding kinetics in the psychostimulant effect elicited by αPVP enantiomers. We found that αPVP enantiomers substantially differ from the DAT-inhibitor cocaine in their binding kinetics. The two enantiomers differ from each other in their association rates, but they show similar slow dissociation rates leading to pseudo-irreversible binding kinetics at DAT. The pseudo-irreversible binding kinetics of αPVP is responsible for the observed non-competitive pharmacology, correlates with persistent

psychostimulant effects in mice and differ from the fast-acting DAT-inhibitor cocaine. Our work shows that drug binding kinetics at DAT can have a significant impact on the psychostimulant effects of drugs in vivo. Given this information, a more detailed assessment of drug-binding kinetics for DAT inhibitors might provide insights for the design of novel DAT inhibitors with improved clinical utility. Furthermore, it shows how psychopharmacological research on illicit drugs may help to reach a better understanding of physiological and toxicological processes.

Abstract: Opioid use disorder has been identified as a public health crisis, affecting over 1.7 million people per year in the US. Therefore, understanding the molecular effects of OUD is essential in this opioid use epidemic. Opioids and opioid withdrawal can also disrupt the circadian rhythm, a 24-hour oscillatory cycle that regulates certain gene networks. Previous studies identified 394 differentially expressed (DE) coding and long non-coding (lnc) RNAs in post-mortem human brains of opioid users. In this study, we aimed to test the hypothesis that some of these differentially expressed genes are correlated with time of death in postmortem brains of opioid users and controls, and are therefore affected by circadian rhythm. We calculated Zeitgeber time of death (zTOD) for each postmortem subject. After correcting for human tissue covariates, we performed sine regression analysis to determine the influence of the time of day on gene expression. We found that 3 canonical genes involved in circadian rhythm (CRY1, NPAS2, PER3) were significantly correlated with zTOD in the postmortem subject. We also found 8 DE coding RNAs and 3 DE lncRNAs that were influenced by the zTOD. In the future, we will compare the genes' zTOD effect in the OUD subjects versus controls, and validate these results in a cell model.

Title: Methamphetamine-induced cellular stress response in primary human brain vascular pericytes

Authors: *N. FATTAKHOV, S. TORICES, M. PARK, M. TOBOREK;
Dept. of Biochem. and Mol. Biol., Univ. of Miami, Miami, FL

Abstract: Methamphetamine (METH) is a powerful, highly addictive psychostimulant that has a pronounced effect on the central nervous system. Recent studies in animal models have indicated that METH can induce impairment of the blood-brain barrier (BBB), suggesting that some of the neurotoxic effects resulting from METH abuse could be the outcome of BBB disruption. The BBB operates within the neurovascular unit, which includes clusters of neurons, endothelial cells, pericytes and glial cells. Pericytes regulate BBB permeability, angiogenesis, clearance, cerebral blood flow, neuroinflammation and stem cell activity. The present study aimed to investigate cellular stress response in METH-treated primary human brain vascular pericytes (pHBVP), particularly the production of mitochondrial reactive oxygen species (ROS) and endoplasmic reticulum (ER) stress markers. Mitochondrial superoxide levels, as detected by MitoSOX Red staining, were increased in pHBVPs in response to the acute treatment (24 hours) with the higher concentrations (10, 25 and 50 µmol) but not the lower concentrations (1 and 5 µmol) of METH in a dose-dependent manner. Western blot analysis showed that the expression of the main ER stress marker, activating transcription factor 6 (ATF6), was significantly higher in pHBVPs treated for 24 hours with 10 µmol METH compared to the vehicle control. No differences in expression of SIRT3, the major deacetylase in mitochondria, were detected between METH-treated and control groups. The data from gene expression analysis and immunofluorescence staining for Toll-like receptor (TLR)2 and TLR4 showed no evidence of their involvement in mediating cellular cytotoxic responses during acute METH treatment in pHBVPs. Overall, our preliminary study suggests that METH-induced mitochondrial oxidative stress can disrupt the protein folding mechanism and enhance the production of misfolded proteins, causing further ER stress in pHBVPs and potential BBB damage. A deeper understanding of how oxidative stress damages the BBB may open up more effective therapy options for the treatment of METH-induced neurotoxicity.

Abstract: Opioid use disorder (OUD) is a public health crisis in the U.S. that causes over 50 thousand deaths annually due to overdose. Using next-generation RNA sequencing and proteomics techniques, we identified 394 differentially expressed (DE) coding and long noncoding (lnc) RNAs as well as 213 DE proteins in Brodmann Area 9 of OUD subjects. The RNA and protein changes converged on pro-angiogenic gene networks and cytokine signaling pathways. Four genes (LGALS3, SLC2A1, PCLD1, VAMP1) were dysregulated in both RNA and protein. We found cell-type specific effects in these OUD gene networks with enrichment in astrocyte, endothelial, and microglia correlated genes. Furthermore, using *ex vivo* magnetic resonance imaging, we identified increased vascularization in postmortem brains from a subset of subjects with OUD. This is the first study integrating dysregulation of angiogenic gene networks in OUD with qualitative imaging evidence of hypervascularization in postmortem brain. Future studies include exploring and validating these cell-specific gene expression signatures using single nuclei RNA sequencing of postmortem brain and investigating gene expression in an *in vitro* neuron model of morphine exposure derived from postmortem human fibroblasts.

Title: Effects of alcohol on brain oxygenation and brain hypoxia induced by intravenous heroin

Authors: *E. KIYATKIN, S. A. THOMAS, C. M. CURAY;
Behavioral Neurosci., NIDA-IRP, NIH, Baltimore, MD

Abstract: Alcohol is the most commonly used psychoactive drug, often taken in conjunction with opioid drugs. Since both alcohol and opioids can induce CNS depression, it is often assumed that alcohol potentiates the known hypoxic effects of opioid drugs, thus contributing to coma and death during opioid overdose. To address this supposition, we used oxygen sensors to examine the effects of alcohol on brain oxygenation and hypoxic responses induced by intravenous heroin in awake, freely moving rats. To eliminate robust sensory effects of alcohol following its oral or intraperitoneal delivery, alcohol was administered directly into the stomach via chronically implanted intragastric catheters at human relevant doses. Alcohol delivered at a 0.5 g/kg dose did not affect brain oxygen levels, except for a weak transient increase during drug delivery. This phasic oxygen increase was stronger at a 2.0 g/kg alcohol dose and followed by a weaker tonic increase. Since alcohol absorption from intragastric delivery is much slower and more prolonged than with intraperitoneal or intravenous injections, the rapid rise of brain oxygen levels suggests direct action of alcohol on sensory afferents in the stomach well before the drug physically reaches brain tissue via circulation. Despite slow tonic increases in brain oxygen, alcohol at the 2.0 g/kg dose strongly potentiates heroin-induced oxygen responses, increasing both the magnitude and duration of oxygen decrease. Therefore, under the influence of alcohol, the use of opioid drugs becomes much more dangerous, increasing brain hypoxia and enhancing the probability of serious health complications, including coma and death. Supported by the NIDA-IRP (NIDA-IRP Grant ZIADA000566).

Title: The behavioural effects of heroin depend on the recruitment of the peripherally-generated effects by the central mechanisms of heroin.

Authors: *D. D. JOSHI[1], M. PUAUD[1], L. MARTI-PRATS[1], M. FUJITA[2], D. BELIN[1];
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Shionogi & Co., Ltd, Osaka, Japan

Abstract: The behavioural effects of heroin have long been considered to be mediated by its actions on μ-opioid receptors (μ-ORs) in the brain. However, heroin, like all drugs of abuse, also produces interoceptive states suggested to depend on the integration by the insular cortex of the peripheral effects of heroin. Our recent demonstration that the anterior insular cortex (AIC) exerts an inhibitory effect on the loss of control of heroin intake and the subsequent propensity to relapse after forced abstinence, suggests a role for interoceptive mechanisms in the development of addictive behaviour. However, whether the functional engagement of the AIC and its associated circuitry underlying the control over behaviour by interoceptive mechanisms results from direct peripheral actions of heroin, central mechanisms downstream to the activation of μ-ORs in the brain or their interplay has not been established. Here we tested the hypothesis that the behavioural effects of heroin, such as its locomotor activating properties, depend on an interplay between its central and peripheral mechanisms. In a between-subject study, we compared in male Sprague Dawley rats (n=102) the effect of systemic administrations of several doses of the selective peripheral μ-OR antagonist *9g* on the locomotor activating effects of heroin to that of μ-OR antagonism by naloxone. As compared to saline (n=12), intraperitoneal (IP) administration of heroin (2mg/kg, n=8) resulted in a delayed but sustained increase in locomotor activity over a 45-minute session. This locomotor effect was equally blocked by the IP administration of 9g (0.01, 0.03 and 0.1 mg/kg, n=7-8 per dose) and naloxone (0.14 mg/kg, n=7), suggesting a role of peripheral μ-ORs in the behavioural effects of heroin. To further probe this effect, we investigated the locomotor effect of the selective peripheral μ-OR agonist loperamide. In contrast to heroin, loperamide across multiple doses (vehicle, 1, 2.5, 5 and 7.5 mg/kg, n=7-8 per group), showed no stimulatory locomotor effects like heroin. This suggests that the activation of peripheral μ-ORs alone is not sufficient to support the locomotor activating effects of heroin.Together, the results of this study indicate that the locomotor activating effects of heroin depend on a centrally-mediated integration of the peripherally-generated interoceptive effects of the drug, thereby providing further evidence for a role of brain-body interactions in the regulation of the behavioural responses to addictive drugs.

Title: A quantitative and morphological analysis of microglia in dopamine target regions following chronic fentanyl self-administration in rats

Authors: *A. N. DAO, A. MONTEMARANO, V. MAYR, A. W. KUSNECOV, M. O. WEST;
Rutgers Univ. - New Brunswick, Piscataway, NJ

Abstract: Opioid addiction is associated with increased prevalence of bacterial and viral infections, reflecting known immunomodulatory effects of opioids in both immune and CNS compartments. Microglial cells, the resident immune cells of the CNS, function as macrophages and assume various activational states in response to neural injury, systemic inflammation, and psychological stress. They also generate and secrete pro-inflammatory cytokines that may regulate neuronal functions and mediate local inflammatory responses. Microglia also express opioid receptors and toll-like receptors, which may allow for direct immunomodulation by opioids resulting in altered microglial activation and morphological states, as well as apoptosis and suppression of proliferation. While there is significant evidence citing the immunomodulatory effects of opioids, there is an absence of research on how neuroinflammatory events involving microglial activation are affected by chronic fentanyl self-administration (SA) or persist after cessation of drug. To test this, the current project employed a rat model of voluntary chronic, long-access fentanyl SA to examine the microglial response to chronic fentanyl abuse after a period of abstinence from drug. Male Sprague-Dawley rats self-administered fentanyl (Fent/SA) for 30 consecutive days before being assigned an abstinence period of either 1 week (N=5) or 1 month (N=5). Control animals (Sal/SA) similarly received access to SA saline and subsequent abstinence periods (N=9). On the last day of abstinence all animals received an injection of lipopolysaccharide (LPS; 1.5 mg/kg, i.p.), an endotoxin that produces a vigorous systemic inflammatory response, followed by perfusion and brain collection. All brains were assayed by IHC for the microglial marker Iba1 to quantitate microglial cell numbers and morphological states. Preliminary analyses have indicated a large effect size for the interactions of SA treatment x Abstinence Period for both IL-1ß concentrations (partial eta^2=0.277) and TNF-α concentrations (partial eta^2=0.445) indicating that these cytokines were initially suppressed after 7 days of abstinence but returned to control levels after 30 days of abstinence. It is expected that ongoing analyses will similarly show microglial suppression in Fent/SA animals after 1 week of abstinence compared to Sal/SA animals, but not after 30 days abstinence. The results of this study will show for the first time whether recovery from systemic and central immunosuppression is possible after an extended period of abstinence from chronic fentanyl abuse.

Title: Pain effects dopaminergic inputs from ventral tegmental area to nucleus accumbens during fentanyl self-administration in a sex dependent manner

Authors: *J. G. ABT[1], J. A. HIGGINBOTHAM[2], J. A. MORON-CONCEPCION[2];
[1]Washington Univ. in St. Louis, St. Louis, MO; [2]Dept. of Anesthesiol., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Up to 50 million people in the US suffer from chronic pain. Opioids are commonly prescribed for pain symptoms but are highly prone to misuse. Clinical evidence suggests that the influence of pain on opioid misuse is sex dependent, but preclinical support for this phenomenon is lacking. Here, we used a model of persistent inflammatory pain and cue-induced relapse to test the hypothesis that pain influences opioid use and mesolimbic dopamine circuit function in a sex-dependent manner. To do this, male and female TH-Cre rats (2-3 months old) were injected with Cre-dependent GCaMP7s in the ventral tegmental area (VTA) to selectively target VTA dopamine neurons. An optic fiber was implanted in the shell of the nucleus accumbens (NAc) to detect calcium transients from GCaMP-expressing VTA terminals in the NAc. Rats were implanted with an IV catheter and subjected to pain (hind paw injection of Complete Freuds Adjuvant) or no pain (saline) prior to undergoing fentanyl self-administration. Correct lever presses during daily 2-hour sessions were reinforced with illumination of a cue light and a fentanyl infusion of 5µg/kg (IV) for the first five days and 2µg/kg for the next ten days. Then rats underwent extinction training (seven days) where fentanyl and drug-paired cues were withheld. Cue-induced reinstatement was assessed the next day by reintroducing drug-paired cues in the absence of fentanyl. Rats were then tested during a final self-administration session in the absence of cues to dissociate effects of drug reinforcement. Wireless *in vivo* fiber photometry recordings were made at least every five days throughout training and signals were aligned with correct lever responses. Each day, mechanical sensitivity was assessed using Von Frey and vaginal smears were collected to track estrus cycling. We found that males in pain escalated their intake of fentanyl over time while males without pain and females in both groups did not show significant changes in fentanyl intake. Moreover, males in pain were less likely to exhibit changes in GCaMP fluorescence at VTA to NAc terminals in response to fentanyl than any other group, suggesting that pain disrupted mesolimbic circuit function, particularly in males. Finally, lever responses during extinction, cue-induced reinstatement, and fentanyl infusions in the absence of cues distinctively impacted VTA to NAc GCaMP fluorescence, suggesting this circuit encodes discrete components of reinforcement. Together, these findings demonstrate a sex-specific influence of pain on opioid use and mesolimbic dopamine function in a circuit- and cell-type-specific manner.

Title: Study of inflammatory pain impact on alcohol-drinking and seeking behavior: implication of sex differences

Authors: *Y. CAMPOS-JURADO[1], J. D. LORENTE[2], L. HIPOLITO[2], J. MORON-CONCEPCION[1]; [1]Anesthesiol., Washington Univ. In St Louis, St Louis, MO; [2]Pharm. and Pharmaceut. Technol. and Parasitology, Univ. of Valencia, Valencia, Spain

Abstract: During the last years, multiple clinical and epidemiological studies have revealed that the presence of chronic pain is closely related to Alcohol Use Disorder (AUD). In fact, previous preclinical studies have shown that inflammatory pain induces relapse-like behavior in female rats whereas only male mice under inflammatory pain increase their alcohol intake during an acquisition phase. However, there is only a few number of studies approchig this problematic and therefore the global effect of pain on AUD remains not fully discern. In this study we aimed to deeply explore wether the development of an inflammatory pain condition induced by the intraplantar injection of the Complete Freud Adjuvant (CFA) could impact alcohol related behaviors depending on the onset of the pain condition. For that, we use a non-operant intermittent alcohol consumption paradigm in rodents with an Arduino controlled two-bottle choice apparatus that allows us to obtain real-time licking measurements. Moreover, we corralate our behavioral data with the study of neural activation of different regions in the mesocorticolimbic system measured by fluorescence immunohistochemistry of delta-Fos B. First, we observed that females and males show differences in their total alcohol intake levels. Interestingly, our preliminary results also show that inflammatory pain differentially affects total alcohol intake and seeking behavioral patterns among different phases of the addiction cycle. These findings may contribute to the better understanding of the intersection between pain and AUD and to the development of more individualized treatments for chronic pain patients with a history of alcohol abuse.

Title: Wireless in vivo fiber photometry to detect sex-specific effects of pain on ventral tegmental area function during IV fentanyl self-administration in freely behaving rats

Authors: *J. A. HIGGINBOTHAM[1], J. G. ABT[2], J. MORON-CONCEPCION[3]; [1]Anesthesiol., Washington Univ., Saint Louis, MO; [2]Washington Univ. Sch. of Med., st. louis, MO; [3]Anesthesiol., Washington Univ. In St Louis, St Louis, MO

Abstract: Chronic pain effects up to one-third of US adults. Opioids are frequently used to treat pain symptoms but are highly prone to abuse. Clinical evidence suggests males are vulnerable to negative outcomes associated with opioid use and preclinical evidence indicates that pain reduces dopaminergic

signaling in the ventral tegmental area (VTA). However, it remains unclear whether pain impacts the ability of VTA dopamine neurons to respond to opioid reinforcement in a sex-dependent manner. To investigate this possibility, GCaMP7s was expressed in a Cre-dependent manner in the VTA of male and female TH-Cre rats (2-3 m.o.) and an optic fiber was implanted. After 14 days, rats were implanted jugular catheters and received right hind-paw injections of saline (No Pain) or Complete Freund's Adjuvant (CFA; Pain). After 3 days, rats underwent self-administration during 15 daily 2-h sessions where correct lever presses were reinforced with an infusion of fentanyl (5 ug/kg or 2 ug/kg, iv) and illumination of a light cue (5 s). This was proceeded by extinction training for 7 days where drug and cue reinforcement were withheld. Next, rats underwent daily test sessions of cue-induced reinstatement, non-cued fentanyl relapse, and non-contingent drug exposure. Von Frey mechanical sensitivity and estrus cycle phase were determined each day. Every 1-5 days, a battery-powered transmitter head stage was secured to the optic fiber and GCaMP fluorescence was measured throughout the duration of the session (1-2 hr) and aligned to correct lever responses. There were no sex differences or effects of pain on the acquisition of fentanyl self-administration but over time, fentanyl intake in males was greater than females. Pain exacerbated these effects in males as indicated by higher escalation ratios than any other group. Interestingly, the ability of pain to facilitate fentanyl self-administration in males coincided with opposite effects on VTA dopamine neuron GCaMP responses to fentanyl, such that, ΔF/F signals time-locked to fentanyl-reinforced lever presses were reduced in amplitude and efficacy compared to all other groups. Moreover, GCaMP fluorescence elicited by lever presses varied as a function of reinforcement. Together, these findings provide evidence for a novel means of conducting fiber photometry in parallel to IV self-administration and suggest that sex-specific effects of pain on fentanyl consumption may be due to impairments in the ability of VTA dopamine cells to respond to opioid reinforcement.

Title: Opioid-induced respiratory depression involves opioid receptors at both central and peripheral sites

Authors: *B. RUYLE, K. YOON, N. MASSALY, J. MORON-CONCEPCION;
Washington Univ. in St Louis, St Louis, MO

Abstract: Intravenous administration of fentanyl produces profound and sustained respiratory depression, and there is abundant evidence that this involves direct actions at mu opioid receptors in brainstem respiratory nuclei. Opioid receptors are also present in the periphery, but the contribution of these

receptors in the generation of opioid-induced respiratory depression (OIRD) is poorly understood. Male and female rats were administered fentanyl (2 and 20 ug/kg, intravenous delivery) and cardiorespiratory parameters (oxygen saturation, heart rate and respiratory rate) were measured using a wired collar oximeter. Intravenous fentanyl produced rapid decreases in all measured parameters, effects which were sustained for up to 20 minutes. To gain insight into the role of central vs peripheral opioid receptors in OIRD, subsets of male and female animals were intravenously pretreated with either the nonselective opioid receptor antagonist naloxone (NLX, 1 mg/kg), or the peripherally-restricted opioid receptor antagonist naloxone methiodide (NLXM, 1 mg/kg) prior to receiving intravenous fentanyl (20 ug/kg). As expected, NLX blocked all cardiorespiratory changes that were evoked by fentanyl. Surprisingly, NLXM pretreatment strongly attenuated fentanyl-induced respiratory depression, with only a small decrease in oxygen saturation observed. Immunohistochemical analysis was then performed for Fos (marker of neuronal activation) in the nTS, which is a critical site of cardiorespiratory integration. Fentanyl induced a dose-dependent activation of nTS neurons. Pretreatment with NLX limited Fos-IR in the nTS. Interestingly, NLXM pretreatment still produced a similar degree of activation that was observed after fentanyl alone. This strong activation occurred even in the absence of respiratory depression. Taken together, these data suggest that fentanyl induces activation in nTS neurons. Furthermore, peripheral opioid receptors may play a larger role in driving fentanyl-induced respiratory depression than previously thought.

Title: Comparison of Central Mu-Opioid Receptor Activity Following Oral Administration of Mitragynine, 7-Hydroxymitragyine, and Mitragynine Pseudoindoxyl

Authors: *S. OBENG[1], A. PATEL[1], N. P. HO[1], L. R. GAMEZ JIMENEZ[1], V. L. C. PALLARES[1], M. MOTTINELLI[2], F. LEON[2], C. R. MCCURDY[2], L. R. MCMAHON[1], T. HIRANITA[1];
[1]Pharmacodynamics, [2]Medicinal Chem., Univ. of Florida, Gainesville, FL

Abstract: Mitragynine (MG) is the most abundant alkaloid contained in kratom (*Mitragyna speciosa*), which is widely used to self-treat pain, mood disorders, and opioid use disorder. MG has active metabolites: our group has demonstrated that MG is metabolized *in vivo* into 7-hydroxymitragynine (7-OH-MG), which is in turn converted into MG pseudoindoxyl (MG-P). MG and the two metabolites might contribute to the *in vivo* μ-opioid receptor (MOR) activity of kratom; however, the relative *in vivo* activity of MG and these metabolites has not been established. Here we compared their MOR pharmacology *in vitro* and *in vivo*. *In vitro* displacement of [^{3}H]DAMGO at human MOR yielded the rank order affinity

(Ki in nM) of MG-P (1.5) > morphine (4.0) > 7-OH-MG (78) > MG (709). Stimulation of [^{35}S]GTPγS binding yielded the rank order efficacy (% stimulation normalized to DAMGO) of morphine (92) > 7-OH-MG (46) > MG-P (32) > MG (4.0). Thermal antinocicpetive effects were measured in mice using a hotplate assay (52°C). 100% maximum possible effects were produced by oral administration of MG and 7-OH-MG whereas MG-P produced significant increases in hotplate response latency with a plateau at approximately 50% maximum possible effects at 17.8-320 mg/kg. The increases in hotplate response latency were obtained without concomitant decreases in locomotor activity relative to oral administration of vehicle. Robust increases in activity counts were obtained with 7-OH-MG and MG-P. The rank order antinociceptive potency (ED_{50}s in μmol/kg, p.o.) was 7-OH-MG (151) > MG-P (161) > MG (568). The antinociceptive effects of MG, 7-OH-MG, and MG-P were reversed to the vehicle levels with the opioid antagonist naltrexone (1 mg/kg). The same dose of naltrexone also fully antagonized the activity-increasing effects of 7-OH-MG and MG-P. In contrast, none of the antinociceptive or activity-increasing effects was antagonized by a 3.2-fold higher dose (3.7 mg/kg) of methylnaltrexone, an analogue of naltrexone that has less capacity to penetrate the blood brain barrier. These results suggest that MG and its metabolites tested are MOR agonists *in vivo*, with the intrinsic activity and potency of 7-OH-MG being greater than both MG and MG-P. Despite MG-P exhibiting the highest MOR binding affinity and intrinsic activity *in vitro* among the compounds tested, these results suggest that MG-P has relatively low bioavailability as compared with MG and 7-OH-MG, and that 7-OH-MG is the most orally bioactive MOR agonist of the compounds tested.

Title: Quantitative description of the interactions among kinase cascades underlying long-term plasticity of Aplysia sensory neurons

Authors: Y. ZHANG, P. SMOLEN, L. CLEARY, J. BYRNE;
Neurobio. & Anat., McGovern Med. Sch. of UTHSC At Houston, Houston, TX

Abstract: It is generally acknowledged that kinases and growth factors play critical roles in synaptic and neuronal changes involved in the formation of memory. However, significant gaps exist in understanding the dynamics, cross talk and feedback interactions among these cascades. These processes will contribute to the mechanistically distinct temporal domains of memory ranging from short-term memory lasting minutes to long-term memory lasting days to lifetimes. Activation of protein kinase A (PKA) and

mitogen-activated protein kinase (MAPK) - ribosomal S6 kinase (RSK) pathways are critical for long-term enhancement of neuronal excitability and long-term synaptic facilitation, essential processes in memory formation. We have combined empirical and computational methods to develop new insights into how these pathways contribute to the distinct temporal domains of memory. Empirical studies of *Aplysia* sensory neurons delineated two new pathways: PKA-dependent, but MAPK-independent, regulation of RSK, and RSK-dependent activation of p38 MAPK. The first pathway suggests the existence of a positive feedforward loop regulating RSK, whereas the second supports a negative feedback loop within a MAPK cascade. A computational model incorporated these findings and others from the literature (e.g., Kopec et al., 2015; Zhang et al., 2017; Jin et al., 2018). It simulated dynamics of kinase activity, and neurotrophin and transforming growth factor-beta feedback loops, produced by different stimulus protocols. A prediction of the critical roles of kinase interactions in the dynamics of these pathways was validated by subsequent empirical studies. These findings may provide insights into the ways in which kinases contribute to aberrant synaptic plasticity observed in disorders such as RASopathies and Coffin-Lowry syndrome.

Title: Operant conditioning engage synergistic in excitability and chemical and electrical synaptic transmission

Authors: *Y. MOMOHARA[1], C. NEVEU[1], H.-M. CHEN[2], D. A. BAXTER[3], J. H. BYRNE[1];
[1]Dept. of Neurobio. and Anat., The Univ. of Texas Hlth. Sci. Ctr., Houston, TX; [2]Ctr. for Nursing Res., Houston Methodist Hosp., Houston, TX; [3]Engin. Med., Texas A&M Univ. Col. and Anat., Houston, TX

Abstract: Operant conditioning (OC) is a ubiquitous form of learning in which animals learn the consequences of behavior. The neural circuit that mediates feeding behaviors in *Aplysia* provides a tractable model system for analyzing neuronal mechanisms that underlie OC. Previous studies found that OC increases the intrinsic excitability and electrical coupling among some neurons involved in the initiation and selection of the reinforced feeding behavior. It is not known, however, whether changes in chemical synaptic transmission and/or whether reduced cellular excitability also contributes to OC. Here, isolated buccal ganglia, which contain key elements of the feeding circuitry, were subjected to an in vitro analog of OC. Contingent reinforcement reduced the excitability of the inhibitory neuron B4. Similar changes in excitability were obtained using a single-cell analog of operant conditioning. In addition, contingent reinforcement reduced the B4-to-B51 inhibitory postsynaptic potential (IPSP) but not the B4-to-B8 IPSP. These results indicated that OC was mediated by both non-synaptic and synaptic changes and that a single neuron manifests target-specific changes in synaptic efficacy. Finally, a conductance-based

model of the circuit was used to investigate the ways in which diverse and distributed forms of neuronal plasticity act synergistically to modify behavior.

Title: Deficient synaptic plasticity in model of Coffin-Lowry Syndrome is rescued by combining pharmacological activation of PKA and ERK

Authors: *R.-Y. LIU, L. J. CLEARY, J. H. BYRNE;
Dept. of Neurobio. and Anat., McGovern Med. Sch. of UTHSC at Houston, Houston, TX

Abstract: Developing treatment strategies to improve cognitive functions in both healthy individuals and people with memory deficits is an important goal of neuroscience research. Recent studies suggest that multiple kinases converge on the transcription factor cAMP response element-binding protein (CREB) to enhance the expression of proteins essential for long-term synaptic plasticity and memory. p90 ribosomal S6 kinase (RSK) is one such kinase. Our previous investigation (Liu et al., 2020) demonstrated that RSK is required in long-term synaptic facilitation (LTF), a cellular correlate of long-term memory (LTM). Inhibition of RSK impairs LTF, suggesting that this may be a useful cellular system to study aspects of deficient synaptic plasticity observed in Coffin-Lowry Syndrome (CLS), a cognitive disorder caused by mutations in *rsk2*. The present study focused on pharmacological approaches to rescue defective LTF. Activation of multiple biochemical signaling cascades, such as the protein kinase A (PKA) and extracellular signal-regulated kinase (ERK) pathways, is necessary to induce LTF. Previously, combining an ERK activator, NSC, and a PKA activator, rolipram, enhanced LTF to a greater extent than did either drug alone (Liu, et al., 2017). The present study exploited the technical advantages of the *Aplysia* sensorimotor culture system to examine whether dual drugs can restore the deficit in LTF induced by inhibition of RSK activity. We found that the impairments in LTF in the cellular analogue of CLS can be rescued by the NSC - rolipram combination, targeting PKA and ERK signaling pathways. The drug combination also enhanced RSK activation, which may contribute to LTF. Therefore, our data further supports the hypothesis that RSK is a site of convergence for training-induced PKA activation and ERK activation, upstream of CREB1. Combined pharmacological activation of PKA and ERK may be a potential approach to rescue synaptic plasticity impairments in disorders that affect neuronal signaling pathways.

Title: Different peptidergic signaling pathways underlying sensitization and dishabituation in C. elegans

Authors: *A. YU, C. RANKIN;
The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Non-associative learning is categorized as the simplest form of learning that helps animals selectively allocate attention or neural resources to promote survival. Sensitization and dishabituation are two forms of non-associative plasticity that facilitate the likelihood and/or magnitude of responses. The dual-process theory, the prevailing theory regarding non-associative learning originally hypothesized that sensitization is an organism-wide facilitatory phenomenon, and viewed dishabituation as a specific case of sensitization, that is exhibited on a habituation background. However, later studies suggest that the two forms of behavioral plasticity are dissociable. Work from Aplysia showed that although both sensitization and dishabituation both require the neuromodulator serotonin, but they can be differentiated by the developmental stages they emerge, the electrophysiological profiles, and the downstream second messengers recruited etc.In this work, we demonstrated that sensitization and dishabituation are mediated by different neuropeptide signaling pathways in *Caenorhabditis elegans*. Using our previously established paradigms to produce mechanosensory-induced facilitation of a nociceptive response, we identified a peptidergic signaling pathway underlying the sensitization of the response; surprisingly, this peptidergic signaling pathway is not involved in the dishabituation of the same response. Further, we found that sensitization of response duration and response speed, two components of nociceptive response, are differentially regulated by additional peptidergic signaling components. We have found that dishabituation is mediated by yet unknown neuropeptides- we are currently performing a screen to identify the molecules and their molecular and cellular signaling pathways.Taken together, these data show that sensitization and dishabituation can be mediated by completely different underlying molecular mechanisms, and that sensitization may not be a global, organism-wide, phenomenon, rather, sensitization of different aspects of behavior can be differentially regulated by multiple neuromodulatory pathways.

Title: Cellular effects of serotonin on the memory impairments caused by prolonged food deprivation in Aplysia

Authors: *X. DENG, R. MOZZACHIODI;
Texas A&M University-Corpus Christi, Corpus Christi, TX

Abstract: Malnutrition causes brain dysfunctions including memory deficits. The ability of the mollusk *Aplysia* to sustain up to fourteen days of food deprivation (14DFD) without health deterioration or behavioral alterations (Kupfermann, 1974; Mac Leod et al., 2018) is difficult to achieve in more complex animals, thus making this organism a suitable model to study memory deficits raised from prolonged food deprivation. In this study, an elementary form of learned fear known as sensitization was utilized to investigate the detrimental effects of prolonged food deprivation on memory formation. In *Aplysia* fed every two days (2DFD), one trial of electrical shocks to the body wall induces short-term sensitization (STS) of the tail-induced siphon withdrawal reflex (TSWR) for at least 15 min (Kandel, 2001). In a reduced ganglionic preparation containing the TSWR neural circuit, cellular correlates of STS, including increased excitability of tail sensory neurons (IE), can be induced *in vitro* by electrical stimulation of afferent nerves (Weisz et al.,2017). Serotonin (5-HT) mediates sensitization and IE in *Aplysia* (e.g., Kandel, 2001). Sensitizing stimuli lead to 5-HT release in the neuropil (Marinesco and Carew, 2002) and hemolymph (Levenson et al., 1999). *In vitro* 5-HT application induces IE for at least 15 min (Walters et al., 1983). Recent work revealed that STS was not observed in 14DFD animals (MacLeod et al., 2018). In addition, 14DFD prevented short-term IE and reduced 5-HT levels in the hemolymph. This project aimed to investigate the role of 5-HT in the absence of short-term IE following 14DFD. We hypothesized that 5-HT application may elicit IE under 14DFD. Four groups of 10 preparations each, dissected from adult *Aplysia* (100-200 g), were utilized: 2DFD preparations treated with 5-HT or artificial seawater (ASW, vehicle), 14DFD preparations treated with 5-HT or ASW. Excitability was measured prior to (pre-tests), 5 min and 15 min after 5-min treatment with either ASW or 50 µM 5-HT (post-tests). 5-min post-test was used to evaluate whether 5-HT induced shorter IE. Percentages of IE in each group were calculated as [(post-pre)/pre]x100% and were analyzed with the Kruskall-Wallis test followed by Student-Newman-Keuls *post-hoc* comparisons. In both 5-min and 15-min post-tests, 5-HT significantly induced IE in 2DFD and 14DFD preparations. Notably, the amount of IE under 14DFD did not significantly differ from that under 2DFD, indicating that 5-HT alone was able to induce the maximal amount of IE in 14DFD animals. The ability of 5-HT to induce normal IE under14DFD suggests that reduced 5-HT may be responsible, at least in part, for the lack of short-term IE and STS in 14DFD *Aplysia*.

Title: Learning that food is inedible in Aplysia affects connectivity from buccal ganglia mechanoafferents to motor neurons

Authors: *A. J. SUSSWEIN[1], S. TAM[1], I. HURWITZ[1], H. J. CHIEL[2];
[1]Bar Ilan Univ., Ramat Gan, Israel; [2]Case Western Res. Univ., Cleveland, OH

Abstract: Memory after learning that food is inedible in *Aplysia* is expressed in part as a bias to reject an object in the mouth, rather than to ingest it. This change has been partially explained by changes in connectivity from a population of buccal ganglia mechanoafferents to motor neurons with different functions. During rejection, protraction is the power phase, and retraction is the return phase. After training, both monosynaptic excitation to a protraction motor neuron (B61/B62), and monosynaptic inhibition to a retraction motor neuron (B3) were enhanced. In addition, excitation to a neuron whose activity biases patterns toward rejection (B4/B5) was increased. After training, both excitation and inhibition increased in a motor neuron closing the radula (B8); radula closing occurs during retraction in ingestion but during protraction in rejection. No changes in connectivity were observed after training to a neuron that contributes to the decision to initiate responses (B31/B32), whether the response is ingestion or rejection. Rather than examining the response to a single spike in the mechanoafferent neurons, we have now delivered 3 trains of 5 spikes to the S1 population of mechanoafferents before or after training. In addition, data were examined separately for 4 anatomically distinct regions of the S1 mechanoafferents, allowing us to determine whether changes in connectivity were localized to specific populations. Spike trains cause changes in amplitude of the fast PSPs, and also reveal the presence of slow PSPs. Patterns of synaptic change were qualitatively similar to those previously found in response to single spikes in mechanoafferents. Training caused increased inhibition of both fast and slow PSPs to the B3 retraction motor neuron, and increased fast excitation to the B61/B62 protraction motor neurons, as well as increased fast and slow excitation to B4/B5, which bias movement to rejection. Training caused mixed effects onto the B8 radula closing neurons, producing decreases in excitation in the most medial and posterior areas of the S1 cluster, but not in the other areas. No effects of training were found in connectivity to B31/B32, which initiates both ingestion and rejection. Additional evidence for localization to sub-populations of the S1 mechanoafferents was present, in that changes in connectivity to B3 and B61/B62 were seen in only 3 of the 4 regions of the S1 cluster. Variability in changes in connectivity as a result of training suggests variability in function of the different areas of the mechanoafferent clusters. Ongoing experiments are examining such functional differences.

Title: Developmental expression of dFoxP is required in motorneurons for operant self-learning in Drosophila

Authors: *A. EHWEINER, B. BREMBS;
Univ. Regensburg, Regensburg, Germany

Abstract: Out of the four FOXP genes in humans the FOXP2 transcription factor was shown to have an unique role in speech learning and articulation. This function is highly conserved as homologous motor learning functions were identified in songbirds, rodents or fruit flies. While *Drosophila* is not a vocal learner, the process of torque learning in tethered flies is an analogous motor learning process to vocal learning. An initially very variable behaviour (e.g. sub-song in finches or torque in flies) is being modulated via an operant feedback (auditory or temperature) loop to shape the variable actions to the desired output (crystalized song, avoidance of heat). Accordingly, the fly orthologue of the FOXP2 gene, *dFoxP* is also involved in this operant self-learning task. Due to the broad expression, it remains unknown which brain regions or gene targets are important for this learning process. We performed different spatial or temporal knockouts of *dFoxP* using CRISPR/Cas9. Knocking out *dFoxP* in individual brain regions did not lead to any learning defects. A knockout of dFoxP in all neurons of adult flies showed no immediate effect, but 14 days old flies were impaired in learning. Knocking out *dFoxP* in motorneurons results in an impairment to fly. As protein kinase C (PKC) is required in motorneurons for torque learning, we expressed PKCi, an inhibitor of PKC in *dFoxP* isoform B (*FoxPiB*)-positive neurons and found a learning impairment. Knocking out only the atypical PKC (aPKC) in motor neurons or *dFoxPiB*-positive neurons via CRISPR/Cas9 also leads to learning defects, suggesting that aPKC is the gene responsible for operant self-learning in *Drosophila*.

Title: Mechanisms of Dominant Electrophysiological Features of Four Subtypes of Layer 1 Interneurons

Authors: *J. MENG[1], B. SCHUMAN[2], B. RUDY[3], X.-J. WANG[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Neurosci., [3]Neurosci. & Physiol., New York Univ. Sch. of Med., New York, NY

Abstract: Neocortical Layer 1 (L1) receives extensive "top-down" information conveyed by long-range inputs from many sources. The integration of these inputs into local processing is thought to be mediated by a population of GABAergic inhibitory interneurons (INs) residing in L1 and INs in deeper layers with dendrites or axons in L1. In a previous study, we identified four unique populations of INs in L1, each with a distinct molecular profile, morphology, and electrophysiology. These four types were Canopy cells, Neurogliaform cells (NGFCs), cells with strong somatic expression of the α7 nicotinic receptor (α7 cells), and vasoactive intestinal peptide (VIP) expressing cells. However, a modeling study at the single-cell level of these subtypes had not been established, which hinders studying the functions of L1 interneurons in a circuit model. In this study, we discovered different dominant electrophysiological features for each IN subtype. Canopy cells showed an irregular firing pattern near rheobase, NGFCs were late-spiking and their firing rate ramped up during positive current injections, α7 cells displayed initial bursting, and VIP cells' most salient features were high input resistance, strong adaptation and irregular firing. Next, we built generic models for each IN subtype. We first showed that an exponential integrate-and-fire (EIF) model with a slow potassium (SK) channel could reproduce the irregular firing observed in Canopy cells through the mechanism of square-wave bursting. Second, by increasing the timescale of the inactivation gating variable of the SK channel, we reproduced the late-spiking and ramping of NGFCs. Third, the initial bursting of α7 cells was reproduced by including a T-type calcium channel. VIP cells in L1 had heterogeneous firing patterns, such as strongly adapting, irregular firing, initial bursting, and high threshold fluctuation. We first reproduced all these features in a generic VIP cell model that included an SK channel, a T-type calcium channel, and a calcium-dependent potassium channel that reproduced a strong adaptation. Further, we showed that heterogeneous firing patterns could be reproduced by choosing different parameters in the generic model. Last, we explained that irregular firing was more frequently observed in VIP cells due to the interaction between strong adaptation and the SK channel. To summarize, the dominant electrophysiological features of the L1 IN subtypes were reproduced in the models, and their mechanisms were explained. This work was an essential initial step to study the function of L1 INs in circuit models. Also, the analysis we used in this study could contribute to the classification of cell types.

Title: Synergetic effects of ionic currents on electrical features of biophysically detailed models

Authors: *M. REVA, A. ARNAUDON, M. ZBILI, W. VAN GEIT, H. MARKRAM;
Blue Brain Project, École Polytechnique Fédérale de Lausanne, Geneva, Switzerland

Abstract: Neuronal membrane potential is sculptured by a large amount of ionic currents present in the cell. Different values of neuronal electrical features (spike duration, interspike interval, afterhyperpolarization amplitude, etc.) can be observed from the combination of various numbers of ionic current densities. While electrophysiological experiments provide us with a general understanding of the contribution of currents to certain electrical features, we lack a systematic exploration of the interplay of ionic currents. However, detailed biophysical models allow us to tackle this issue in greater detail by unravelling the inner mechanisms of the interactions between currents. In this study, we explore the synergetic effect of ionic currents and their role in shaping neuronal electrical features using statistical methods and information theory. Using Monte Carlo Markov Chain methods on a detailed model of juvenile rat layer 5 pyramidal cell (L5PC) with 33 parameters (representing maximum conductances of ionic channels and calcium dynamics) and 61 electrophysiological features, we generated thousands of non-identical electrical models with biologically plausible features. We leveraged this large amount of data, with several measures from information theory to detect correlations between model parameters and features at all orders, beyond pairwise correlations. In particular, we use multivariate generalisation of mutual information, such as the total correlation (Watanabe, 1960) or O-information (FE Rosas et al, 2019) to show that most features depend on the synergetic or redundant combinations of several parameters. Only a small fraction of the features were influenced by two to three ionic currents while most were correlated with more than 5 model parameters. In our L5PC model, we were able to map the landscape of synergies and redundancies between ionic currents and showcase the complexity of the relations between electrophysiological properties and ion channel dynamics. Further studies could be undertaken to analyse other cell types, more detailed models or even their dependency on morphological properties.

Title: Extracellular stimulation in pyramidal cell models with full axonal arbor

Authors: *J. THARAYIL[1], M. ZBILI[1], A. ARNAUDON[1], W. VAN GEIT[1], E. NEUFELD[2], M. REIMANN[1], F. SCHÜRMANN[1], H. MARKRAM[1];
[1]Blue Brian Project, École Polytechnique Fédérale de Lausanne Campus Biotech, Geneva, Switzerland; [2]Computat. Life Sci., IT'IS Fndn., Zuerich, Switzerland

Abstract: Joseph Tharayil and Mickael Zbili contributed equally to this work
Extracellular electrical stimulation with small electrodes, also known as intracortical microstimulation (ICMS), can be used to perturb neurons and neuronal circuits. It is believed that ICMS primarily affects axons, but it is unclear how this effect depends on axonal properties. In silico experiments with realistic axon models may therefore provide insight into the mechanisms of ICMS. It is also known that a significant proportion of neural activity triggered by ICMS can be attributed to synaptic effects rather than direct recruitment by electrical stimulation. In this study, we analyze synaptic activation triggered by extracellular stimulation.
In this work, we present an extension of the juvenile rat pyramidal cell models of Markram et al. 2015, by adding a full axon model comprising axon initial segment (AIS), myelinated internodes, nodes of Ranvier and unmyelinated collaterals; with an axon-specific pool of ion channels and optimized ion channel densities. We show that this model reproduces the main axonal electrical features (axonal action potential (AP) waveform, preferential AP initiation at the AIS, propagation of high frequency AP trains throughout the axonal arbor), and that the modelling approach generalizes to a wide range of reconstructed pyramidal morphologies.
To study ICMS of a population of cells, we instantiate a population of pyramidal cells. We simulate ICMS of this population, with the electrode location scanned systematically throughout the entire space, and calculate recruitment curves for the population. We find that ICMS triggers action potentials largely in the middle of axonal sections, with threshold currents that depend on the reciprocal of the cubed distance between the neurite and the electrode, and on pulse width. Moreover, stimulus locations near the AIS tends to have lower threshold currents.
For certain stimuli, action potentials are triggered in part of the axonal arbor, but do not propagate throughout the entire arbor. It may be possible to take advantage of this effect to trigger selective activation of postsynaptic targets. We identify synaptic terminals of the simulated neurons that are activated by electrical stimulation-triggered activity. We then identify the postsynaptic cells that receive stimulation-triggered synaptic activity. We find that the properties of the postsynaptic targets, including cell type and location, vary with stimulus parameters. Our model may therefore help in clarifying the mechanisms of ICMS stimulation and in optimizing stimulation parameters.

Title: Utilizing deep neural networks to infer ionic conductances of mutli-compartmental models.

Authors: *R. BEN-SHALOM[1], J. BALEWSKI[2], V. BARATHAM[3], S. SHOREWALA[3], Y. SHUE[3], K. J. BENDER[4], K. E. BOUCHARD[5];
[1]Univ. of California Davis Med. Ctr., Sacramento, CA; [2]Lawrence Berkeley Natl. Lab., Berkeley, CA; [3]Univ. of California, Berkeley, Berkeley, CA; [4]Dept. of Neurol., [5]UCSF, UCSF, San Francisco, CA

Abstract: A major focus of cellular and systems neuroscience has been to determine how ionic conductances are distributed within a neuron's morphology to support neuronal excitability. Unfortunately, careful empirical dissection of the complement and distribution of conductances across a given neuronal class' morphology is experimentally laborious, and have been performed on relatively few neuronal classes. Ideally, one could infer the values of microscopic variables, including ion channel classes and their distribution, from the membrane potential alone, which is a macroscopic variable that is experimentally accessible *ex vivo* and *in vivo***.** However, we currently lack methods to accurately infer ionic conductances from membrane potentials in real neurons. Here, we present a novel approach to solve this problem using deep neural networks.

Deep learning and convolutional neural networks (CNNs) techniques are potentially well suited to address the inverse problem by learning how each conductance contributes to the membrane potential. We trained CNNs to predict ionic conductances (output) from membrane potentials (inputs) using simulated data, where the ground truth correspondence between the input-output is known. Using 169 different neuronal compartmental models (12 excitatory and 157 inhibitory) from the Blue Brain Project portal we tested if CNNs can predict their ionic conductaces only from the voltage responses at different recording locations (67 probes) along the membrane. Using this data, we studied the correlation between the conductacnes prediction error and number of recording electrodes. We found that measuring membrane potentials from 3-4 locations is sufficient to accurately recover the vast majority of the conductances of the model. We trained and optimized CNNs under two different conditions. The first was tailored to each neuron type and can predict most of the conductances with very low error. The second CNN is a general network that predicts conductances for all different inhibitory models without prior knowledge of the neuron's type. This second CNN has slightly higher error but can recover the same conductances as the per-neuron CNN.

These results shows that CNNs are an efficient tool to infer ionic conductances from membrane potentials. Utilizing this approach to infer the ionic conductances of experimentally recorded neurons would aid understanding etiology of diverse human illnesses that affect the integrative properties of neurons, including many forms of neurodevelopmental and neuropsychiatric disorders.

Title: Frequency-dependent modulation of neural reliability

Authors: *P. PUIGVERT[1], A. FRANCI[2];
[1]Facultad de Cencias,Universidad Autonoma de Mexico, Ciudad de México, Mexico; [2]Dep. Matematicas, Facultad De Ciencias, UNAM, Ciudad De México, Mexico

Abstract: Neurons are not always reliable in the transmission of action potentials. In other words, the same neuron can respond to the same stimulus in different ways. Reliability can be quantified by spike timing of neurons in a network (Mainen *et al.*, 1995). Furthermore, the reliability spike timing depends on the stimulus temporal properties. It was observed that a stimulus with constant or rapidly fluctuating applied current could cause unequal or more accurate and reliable spike times, respectively. On the other hand, the reliability with which a neuron transmits information, changes with the mental state of the animal studied (Goard, 2009). In particular, the level of reliability of neurons increases in the attentive state. Modulation of neural electrical activity is the basis for many long-lasting changes in animal behavior (Levitan *et al*, 1996), including alterations of the attention state of the animal.
In this work we use computational modeling to analyze how neuromodulation shapes neural reliability as a function of the input frequency content. In particular, we use a modification of the McCormick-Huguenard model for thalamo-cortical neurons and analyse the reliability of its response to an incoming Poissonian train of synaptics pulses. Reliability is quantified as a function of exogenous (average frequency of the incoming spike train), synaptic (synaptic maximal conductance and activation time constant), and endogenous (neural polarization level, modulation of intrinsic conductances) parameters. The resulting reliability parameter chart reveals that neuromodulation can have opposite effects on neuronal reliability depending on the frequency content of the input, as determined by the average frequency of the incoming spike train and by the synaptic activation time constant.
Our results show that neuromodulation can effectively change the timescale of salient stimuli, with rapidly (reps. slowly) changing stimuli reliably transmitted in one neuromodulatory state and unreliably transmitted in another.

Title: An ISI study of a stochastic ML bursting neuron

Authors: *P. ROWAT[1], P. GREENWOOD[2];
[1]Inst. for Neural Computation, UC San Diego, La Jolla, CA; [2]Mathematics, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: In Chapter 9 of his book, "Dynamical systems in neuroscience", Izhikevich describes the deterministic dynamics of various types of neurons which emit a number of rapid spikes with quiet intervals between these bursts.

In this study we explore the stochastic pattern of bursts which results from including in the model the random noise which plays a part in the behaviour of any active neuron. The inter-spike interval histogram, which uses long simulation runs of the process and plots the number of occurrences of times between bursts as a function of time, is an estimator of the probability distribution of times between bursts, and is a useful characteristic of such a model. Here we extend an earlier study of the sample path behaviour of the stochastic Morris Lecar process to the case of a Morris Lecar family of bursters.

Title: Automated tool for modeling single neurons

Authors: P. CANFIELD[1], D. DOPP[1], M. STROUD[2], *S. S. NAIR[2];
[1]Electrical Engin. & Computer Sci., [2]Univ. of Missouri, Columbia, MO

Abstract: Neurons receive input from excitatory and inhibitory neuronal cells and integrate the information causing the cell to fire. The dynamics involves a complex set of intrinsic conductances that seemingly work in coordinated groups although prevalent single cell modeling techniques do not consider such potential interactions. A recent paper suggesting possible grouping of currents into distinct modules associated with specific neurocomputational properties suggests that the process of selection of model parameters could be simplified (Alturki et al., 2016). That insight led to the development of design methodology that simplified the biophysical conductance-based cell design process by allowing the designer to focus on specific attributes of the cell one at a time: starting with passive properties, moving to base-line firing dynamics, then adding features such as burst firing and low- and high-threshold oscillations. By separating the cell design process into these stages, parameter selection can be simplified due to decreased interaction between extraneous conductance groups. The present work extends the study by incorporating a Bayesian based machine learning approach to automate this design process. Preliminary results using biological data related to passive and constant current injection responses at three levels for one of our example cases, a hippocampal neuron, was replicated well by the automation scheme. This specific neuron showed burst firing followed by tonic spiking, and the parameters tuned by the scheme were the maximal conductances for the following channels: NaT, Kdr, Km, and Nap, and the

time constant for the Km current. Usage of the segregation approach thus permitted rapid optimization of parameters over a large 5-dimensional space in this case. Leveraging the segregation approach, we are finalizing a pipeline which automates the biophysical neuronal model design process of cells exhibiting complex dynamics starting from biological data supplied by the neuroscientist. This software pipeline will be made available for public download on our site cyneuro.org.

Title: Experimental analysis of serotonergic fibers utilizing a von Mises-Fisher model

Authors: *K. C. MAYS[1], J. H. HAIMAN[1], M. MILLWATER[1], S. JANUSONIS[2];
[1]Psychological and Brain Sci., Univ. of California, Santa Barbara, CA; [2]Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: All neural processes in the brain take place in a dense matrix of axons (fibers) that release serotonin (5-HT), a neurotransmitter with powerful effects on brain cells. This matrix is present in all vertebrates and appears to represent an ancestral state of neural tissue. In humans, it modulates global brain states and, in particular, supports waking consciousness and perception. Many mental disorders have been associated with perturbations of serotonin signaling (Major Depressive Disorder, Autism Spectrum Disorder, Obsessive Compulsive Disorder, and others). We have recently shown that serotonergic fibers can be modeled as paths of spatial stochastic processes. Here, we focus on experimental analyses using a step-wise model based on the directional von Mises-Fisher (vMF) distribution. We have previously shown in simulations that the value of the vMF concentration parameter (κ) can determine the resultant density of serotonergic fibers in a given brain region. Therefore, this model can bridge the behavior of individual fibers and the regional densities of the serotonergic matrix. In addition, it can provide quantitative data about the heterogeneity of serotonergic fibers.In the present study, we visualized the continuous trajectories of individual serotonergic fibers in a transgenic mouse model (a Tph2-iCre line crossed with a Cre-reporter line (tdTomato/EGFP)). The signal was further enhanced with immunohistochemistry and high-resolution confocal images were obtained in a set of brain regions. Fiber trajectories were automatically traced in 3D using an algorithm developed in our laboratory and the regional estimates of κ were obtained (e.g., $\kappa \approx 20$ in the inferior colliculus, with the 1.5 μm step). In order to achieve reliable separation of individual serotonergic trajectories in dense regions, fibers were visualized with a random combination using Brainbow AAVs stereotaxically injected into the dorsal raphe nucleus of Tph2-iCre mice. This approach also allows us to differentiate fibers and determine how extensively unique serotonergic fibers intermingle in a small brain region.

Title: Spatiotemporal dynamics of single serotonergic axons in ex vivo systems

Authors: *M. T. HINGORANI[1], A. M. VIVIANI[1], J. C. CHIU[2], A. M. VARGAS[1], R. STOWERS[3], C. M. BATES[4], S. JANUSONIS[1];
[1]Psychological and Brain Sci., [2]Biol., [3]Bioengineering, [4]Materials, Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Previous work in our group has shown that the self-organization of the serotonergic matrix depends in part on the decisions made by individual fibers. Evidence suggests that the trajectories of serotonergic fibers are strongly stochastic and can be well described by step-wise random walks or fractional Brownian motion (a time-continuous process). The success of these modeling efforts crucially depends on experimental data which are necessary to validate the general structure of a model and to constrain the values of its parameters. In particular, further progress crucially depends on the experimental capability to track individual serotonergic axons in *time* and *space*. However, visualizing this dynamic behavior *in vivo* is currently extremely challenging. In this study, we cultured primary mouse brainstem neurons in several *in vitro* and *ex vivo* systems. Using a combination of methods such as confocal microscopy, digital holotomography, false fluorescent neurotransmitters, and novel 3D hydrogel systems, we investigated serotonergic neurons and their axons with unprecedented spatiotemporal precision. The dynamics of axon growth cones, branching events, and other key processes were analyzed with respect to the properties of the tunable extracellular environment and to the refractive index-sensitive intracellular movements. These experimental data include the first holotomographic images of serotonergic axons and provide essential information for the predictive modeling of the serotonergic matrix. In addition to the importance of these findings for fundamental neuroscience, they may also support future efforts in the restoration of brain tissue (serotonergic fibers are almost unique in the mammalian brain in their ability to robustly regenerate). Some of the novel approaches developed in this study may be applicable to other axons in the ascending reticular activating system.

Title: A combined time- and frequency- domain processing pipeline for parameterizing neural periodic and aperiodic activity.

Authors: *R. HAMMONDS[1], T. DONOGHUE[2], B. VOYTEK[1];
[1]Cognitive Sci., Univ. of California San Diego Dept. of Cognitive Sci., La Jolla, CA; [2]Columbia Univ., New York, NY

Abstract: Analysis of neural oscillations are typically performed using either time or frequency domain approaches. Fourier based methods reduce the dimensionality of neural signals by decomposing it into a set of sinusoids, facilitating simpler interpretations and comparisons. Time domain methods allow the exploration of non-sinusoidal features. While both of these approaches are powerful, and have provided many insights into the physiology and function of neural oscillations, they are each also limited in their own ways. For example, without careful consideration, Fourier based approaches can conflate oscillations with aperiodic activity, and the harmonics that arise from nonsinusoidal rhythms can look like multiple oscillations. Similarly, traditional time-frequency analyses fail to associate high spectral power with nonsinusoidal rhythms. Time domain approaches suffer from high dimensionality and the difficulty in identifying oscillatory cycles in noise. Analyses of spectral peaks and waveform shape are typically performed independently and rely heavily on parameter optimization, such as spectral peak width and height ranges or frequency ranges of interest when examining waveforms. Here we provide a signal processing pipeline that combines frequency and time domain approaches to help address these shortcomings. Rather than having two independent processing pipelines for time and frequency domains, this approach identifies spectral peaks in the frequency domain to uncover nonsinusoidal oscillatory motifs in the time domain. We demonstrate this approach using both simulated and real data. This pipeline allows spectral and waveform parameterization to inform one another. The proposed pipeline is not limited to neural signals and may be broadly applied to any time series that contains spectral peaks.

Title: Seecog: an interactive browser-based visualization tool for intracranial electrodes and multi-modal data

Authors: *N. B. MARKOWITZ[1], A. D. MEHTA[2], S. BICKEL[3];
[1]Feinstein Inst. for Med. Res., Manhasset, NY; [2]Neurosurg., Hofstra North Shore LIJ Sch. of Med., Great Neck, NY; [3]Neurosurg. / Neurol., Hofstra Northwell Sch. of Med., Manhasset, NY

Abstract: Objective: SEECOG: An interactive browser-based visualization tool for intracranial electrodes and multi-modal data
Rationale: Data acquired from a participant undergoing intracranial electroencephalography (iEEG) is multi-modal in nature. Simultaneously visualizing this multi-modal data is difficult and becomes even more so when looking at data acquired across multiple patients. Viewing and interacting with such data is challenging and can take multiple softwares that specialize in visualizing each unique modality. To overcome this, we developed an easy to use and intuitive browser-based program for visualizing this multi-modal data for single and multiple subjects.
Methods: The application is developed using a combination of html, css and javascript files that can be run online or locally and on any operating system. The application directly integrates with a variety of file formats such as BIDS, NWB, nifti and Freesurfer meshes. Volumes, surfaces and individual electrodes are rendered in an interactive 3D environment. An accompanying electrode table allows further labeling and annotating of individual and groups of electrodes. These applied labels can then be reflected in how the electrode appears in the 3D environment.
Results: An interactive application that allows the visualization and manipulation of multi-modal data across many subjects. Channel locations can be visualized in a single subject's native space or in one of the commonly used standard spaces (such as fsaverage). Using the accompanying table, channel properties can be changed at will to mark channels of specific interest such as those that display significant activity in an analysis. These properties can then be reflected by the channels appearance to differ special or significant channels from others. Multiple channels can be queried based on custom properties, names and general location. The annotated table can be downloaded for use in other softwares.
Conclusion: Visualizing multi-modal data that is inherent to iEEG cases is necessary and invaluable. However, no such program has yet been created that provides an easy interface for all users and allows working with multiple subjects. SEECOG allows iEEG labs to more easily aggregate and examine their data collected from multiple subjects and different modalities to better understand, interpret, and present their work. The easy interface also lets the data become more accessible to those without technical knowledge or familiarity with other complex softwares. The viewing and querying of this large and varied amount of data is invaluable to researchers working with iEEG data.

Title: Reimagining value in academia through the blockchain: Ants-Review, a decentralised platform for incentivising peer-reviews

Authors: *B. TROVÒ[1,2];
[1]Sorbonne University, Fac. of Sci. and Engin., Paris, France; [2]CEA Saclay, Gif-sur-Yvette, France

Abstract: Peer review is a necessary and essential quality control step for scientific publications but lacks proper incentives for being not only very costly in terms of time and intellectual investment, but also not remunerated by the journals and not openly recognized by the academic community as a relevant scientific output for a researcher. In addition to that, the number of manuscripts submitted to journals and preprints keeps increasing every year. Therefore, scientific dissemination is affected in timeliness, quality, and fairness. This problem is particularly evident in the biomedical field like in neuroscience in which the peer review process can take up to years. Some solutions to incentivize and reward peer review services have been proposed but without much success. This is because traditional systems do not manage to capture the scientific value of the peer review into an actual impact factor measure or fail to see in it a commodity that can be fungible. A conceptually similar system to peer review is the peer-to-peer validation process in a blockchain, in which blocks must be first verified in order to be added to the network. Blockchains, though, act as 'incentive machines' by programming rewards that push to work for the honest nodes. Here, leveraging this analogy, we propose to solve this issue through a blockchain-based incentive platform that rewards scientists for peer-reviewing other scientists' work and that builds up trust and reputation. We designed a privacy-oriented protocol of smart contracts called Ants-Review that allows authors to issue a bounty for open access, double-blind peer reviews on the Ethereum blockchain. If requirements are met, peer reviews will be accepted and paid by an approver proportionally to their assessed quality. To promote ethical behavior and inclusiveness and reduce biases the platform will implement a gamified mechanism and cryptographic tools that allow the whole community to anonymously evaluate the peer reviews and vote for the best ones while remaining accountable. The platform is currently at the MVP stage on the Kovan Testnet. Future research (such as large-scale surveys and computational modeling) will be needed to study the effect of reward mechanisms on human agents in such a complex scenario and evaluate the advantages of mechanism design on accelerating biomedical publications.

Title: Umit: an open-source toolbox for management of large-scale widefield cortical imaging datasets.

Authors: *B. DE SOUZA[1,2], S. BELANGER[2], S. TISSIER[1], M. ABRAN[2], M. VANNI[1];
[1]Univ. of Montreal, Montreal, QC, Canada; [2]Labeo Technologies, Montreal, QC, Canada

Abstract: *In vivo* widefield optical imaging techniques have been used for decades to investigate the brain function. Recent advances in genetic tools, such as fast-responding calcium indicators (e.g., GCaMP6f) as well as the increasingly accessible high-speed, high-resolution and high throughput longitudinal recording systems allowed the acquisition of faster and more detailed images at mesoscale level for months on large cohorts of animals. This generates large amounts of data that need to be stored, pre-processed and analysed in a timely manner. This can be a limiting factor as experiments become larger and more complex. In order to address this issue, we have built a high-throughput toolbox named *umIT* (*u*niversal *m*esoscale *I*maging *T*oolbox) that provides a set of tools to manage and automate critical steps of processing large-scale imaging datasets.
The toolbox was created in MATLAB. It consists of four main modules that manages the experiment metadata (i.e., information about experimental subjects and recordings), creates pipelines to import and pre-process data, provides data visualization tools and basic group comparison and statistical analysis. The toolbox was developed using datasets from a longitudinal mesoscale cortical imaging experiment with a cohort of GCaMP-expressing mice (n = 30) that were recorded several times for 60 days. It managed a large amount of data (>16TB) consisting of distinct protocols (e.g., resting state, retinotopy of visual cortex, event-triggered average response) which provided an opportunity to test the adaptability and extensibility of the toolbox in a real-world setting.
The use of the toolbox during the cortical imaging experiment provided a structured framework that organized the experiments data (raw and processed) as well as metadata. In addition, the automated processing pipelines and visualization tools greatly improved the efficiency of the data processing and analysis. Although, as of today, the toolbox covers most of the needs of a typical imaging experiment, it was designed to be as adaptable and extensible as possible with the option for the user to create custom functions that can be fully integrated in the processing pipeline. Thus, these features make *umIT* a valuable tool for large-scale imaging experiments.

Title: The Open Ephys GUI: a collaboratively developed platform for high-channel-count electrophysiology data acquisition

Authors: *J. SIEGLE[1], A. DOSHI[1], P. KULIK[1], A. CUEVAS LOPEZ[2], J. VOIGTS[3];
[1]Allen Inst., Seattle, WA; [2]Ctr. for biomaterials and Tissue engineering, Univ. Politècnica De València, Valencia, Spain; [3]Brain and Cog. Sci., MIT, Cambridge, MA

Abstract: The Open Ephys GUI (https://open-ephys.org/gui) is an open-source, cross-platform application for acquiring data from multichannel implanted electrodes, a technique that has fostered countless discoveries in systems neuroscience. The GUI is compatible with a variety of data sources, including the Open Ephys acquisition board, Intan data acquisition systems, and Neuropixels probes. Unlike most other software in this domain, the GUI was designed from the ground up with collaborative development in mind. Modules for real-time analysis and visualization are encapsulated within plugins that adhere to a standardized interface, providing a straightforward way for users to write their own extensions without needing to understand the entire code base. To facilitate plugin dissemination, we have created a centralized repository for pre-compiled plugin binaries, which can be downloaded and installed via a single click. Support from a BRAIN Initiative U24 award has allowed us to collect, polish, and document additional community-developed plugins in order to expand the capabilities of the GUI. Providing free, user-friendly, and performant software for recording spiking activity makes extracellular electrophysiology experiments more accessible to labs around the globe.

Title: Deep Learning Classifier for the Combined Scoring of Sleep-Wake and Seizures in Mice

Authors: *B. HARVEY[1], V. OLÁH[1], L. AIANI[1], L. ROSENBERG[1], M. ROWAN[1], N. P. PEDERSEN[2];
[2]Neurol., [1]Emory Univ., Atlanta, GA

Abstract: The relationship between sleep and seizure is complex and bidirectional, including seizure-frequency-associated sleep fragmentation as well as sleep-deprivation-induced increases in seizures. In order to provide better throughput for sleep studies in Intra-Amygdalar Kainic Acid (IAKA) Temporal Lobe Epilepsy (TLE) model mice, we have designed a data processing pipeline and Keras-based deep learning classifier for sleep staging and seizure scoring. While sleep-wake classifiers and seizure detection algorithms abound, the combination is difficult given the abnormal EEG background in mice

with epilepsy. We obtained electrocorticogram (ECoG), electromyogram (EMG), video and bilateral hippocampal depth electrode data from mice implanted using a customized 3D-printed headplate designed in our lab. Our dataset included 972 12-hour recordings (11,664 hours of data), from a group of 47 mice (including 23 mice that developed spontaneous seizures and 10 control mice), that included 642 seizures. We used 80% of the data for training and 20% for testing. The classifier was trained on previously manually scored 20-second epochs from existing downsampled recordings (from 2kHz to 200Hz), using Fourier bins of alpha, beta, delta, gamma, and theta frequency bands in downsampled recordings from this montage. With a sequential model in Keras using TensorFlow, the classifier has achieved >90% scoring accuracy in most categories for our epileptic mice, with a categorical accuracy of 93% for Wake, 91% for Non-REM sleep, 86% for REM, and 95% for seizure states. This reliable classification will allow for rapid combined sleep-wake and seizure scoring in our IAKA sleep-wake paradigm. Using this classifier to improve our throughput, we hope to improve the mechanistic and symptomatic understanding of sleep disruption in epilepsy, leading to improved patient treatment and outcomes.

Title: Detecting artifacts in brain MRI with a deep-learning algorithm: implementation in large databases

Authors: *R. PIZARRO[1], H.-E. ASSEMLAL[2], S. K. B. JEGATHAMBAL[1], T. JUBAULT[2], S. ANTEL[2], D. ARNOLD[1], A. SHMUEL[1];
[1]McGill Univ., Montreal, QC, Canada; [2]NeuroRx Res., Montreal, QC, Canada

Abstract: MRI is increasingly being used to delineate morphological and organizational changes underlying neurological disorders. Successfully detecting these changes depends on the MRI data quality. Image artifacts frequently compromise the utility of MRI and cause irreproducible results. Therefore, it is critical to screen MRI data for artifacts prior the analysis. Currently, quality assessment requires visual inspection by experts. This process is time-consuming and impractical for ‘big-data’ analysis. Automating the quality rating of MRI could improve the efficiency of the process, in particular when dealing with a large database.
We analyzed a database constructed through a software pipeline to process over 10^5 MRI datasets. MRI artifacts were identified by visual inspection and the results used as the ground truth. We developed a deep-learning (DL) algorithm based on convolutional neural networks (CNNs) to automatically detect MRI artifacts. In the testing phase, we incorporated dropout layers to generate *N* Monte Carlo (MC) inferences summarized with a prediction probability, *p*, and three uncertainty metrics: sample variance

(σ;^{2}), entropy (H), and mutual information (MI). We normalized the uncertainty metrics and compared the baseline (no threshold) to setting a threshold: η; < [0.5, 0.1, 0.01, 0.001]. For each η;, we set a classification threshold on p to generate ROC plots to evaluate the DL algorithm performance. For each ROC curve, we computed J, the operating point that maximized Youden's index.

We illustrate the results by using η; on σ;^{2} in Figure 1. As η; is lowered, the number of the retained datasets decreased, but the AUC increased, and J moved closer to the top left. For each J, we computed the corresponding statistics as η; was lowered, summarized in Table 1. We developed a DL algorithm to detect artifacts in brain MRI automatically. The algorithm has been successfully implemented into the processing pipeline. The tool we developed has saved database management teams valuable resources, including hours spent by technicians for identifying artifacts in the MRI volume.

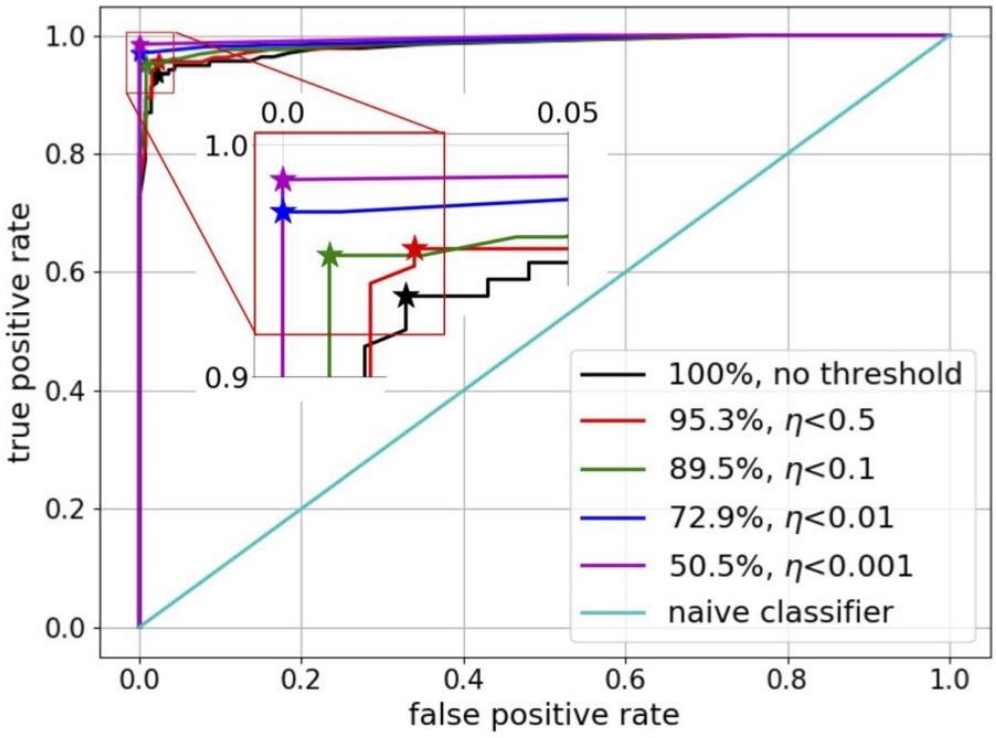

Figure 1 - ROC plots generated by computing 100 Monte Carlo (MC) inferences on the test set. We used the MC inferences to compute the prediction probability p and the sample variance σ^2. We set an uncertainty threshold η on the normalized σ^2 to screen volumes classified with low confidence, i.e., high σ^2. The legend specifies the η value used along with the resulting percent retained. Youden's index is denoted with a color-coded star for each curve. The inset is a zoomed-in version over the red square to highlight how Youden's index move as η is lowered.

Table 1. Summary statistics computed from each ROC curve and corresponding Youden's index (***J***) as the uncertainty threshold η on the sample variance is lowered. We color-coded the rows to correspond to the same colors used in Figure *1*.

η	% retained	AUC	Youden	accuracy	specificity	tn	fp	sensitivity	fn	tp
N/A	100.0	0.987	0.69	0.957	0.935	129	9	0.978	3	136
0.5	95.3	0.990	0.72	0.966	0.955	128	6	0.977	3	127
10^{-1}	89.5	0.993	0.91	0.972	0.952	120	6	0.992	1	121

Title: Training and Validating an Accessible Automatic Cell Counting Methodology Using Precision and Recall

Authors: *T. KATARAS[1], J. KOURY[2], H. SINGH[2], M. KAUL[2];
[1]Genetics, Genomics and Bioinformatics, [2]Biomed. Sci., Univ. of California, Riverside, Riverside, CA

Abstract: Trainable Weka Segmentation (TWS) provides user-friendly access to machine learning tools for cell quantification. However, analyzing whole datasets requires further development of methods for training, validation and processing. We present here the advancement in our automatic cell counting methodology, which leverages iterative use of the TWS plugin within ImageJ with cell-level accuracy validation. Cell counting remains one of the primary methods of assessing disease progression in neuroscience. However, this analysis is commonly time-intensive even for trained observers, and is difficult to standardize between different observers. We compared our automatic counts to hand counts of immunofluorescence stained microglia in mouse cerebral cortex. The analysis included microglia of wild-type (Resting) and a transgenic mouse model for HIV-induced brain injury (HIVgp120tg, Activated microglia). HIVgp120 mice showed behavioral deficits, and an increase in microglia numbers presumably driven by chronic exposure to the gp120 protein. For the analysis, images were collected from sagittal brain sections of 11-14 month-old mice at 10X magnification. Manual counts obtained by two observers were compared to automated quantification of cells. The results demonstrate the accuracy achievable with TWS while addressing the challenges that come with imaging under experimental conditions which can induce morphological changes in cells of interest. A large advantage of this strategy is the much shorter time required to apply the automatic counting strategy compared to a manual count and the accessibility of the software in ImageJ. Using TWS took less than a fifth of time of the manual count, including time spent training the program. As with all ImageJ plugins, the TWS software is free to use and integrated with a host of other image analysis tools. Our study demonstrates the applicability of this technique to quickly explore large amounts of image data, leaving open the possibility to audit the results by manually counting a randomly selected subset of images.

Title: Assessing Agreement of Measures of Heart Rate Variability Between Kubios and AcqKnowledge

Authors: *F. GILBERT, N. THOM;
Wheaton Col., Wheaton, IL

Abstract: Objective: Although heart rate variability (HRV) is a common measure of autonomic influence on the heart, the reliability of commonly-used software programs utilized to analyze HRV data remains untested. Therefore, the present study sought to compare Kubios and AcqKnowledge in order to evaluate the agreement between these programs. **Methods:** Electrocardiogram (ECG) recordings were collected from 14 college students at three different time points across a semester for a total of 34 recordings after data pre-processing. HRV parameters were then transformed by the natural log and input into MedCalc to calculate the 95% limits of agreement (LoA) between programs. Limits were deemed appropriate if they fell within the a priori limits calculated from normalized HRV ranges and showed minimal or no amount of bias. **Results:** Assessment of the LoA and means demonstrated poor agreement under paced breathing conditions for the measures of RMSSD (mean = 0.026, [LoA = 0.121, -0.069]), VLF (mean = -1.325, [LoA = -0.599, -2.052]), and LF (mean = -0.040, [LoA = 0.260, -0.341]), but good agreement for HF (mean = -0.008, [LoA = 0.152, -0.169]). A large constant bias was present for the measure of VLF (mean bias = -1.325), while the measures of HF (R^2 = 0.122, F = 4.445, b-value = -0.033, p = 0.043) and RMSSD (R^2 = 0.355, F = 17.624, b-value = -0.062, p = 0.000) demonstrated proportional bias between programs. **Conclusions:** These results suggest that while some metrics of HRV may be comparable between these software programs, they do not all meet standards of comparability. Future studies should consider the differences in program accessibility and data output when choosing an HRV software program, and explicitly state which program was utilized and what analysis settings were used to preserve accuracy and transparency of data reporting.

Title: Online spike sorting and rapid data analysis to identify selective neuronal responses

Authors: F. J. CHAURE[1], S. A. SHETH[2], ***H. G. REY**[2,3];
[1]Inst. of Biomed. Engin., Univ. of Buenos Aires, Buenos Aires, Argentina; [2]Neurosurg., Baylor Col. of Med., Houston, TX; [3]Neuroscience, Psychology and Behavior, Univ. of Leicester, Leicester, United Kingdom

Abstract: When extracellular electrodes are implanted in the brain, one important methodological issue is identifying the relevant stimuli that will elicit a neural response from the neurons that are close to the recording tip. This is particularly important when the electrodes cannot be moved to focus on different neurons (as it is the case of single cell recordings in the human brain) and instead we have to rely on showing a large number of stimuli. However, this task can be very time consuming, not just for the data acquisition but also for its analysis. Although the proposed framework is very general, we focus here on the screening procedure to find “concept cells” in the human medial temporal lobe. This typically involves showing ~100 pictures, 6 trials each, which takes ~25 minutes of data acquisition.The main features of the proposed method include: 1) Use of APIs from electrophysiology acquisition systems to acquire the data online as the task is being performed (we developed our method for Blackrock Microsystems and Ripple Neuromed). 2) Use of parallel processing so that some cores can focus on presenting the stimuli during the task while others perform spike extraction and clustering (the latter being done with the iso-split algorithm to improve the computing time). 3) Develop a statistical criterion so that neural responses can be ranked, with stimuli ranking poorly being replaced with new ones.In terms of performance, the online and fully automatic spike sorting algorithm led to very similar results to those from other offline methods. The ranking criterion was also robust and effective. First, it did not exclude any of the responses that would have been obtained with the standard screening procedure followed by a scoring from an expert. In ~30 minutes, recording from 32 microwires and using an 8-core desktop, we were able to screen 330 pictures, with the candidate stimuli eliciting neural responses being presented at least 15 times each. This way, the number of false positive responses was largely reduced in comparison to the standard screening procedure. Finally, when the number of active channels is large, the processing time can be compensated by using more cores in parallel. Overall, the proposed method not only increases the number of response-eliciting stimuli that can be obtained during a given screening session, but also reduces dramatically the processing time to analyze the data and start a follow up experiment with the response-eliciting stimuli . This is essentially the time to plot the rasters and instantaneous firing rate for the candidate neural responses on each microwire, which is only in the order of a few tens of seconds.

Title: Modeling SARS-CoV-2 infection of the developing brain using human cortical organoids

Authors: *C. L. MCMAHON[1], H. STAPLES[2], M. GAZI[2], R. CARRION[2], J. HSIEH[3];
[1]Biology/Neurobiology, Univ. of Texas At San Antonio, San Antonio, TX; [2]Texas Biomed. Res. Inst., San Antonio, TX; [3]Biol., The Univ. of Texas At San Antonio, San Antonio, TX

Abstract: The prevalence of neuropsychiatric disorders is increasing, and a major cause of these disorders is aberrant fetal brain development. There is growing evidence implicating prenatal exposures as a driving factor. A common exposure that has undergone an exponential increase in incidence during recent years is that of viral infections, due in part to the novel coronavirus disease 2019 (COVID-19) pandemic. Up to 30% of COVID-19 patients have manifested neurological complications, and SARS-CoV-2 RNA has been found in brain biopsies from fatal cases. Furthermore, increasing rates of pre-term birth, miscarriages, and other defects have been seen following a maternal infection. The neurotropism of SARS-CoV-2 and the implications of neuroinflammation on the adult and developing brain are still poorly understood, therefore, it is imperative to gain insight into the mechanism(s) responsible for these complications. We hypothesize that SARS-CoV-2 infection and neuroinflammation trigger neurodevelopmental changes leading to a disruption of neural structure and circuit function in the developing cortex. Due to the inaccessibility of brain tissue from COVID-19 patients, we will address these questions using human stem cell-derived cortical organoids. To elucidate the cellular effects of SARS-CoV-2 infection on the development of the fetal brain, we first examined the neurotropism of SARS-CoV-2 in cortical organoids by identifying the cell types susceptible to SARS-CoV-2 infection, viral infection levels, viral replication, and the consequential effects on infected cells. We next determined the mechanisms by which neuroinflammation causes cellular alterations in cortical organoids by evaluating cellular integrity and neuronal networks. This study aims to reveal novel insight into the human-specific cellular etiology of potential neuropsychiatric disorder development from prenatal COVID-19 exposure, potentially contributing to future therapies and interventions.

Title: Molecular and cellular mechanisms regulating brain overgrowth in autism

Authors: *S. CHETTY;
Stanford Univ., Stanford, CA

Abstract: Approximately 15-20% of individuals with Autism Spectrum Disorder (ASD) have disproportionate megalencephaly (ASD-DM), with disproportionate enlargement in both gray and white matter volume. Individuals with ASD-DM have more severe behavioral and cognitive problems and are less responsive to standard therapeutic interventions, leading to very poor prognoses relative to

individuals with ASD and normal head circumferences. Increases in brain size often precede clinical symptoms, suggesting that understanding the underlying mechanisms regulating brain overgrowth could provide a window of opportunity for intervention or mitigation of symptoms. Here, we generated ~40 human iPSC lines from cohorts of children (2-4 years old) with complete clinical and phenotypic data, including A) ASD subjects with disproportionate megalencephaly, ASD-DM; B) ASD subjects with normal sized brains, ASD-N; C) Typically developing (TD) subjects with disproportionate megalencephaly, TD-DM; and and D) TD subjects with normal sized brains, TD-N. We differentiated each of the iPSC lines into neural progenitor cells (NPCs) and oligodendrocyte progenitor cells (OPCs) and investigated changes at the molecular and cellular levels contributing to brain overgrowth. In the differentiated neural and glial progenitor cells, we observe increased proliferation and suppressed phagocytosis of NPCs/OPCs by macrophages in ASD-DM. RNA-sequencing of the differentiated progenitor cells reveals important signaling mechanisms related to the neuroimmune system in regulating cellular phagocytosis. In prior work, we have demonstrated that CD47 (a 'don't eat me' signal) is overexpressed in both NPCs and OPCs in 16p11.2 deletion carriers with macrocephaly contributing to reduced phagocytosis in vitro and in vivo. Treatment of 16p11.2 deletion NPCs and OPCs with an anti-CD47 antibody to block CD47 restores phagocytosis to control levels in cellular and mouse models. Here, we show that similar neuroimmune mechanisms commonly implicated in cancer regulate cellular homeostasis in idiopathic forms of autism. Furthermore, we highlight new forms of therapy for selected autistic individuals with brain overgrowth early in the disease.

Title: Loss of Atypical Kinesin KIF26A Causes Brain Malformations via Aberrant Radial Migration and Increased Apoptosis

Authors: *X. QIAN[1,2], E. M. DEGENNARO[1,2], M. TALUKDAR[1,2], A. LAI[1,2], S. AKULA[1,2], C. A. WALSH[1,2];
[1]Div. of Genet. and Genomics, Howard Hughes Med. Inst., Boston Children's Hosp., Boston, MA;
[2]Departments of Pediatrics and Neurol., Harvard Med. Sch., Boston, MA

Abstract: Kinesins (KIFs) are molecular motors that transport cargo along microtubules intracellularly, and may serve as modulators of signaling pathways by altering the localization of signal-associated

factors. KIF26A, an unconventional kinesin that lacks ATPase activity, can bind to and sequester Grb2 and focal adhesion kinase (FAK) onto microtubules, suppressing their activity in signal transduction. Mice with homozygous deletion of Kif26a developed megacolon with enteric nerve hyperplasia. Nevertheless, the role of KIF26A in the central nervous system has not been characterized. We recently discovered a patient cohort with homozygous frameshift or compound heterozygous mutations in the KIF26A gene. The affected individuals displayed a spectrum of brain malformations including polymicrogyria, schizencephaly, cerebral atrophy and ventriculomegaly. Analysis of bulk and single-cell RNA sequencing (scRNA-seq) datasets of human fetal and postnatal cerebral cortex revealed KIF26A is specifically expressed in the first and second trimesters of gestation by migrating excitatory neurons. To investigate KIF26A's function in human brain development, we created KIF26A knockout (KO) human induced pluripotent stem cell (hiPSC) lines and generated forebrain organoids to compare with isogenic controls. We found KO organoids exhibited altered lamination of the subventricular zone (SVZ) and cortical plate (CP), and showed aberrant excitatory neuron radial migration, a FAK-dependent process. In KO organoids, migrating neurons were stalled in the SVZ, unable to reach the CP, and apoptotic cell death was elevated. In mouse embryonic cortex with shRNA knockdown of Kif26a, we observed similarly arrested radial migration in a cell-autonomous manner, but the knockdown didn't induce increase in apoptosis. To explore the underlying molecular mechanisms, we performed scRNA-seq on these organoids and discovered cell type-specific transcriptional changes in migrating and maturing excitatory neurons upon loss of KIF26A. Consistent with KIF26A's function as a Grb2 inhibitor, genes related to MAPK and p53 signaling were among the top differentially expressed genes. Gene set enrichment analysis further revealed dysregulation of MYC and E2F pathways, underscoring KIF26A's functions in modulating multiple signaling cascades related to cell survival. Together, our work uncovered the novel role of KIF26A in human brain development and diseases. Combining hiPSC-derived models and animal model, our multi-dimensional investigation illustrated that KIF26A regulates excitatory neuron migration and survival, and provided platforms for further mechanistic studies.

Rare loss-of-function (LoF) mutations in *SETD1A* are strongly associated with schizophrenia (SZ), a debilitating mental disorder affecting 1% of the population, and other severe neurodevelopmental disorders. *SETD1A* encodes a component of the histone methyltransferase complex producing mono-, di, and trimethylated histone H3 at Lysine 4 (H3K4). H3K4 trimethylation (H3K4me3) and H3K4me1 are epigenomic marks of active gene transcriptional promoters and enhancers, respectively. Interestingly, histone methylation has also been suggested as one of the most enriched gene pathways in common variant-based genome-wide associations studies (GWAS) of major psychiatric disorders. However, the detailed molecular mechanism by which it causes neuronal dysfunction is still unclear. Recent advances in stem cell biology have allowed the efficient conversion of human stem cells into defined neuron subtypes allows to address this question. Using CRISPR/Cas9 gene editing, we have generated isogenic hiPSC lines carrying heterozygous LoF mutations on different genetic backgrounds of *SETD1A*. Preliminary results showed that mutant lines were defective in neuronal development with premature neuronal differentiation at early developmental stages. Furthermore, morphological, electrophysiological and transcriptomic analyses of hiPSC neurons carrying *SETD1A* LoF mutation showed defective synaptic neurotransmission. Ongoing experiments are evaluating *SETD1A* LoF with functional, morphological, biochemical and genomic parameters to understand the cellular mechanisms that how *SETD1A* LoF contributes to the pathogenesis of SZ. The study enables us to perform a well-controlled assessment of the impact of *SETD1A* LoF mutations on the molecular and cellular mechanisms underlying deficits in early neurodevelopment and synaptic properties.

Title: Examining AUTS2 deficiency on human neurons

Authors: *C. MARCHETTO[1], V. M. CEREDA[2], A. SHARMA[3], J. T. WHITELEY[4];
[1]Anthrop., Univ. of California San Diego, La Jolla, CA; [2]Dept. of Biochem. and Tissue Biol., Univ. of Campinas, Campinas, Brazil; [3]Salk Inst., La Jolla, CA; [4]Columbia Univ., New York, NY

Abstract: The *Autism susceptibility candidate 2* (AUTS2) gene has been implicated in neurodevelopment and as a candidate gene for numerous neurological disorders, including autism spectrum disorders and intellectual disability. Individuals with mutations in this gene commonly show microcephalic features, craniofacial abnormalities and repetitive behaviors. Additionally, the genomic structural variants and single nucleotide polymorphisms in the *AUTS2* locus are also associated with a wide range of other neurological disorders such as epilepsy, schizophrenia, attention deficit hyperactivity disorder, dyslexia and depression as well as addiction-related behaviors, implicating that *AUTS2* is broadly involved in neurodevelopment. While *AUTS2* is often disrupted in patients with neurodevelopmental conditions above mentioned, the mechanisms underlying the neuronal pathogenesis in developing human neurons are still unclear. To bridge this gap, we use CRISPR/ Cas9 DNA editing technology to knockdown *AUTS2* gene on human stem cell lines and study the mechanistic consequences of lack of AUTS2 expression on transcriptomics and neuronal function. Our initial data analysis show that Wnt and Hippo signaling pathways are significantly affected on *AUTS2* knockdown human neuronal progenitors. We will present data characterizing unique phenotypical properties of *AUTS2* knockdown human neural progenitors. Understanding the cellular dysfunction and molecular pathways involved in AUTS2 deficiency could shed a light on the neuropathology of neurodevelopmental conditions such as ASD, ID and others.

Chemistry, Michigan Med., [6]Dept. of Neurology, Dept. of Pharmacology, and Dept. of Mol. and Integrative Physiol., Michigan Med., [7]VA Ann Arbor Healthcare Sys. and Dept. of Neurology, and Michigan Neurosci. Institute, Michigan Med., Univ. of Michigan, Ann Arbor, MI

Abstract: *SCN1B*-linked developmental and epileptic encephalopathy (DEE) is characterized by pharmacoresistant seizures and sudden unexpected death in epilepsy (SUDEP). A subset of DEE patients exhibits homozygous putative loss of function variants in *SCN1B*, the gene that encodes the voltage-gated sodium channel (VGSC) β1 subunit. These *SCN1B* gene variants negatively affect neuronal development and alter neuronal excitability, leading to seizures and severe intellectual disability. We aim to understand how mutations in the *SCN1B* gene cause DEE to identify precision therapies. To this end, we generated induced pluripotent stem cells (iPSCs) from fibroblasts/blood of two patients with homozygous *SCN1B* p.R89C variants and healthy controls (one parent and one unrelated control). These iPSCs were differentiated to form excitatory neurons using dual-SMAD inhibition as well as induction with *NGN2* expression. Electrophysiological recordings showed that, as compared to control, *SCN1B* mutant excitatory neurons exhibit increased transient sodium current (I_{Na}) and spontaneous firing suggesting neuronal hyperexcitability. We hypothesize that *SCN1B*-linked DEE patient-derived inhibitory neurons will exhibit reduced excitability, hence leading to further neural circuit instability and seizures. Our previous study using a mouse model of *SCN1B*-linked early infantile DEE (EIEE52) supports this model (Hull et al., 2020). We generated cultures of mature GABAergic inhibitory neurons from control and patient-derived iPSCs using a small molecule-directed differentiation protocol. Additionally, we used an induced differentiation approach based on the expression of transcription factors *ASCL1* and *DLX2*, resulting in the rapid generation of a homogeneous population of GABAergic interneurons. We confirmed the GABAergic identity of generated neuronal cultures based on real-time qRT-PCR analysis of *GAD65*, *GAD67*, and *VGAT* (n=3). Immunostaining analysis revealed the generation of multiple GABAergic interneuron subtypes including somatostatin- and calbindin-positive interneurons. Using calcium imaging and electrophysiological recordings, we are examining the mutant cultures of inhibitory interneurons to investigate whether they have altered excitability. This work offers the potential for delineating the mechanisms underlying cortical dysfunction in *SCN1B*-linked DEE and for developing precision therapies designed to alleviate seizures and cognitive dysfunction in patients with *SCN1B*-linked and other DEEs.

Title: Uncovering a neurodevelopmental role for fAD linked PSEN1 mutations

Authors: *E. HURLEY[1], R. DOBROWOLSKI[2], J. HSIEH[3];
[1]Biol., Univ. of Texas San Antonio, San Antonio, TX; [2]Biol. Sci., Rutgers Univ., Newark, NJ; [3]Biol., The Univ. of Texas At San Antonio, San Antonio, TX

Abstract: Mutations in Presenilin1 (PSEN1), the catalytic subunit of gamma secretase, account for over 80% of familial Alzheimer's Disease (fAD). Another substrate of the gamma secretase is Notch1, a critical signaling molecule with roles in neural progenitor maintenance, neurogenesis and gliogenesis. Previous reports suggest that mutations in PSEN1 reduce Notch signaling and lead to premature neurogenesis. However, it is not clear whether altered neurogenesis is linked to AD related pathology and neurodegeneration. Using human induced pluripotent stem cell (iPSC) derived 3D cortical organoids, we focus on PSEN1 mutations that have not been widely studied in the literature. We perform CRISPR/Cas9 editing in an isogenic control iPSC line to generate distinct PSEN1 mutations predicted to cause a loss or gain of function in the gamma secretase complex. In contrast to previous reports, we observe increased Notch signaling, an increase in neural progenitor cells and reduced neuronal differentiation in PSEN1 mutant organoids. We also observe increased size and morphological changes in cortical organoids harboring PSEN1 mutations, which is blocked by treatment with a Notch1 specific inhibitor, consistent with Notch signaling defects that depend on gain of function PSEN1 mutations. We will be determining if any of the neurodevelopmental changes due to PSEN1 mutations have further effects on AD-related neuropathology. Using this human cell-based model, these findings suggest that fAD mutations alter neural progenitor expansion and neurogenesis during development, possibly predisposing neurodegeneration.

Title: Neurotropic infections impair neural stem cell activity in the pediatric central nervous system

Authors: *Y. S. KAMTE, M. N. CHANDWANI, A. G. FADARE, L. A. O'DONNELL;
Duquesne Univ., Pittsburgh, PA

Abstract: Outcomes of a viral infection in the CNS are often age-dependent. Several neurotropic viruses lead to profound neuropathology in younger hosts compared to older hosts. In pediatric mice, key neurodevelopmental processes such as synaptogenesis, myelination, and pruning are still underway. Neural stem cells (NSCs) are multipotent progenitor cells that populate the brain with neurons, astrocytes, and oligodendrocytes. The NSC pool contracts with age and is restricted to two neurogenic niches in the brain [hippocampus and sub-ventricular zone (SVZ)]. Thus, we hypothesized that a viral infection at the pediatric age could disrupt ongoing physiological development in the brain, potentially through changes

in the NSC pool. To test this hypothesis, we determined the effect of a viral infection and anti-viral immunity on NSCs in transgenic NSE-CD46+ pediatric mice (postnatal day 10), where measles virus (MV) only infects neurons and NSCs are spared from the infection. MV (2 X 10^4 PFU/ml) and mock-infected mice were evaluated for illness, viral antigen expression, and neural cell populations at 9- and 90-days post infection (dpi). Flow cytometric analysis revealed increased innate and adaptive immune cells in the CNS at 9 dpi while only B cells were present at 90 dpi. However, MV antigen was detected at both 9 and 90 dpi in the hippocampus. Thus, the pediatric anti-viral immune response fails to control the virus within the time frame of our studies. Additionally, the anti-viral immune response led to a drastic decrease in the NSC pool (Nestin+) in both the hippocampus and SVZ at 9 dpi, but NSC numbers were unchanged at 90 dpi. Oligodendrocyte progenitor cells (OPCs; O4+) increased at 9 dpi only in the hippocampus but increased in both the neurogenic niches at 90 dpi. These studies showed that both the NSC and OPC pool are perturbed during infection, but the OPCs are increased long-term. In the hippocampus, immature neurons (DCX+) decreased at 9 dpi while immature glia (A2B5+) increased at 90 dpi, suggesting a shift in NSC commitment to new neural cells. In the SVZ, mature neurons (β-III tubulin+) and immature glia (A2B5+) increased at 9 dpi and immature neurons (DCX+) decreased at 90 dpi, implying long-term changes in neurogenesis. Thus, the pediatric anti-viral immunity impairs neural cells not only during infection but also long-term. As neurons are the target cells of MV infection in our model and synaptogenesis is ongoing during the pediatric period, our current studies focus on understanding whether synaptic impairment occurs after infection. Our future experiments aim to understand whether long-term impairments in behavior occur after infection in pediatric mice.

Title: Impact of bedding material on tactile behavioral phenotypes of a Camk2a E183V mutant mouse model of ASD

Authors: *J. R. THOMAS[1], R. J. COLBRAN[2];
[1]Mol. Physiol. and Biophysics, Vanderbilt Univ., Nashville, TN; [2]Dept Molec Physiol & Biophysics, Vanderbilt Univ. Sch. Med., Nashville, TN

Abstract: Impaired social communication and restricted behaviors are primary hallmarks of autism spectrum disorder (ASD). However, individuals with ASD also display abnormal tactile sensitivity and responses to sensory inputs, but underlying molecular mechanisms are poorly understood. Here, we assessed tactile phenotypes of an ASD mouse model with a Glu-183 to Val CaMKIIα catalytic domain

mutation (E183V-KI mice) which display abnormal social and motor behaviors[1]. The impact of raising mice in cages with cob or paper bedding was assessed. In von Frey filament tests, homozygous (HOM) E183V-KI mice were less sensitive to touch compared to wild-type (WT) and heterozygous (HET) mice, and this phenotype was exaggerated in HOM mice raised on cob bedding compared to paper bedding. Tactile discrimination was then assessed using three tests. **1.** Texture preference (TP) test: Mice freely explore a novel open field arena containing two visually-similar solid white plastic cubes with rough or smooth surfaces for 10 min. WT mice, but not HOM mice, raised on cob bedding spent significantly more time exploring a rough cube rather than a smooth cube. However, mice raised on paper bedding had no preference for the rough vs. smooth cubes, independent of genotype. **2.** Sandpaper (SP) test: Mice freely explore a novel open field arena with two equal floor zones covered with either coarse sandpaper or smooth paper for 30 min. During the first 10 min. (the TP test duration), WT mice raised on either paper and cob bedding spent more time in the rough floor zone. HET and HOM mice raised on cob bedding retained a significant preference for the rough floor zone, but HET and HOM mice raised on paper bedding spent equal amounts of time in the rough and smooth floor zones. However, the zone preference of HOM, but not HET or WT mice, raised on cob bedding was lost during the last 10 min. of the SP test. **3.** Textured novel object recognition (tNOR) test: To assess interactions between texture and cognition, mice are habituated to open field arenas containing either two rough or two smooth cubes on days 1 and 2, and on day 3 one of the cubes is replaced with a cube of the opposite (novel) texture, such that equal numbers of mice within each group were tested with novel rough or smooth cubes. WT mice, but not HET or HOM mice, raised on cob bedding explore the novel cube more than the familiar cube. However, none of the mice raised on paper bedding discriminated between novel and familiar cubes. Taken together our data demonstrates that tactile sensitivity and discrimination is impaired in HOM E183V-KI mice and can be modulated by environmental factors, such as bedding. 1. Title: Modeling phenotypic heterogeneity in autism spectrum disorder by leveraging a mouse model of global genetic diversity, the Collaborative Cross Genetic Reference Panel, with Chd8 haploinsufficiency.

Authors: M. TABBAA[1,2], A. KNOLL[1,2], P. LEVITT[1,2];
[1]Dept. of Pediatrics, Keck Sch. of Med. of the Univ. of Southern California, Los Angeles, CA; [2]The Saban Res. Inst. and Developmental Neurosci. and Neurogenetics Program, Children's Hosp. Los Angeles, Los Angeles, CA

Abstract: An individual's combination of rare and common genetic variants interact with experience to impact risk for clinical disorders. For example, children with identical mutations in disease-causing genes show significant heterogeneity in symptom occurrence and severity. Thus, clinical heterogeneity remains a major challenge for developing effective models of treatment efficacy. This is highly relevant to disorders characterized by marked behavioral heterogeneity, such as in autism spectrum disorder (ASD). Currently, behavioral measures are largely conducted in a limited number of inbred rodent strains which can result in findings that are not generalizable due to a lack of understanding the effects of genetic variability on complex behaviors. Towards addressing this issue, we have embarked on a systematic analysis of risk gene penetrance using mouse models of global genetic diversity, the Collaborative Cross (CC) and BXD genetic reference panels, with mutations in a high-confidence ASD risk gene, *CHD8*, to identify how genetic background impacts risk and resilience. In clinical populations, functional mutations in *CHD8* are associated with ASD, intellectual disability, anxiety, and macrocephaly with variable penetrance and severity. These effects are replicated in C57BL/6J (B6) mice heterozygous for *Chd8* (*Chd8*$^{+/-}$) with variability for some phenotypes across studies. In this study, B6-*Chd8*$^{+/-}$ dams were mated with sires from 27 CC strains and 5 BXD strains. The resulting F1 wildtype (WT; n=8) and *Chd8*$^{+/-}$ (n=8) male and female littermates were phenotyped deeply. Dam and pup behaviors were recorded during litter observations, and adult social behaviors, contextual fear learning, anxiety-like and ambulatory behaviors were measured. Body weight trajectories and brain weights were also recorded. Strain impacted litter size, maternal care, pup behavior, and body weights. We also show an expansion of adult phenotypes in WT mice. The occurrence and severity of *Chd8* heterozygosity varies by strain and sex. Specifically, *Chd8* heterozygosity was highly penetrant for macrocephaly, body weight loss, social dominance, and reduced activity levels, with variable severity across strains. Additionally, we observed diverse sex- and strain-specific effects of *Chd8* heterozygosity on fear acquisition, expression and extinction. Resilient strains for specific phenotypic deficits also were identified. The B6-CC1 F1 strains thus revealed expanded mouse behavioral and physiological spectrums and differential susceptibility to *Chd8* heterozygosity. This effort creates potentially new models for determining factors that influence clinical heterogeneity.

Title: Study of autistic behaviors in transgenic mouse model with compromised Wave Regulatory Complex (WRC) function

Authors: *G. YANG[1], J. M. RAKOTOMAMONJY[2], A. D. GUEMEZ-GAMBOA[3];
[1]Northwestern Univ., Evanston, IL; [2]Physiol., Northwestern University, Feinberg Sch. of Medici, Chicago, IL; [3]Physiol., Nortwestern Univ., Chicago, IL

Abstract: *De novo* truncating variants in WAS protein family member 1 (*WASF1*) cause a rare form of intellectual disability with autistic features and seizures. *WASF1* encodes the protein WAVE1, one of five

components comprising the Wave Regulatory Complex (WRC). The WRC mediates interactions of membrane receptors with the actin cytoskeleton to regulate crucial developmental steps such as neural adhesion and migration. WRC is activated by different classes of ligands including the recently identified group of proteins containing the WRC interacting receptor sequence (WIRS). Over 40% of the identified proteins containing the WIRS domain are high confidence or strong candidate autism risk genes. Previous studies showed that *Wasf1* knockout mice exhibited reduced viability and behavioral abnormalities, such as poor balance, reduced coordination, and impaired learning and memory. To study WRC function more closely while circumventing the reduced viability observed in the conventional *Wasf1* knockout mouse model, we introduced point mutations in Abi2, another component of the WRC, to disrupt the WIRS binding motif that mediates WRC recruitment to cell membrane partners. Abi2$^{\Delta WIRS}$ mice showed no reduced viability. This study reports the characterization of anxiety, repetitive, and compulsive-like behaviors, cognitive performance, and seizure susceptibility in Abi2 $^{\Delta WIRS}$ mice. We also investigated brain anatomy, neuronal morphology and arborization to uncover the potential function of the WIRS/WRC interaction during brain development, and the suitability of the Abi2 $^{\Delta WIRS}$ mice as a model to study downstream signaling that would contribute to relevant neurodevelopmental disorders phenotypes.

Title: Female mice postnatally exposed to estradiol show altered autism related behaviors

Authors: *A. SEIFFE[1,2], M. RAMIREZ[1,2], L. M. DI GUARDIA CASELLA[1,3], C. BARRIOS[1,2], M. M. ALBARRÁN[1,3], A. M. DEPINO[1,4];

Abstract: Autism spectrum disorders (ASD) are characterized by reduced sociability, diminished communicative skills and repetitive behaviors. Notably, the proportion between boys and girls diagnosed with ASD is about 4 to 1. A striking difference between males and females in humans and other mammals is that males suffer a process of brain masculinization, due to the early exposure to gonadal hormones. In rodents, this developmental organization of the brain is essential for the proper display of sexual behaviors in adulthood, but it also determines other sex differences in brain function and behavior. Our first aim was to evaluate whether this process of brain masculinization influences the performance in behaviors relevant to ASD. To this aim, we studied sex differences and the effect of neonatal 17β-

estradiol benzoate (E2) treatment of female mice (CF1 outbred) on different ASD-relevant behaviors. On postnatal days (PND) 2, 5 and 8, female pups were injected (s.c.) with estradiol (50 µg; E2, n = 19) or vehicle (OIL, n = 12). On adulthood (from PND60), we found that the sex differences observed in exploration (distance in the Y maze, one-way ANOVA $p = 0.001$; and open field, one-way ANOVA $p = 0.014$), repetitive behaviors (self-grooming, one-way ANOVA $p = 0.020$), and depression-related behaviors (immobility in the forced swim test, one-way ANOVA, $p = 0.004$) are largely reduced when females are neonatally treated with E2. Recently, we observed that the prenatal exposure at gestational day 12.5 to 600 mg/kg valproic acid (VPA) results in decreased sociability of male offspring, while female littermates express normal levels of social interaction. Our second aim was then to identify the biological mechanisms involved in this differential impact of VPA in male and female mice. Our hypothesis is that brain masculinization is necessary for prenatal VPA exposure to affect autism-related behaviors, neuronal alterations and gliosis. To test this hypothesis, we studied the effect of postnatal exposure to E2 in female mice of the VPA model of autism, analyzing four experimental groups: SAL-OIL (n = 13), SAL-E2 (n = 17), VPA-OIL (n = 12) and VPA-E2 (n = 14). Our results show that only VPA-E2 females present no habituation to the stimulus mouse throughout the four consecutive presentations (three-way ANOVA followed by Fisher's LSD test, presentation 1 vs 4 $p > 0.05$). These results demonstrate that the combination of prenatal VPA exposure and postnatal E2 treatment results in altered sociability in female mice. Further studies of the VPA-E2 mice could help us identify possible biological mechanisms underlying the higher incidence of ASD observed in boys.

Title: Social Transmission of fear in prairie voles

Authors: *D. GAMBOA PABON, S. K. PATEL, J. P. BURKETT, E. ANDARI;
Univ. of Toledo, Toledo, OH

Abstract: Autism is a neurodevelopmental disorder characterized by deficits in social communication, social interaction, and repetitive behaviors. Social deficits are characterized by impairments in social reciprocity, empathy, and social recognition. Prairie voles are social species that are monogamous and able to form social bonds with their partners. Here, we are developing a behavioral assay of social learning by being inspired by the social transmission of fear paradigm that has been used in rats. The goal of this test is to assess social learning in prairie voles. We were able to find that following habituation, prairie voles show partner-directed grooming toward the stressed partner following fear conditioning. We were also able to find that the non-shocked observer shows significantly more freezing to tones following

exposure to the stress of the partner compared to the control observer that was exposed to the non-stressed partner. Therefore, we believe that it is possible to socially condition prairie voles via the stress of the partner. These findings will help provide new outcome measures to study social cognition in rodents and future pharmacological manipulations.

Title: Ai deep learning motor diagnostic analysis of neurodevelopmental disorders

Authors: *J. JOSE[1], **K. DOCTOR**[3], A. PHADNIS[2], D. WU[4], J. I. NURNBERGER[2], M. H. PLAWECKI[2];
[1]Indiana Univ., Bloomington, IN; [2]Psychiatry, Indiana Univ., Indianapolis, IN; [3]Computer Sci., Univ. of Massachusetts, Amherst, MA; [4]Physics, Indiana Univ. Bloomington, Bloomington, IN

Abstract: We have studied the motor abilities of individuals with Neurodevelopmental Disorders (NDD). In particular, 12-ASD subjects with Autism Spectrum Disorder (ASD), 9 comorbid ASD plus ADHD (ASD+ADHD) vs 7 Typically Developing (TD). We used *XSENS* high definition kinematic sensors, (www.xsens.com), to measure the angular *velocity plus linear acceleration* of arm *movements. T*he subjects performed a reaching task moving their arms towards touch screen targets appearing intermittently on the monitor. We implemented a supervised deep neural network to predict NDD conditions based on the raw kinematic sensors data, without any preconceived assumptions about the data. Our hypothesis is that movement contains latent hidden physiological information about cognitive neurodevelopment abilities. We assumed that the sensors raw kinematic data would contain such NDD classification information that would unravel when using AI Deep Learning techniques. We generated training sets with, typically, 75% of the full NDD plus TD data measured with the sensors to train a neural network. To model the temporal signal, we used Long Short-Term Memory (LSTM) cells as the neurons of the network. To transform the memory-based output from the LSTM layer into a representation capable of predicting NDD conditions, we passed the LSTM output to a Linear Layer used to model a linear relationship between inputs plus outputs using the learned parameters defining a line (slope plus bias). Each of these output neurons are trained to represent a different NDD condition. The predicted strength of the individuals having that condition is proportional to the activation of the output neuron. Thus, to make a prediction of an individual's NDD condition we transformed the output of the Linear layer to a probability distribution by normalizing their activations plus selecting the NDD condition with the maximum probability. We could show that the network was not overfitting through the accuracy on the held out set that was never used to train the network. Given the small size of the dataset, we applied K-Fold Cross Validation to further train the network. The final accuracy on the held out set

was 71.4% (5 out of 7 individuals). This shows that DL is indeed able to correctly identify the diagnostics of most of the remaining NDD subjects without any *a priori* information about their cognitive abilities. It also clearly separates the NDDs from the TDs. This remarkable DL motor predictive power could be used as an early step in diagnosing the condition that is so needed for potential young NDD subjects' treatments.

Title: Rethinking the McGurk Effect in autism: Hierarchical drift diffusion modeling reveals decision-making differences in autistic and neurotypical children and adolescents

Authors: *S. G. VASSALL[1,2], R. A. STEVENSON[7,8], M. T. WALLACE[1,3,4,5,6];
[1]Vanderbilt Brain Inst., Nashville, TN; [2]Neurosci. Grad. Program, [3]Dept. of Psychology, [4]Dept. of Hearing and Speech, [5]Vanderbilt Vision Res. Ctr., [6]Dept. of Psychiatry and Behavioral Sci., Vanderbilt Univ., Nashville, TN; [7]Brain and Mind Inst., [8]Dept. of Psychology, Western Univ., London, ON, Canada

Abstract: Broken into its simplest components, decision-making comprises three general phases: accumulation of sensory evidence over time, reaching a decision, and initiating a motor action. Using hierarchical drift diffusion modeling (HDDM) and Bayesian analyses, a dataset from prior research by Stevenson et al. (2014) was reanalyzed in order to elucidate differences in decision-making processes between autistic and neurotypical children and adolescents ages 6-18 years performing a modified McGurk task. Using these methods, we expanded upon prior findings to reveal differences in decision-making processes across both age and diagnostic group. We found that on unisensory trials, autistic children displayed significantly faster rates of evidence accumulation (i.e., drift rate) compared to neurotypical children in response to visual-only stimuli, an effect that was amplified in the younger cohort. However, under multisensory conditions, in children with autism this advantage disappeared, and drift rate was slower than that of the neurotypical groups. Importantly, we observed that the diagnostic group differences in drift rate increased with age. A principal component analysis also revealed an age-dependent relationship between clinical measures of autism and estimates of drift rate. Specifically, for

both unisensory and multisensory conditions the Social Responsiveness Scale, 2nd Edition Social Communication Impairment (SRS SCI) subscale was identified as the first principal component. However, while high SRS SCI scores predicted superior unisensory drift rate in younger autistic children and lower unisensory drift rate in older autistic children compared to neurotypical groups, no significant predictive relationship was observed for multisensory trials. From this evidence, we propose that accumulation of auditory and visual information slows in older children with autism. Furthermore, we put forward that slowed auditory and visual drift rate in older autistic children is predictive of increased social communication impairments as quantified by standardized clinical measures.

Title: Increased volume of amygdala nuclei in autistic youth with elevated anxiety

Authors: *G. A. MCQUAID[1], A. JOB SAID[2], A. JACK[1], K. A. PELPHREY[3], G. L. WALLACE[2]; [1]George Mason Univ., Fairfax, VA; [2]George Washington Univ., Washington, DC; [3]Univ. of Virginia, Charlottesville, VA

Abstract: Introduction The amygdala plays a central role in processing socio-emotional information and thus has been featured prominently in some pathophysiological models of autism spectrum disorder (ASD). Nevertheless, findings have been mixed regarding ASD-related differences in amygdala structure. One factor in these mixed findings may be frequently co-occurring anxiety symptoms and disorders in ASD. A handful of studies to date have linked anxiety symptoms/disorders with amygdala volume in autistic youth. However, these studies have used global metrics of amygdala morphometry. Recent advances enable more fine-grained examination of amygdala structure (i.e., nuclei), which promise to advance our understanding of amygdala morphometry in ASD and its links with anxiety symptoms. **Method** 130 ASD (47.8% female) and 126 typically developing (TD) (50.8% female) youth aged 8-18 years (ASD: M=13.0 $\pm$ 2.8; TD: M=13.6 $\pm$ 3.0) completed a T1-weighted structural magnetic resonance imaging (MRI) scan. MRI data processing was carried out in FreeSurfer, generating not only cortical & subcortical volumes, but also 9 amygdala nuclei volumes via a specialized pipeline. Parent report on the Childhood Behavior Checklist (CBCL) was used to assess anxiety symptoms and to subgroup ASD participants into those who were high anxiety (HI-ANX, n=65; T score ≥65) or low anxiety (LO-ANX, n = 65; T score <65). Multivariate analysis of covariance (MANCOVA) accounting for the effects of age, sex, total intracranial volume, and scan site were conducted. Dependent variables were volume of the 9 amygdala nuclei. The independent variable was group: ASD HI-ANX, ASD LO-ANX, TD. **Results** Using Pillai's Trace, the MANCOVA revealed a significant effect of group (F(18,474) = 2.1, p =

.006, $V = .15$). Regions significant in follow-up ANCOVAs were the Basal ($p = .018$); Medial ($p = .020$); Cortical ($p = .03$); and Paralaminar ($p = .005$) nuclei, with only the last of these surviving FDR correction. These group differences were driven by greater volume in the HI-ANX compared to the LO-ANX group. **Discussion**Autistic children and adolescents with elevated anxiety had larger amygdala nuclei volume compared to their autistic peers with lower levels of anxiety. In particular, four amygdala nuclei show these effects. To our knowledge this is the first study to show differences in amygdala nuclei volume for autistic youth with elevated anxiety compared to those with lower anxiety levels. The reported granularity in amygdala morphometry differences may inform models of co-occurring anxiety in ASD.

Abstract: Introduction: Autism spectrum disorder (ASD) is a neurodevelopmental disorder that is characterized by challenges in social communication and the presence of restrictive and repetitive behaviors. Environmental and genetic factors have been shown to contribute to ASD, but the interaction between them is less understood. Previous research indicated that presence of a short allele of the promotor region of 5-HTTLPR was associated with an increased vulnerability to anxiety under stressful conditions, and higher levels of stress in pregnant mothers were associated with ASD. Additionally, previous studies found immune dysregulation during pregnancy to be associated with a diagnosis of ASD in the child. However, the relationship between prenatal stress exposure, maternal genetic stress susceptibility, and maternal antibodies in mothers whose children are diagnosed with ASD is unclear. **Methods:** This study examined whether the maternal antibody response was related to prenatal stress in their association with ASD. Additionally, the study examined whether the interaction between prenatal stress and the 5-HTTLPR polymorphism correlated with maternal antibody response. Samples from 53 mothers who have at least one child diagnosed with ASD were examined. Maternal antibody presence, stress level during pregnancy (high or low), and maternal 5-HTTLPR polymorphism (presence or absence

of at least one copy of the short allele) were recorded and used to conduct statistical analyses. Four groups were created for the allele x prenatal stress interaction (short allele present and high stress, short allele present and low stress, short allele absent and high stress, short allele absent and low stress). **Results:** A chi-squared analysis indicated that the association between maternal antibody presence and prenatal stress was not significant (p=0.709, Cramer's V=0.051). Furthermore, a chi-squared analysis to examine the association between maternal antibody presence and the interaction between 5-HTTLPR genotype and stress was not significant (p=0.729, Cramer's V=0.157). **Discussion:** The results revealed that prenatal stress, and the interaction between the 5-HTTLPR polymorphism and prenatal stress, were not associated with presence of maternal antibodies, in their association with ASD. These results are interesting, given the known associations between ASD diagnosis and prenatal stress, 5-HTTLPR polymorphism, and immune dysregulation. These results point to the notion that prenatal stress and immune dysregulation are independently associated with a diagnosis of ASD.

Title: Investigating common gene networks underlying sensory over-responsivity and habituation impairments in Autism Spectrum Disorders

Authors: *L. D. KEPLER[1], C. H. RANKIN[2];
[1]Cell and Developmental Biol., [2]Psychology, Univ. of British Columbia, VANCOUVER, BC, Canada

Abstract: The genetic complexity and phenotypic heterogeneity of Autism Spectrum Disorder (ASD) pose significant challenges to our ability to understand disorder etiology and identity effective treatments. Alterations in sensory processing and habituation (a type of learning where one learns to stop responding to repetitive stimuli) are reported in up to 90 percent of ASD cases. The high presence of sensory processing and habituation impairments suggests that ASD-associated genes may be acting together to control these behaviours, offering a unique opportunity to investigate commonly affected pathways underlying ASD. Our lab recently published an in-depth phenomic database of 135 *C. elegans* strains with loss-of-function mutations in 98 ASD risk gene orthologs. Here, we used the data generated by our high-throughput machine vision tracking system to investigate the relationships between phenotypes such as mechanosensory hypo or hypersensitivity and altered habituation to mechanosensory stimuli. By exploring our dataset, we identified subsets of ASD risk genes that similarly affected initial responsivity

and degree of habituation for response probability, duration, and speed. Alternations in initial response duration and habituation of response duration showed a strong positive correlation, suggesting a high degree of mechanistic overlap underlying these phenotypes. Identifying common pathways contributing to sensory processing and habitation alterations provides a unique opportunity to investigate why sensory and learning impairments occur when different ASD-associated genes are affected and aid in identifying new therapeutic targets to help individuals with these behavioural and learning difficulties.

Title: Hippocampal Astrocytes Regulate Heroin Withdrawal and Future Enhanced Fear Learning

Authors: *S. V. PAREKH, J. E. PANICCIA, G. A. BARKELL, L. O. ADAMS, K. J. REISSNER, D. T. LYSLE;
Psychology and Neurosci., Univ. of North Carolina, Chapel Hill, NC

Abstract: Converging evidence suggests the neural immune system is altered following opioid use and withdrawal and post-traumatic stress disorder (PTSD). Using an innovative rodent model that combines escalating heroin administration and spontaneous withdrawal with enhanced fear learning, we demonstrated neuroimmune alterations mediate withdrawal-induced fear learning. Specifically, heroin withdrawal enhanced fear learning is driven by dorsal hippocampal (DH) interleukin-1 (IL-1) and tumor necrosis factor alpha (TNF-α) signaling, and withdrawal from escalating heroin administration induces both DH IL-1β and TNF-α expression. Moreover, the IL-1β and TNF-α involved in heroin withdrawal enhanced fear learning is primarily expressed in hippocampal astrocytes. Interestingly, we found that heroin withdrawal upregulates hippocampal glial fibrillary acidic protein (GFAP), a marker for astrocyte reactivity. Astrocytes critically modulate the neural environment and opioid-induced changes in astrocyte physiology may contribute to heroin-related behavioral maladaptation. To better understand the role of DH astrocytes in heroin withdrawal-induced fear learning, we investigated whether astrocyte activity is causally related to heroin withdrawal enhanced fear learning and if withdrawal from chronic heroin altered astroglial structure and synaptic interactions. Thus, Experiment 1 employed G_i-coupled designer receptors exclusively activated by designer drugs (DREADDs) to manipulate astrocyte signaling *in vivo*. Male rats were infused with AAV8-GFAP-hM4D(Gi)-mCherry into the DH, and underwent the chronic escalating heroin administration paradigm. Clozapine-n-oxide (3 mg/kg, s.c.) or vehicle was administered

0-hour, 24-hours, and 48-hours into heroin withdrawal, and animals were then exposed to the enhanced fear learning paradigm. Experiment 2 used an established method to visualize DH astrocytes in detail using a membrane-tagged GFP, advanced microscopy, and image analysis. Male rats were administered bilateral intra-DH infusions of AAV5-GFAP-Lck-GFP, and underwent the chronic escalating heroin administration paradigm. Tissue was collected 24-hours into heroin withdrawal. Using high resolution confocal microscopy and analysis of 3-dimensional cellular reconstructions, astrocyte surface area, volume, and colocalization with postsynaptic density-95 were quantified to assess the consequence of chronic heroin and spontaneous withdrawal on astrocyte structure and neuronal interactions. Together, these studies examine the role of hippocampal astrocytes in heroin withdrawal-enhanced fear learning.

Title: Sex-differences in heroin withdrawal enhanced fear learning behavior

Authors: *L. O. ADAMS, S. V. PAREKH, J. E. PANICCIA, G. A. BARKELL, D. T. LYSLE; Psychology and Neurosci., Univ. of North Carolina Chapel Hill, Chapel Hill, NC

Abstract: Opioid use disorder (OUD) and post-traumatic stress disorder (PTSD) are highly comorbid in clinical populations. However, the biological mechanisms underlying this relationship are not fully understood. Our laboratory has established that chronic escalating heroin administration and withdrawal produces future enhanced fear learning and induces expression of dorsal hippocampal (DH) interleukin-1β (IL-1β) and tumor necrosis factor alpha (TNF-α). Further, heroin withdrawal enhanced fear learning is blocked by inhibiting DH IL-1β and TNF-α signaling. Excitingly, blockade of DH TNF-α signaling mitigated withdrawal-induced weight loss, suggesting that TNF-α signaling may drive neurobiological changes resulting in PTSD/OUD comorbidity. However, previous experiments have studied only male rats and it is currently unknown whether these findings extend to females. There are substantial gaps in knowledge about the effects of opioids in females, and it is imperative to explore heroin-enhanced maladaptive behaviors across sex. Thus, the current study examined sex differences in heroin withdrawal enhanced fear learning. Experiment 1 tested whether chronic escalating heroin administration produced a withdrawal phenotype and an enhanced fear learning response in female Sprague Dawley rats. Rats underwent the escalating heroin administration in which they received 3 injections of heroin per day for

10 days. The dose was increased every 2 days, culminating to a final dose of 10 mg/kg. Animals then underwent the enhanced fear learning paradigm, and estrous cycle stage was assessed on each test day. Females displayed comparable withdrawal behaviors to males, however, did not display heroin withdrawal-enhanced fear learning. As we have previously established a role for hippocampal cytokine signaling in the development of heroin withdrawal-enhanced fear learning in male rats, we sought to determine whether sex differences were present in brain cytokine expression. In Experiment 2, female rats underwent the chronic escalating heroin administration paradigm and tissue was collected 24-hour into withdrawal. DH IL-1β and TNF-α were assessed, as elevated levels of these cytokines may indicate that the mechanism underlying the females' fear learning response to heroin is different than that of males, or that females may have a protective factor that mitigates the effect of elevated cytokines. Collectively, these experiments provide the first evidence that female rats may possess a protective biological factor that lessens the effects of heroin administration and withdrawal on future fear learning, potentially by suppressing neuroinflammatory pathways.

Title: Chronic Ethanol Consumption Exacerbates Future Stress-Enhanced Fear Learning and Alters Neuroimmune-Related mRNA Expression

Authors: *G. A. BARKELL, S. V. PAREKH, J. E. PANICCIA, A. J. MARTIN, T. E. THIELE, D. T. LYSLE;
Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Alcohol use disorder (AUD) and post-traumatic stress disorder (PTSD) are highly comorbid in clinical populations. While it is hypothesized this comorbidity is a result of alcohol use to cope with PTSD symptomology, it is still unknown whether a prior history of chronic alcohol consumption alters the development of a PTSD-like phenotype. The neuroimmune system has been implicated in regulating both AUD- and PSTD-related behaviors, as well as being influenced by ethanol consumption and stress exposure. Our laboratory has developed a novel rodent model to explore the outcome of prior chronic

ethanol consumption and withdrawal on the development of a PTSD-like phenotype, and uncover the neurobiological mechanisms driving this relationship. In Experiment 1, adult male Sprague Dawley rats were given either ethanol (5% w/v) or control formula of low-fat Lieber-DeCarli liquid diet for 15 days. This 15-day exposure produced withdrawal behaviors and blood ethanol concentrations (BECs) above 80 mg/dL. Subsequently, all animals were placed on control diet. Twenty-four hours post ethanol removal, rats were exposed to a novel context (Context A) for 90 min where they received a severe stressor (15 scrambled footshocks (2 mA, 1s) on a 6 min variable interval schedule) or remained unshocked controls. One week later, all animals were placed into a distinctly different context (Context B) and administered a mild footshock (1 mA, 1 s). On test days, conditioned freezing behavior to Context B was quantified. Animals with a prior history of chronic ethanol and severe stress exposure displayed increased conditioned freezing behavior relative to all other animals, demonstrating enhanced fear learning behavior. Experiment 2 examined the neuroimmune consequences of chronic ethanol combined with severe stress exposure using a 2 (drug) x 2 (stress) design. Male rats were given ethanol (5% w/v) or control diet for 15 days and placed into Context A 24-hours post ethanol removal. In Context A, animals either underwent the severe footshock stress or remained as unstressed controls, and tissue was collected 24 hours post shock. Using RT-qPCR we detected ethanol-induced increases in glial fibrillary acidic protein (GFAP), a marker of astrocyte reactivity, in both the dorsal and ventral hippocampus and amygdala. Additionally, we observed stress-induced decreases in the neuroimmune targets CD68 and TNF-α, as well as neuropeptide Y in the dorsal hippocampus. Collectively, results indicate prior ethanol exposure and severe stress result in the development of a PTSD-like phenotype, and alter neuroimmune targets across multiple brain regions.

Title: Assessing the computational power of Ca2+ transients in astrocyte microdomains of the visual cortex

Authors: *J. SHIH[1], G. O. SIPE[1], N. M. LE[1], E. S. BOYDEN[2], M. SUR[1];

Abstract: Astrocytes are the most abundant glial cell type in the brain. Increasing evidence shows that they respond to and influence neuronal function at the synaptic, cellular, and network levels, and that this

relationship may be reflected in transient astrocytic calcium (Ca2+) activity. These Ca2+ transients are spatiotemporally diverse, particularly the microdomain Ca2+ events in astrocyte fine processes, which are closely associated with synapses. Astrocyte fine processes contain a number of neurotransmitter reuptake transporters and ion channels, which contribute to how astrocytes shape synaptic transmission and neuronal signaling. Transporter function and ion channel flux are dependent on concentration gradients of monovalent and divalent cations across the astrocytic cell membrane, particularly the sodium gradient, which drives key mechanisms such as glutamate uptake and sodium-calcium exchange. How ion flux and transporter function at astrocyte fine processes affect microdomain Ca2+ transients and correlate with neuronal activity in complex cortical circuits has not been characterized. We hypothesize that astrocytic Ca2+ transients in microdomains encode neuronal activity and behavioral task parameters in the visual cortex, and that this encoding feature is disrupted when ion concentration gradients, particularly the sodium gradient, is perturbed. We first measured and characterized neuronal and astrocytic Ca2+ activity in the primary visual cortex of awake mice using in vivo two-photon microscopy during passive visual stimulus presentation and used generalized linear models to determine the encoding power of microdomain Ca2+ activity. We then used the sodium selective channelrhodopsin variant ChromeQ to show that alteration of sodium flux across the astrocyte membrane increased Ca2+ microdomain events. These preliminary results suggest that perturbation of sodium flux in astrocytes in vivo may allow us to target Ca signaling in a specific compartment of the astrocyte domain to determine their contributions to visual processing and encoding.

Title: Serotonin and Norepinephrine Modulate Vascular and Astroglial Activities During Sensory Stimulation in Awake Mice

Authors: *K. SHARMA, C. TRANTHAI;
Univ. of Nevada Reno, Reno, NV

Abstract: Serotonin and Norepinephrine Modulate Vascular and Astroglial Activities During Sensory Stimulation in Awake Mice
Kushal Sharma and Cam Ha T. Tran
The brain possesses control mechanisms to regulate blood flow to meet metabolic demands. Neurovascular coupling (NVC) is one of those essential processes in which all members of the neurovascular unit including neurons, astrocytes and vascular cells, coordinatively respond to increases in neuronal activity to enhance cerebral blood flow. Studies showed behavioral state of the animal affected astrocytic Ca2+ dynamics. Wakefulness, increases in arousal or engagement are often associated with the

release of a number of neuromodulators including serotonin, acetylcholine, and norepinephrine. Previous work demonstrated that norepinephrine mediated astrocytic responses to increases neuronal activities. Whether these neuromodulators contribute to NVC remains poorly understood. Our objective was to uncover the role of serotonin and norepinephrine in NVC during sensory stimulation in fully awake, behaving mice. A craniotomy over the barrel cortex with the dura removed was performed. Two-photon imaging was used to image the vasculature and astrocytes Ca2+ from either C57Bl/6 mice or Aldh1l1Cre ERT x GCaMP6f mice. Fluorescein isothiocyanate dextran conjugated or Rhodamine B isothiocyanate dextranconjugated was used to visualize the vasculature while synthetic Ca2+ indicator (i.e. Rhod2-AM) or genetically engineered Ca2+ indicator (i.e. GCaMP6f) was used to examine astrocytic Ca2+ responses to 5s whisker stimulation. We found that blocking serotonin and norepinephrine receptors as well as manipulating the release of these neurotransmitters by neurotoxin differentially affected sensory-induced functional hyperemia and astrocytic Ca2+ dynamics. Our data introduce the contributions of neuromodulators to NVC and propose that these neurotransmitters act in conjunction with glutamatergic signaling pathway to regulate NVC and consequently cerebral blood flow.

Title: Chronic stress induces astroglial atrophy in the prefrontal cortex of rodents

Authors: *S. A. CODELUPPI[1], D. CHATTERJEE[1], T. D. PREVOT[1], Y. BANSAL[1], K. A. MISQUITTA[1], E. SIBILLE[2], M. BANASR[1];

Abstract: Neuromorphological changes are consistently reported in the prefrontal cortex (PFC) of patients with stress-related disorders and in rodent stress models, but the effects of stress on astrocyte morphology and potential link to behavioral deficits are relatively unknown. To answer these questions, transgenic mice expressing green fluorescent protein (GFP) under the glial fibrillary acid protein (GFAP) promotor were subjected to 7, 21 or 35 days of chronic restraint stress (CRS). CRS induced behavioral effects on anhedonia- and anxiety-like behaviors were measured using the sucrose intake and the PhenoTyper tests, respectively. PFC GFP+ or GFAP+ cells morphology was assessed using Sholl analysis and associations with behavior were determined using correlation analysis. CRS-exposed male and female mice displayed anxiety-like behavior at 7, 21 and 35 days and anhedonia-like behavior at 35 days. Analysis of GFAP+ cell morphology revealed significant atrophy of distal processes following 21 and 35

days of CRS. CRS induced similar decreases in intersections at distal radii for GFP+ cells, accompanied by increased proximal processes. In males, the number of intersections at the most distal radius step significantly correlated with anhedonia-like behavior (r=0.622, p&lt0.05) for GFP+ cells and with behavioral emotionality calculated by z-scoring all behavioral deficits (r=-0.667, p&lt0.05). Similar but not significant correlations were observed in females. No correlation between GFP+ cell atrophy with anxiety-like behavior was found. Overall we found that, chronic stress exposure induces a progressive atrophy of cortical astroglial cells, potentially contributing to maladaptive neuroplastic and behavioral changes associated with stress-related disorders. Current work aims to investigate the consequences of region specific astroglial manipulations on stress-related behavioral and cellular deficits.

Title: Coordinated neuron and astrocyte activity in developing sensory domains

Authors: *V. KELLNER[1], C. J. KERSBERGEN[1], S. LI[1], D. HEO[1], T. A. BABOLA[1], G. SAHER[3], D. E. BERGLES[1,2,4];

Abstract: Spontaneous neuronal activity in developing sensory systems enables periodic, coordinated firing of neurons that will eventually process similar aspects of sensory information. This burst firing is conserved between species, resistant to perturbation, and important for both neuron survival and circuit refinement. Astrocytes secrete factors that promote synapse maturation and mature in parallel with neurons in the developing brain. However, little is known about the mechanisms that coordinate the maturation of astrocytes and neurons during this critical developmental period. Using *in vivo* calcium imaging in awake neonatal mice from both sexes, we show that bursts of neuronal activity passing through sound processing networks in the midbrain and cortex reliably induce calcium transients in astrocytes before the onset of hearing. Astrocyte transients were dependent on high levels of neuronal

activity and constrained to regions near active synapses, ensuring close spatial and temporal coordination of neuron and astrocyte activity. Using *in vivo* pharmacology and astrocyte-specific knock-out mice, we determined that astrocyte responses were induced by synergistic activation of two metabotropic glutamate receptors, mGluR5 and mGluR3, which promoted IP3R2-dependent calcium release from intracellular stores. This spatially and temporally coordinated neuron-astrocyte activity was restricted to the pre-hearing period, as sound induced activation of neurons in auditory cortex did not elicit calcium increases in nearby astrocytes, consistent with the developmental decline in expression of mGluR5 by astrocytes. Single-nucleus RNA sequencing of the auditory midbrain from mice in which astrocyte calcium signaling was selectively abolished during development, revealed that this activity influences the expression of genes within astrocytes that are involved in neurotransmitter clearance and cytoskeletal reorganization, suggesting that periodic, coordinated neuron-astrocyte calcium signaling during development promotes the structural and functional maturation of astrocytes within sound processing circuits.

Title: Female-specific role of ciliary neurotrophic factor in the medial amygdala in regulating chronic stress responses

Authors: *C. JIA[1], D. W. GILL[2], C. LOVINS[2], R. W. BROWNS[2], T. HAGG[2];
[1]Biomed. Sci., [2]East Tennessee State Univ., Johnson City, TN

Abstract: Ciliary neurotrophic factor (CNTF) is produced by astrocytes and is known for its neuroprotective and neurogenic actions. Recent evidence implicates astrocytes in the regulation of stress responses. Whether CNTF affects stress responses is unknown. We previously identified a striking sex-specific effect of CNTF on stress-coping behavior in the forced swim test. CNTF promotes passive stress coping, i.e., immobility time, in female mice while reducing it in males. Female mice have higher levels of CNTF in the amygdala than males, suggesting the CNTF effect may be through mechanism(s) involved in the amygdala. Here, we further defined the region-specific CNTF effect within the amygdala. CNTF neutralizing antibody was stereotaxically injected into the medial, central or basolateral amygdala of female and male C57BL/6 mice. CNTF antibody reduced intracellular signaling of STAT3 (Y705), which is downstream of CNTF, at 24 and 48 h post-injection. Injecting CNTF antibody in the medial

amygdala reduced immobility time in the forced swim test at 24 h post-injection in female but not male mice, or in the central or basolateral amygdala. These data reveal a female-specific effect of CNTF in the medial amygdala on promoting passive stress-coping behavior. To test the roles of CNTF in chronic stress responses, we performed 4 weeks of chronic unpredictable stress (CUS) in female and male wild type CNTF+/+ compared to CNTF-/- littermate mice. In females, CUS increased passive stress-coping in the forced swim test and reduced sucrose preference in CNTF+/+, but not CNTF-/-, mice. Following CUS, a 5 min of immobilization restraint induced plasma corticosterone in female CNTF+/+ but not CNTF-/- mice. These CUS effects were also found in male mice but without genotype differences. Further, CUS increased CNTF expression in the medial amygdala of female but not male mice. CUS did not alter CNTF in the female hippocampus and hypothalamus. These data suggest a female-specific role of CNTF in promoting chronic stress-induced stress-coping deficit, behavioral anhedonia and neuroendocrine response, which could be involved in the medial amygdala. No CNTF-specific roles were found in the exploratory behavior and sensory-motor function measured by the elevated T-Maze and pre-pulse inhibition tests, respectively, in both female and male control and CUS mice. This suggests that a different mechanism other than CNTF may underlie these behaviors. Together, this study reveals a novel CNTF-mediated female-specific mechanism in stress response and points to opportunities for female-specific treatments for stress-related disorders, e.g. CNTF inhibitors or antagonists.

Title: Astrocytic calcium modulates cortical neuronal activity during the REM sleep-wake transition

Authors: *B. LAI[1,2], W. GAN[1];
[1]Skirball Inst., New York Univ. Langone Med. Ctr., New York, NY; [2]Peking Univ. Shenzhen Grad. Sch., Shenzhen, China

Abstract: Recent studies have suggested that astrocytes play an important role in modulating sleep duration and pressure. To better understand the role of astrocytes in sleep regulation, we performed in vivo two-photon Ca^{2+} imaging of cortical astrocytes while monitoring animals' sleep-wake cycles. We observed highly synchronized Ca^{2+} activity in astrocytes using AAV5-gfaABC1D-cyto-GCaMP6f across different cortical regions immediately after REM sleep. This increased astrocytic Ca^{2+} was independent of animals' locomotion activity. Simultaneous recording of astrocyte and pyramidal neuronal Ca^{2+} showed that this increase in astrocytic Ca^{2+} was associated with a decrease in neuronal activity during the REM-wake transition. When astrocytic Ca^{2+} was suppressed by using IP3R2 KO mice, bath application of prazosin or chemogenetic manipulation, we observed increased activity of pyramidal neurons during this

transition period, under both resting and forced running conditions. Together, these findings reveal a role of astrocytes in transiently reducing cortical neuronal activity during the REM sleep-wake transition, which may reduce information processing before the brain switches to a fully awakened state.

Title: The parkinson's disease kinase lrrk2 orchestrates dendritic spines dynamics via bdnf signaling pathway

Authors: *G. TOMBESI[1], G. FAVETTA[1], A. MARTE[2], I. BATTISTI[1], S. COGO[3], L. IANNOTTA[1], N. PLOTEGHER[1], G. ARRIGONI[1], F. ONOFRI[2], E. GREGGIO[1];
[1]Univ. of Padova, Padova, Italy; [2]Univ. of Genova, Genova, Italy; [3]Univ. of Reading, Reading, United Kingdom

Abstract: Dendritic spines (DS) are small protrusions originating from neuronal dendrites. These structuresconstitute the postsynaptic element of excitatory synapses and possess the ability to change theirnumber, density and morphology within short timeframes, representing highly dynamic and plasticelements. DS are particularly rich in some classes of neurons, such as medium spiny neurons (MSNs),the most abundant cell type in the striatum. In this brain region, which receives dopaminergicprojections from the substantia nigra pars compacta, the structural plasticity of dendritic spines isinfluenced by brain derived neurotrophic factor (BDNF). Accumulating evidence indicates thatsynaptic vulnerability, including alterations in DS, is a common feature of neurodegenerativedisorders. In Parkinson's disease (PD) synaptic dysfunction is an early event that precedes neuronaldeath and disease clinical manifestation.Starting from the well-established role of the PD-associated kinase LRRK2 at the synapse, here weinvestigated the possible link between LRRK2 and BDNF signaling in regulating DS dynamics. Byperforming Golgi-Cox staining, immunofluorescence and electron microscopy analysis on striatalbrain slices, we carried out a longitudinal characterization of striatal synapse morphology, numberand ultrastructure in developing, mature and aged brains of Lrrk2 wild-type and knockout (KO) mice.One-month old Lrrk2 KO mice display an increased amount of immature DS and reduced synapticcontacts, an effect that disappears in older animals. From the functional point of view, we collectedevidence that LRRK2 phosphorylation at Ser935 is quickly increased upon BDNF stimulation indifferentiated SH-SY5Y neuroblastoma cells and primary mouse neurons. Conversely, primary LRRK2KO neurons display attenuated BDNF signaling (ERK1/2 and AKT phosphorylation) and bluntmorphological response to 24 hour-BDNF treatment, which fails to promote the formation of newsynaptic contacts as it occurs in WT neurons. An unbiased proteomic analysis suggested that severalLRRK2 interactions are re-shaped upon 15 minutes of BDNF stimulation, providing

further evidenceof a functional involvement of LRRK2 in BDNF signaling. Of note, we found that two mouse modelscarrying the most common LRRK2 PD mutation (knockin G2019S and BAC overexpressing murineLrrk2 G2019S) display morphological alterations of striatal spine morphology during aging, furthersupporting a mechanism whereby LRRK2 activity is important in synaptic structure and function.Overall, our data uncovered a novel role for LRRK2 in orchestrating spine dynamics via the BDNFsignalling pathway.

Title: Highly potent LRRK2 inhibitors show different potencies, kinetic properties and cellular activities on WT vs. G2019S LRRK2

Authors: A. SAVA[1], C. GRIFFANTE[1], L. MENGATTO[1], E. TORCHIO[1], ***L. CABERLOTTO**[1], H. J. CARLISLE[2];
[1]Aptuit, an Evotec company, Verona, Italy; [2]ESCAPE Bio, San Francisco, CA

Abstract: Genetic and biochemical evidence support the hypothesis that elevated LRRK2 kinase activity is pathogenic in familial *LRRK2* Parkinson Disease (PD) and potentially in sporadic PD, suggesting that LRRK2 kinase inhibitors may have broad therapeutic value for PD. In this study, we characterized the biochemical activity, binding affinity, and cellular potency of four widely studied LRRK2 inhibitors (MLi-2, PFE-360, GNE-7915 and LRRK2-in-1) on both the wild type (WT) and pathogenic G2019S LRRK2 isoforms. Biochemical tests were carried out using purified truncated human LRRK2 enzymes. Inhibition of LRRK2-mediated phosphorylation of the peptide substrate, LRRKtide, was assessed using an HTRF assay. To overcome the lower limit of inhibitor potency detection, which is defined by the concentration of LRRK2 in the reaction, the Morrison equation for tight binders was applied to obtain functional pK_i values for picomolar potent compounds. From these biochemical studies, MLi-2 and PFE-360 were greater than 8 fold more potent on WT compared to the G2019S isoform, whereas GNE-7915 and LRRK2-in-1 showed comparable potencies at the two isoforms. To obtain kinetic parameters of the binding interaction between compounds and enzymes, the association of the Kinase Tracer 236 was followed in the absence or presence of inhibitor and analysed with the Motulsky & Mahan method. Interestingly, MLi-2 and PFE-360 also showed longer binding residence times on the WT isoform ($t_{1/2}$=38 min for MLi-2 and 23 min for PFE-360) compared to G2019S isoform ($t_{1/2}$=27 min for MLi-2 and 5 min for PFE-360). Cellular activity assays were carried out in HEK-293 cells overexpressing WT or G2019S LRRK2 after two hours incubation with compound. Inhibition of phosphorylation at S935 was assessed with a Cisbio HTRF kit following manufacturer instructions. Inhibition of the S1292 autophosphorylation site was assessed using Meso Scale Discovery technology. In WT LRRK2 cells, GNE-7915 and LRRK2-in-1 inhibited the pS1292 site more potently than the pS935 site (pS1292 IC50 =20 nM for both

compounds, pS935 IC_{50}=160nM for GNE-7915, pIC_{50}= 100 nM for LRRK2-in-1) while MLi-2 and PFE-360 showed similar potencies at the two phosphorylation sites. In G2019S LRRK2 cells, potencies at pS935 and pS1292 were aligned. In conclusion, these results suggest that the highly potent LRRK2 inhibitors MLi-2 and PFE-360 have differential activities and kinetic binding properties on WT vs. G2019S LRRK2. Furthermore, a differential inhibition of the pS935 and pS1292 sites on WT LRRK2, as observed with GNE-7915 and LRRK2-in-1, suggests that the two phosphorylation sites might be differently modulated by LRRK2 inhibitors.

Abstract: Impairment of the autophagy-lysosome pathway (ALP) causes aberrant protein accumulation, a common feature of Parkinson's Disease (PD). Mutations in leucine-rich repeats kinase 2 (LRRK2), among which p.G2019S is the most prevalent, are associated with familiar and sporadic PD. Dysregulation of ALP has been proposed as a mechanism underlying LRRK2-related PD. Therefore, the role of LRRK2 in ALP regulation, its kinase- and age-dependence and relation with pSer129 α-synuclein inclusions were investigated *in vivo*. Striatal ALP markers were analyzed by Western blotting in 3 and 12-month-old LRRK2 G2019S knock-in mice (bearing enhanced kinase activity), LRRK2 knock-out mice, LRRK2 D1994S knock-in (kinase-dead) mice and wild-type controls. Chloroquine (CQ), a lysosomotropic agent, was administered to block the autolysosomes formation and, thus, measure the autophagic flux *in vivo*. Quantitative Real-time PCR was used to quantify the transcript levels of key ALP genes. The activity of the lysosomal enzyme glucocerebrosidase was measured using enzymatic assay. Immunofluorescence analysis was used to study the expression of LC3B puncta and pSer129 α-synuclein inclusions in striatal MAP2-positive and nigral TH-positive neurons. No differences in macroautophagy and chaperone-mediated autophagy markers were observed among genotypes at 3 months of age. Conversely, increase of LC3-I, p62, LAMP2 and GAPDH levels, decrease of p-mTOR levels and downregulation of *mTOR* and *TFEB* expression was observed in 12-month-old kinase-dead mice. Upon CQ administration, LC3-II/LC3-I ratio was reduced, suggesting a defective autophagic flux. G2019S

knock-in mice showed LAMP2 accumulation and a significant downregulation of several ALP genes: *MAP1LC3B*, *LAMP2*, *mTOR*, *TFEB* and *GBA1*. Both LRRK2 knock-out and kinase-dead mice displayed an increase in the striatal glucocerebrosidase activity at 3 and 12 months. *GBA1* expression was reduced only in 12-month-old G2019S knock-in mice. Immunofluorescence revealed no correlation between LC3B puncta accumulation and pSer129 α-synuclein inclusions in striatal and dopaminergic neurons of LRRK2-mutant mice. We conclude that LRRK2 kinase activity inhibits striatal glucocerebrosidase activity *in vivo*. Early deregulation of GCase activity precedes a late impairment of macroautophagy and chaperone-mediated autophagy in the striatum of mice devoid of LRRK2 kinase activity. In G2019S knock-in mice, striatal pSer129 α-synuclein accumulation observed under basal conditions appear unrelated to autophagy impairment.

Title: Phosphorylated Rab12 reveals activity of the Parkinson's disease-related LRRK2 kinase in the Nucleus Basalis of Meynert.

Authors: *V. G. CHITTOOR-VINOD[1], ***J. SINGH**[2], N. NIKULINA[2], S. BUKHARI[1], P. CHU[1], C. GAJERA[1], O. BRAUBACH[1], T. MONTINE[1], J. NICHOLS[1], J. NICHOLS[1];
[1]Stanford Univ., San Jose, CA; [2]Akoya Biosci., Menlo Park, CA

Abstract: The Leucine Rich Repeat Kinase 2 (LRRK2) protein kinase is a large bifunctional enzyme with both GTPase and kinase activities. Mutations in the *LRRK2* gene are the most common familial genetic predisposition for Parkinson's disease (PD). LRRK2-PD patients present clinically similar to idiopathic PD (iPD) patients. All pathogenic mutations of LRRK2 increase their kinase activity against exogenous and endogenous substrates. Biochemical studies have identified a subset of Rab GTPases as bone fide substrates of LRRK2, that are hyperphosphorylated by LRRK2 PD mutants. The prevailing hypothesis is that LRRK2-PD mutant linked hyperphosphorylation of substrates underlies the onset of LRRK2 PD; due to clinical overlap, it is suspected that similar molecular pathogenicity may underly iPD. This presents two questions: 1) Where in the human brain and what type of cells exhibit LRRK2 signaling? and 2) Is LRRK2 kinase-related signaling enhanced in LRRK2 PD and/or iPD. To address in which brain region and cell type exhibit LRRK2 kinase signaling, we established immunocytochemical and immunohistochemical assays to detect substrate Rab phosphorylation in human autopsy brains. Though much work has elucidated the functional impact of Rab phosphorylation by LRRK2, we still lack spatial and cellular resolution of signaling events in the disease. In this study we examined the

LRRK2◊Rab12 signaling axis, in which Rab12 is phosphorylated by LRRK2 on Ser106. We validated a recombinant rabbit monoclonal antibody against Rab12 pSer106 in immunocytochemistry for responsiveness to genetic and pharmacological modulators of LRRK2 kinase activity, and found a strong correlation of pRab12 with LRRK2 kinase function. We next surveyed regions from throughout the human brain and found that although total Rab12 was detectable in multiple brain regions, pRab12 was only detected in the Nucleus Basalis of Meynert (NBM). Highly-multiplexed fluorescent imaging with the CODEX imaging technology was used to further correlate the localization of pRab12 in ChAT-positive cholinergic neurons of the NBM. Other regions, including substantia nigra which is a critical region in PD pathology, lack prominent pRab12 immunoreactivity across all of the experiments conducted here. We established ICC, IHC and CODEX multiplex imaging techniques to observe LRRK2 signaling in autopsy brains, and identified the NBM as a prominent site of LRRK2àRab12 signaling. The NBM is a region implicated in cognitive dysfunction in AD and PD. Thus, our study offers a potential link between PD-associated LRRK2 mutation and cognition, through Rab12 phosphorylation.

Title: Function of LRRK2 in striatal cholinergic interneurons

Authors: *P. SKELTON[1], C. CHEN[1], Y. KOZOROVITSKIY[2], L. PARISIADOU[1];
[1]Pharmacol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Neurobio., Northwestern Univ., Evanston, IL

Abstract: Leucine-rich-repeat kinase 2 (LRRK2) mutations represent the most common monogenetic form of Parkinson’s disease (PD). The clinical similarity between LRRK2-linked and idiopathic cases suggests that LRRK2 mutations are a useful and valuable tool for understanding PD in general. LRRK2 is significantly enriched in spiny projection neurons (SPNs) in the dorsal striatum, in contrast to the

relatively low expression in midbrain dopaminergic neurons that degenerate and die in PD. Prior to the onset of overt neurodegeneration, LRRK2 mutations reduce evoked dopamine release from midbrain dopamine neurons and disrupt the glutamatergic synaptic inputs onto spiny projection neurons. Meanwhile, data from rodent models suggest that striatal cholinergic interneurons (CINs) are specifically vulnerable to LRRK2 mutation, and clinical evidence indicates cholinergic abnormalities in LRRK2-linked PD. We therefore sought to determine whether LRRK2 mutations influence the physiology of striatal CINs.
We first confirmed that LRRK2 is expressed in striatal CINs by immunostaining for LRRK2 and choline acetyltransferase (ChAT). We then investigated LRRK2 function in CINs by generating cholinergic-neuron-specific conditional Lrrk2 knockout and LRRK2-R1441C knock-in mouse lines generated by a crossing ChAT-Cre driver line to Lrrk2-Floxed and Rosa26 LRRK2-R1441C lines, respectively. Controls were generated by crossing ChAT-Cre mice to wild-type mice. We used AAV delivery of a Cre-dependent EGFP construct to target CINs for experiments in ex vivo brain slices. Experiments were performed on adult (8-16 weeks old) mice of both sexes. We found no differences in resting membrane potential, input resistance, action potential shape, sag potential, or excitability. R1441C overexpression increased the magnitude of the slow afterhyperpolarization . Dopamine and acetylcholine function in the striatum are tightly linked, as nicotinic acetylcholine receptors on dopaminergic terminals allow CINs to stimulate local dopamine release. Therefore, ongoing work will determine the effect of LRRK2 on neurotransmitter release using virally encoded optogenetics to target cholinergic neurons and virally encoded fluorescent sensors to measure extracellular acetylcholine and dopamine.
Overall, our data show that LRRK2 does not affect the membrane properties of cholinergic interneurons that determine their excitability and tonic activity. Future experiments will study the LRRK2-mediated neurotransmitter release from CINs and determine whether LRRK2 in CINs affects acetylcholine and acetylcholine-evoked dopamine release in the striatum.

Title: Neural mechanisms driving comorbid Parkinson's and melanoma

Authors: *P. DEL VALLE[1], J. DI MARTINO[2], G. W. HUNTLEY[3], J. J. BRAVO-CORDERO[2], D. L. BENSON[3];
[1]Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai Grad. Training Program In Neurosci., New York, NY; [2]Dept. of Hematology and Med. Oncology, [3]Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Epidemiological studies have shown that people with Parkinson's disease (PD) have a significantly higher risk of developing melanoma and vice-versa. However, research on this comorbidity is sparse. One possible point of convergence lies in the sympathetic nervous system. Studies show that activating sympathetic axons residing in breast adenocarcinomas increases cancer growth and metastasis. Extending this, our preliminary data suggest that mice implanted with melanoma allografts and carrying a knock-in LRRK2-G2019S mutation, one of the most common genetic contributors to PD, have enriched populations of sympathetic axons in their tumor microenvironment. Therefore, we hypothesize that a PD environment produces an altered melanoma response by regulating the activity and innervation of sympathetic axons in the tumor microenvironment. To investigate this, we are characterizing melanoma progression and its neural microenvironment in WT and LRRK2-G2019S-knock in (GSKI) mice. The preliminary data show that the extent and pattern of melanoma growth is altered significantly in GSKI mice and that tumors have altered patterns of innervation and macrophage infiltration. These and additional data will be used to establish conditions and timing for testing whether LRRK2-G2019S-mediated alterations in melanoma growth lie downstream of local sympathetic axonal activity and to ascertain whether positive results can be reversed by LRRK2 kinase inhibition, which is significantly elevated with the G2019S mutation. Studying the downstream effects of sympathetic axonal activity and innervation in a tumor microenvironment will create a fuller understanding of the neural mechanisms connecting PD and melanoma.

Abstract: Leucine-rich repeat kinase 2 (LRRK2) has a critical role in both inherited and idiopathic forms of Parkinson's disease (PD). LRRK2 is highly expressed in the spiny projection neurons (SPNs) of the striatum. Evidence suggesting a critical role for LRRK2 in regulating glutamatergic excitatory synaptic activity. Our previous findings showed that LRRK2 contributes to glutamatergic synaptic functions by directing PKA signaling events in SPNs, which resulted in altered GluA1 synaptic incorporation in the striatum of R1441C mice. To access how the two most common pathogenic mutations (R1441C and

G2019S) alter the structure and function of individual synapses on direct (d-) and indirect (i-) pathway SPNs, we conducted subcellular fractionation biochemistry super-resolution imaging and 2-photon glutamate uncaging of R1441C and G2019S knock-in mice. This study showed that R1441C but not G2019S dSPNs had altered synaptic GluA1 receptor distribution and larger single-spine glutamate uncaging-evoked ESPCs. Our data provide a coherent framework for understanding how the two distinct *LRRK2* pathogenic mutations selectively alter excitatory synaptic function in specific cell types.

Abstract: Parkinson's disease (PD) is a disorder characterized by loss of substantia nigra pars compacta (SNpc) dopamine neurons that innervate the striatum. Mutations in *LRRK2* that increase kinase activity, exemplified by the G2019S variant, are associated with PD pathogenesis. Recent work suggests pharmacological inhibition of LRRK2 kinase activity reduces the neurodegenerative effects of toxin-induced Parkinsonism in rodents. We developed a rotenone-exposure model in G2019S*LRRK2 knock-in rats, and evaluated the potential neuroprotective properties of the LRRK2 kinase inhibitor PF-06685360 (PF360). Rotenone injections (2.8 mg/kg s.c. SID) in 5-6 month old male rats produced rapid onset of PD-like motor and postural symptoms, and loss of nigrostriatal tyrosine hydroxylase (TH, dopaminergic neurons). We applied our rotenone exposure procedure and investigation to male and female 13-15 month old G2019S*LRRK2 knock in rats (homozygous, heterozygous, and wild-type), with daily exposure to rotenone (2.0 m/kg s.c. SID) and treatment with PF360 (10 mg/kg p.o. BID). PF360 treatment inhibited pS935 LRRK2 in the striatum, confirming target engagement. Rotenone caused gait and locomotor deficits not corrected by PF360 treatment. Rotenone increased neurofilament light chain amounts in CSF which was reduced by PF360 in WT and G2019S homozygous males. Rotenone induced TH loss in striatum and SNpc. PF360 partially protected striatal TH loss in wild-type and heterozygous rats, but exacerbated TH loss in homozygous rats. Rotenone caused mild TH loss in male rat SNpc across all genotypes, which was partially suppressed by PF360. This report highlights animal model utility for detecting neuroprotective efficacy and genetic interactions.

All studies were conducted in accordance with the GSK Policy on the Care, Welfare and Treatment of Laboratory Animals and were reviewed the Institutional Animal Care and Use Committee either at GSK or by the ethical review process at the institution where the work was performed.

Title: Sensitrak Performs Reproducible Measurements of Rat Forepaw Sensory Function

Authors: D. YOO[1], *A. RAMAMURTHY*[1], J. LEE*[1], A. M. SLOAN[2], J. B. CARMEL[1];
[1]Columbia Univ. Med. Ctr., New York, NY; [2]Vulintus, Inc., Louisville, CO

Abstract: There are currently no turnkey systems for behavioral testing and assessment of forelimb touch and loss of function. We developed SensiTrak, a semi-automated system that quantitatively assesses the sensitivity of rodents to vibration applied to the forepaw. Rats are trained to hold a lever and release it once they feel a vibration (a go/no-go task). The vibration duration is altered to determine the threshold for detection. Baseline criteria are met when rats reach: a true positive rate of at least 80%, a false alarm rate (releasing the lever during no stimulus trials) below 25%, and a steady increase in detection ability with longer stimulus durations. Rat performance is assessed by calculating the 50% threshold representing the vibration duration at which rats correctly identify the stimulus 50% of the time. Our rats achieved the 50% threshold at a stimulus duration of 21 +/- 6ms (3 to 5 stimuli at a frequency of 166 Hz). To determine the rat's sensitivity to vibration, we plot the response rate and the response time against the vibration length at 11 stimulus points. The resulting sigmoidal-shaped psychophysical profiles allow for reproducible sensory thresholds with good inter and intra-subject reliability. We found after testing seven rats, this task can operantly condition rats in 8 weeks to perform 50 outcome trials over 30-minute sessions with average hold times of 7-8 seconds. In addition to this relatively narrow range between rats, each rat showed stability within their respective thresholds as far out as 25 weeks after beginning testing. Control experiments including dampening materials, auditory masking, and injury/inactivation of sensory tracts suggest that this is a test of paw somatosensation and not auditory function. Backed by these results,

SensiTrak is a reliable measure of somatosensation in rats. Future studies will test the utility of this system for mice and other sensory modalities like proprioception and texture discrimination.

Title: Jaw movement-modulated activity of sensory neurons in the mesencephalic trigeminal nucleus during a directional licking task

Authors: *W. P. OLSON[1], M. VASS[1], V. B. CHOKSHI[2], D. H. O'CONNOR[3];
[1]Dept. of Neuroscience, Krieger Mind/Brain Inst., [2]Biol., Johns Hopkins Univ., Baltimore, MD; [3]Dept. of Neurosci., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: While the activity of muscle spindle (MS) sensory afferents is known to be modulated by position and movement of the body, the movement coding of these neurons remains poorly defined in the context of voluntary behavior. Here, we record from MS afferents innervating the jaw musculature (located in the mesencephalic trigeminal nucleus, MEV) of mice performing a directional licking task. In this task, head fixed mice are trained to lick a moving ‘port’ through an arc of seven locations surrounding the mouse’s face to receive a water reward. This task elicits jaw trajectories along three anatomical axes (dorsoventral, mediolateral, anterior-posterior) that we can track in high speed video recordings of the face. To define the sensory coding of MS afferents, we isolate single units from MEV extracellular tetrode recordings and relate their neural activity to jaw kinematics. We furthermore validate MEV expression of a set of published molecular markers for MS afferent subtypes and present a strategy for imaging long-range MEV projections in cleared skeletal-muscular face samples. Taken together, these data will allow us to better define the ways in which the rich diversity of MEV in vivo physiological responses may be built from the subtype identities and/or long-range anatomies of single MEV neurons.

Title: Characterization of chronic pain-dependently activated neurons in the spinal cord

Authors: *A. OZAWA, K. TARGOWSKA-DUDA, D. PETERS, J. L. MARCUS, G. ZRIBI, L. TOLL; Dept. of Biomed. Science, Charles E. Schmidt Col. of Med., Florida Atlantic Univ., BOCA RATON, FL

Abstract: Decades of efforts in elucidating pain mechanisms, including pharmacological, neuroanatomical, and physiological studies have provided insights into how nociceptive information transmits from the periphery to the brain and the locations receiving pain signals. However, little is known about which specific stimulus-dependently activated neurons, amongst heterogeneous neural environments, discriminatively evoke the cognate pain behavior. In this study, we shed light on activated neuron populations in the spinal cord to determine chronic pain-dependently activated neuronal subsets using Fos2A-iCreER (TRAP2) mice, which allow us to monitor reporter gene expression triggered by specific pain stimuli as reference for c-Fos expression, a neural activation marker. Using TRAP2 mice crossed with Ai9 (Cre-dependent tdTomato reporter) mice, we have found a larger number of neurons chronic pain-dependently activated (pain-TRAPed neurons) in the spinal cord in spinal nerve-ligated mice compared to sham. Further neuroanatomical analyses identified different subsets of spinal neurons that were activated by distinct pain modalities (i.e., mechanical allodynia vs. heat hyperalgesia) under chronic pain conditions. In addition to the neuroanatomical analyses, we also examined the functionality of these pain-TRAPed neurons in the context of the regulation of pain behavior using chemogenetic neuronal manipulation. Selectively inhibiting pain-TRAPed neurons via hM4Di receptors (an inhibitory DREADD, Designer Receptors Exclusively Activated by Designer Drugs) significantly reduced the response to the pain stimuli associated with chronic pain originally given to the animals. Interestingly, this reduction was not observed when mice were tested on the stimuli different from the original pain stimulation given the animals. These findings support the idea that spinal neuronal ensembles underlying pain transmission undergo dynamic changes regulating selective pain transmission. Altogether, the methods established here will be useful and represent a unique opportunity to further understand the roles of pain-dependently activated neural circuits regulating specific pain behaviors.

Title: Transformation of spinal sensory codes in neuropathic pain

Authors: *D. A. YARMOLINSKY[1], C. GREENE[1], Y.-T. CHENG[1], S. CHOI[2], D. D. GINTY[3], C. J. WOOLF[1];
[1]Neurobio., Children's Hosp. Boston, Boston, MA; [2]Dept. of Neurobio., [3]Dept Neurosci, Harvard Med. Sch., Boston, MA

Abstract: Pathological pain states are defined by an abnormal input-output relationship within the somatosensory system. Under normal conditions, the nociceptive outputs of acute pain perception and protective behavioral responses are evoked only by intense stimuli that threaten or cause tissue damage, while in pathological states such as neuropathic pain, the same perception is triggered by normally harmless stimuli or by no stimulus at all. A primary locus implicated in this maladaptive plasticity is the spinal dorsal horn, which integrates, processes, and relays information regarding touch, temperature, and bodily harm from peripheral sensory neurons to the brain. Our current work aims to define, at a cellular resolution, how normal dorsal horn sensory coding evolves to a pathological state during the progression of neuropathic pain. We image neuronal population activity in the spinal cord of mice genetically engineered to express GCaMP in genetically and anatomically defined populations. These populations encompass spinal projection neurons giving rise to the anterolateral tract, the primary pathway transmitting pain and thermosensory signals from spinal cord to brain. A chronically implanted spinal window permits longitudinal imaging of population responses to mechanical and thermal stimulation of cutaneous receptive fields before, during, and after induction of neuropathic pain by spared nerve injury. Our results define the normal patterns of population response to somatosensory stimuli in the superficial dorsal horn and identify dorsal horn neuronal populations displaying altered function in neuropathic pain states. This approach may reveal targets and strategies to restore normal somatic perception and treat pain.

Title: Glycinergic neurons in laminae I-IV of the mouse spinal dorsal horn: morphological and neurochemical characterization

Authors: C. MIRANDA[1], H. WILDNER[3], H. U. ZEILHOFER[4], *M. ANTAL[2];
[1]Dept. of Anatomy, Histology and Embryology, [2]Univ. of Debrecen, Debrecen, Hungary; [3]Univ. of Zurich, Zurich, Switzerland; [4]Inst. of Pharmacology, Univ. of Zurich, Zurich, Switzerland

Abstract: It is becoming increasingly evident that glycinergic neurotransmission in the spinal dorsal horn plays an important role in the development of allodynia and hyperalgesia. However, how glycinergic neurons contribute to the formation of neural circuits underlying spinal pain processing is poorly understood. The lack of this essential knowledge makes the interpretation of the role of glycinergic neurons in spinal pain processing vague. Therefore, in our present experiments we investigated the morphological and neurochemical properties of glycinergic neurons in laminae I-IV of the spinal dorsal horn using a GlyT2::CreERT2-tdTomato transgenic mouse line. Most of the glycinergic neurons were found in laminae III-IV, whereas they were only sparsely distributed in laminae I-II. We unequivocally showed that in addition to GABA-glycine neurons there are also glycine-only neurons not only in laminae III-IV but also in laminae I-II. According to their morphological properties, we divided the glycinergic neurons into 3 and 6 groups in laminae I-II and laminae III-IV, respectively. Concerning the neurochemical characterization, we found that some of the glycinergic neurons co-express parvalbumin, neuronal nitric oxide synthase, RORb and RET, but further neurochemical properties need to be investigated. Our present results can contribute to a better understanding of the role of glycinergic inhibition in spinal pain processing.

Title: Identification of the spinal circuit for cooling sensation

Authors: *L. HORWITZ, C. C. HOR, R. FUNG, B. DUAN;
Dept. of Molecular, Cell. and Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: A healthy internal body temperature falls within a narrow window and is dependent upon homeostatic mechanisms of thermoregulation. It is vital then to detect even the slightest change in external temperatures. While progress has been made in characterizing temperature-sensitive neurons in the periphery, the molecular identity of cool temperature-sensing neurons in the spinal cord is not well defined. Using a combination of intersectional genetic strategies and chemogenetic tools, Calbindin 1::Cre (Calb1^{+}) neurons in the dorsal horn of the spinal cord were identified as essential for innocuous cool (15 - 20˚C) but not noxious cold (below 15°C) responses in mice. These results suggesting distinct neural pathways transmit cool and cold sensations. Calb1+ neurons present a heterogenous population of excitatory interneurons in the dorsal horn, and selectively ablating or silencing Calb1+ neurons in the dorsal horn results in several behavioral deficits, including loss of punctate mechanical pain and cooling

sensation. Further molecular quantification revealed a unique subpopulation of Calb1^{+}; SOM^{-}; Calb2^{-} neurons is responsible for relaying cool environmental temperature information, whereas Calb1^{+}; SOM^{+}; Calb2^{+} spinal neurons transmit punctate mechanical pain. Our studies uncover a distinct neural mechanism by which cool but not noxious cold temperatures or mechanical pain are transmitted in the dorsal horn of the spinal cord.

Title: Distinct modes of spinal cord inhibition regulate tactile sensitivity in mouse models of autism spectrum disorders

Authors: *A. TASNIM[1,3], L. OREFICE[4,2], I. ALKISLAR[1,3], A. ABDELAZIZ[1,3], D. D. GINTY[1,3]; [1]Dept. of Neurobio., [2]Dept. of Genet., Harvard Med. Sch., Boston, MA; [3]Howard Hughes Med. Institute, Harvard Med. Sch., Boston, MA; [4]Dept. of Mol. Biol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Individuals with autism spectrum disorders frequently report altered reactivity to sensory stimuli, with many individuals displaying over-responsivity to tactile stimuli. Previous work in our lab revealed that appropriate feedback (or presynaptic) inhibition (PSI) of primary somatosensory neurons is critical for normal touch reactivity in adult mice, and loss of PSI drives tactile hypersensitivity in at least some mouse models of ASD (Orefice et al., 2016). In this study we found that genetic ASD models in which feedforward inhibitory (FFI) control of sensory inputs onto spinal cord neurons is disrupted also display tactile over-reactivity in adulthood. Interestingly, using a new measure of tactile reactivity in neonatal mice, we observed that ASD models that exhibit deficits in PSI of sensory neurons are over-reactive to light touch from birth, whereas animals with disruption to FFI of spinal cord neurons show normal tactile reactivity until late stages of postnatal development. Furthermore, though both PSI and FFI are critical for regulating tactile sensitivity in adults, animals that exhibit disruptions to PSI display aberrant anxiety-like behaviors, as previously described, but the same is not observed in mice with altered spinal cord FFI. Addressing the cellular and synaptic mechanisms underlying the development of PSI and FFI of somatosensory input to the spinal cord, we find that the differences in onset of tactile hyper-reactivity as well as comorbid behavioral consequences relate to the observation that PSI and FFI in the spinal cord mature at different stages: PSI develops by late embryonic or neonatal ages, whereas FFI develops late postnatally. These findings suggest that the precise timing of altered modes of inhibition of somatosensory input to the spinal cord determines the timing of aberrant sensory reactivity, and this in turn is a critical determinant in the genesis of other, comorbid ASD-associated behaviors such as anxiety.

Title: Muscle stretch reflexes assessed in real and virtual environments

Authors: *D. HODGSON[1], O. DAIRCI[1], T. BUTT[1], S. AJAO[1], A. KUO[1], T. CLEWORTH[2], R. PETERS[1];
[1]Univ. of Calgary, Calgary, AB, Canada; [2]York Univ., Toronto, ON, Canada

Abstract: **Research Objective and Rationale:** Altered states of fear, anxiety, and postural (i.e., balance) control occur similarly when stressed with threatening real and virtual scenarios such as standing at height. However, mechanisms underlying neuromodulation of balance control in response to heightened threat remain unknown. Here we use Noisy Tendon Vibration (NTV) applied to the Achilles with a novel wearable device to characterise somatosensory reflexes during standing in real and virtual environments. The objective of this exploratory study is to examine threat-related changes in somatosensory reflexes as a possible mechanism of fear-induced changes to postural control.**Methods:** Preliminary data was collected from five (target sample size is 20 based on previous work) healthy young adults during quiet standing in real (eyes open, eyes closed) and VR (low, high) environments. In the virtual environment, subjects stood at the edge of a platform which was elevated from ground level (low) to 6m (high). NTV (40 to 120 Hz) was delivered to the right Achilles tendon throughout 120-second trials in each condition. Hoffman's reflexes (H-reflex) were delivered prior to and immediately following NTV. Muscle activity was monitored using surface electromyography (EMG) in the soleus, medial gastrocnemius, and tibialis anterior muscles, and ground reaction forces and moments (centre of pressure) were collected. Electrodermal activity (EDA) data was collected throughout testing to gauge anxiety levels objectively. Questionnaires assessed fear and anxiety subjectively. Eyes open and VR low conditions were compared to assess postural control and reflex modulation in real vs. virtual environments. The relationships between reflex modulation and postural control with altered threat perception was examined in the eyes closed, VR low, and VR high conditions. **Results:** Early results indicate an initial enhancement of reflex coupling in the Real Eyes Closed and both VR conditions compared to Real Eyes Open. There were no group effects of VR high on the stretch reflex compared to VR low, however individual differences showed some subjects increased while others decreased coupling or demonstrated no change. Further Investigation of the relationship between fear/anxiety and reflex coupling is pending additional data. **Conclusions:** Understanding the neuromodulation of balance control and reflexes in real and virtual setting is a crucial step towards developing wearable technologies to improve neuromuscular function and reduce injury risks in vulnerable populations. This research demonstrates the ability to assess muscle stretch reflexes using a novel wearable NTV system.

Title: Effects of sensory spinal injuries on the dorsal and ventral horn in the primate

Authors: *K. FISHER, J. P. GARNER, C. J. DARIAN-SMITH;
Stanford Univ., Stanford, CA

Abstract: Our work examines the effects of focal spinal injuries affecting hand function and fine dexterity. Though it is known that even small sensory injuries induce plasticity across the neuraxis, the extent of different peripheral inputs to the spinal cord, and thus their potential to contribute to post-injury recovery, remains poorly defined. Understanding this is critical for correctly interpreting clinical injury extent, outcome, and for developing effective therapeutic approaches. To address this gap in our knowledge, we determined the extent of cutaneous and muscle afferent inputs to the cord in both normal and lesioned monkeys, at a greater resolution than previously reported.

Macaques (*M. cynomolgus*) were used, and the injury model comprised a unilateral combined dorsal root/dorsal column lesion (DRL/DCL), guided electrophysiologically and affecting just digits 1-3. Six months post-lesion, cholera toxin subunit B injections (CT-B) were made into either the distal pads of digits 1-3, or related muscles (first dorsal interosseous and abductor pollicis brevis), to label inputs to the cord bilaterally, as well as motor neurons within the ventral horn. Monkeys were euthanized 8 days later and tissue processed to visualize CT-B. Immunolabeling and confocal microscopy were used to analyze terminals, cell membrane and extracellular matrix proteins, as well as neurotransmitters of interest.

In controls, cutaneous afferents from digits 1-3 terminated in the dorsal horn from C1-T2, as reported previously. Proprioceptive afferents similarly projected to the dorsal horn between C1-T2. However, these muscle injections also resulted in a more focused retrograde labeling of ventral horn motor neurons, across just 2 segments (C7-8).

In lesioned monkeys, both cutaneous and muscle inputs to the dorsal horn were drastically reduced across all segments. Primary afferents directly contacting motor neuron cell bodies (i.e. VGLUT1+ terminals), also decreased by 50%, compared with the contralateral side.

On the cell membrane of affected motor neurons, excitatory neurotransmitters, monoamine input & KCC2 receptors all showed changes following DRL/DCL, even at this relatively chronic time point. Inhibitory neurotransmission and perineuronal net integrity, in contrast, showed no significant difference from baseline. Though our findings show just a snapshot in time, they indicate dynamic changes during recovery leading to longer term consolidation. Our findings underscore the considerable impact even a small, sensory injury has on the motor machinery of the spinal cord.

Abstract: The spinal cord dorsal horn is composed of a large number of interneuron populations that serve to process peripheral somatosensory information prior to relaying it to the brain via dorsal horn projection neurons. However, our understanding of the functional organization of the interneurons and therefore, of the processing mechanisms is still limited. The functional organization of the spinal cord grey matter depends, in part, on the Rexed laminae (I-X), which are generally dorsoventrally oriented, non-overlapping layers of neurons, and also, by the termination patterns of distinct classes of primary afferents. Previous metrics for defining neuronal populations within these laminae included morphology, neuronal connectivity, intrinsic firing pattern as well as the expression of general molecular markers. More recent efforts include single-cell or nucleus RNA sequencing (scRNA-seq/snRNA-seq) studies of the mouse spinal cord and a meta-analysis that attempted to reconcile the differences arising from these studies. To achieve a consensus in the cell types and their organization, for the purpose of translating rodent dorsal horn studies to humans, we performed snRNA-seq of the macaque. From this, eight major cell types were identified including oligodendrocytes, neurons, astrocytes, oligodendrocyte precursor cells, microglia, meninges, ependymal and Schwann cells. The neurons (~22% of the total cells), were sub-clustered further into discrete excitatory (GLUTs1-11) and inhibitory (GABAs1-5) clusters with novel marker genes. Mapping these computationally defined clusters using *in situ* hybridization show that they largely reside within specific laminae. We also performed a comparative analysis between dorsal horn neurons of the macaque and those of the mouse meta-analysis. Clusters of each species are highly correlated and show a similar conservation of their laminar distribution. Interestingly, sub-clustering of the macaque GABA2 and GABA4 clusters resulted in a strong correlation with two of the mouse meta-analysis derived families (groups of similar clusters)- the Rorb and Adamts5. These two molecularly

distinct clusters, which reside in laminae III-IV, may therefore have concerted functional roles. Species-specific differences were also observed in select genes, such as an enrichment of *PIEZO2*, an ion channel important for light touch and proprioception, in the macaque GLUT8 cluster. Lastly, we examined the expression pattern of the major neuropeptides in the macaque and human dorsal horn and found that their laminar distribution is highly conserved across all three species with the interesting exception of cholecystokinin.

Abstract: Manual interactions with objects are critically dependent on tactile and proprioceptive feedback from the hand, as evidenced by severe deficits that result from deafferentation. Indeed, signals from the skin, joints, and muscles, convey information about the state of the limb, its interactions with objects, and the objects themselves to support object manipulation. Three aspects of somatosensation relevant to manual dexterity have yet to be systematically investigated. First, perhaps more than any other sensory modality, touch occurs during active movements. Despite this, the neural basis of touch has been studied almost exclusively with stimuli delivered passively to the skin. Second, proprioceptive signals carry information not only about the time-varying conformation of the hand, but also about manually applied forces. While kinematic representations have received some recent experimental attention, their kinetic (force-related) counterparts remain to be characterized. Third, stereognosis - the sense of the three dimensional shape of objects - implies the integration of tactile and proprioceptive signals. At each point of contact with the object, tactile signals convey information about the object's local contours, for example curvature and edge orientation. Cutaneous signals about local geometric features are then interpreted in the context of where the contact points are relative to one another in space, information that is conveyed by proprioceptive signals. The study of active touch, hand proprioception, and stereognosis has been hindered by technical obstacles, such as characterizing contact events and tracking hand movements with sufficient precision and reliability. To overcome these obstacles, we have developed an experimental apparatus that allows us to simultaneously measure contact events, time-varying forces and

hand postures while monkeys grasp instrumented objects of varying sizes and orientations. We recorded neural responses evoked in the hand representation of the somatosensory cortex, including Brodmann's areas 3a, 3b, 1 and 2. We then fit generalized linear models (GLM) to individual neurons from each area to assess to what degree they encode kinematic and/or kinetic variables. We also examined tactile and proprioceptive representations at the population level to assess how features of objects and our interactions with them are encoded in the central nervous system.

Title: A cutaneous mechanoreceptor and its role in the detection of slip

Authors: *I. ALKISLAR[1,2], B. P. LEHNERT[1,2], C. SANTIAGO[1,2], T. C. BAUER[1,2], Q. ZHANG[1,2], L. BAI[1,2], Y. ZHENG[1,2], L. GARIBYAN[3], D. D. GINTY[1,2];
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]Howard Hughes Med. Inst., Boston, MA; [3]Dermatol., Harvard Med. School; Wellman Ctr. for Photomedicine, Massachusetts Gen. Hosp., Boston, MA

Abstract: Our sense of touch depends on low-threshold mechanoreceptors (LTMRs) that innervate hairy or glabrous (non-hairy) skin and form specialized mechanosensitive endings that are intimately related to their function. Meissner corpuscle associated Aβ RA-LTMRs that innervate glabrous skin respond to forces generated during slip and are hypothesized to provide critical feedback for grip control. We developed a mouse slip assay and demonstrated that glabrous skin tactile feedback is important for maintaining stable contact with an angled ramp. Unexpectedly, we find that mutants lacking Meissner corpuscles do not have slip avoidance deficits. To identify other populations of mechanoreceptors that underlie the avoidance of slip, we performed optogenetic receptive field mapping of A-fiber neurons that innervate glabrous skin and discovered an uncharacterized class of neurons with large (1 mm^2) receptive fields. Electrophysiological recordings indicated that these neurons correspond to a class of mechanoreceptors that respond to innocuous tangential forces that stretch the skin. To gain genetic access to this population, we generated a mouse line in which Cre recombinase is inserted into the Ptgfr locus and found that it can be used to selectively label these uncharacterized glabrous skin LTMRs. Sparse genetic labeling experiments revealed that $Ptgfr^+$ neurons innervate the skin and exhibit large terminal fields that occasionally span multiple digits. Central projections in the lumbar spinal cord terminate within the LTMR recipient zone of the dorsal horn, consistent with a mechanoreceptor function. Surprisingly, $Ptgfr^+$ neuron terminals in glabrous skin are free nerve endings (FNEs) that penetrate the epidermis, an anatomical feature that is often associated with nociceptors capable of signaling damaging

stimuli. Optogenetic activation of Ptgfr$^+$ neurons in awake behaving mice failed to elicit nocifensive responses, but instead triggered a gripping motion. As slip can be avoided through tactile feedback to actively manage the shear force between the body and an object at the contact surface, we hypothesize that this uncharacterized Ptgfr$^+$ mechanoreceptor functions to detect incipient slip through its unique sensitivity to tangential forces acting on glabrous skin.

Title: Tactile intensity perception is shaped by temporal integration: evidence from single afferent recording and stimulation in humans

Authors: R. WATKINS[1], M. AMANTE[2], R. ACKERLEY[1], V. HAYWARD[4], J. WESSBERG[3];
[1]Lab. de Neurosciences Cognitives UMR 7291, Aix Marseille Univ. - CNRS, Marseille, France; [2]Inst. of Neurosci. and Physiol., Univ. of Gothenburg, Göteborg, Sweden; [3]Inst. of Neurosci. and Physiol., Univ. of Gothenburg, Goeteborg, Sweden; [4]ISIR, Sorbonne Univ., Paris, France

Abstract: In glabrous hand skin, four types of fast conducting mechanoreceptive afferent encode different aspects of touch interactions, e.g. pressure, edges, velocity, textural quality. Temporal firing patterns in these afferents reveal components relating to the stimulus quality, whereas the firing rate relates to the perceived intensity. However, intensity coding breaks down for short duration stimuli (<400 ms), where vibration of equivalent magnitude is perceived as weaker for shorter stimuli. We sought to use this phenomenon to study afferent intensity coding. We used broadband vibration reflecting real world tactile interactions, and found intensity ratings dropped markedly when stimulus duration was reduced below 400 ms. However, intensity was perceived as equivalent when increasing absolute stimulus magnitude. We combined single afferent recordings in humans using microneurography, with the perceptual equivalence judgements of intensity at different durations, and used different parameters in the afferent firing as predictors of perceived intensity. Firing rate gave a poor prediction of intensity, which was instead best predicted by binned firing rate across 100 ms time windows. Preliminary evidence of the specificity of this effect was gained by electrically stimulating individual afferents, combining single unit microneurography and intraneural microstimulation. Tactile percepts were evoked by stimulating both fast-adapting type I (FA-I, n=5) and slowly-adapting type I (SA-I, n=3) afferents using comparable spike trains to vibration. At the same frequency, intensity was perceived as lower at durations below 100 ms,

but delivering the same number of impulses produced equivalence. However, in FA-II (n=2) or SA-II (n=2) afferents, intensity judgements were also reduced at longer stimulus durations (>200 ms). These data suggest that tactile perception related to intensity judgment is integrated over short time windows for SA-I and FA-I afferents, but this might be different in type II afferents. This work relates to the concept of perceptual cycles, where stimuli must be separated perceived as separate events, only when during different cycles of somatosensory cortical oscillations, suggesting intensity representation may have a similar mechanism. Knowledge of the afferent determinants of the determinants of tactile intensity perception will aid in the design of artificial tactile feedback, such as with prostheses incorporating direct nerve stimulation.

Title: Characterizing the tactile acuity and sensitivity of the human breast

Authors: *A. FAWAZ[1], K. H. LONG[2], S. J. BENSMAIA[3];
[2]Interdisciplinary Scientist Training Program, sp. Computat. Neurosci., [3]Dept. of Organismal Biol. and Anat., [1]Univ. of Chicago, Chicago, IL

Abstract: In the US alone, more than 100,000 women undergo mastectomy to treat or prevent breast cancer. This procedure involves amputating all breast tissue, including the cutaneous sensory nerves that mediate breast sensation, often leading to partial or complete numbness of the breast. In an effort to develop technologies to address this loss of sensation and its downstream effects, we set out to characterize the cutaneous sensitivity of the nipple-areolar complex (NAC) of healthy, intact breasts to gain some insights as to the underlying tactile innervation. We specifically aimed to evaluate (1) the spatial acuity of the NAC and breast compared with the back and hand, and (2) the vibrotactile thresholds of the nipple, areola, and breast skin. To these ends, we designed and constructed an experimental apparatus to passively deliver well-controlled tactile stimuli to the breast and NAC while subjects performed well-established psychophysical paradigms. First, to evaluate spatial acuity, we sequentially presented two skin indentations and asked subjects to indicate whether the second stimulus was above (closer to the head) or below (closer to the feet) the first. From these measurements, we computed the spatial just-noticeable difference (JND) - the distance at which subjects can reliably perceive a change in position. We found that these JNDs are highest in the breast and NAC - more than fivefold greater than those observed in the hand, and more than double those found on the back. Furthermore, the spatial acuity decreased with increased breast size. Second, to establish the vibrotactile sensitivity of the nipple, areola,

and breast tissue, we evaluated the minimum amplitude required for subjects to detect a vibratory stimulus applied to the skin to shed light on the nature of the underlying innervation, as different classes of nerve fibers exhibit different frequency sensitivity profiles. We tested this across a broad range of frequencies and compared these detection thresholds to those of the hand. We found that, while the spatial acuity in the NAC and breast is much lower than that of the hand, the vibrotactile sensitivity is similar, implying that the breast is innervated with the same tactile nerve fibers as the hand, but at a substantially lower density.

Title: Investigating tactile innervation and unit responses in mouse tongue

Authors: *L. ZHANG[1,2,3], D. XU[1,2,3], W. P. OLSON[1,2,3], D. H. O'CONNOR[1,2,3];
[1]Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Krieger Mind/Brain Inst., Baltimore, MD; [3]Kavli Neurosci. Discovery Inst., Baltimore, MD

Abstract: The mammalian tongue is richly innervated with somatosensory, gustatory and motor fibers. These form the basis of sophisticated sensorimotor functions such as the determination of object shape and texture during active touch. Despite high tactile acuity and sensitivity revealed by human studies (Trulsson & Essick, 1997)[1], the response properties and underlying innervation patterns and ending types of the tongue remain largely unknown. In this study, we found that the anterior two-thirds of the dorsum of the mouse tongue is innervated by NFH-positive myelinated afferents, consistent with prior work (Moayedi et al., 2018)[2]. Unlike gustatory afferents, which innervate only taste buds (Fei et al., 2014)[3], sensory neurons in the trigeminal ganglion (TG) innervate both the fungiform papillae that host taste buds and the filiform papillae of the tongue. By screening Cre/CreER mouse lines, we identified 2 Cre markers (Pirt-Cre and VGlut2-Cre) that labeled myelinated afferents at the tongue surface. Optogenetic stimulation of the tongue during single-unit recordings from the TG of Pirt-Cre/+; Ai32/+ mice suggests that Pirt-Cre labels tongue low-threshold mechanoreceptors (LTMRs) in TG. Interestingly, by labeling terminal Schwann cells with S100β or PLP1-EGFP, we did not find any specialized sensory end organs in the mouse tongue, but rather only free nerve endings. In contrast, we identified corpuscular end organs at the dorsum of ferret tongue by immunostaining for NFH and S100β. Single-unit recordings from anesthetized mice showed that tongue LTMRs in TG are highly sensitive to static force stimulation or stretch and have small receptive fields (RFs, around 0.1 mm^2). The tongue LTMRs recorded so far (n = 12) exhibit either an intermediately adapting (IA) property or a rapidly adapting (RA) property, with the ratio between IA and RA units being 10:2. 10 of 12 recorded units had a Von Frey threshold equal to or less than 0.4 mN, and had a receptive field located near the midline or the tip or the edge of the tongue,

with the distance between the RF center and the midline/edge of the tongue less than 0.5 mm. In contrast, a unit with an RF located at the middle region of the left side of the tongue had a higher threshold of 0.7 mN. This suggests the possibility that tongue LTMRs innervating the edge, the tip and the midline regions of the tongue may be more sensitive to innocuous mechanical stimuli compared with those innervating the middle regions.

Title: Clinical skin sensitivity assessed using a vibration-emitting smartphone application

Authors: *O. LINDSAY[1], A. YOUNG[1], H. HAMMAD[1], J. BAYSIC[1], R. M. PETERS[2];
[2]Fac. of Kinesiology, [1]Univ. of Calgary, Calgary, AB, Canada

Abstract: Background: Peripheral neuropathy (PN) is a neurological condition involving thegradual death of sensory and motor neurons. Measures of cutaneous sensitivity,including the Semmes-Weinstein monofilament (SWMF) test and 128 Hz tuning fork(TF) test, detect higher-than-normal perceptual thresholds to inform a clinical diagnosisof PN. Whether these assessments are capable of providing valid and reliable estimatesof perceptual thresholds remains unclear. As an alternate, detection estimates derivedfrom computerized instruments demonstrate improved precision and reliability whencompared to manual assessments.**Rationale:** Smartphones contain well controlled vibrating motors capable of assessinghigh-frequency (128 Hz) perceptual thresholds at varying amplitudes. Assessment ofvibrotactile detection along a spectrum of preprogrammed amplitudes is suitable forperception threshold estimation for varying health conditions.**Objective:** This study aims to assess the validity and reliability of the SWMF, TF, and anovel vibration-emitting smartphone application (ie, Vibratus App or VA) against thegold-standard nerve conduction studies (NCS) on a sample of healthy adults andchemotherapy-induced PN (CIPN) patients.**Methods:** Preliminary data was collected from nine healthy adults assessed for skinsensitivity during SWMF, TF, and VA testing, in addition to peripheral nerve functionobtained from NCS. SWMF and VA thresholds were determined from a twenty-trial 4-2-1 stepping algorithm. VA threshold values are described as a percentage of the totalpossible amplitude delivered by the smartphone. The timed TF method was conductedand discrepancies between rater and participant perceived duration of vibration wererecorded. NCS analysis was comprised of sensory nerve action potential (SNAP)amplitude and latency. Ongoing research will determine assessment validity andreliability on a sample of healthy young and older adults (n=60, young: 18-45y, old:+65y) and CIPN patients (n=30, +18y).**Results:** Early findings suggest that these assessment methods correctly quantifyperceptual thresholds according to health status (SWMF = 0.02 ± 0.01 g, TF = 3.52 ±2.52 s, VA = 0.27 ± 0.18 au), as determined by NCS parameters (amplitude = 62.18 ±15.2 μV, latency = 3.11 ± 0.33 ms). Individual

differences in perception have beenidentified but must be explored further to determine cut-off values for the diagnosis ofPN.**Significance**: Smartphone-based testing will allow users to self-administer neurologicalexams as often as desired, empowering them as agents in their own healthcare team.

Title: Functional classification of tongue-innervating mechanosensory neurons based on in vivo calcium imaging

Authors: *Y. MOAYEDI[1], S. XU[3], S. OBAYASHI[4], B. U. HOFFMAN[2], G. J. GERLING[3], E. A. LUMPKIN[4];
[1]Neurol. and Otolaryngology-Head & Neck Surgery, [2]Columbia Univ., New York, NY; [3]Univ. of Virginia, Charlottesville, VA; [4]Univ. of California, Berkeley, CA

Abstract: Lingual mechanosensory neurons provide essential information for guiding food choice, feeding ability, and speech. Yet, little is known about the identities of neurons that contribute to these daily tasks. In our previous work, we identified putative mechanosensory endings in the tongue with novel morphologies; the functions of these neurons in sensation are not known. To identify functional classes of lingual mechanosensory neurons, we employed in vivo calcium imaging of trigeminal ganglia (n>3 male and female mice/experiment). We first investigated calcium responses of tongue-innervating trigeminal neurons to thermal and mechanical stimulation (e.g. pressure, fluid flow, temperature changes). We found that around 17% of neurons responded to pressure, and that these pressure responders were significantly larger in size than neurons that only responded to temperature changes. To further investigate the cadre of functionally distinct mechanosensory neurons, we tested responses to brushing and sustained pressures and found that brush-sensitive neurons comprise the majority of tongue-innervating mechanosensory trigeminal neurons. We next developed an unbiased multilevel K-means clustering approach to classify calcium response characteristics to pressure stimulation. This approach revealed that mechanosensory neurons displayed five distinct stimulus-response profiles to pressure. These classes include neuronal populations with sustained and transient responses to force, as well as neurons with no response or negative responses to force application. These studies lay the foundation for defining functional differences between somatosensory neurons in the tongue and how they encode tactile features of foods and contribute to oral functions.

Title: Using a gel elastomer to characterize the neuromechanics of texture perception

Authors: *N. B. ORNSTEIN[1], C. M. GREENSPON[2], S. J. BENSMAIA[3];
[1]Organismal Biol. and Anat., [2]Dept. of Organismal Biol. & Anat., [3]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: We are exquisitely sensitive to texture: We can tell the difference between satin and silk and can discern features as small as 10 nanometers in size. While much is known about the neural mechanisms that mediate texture perception, the role of the skin in shaping the percept remains unclear. Surfaces often comprise compliant elements, which not only deform the skin but are themselves deformed by it, an interaction that is nearly impossible to characterize with most natural textures. It is therefore difficult to relate a textural percept and its neuronal representation to the stimulus because the latter is not suitably characterized. To overcome this problem, we constructed a silicone elastomer gel that mimics the mechanical properties of human skin. We then indent textured surfaces into this elastomer and measure the patterns of deformation produced in the elastomer using a laser profilometer. The patterns of elastomer deformation then serve as a proxy for the corresponding skin deformations, hitherto unknown. For example, fleece comprises small elements (top panel, max depth, 0.91 mm). The gel compresses those elements, revealing the corresponding skin deformations (bottom panel, max depth, 0.3 mm). We find that the measured deformations yield better predictions of psychophysical judgments of texture and better predictions of afferent responses to texture than do raw texture profiles. This study contributes to a growing literature on neuromechanics that seeks to elucidate how biomechanics shape our perception of the external world.

Title: Tmem120a/tacan inhibits mechanically activated piezo2 channel activity

Authors: J. S. DEL ROSARIO, **M. GABRIELLE**, Y. YUDIN, *T. ROHACS;
Pharmacology, Physiol. and Neurosci., Rutgers New Jersey Med. Sch., Newark, NJ

Abstract: Mechanically activated Piezo2 channels are key mediators of light touch and proprioception in mice and in humans. Relatively little is known about what other proteins regulate Piezo2 activity in a cellular context. TMEM120A (TACAN) was proposed to act as a high threshold mechanically activated ion channel in nociceptive dorsal root ganglion (DRG) neurons. Here we find that TMEM120A co-expression robustly reduced mechanically activated Piezo2 currents, but did not inhibit mechanically activated Piezo1 and TREK1 currents. TMEM120A co-expression did not affect cell surface expression of either Piezo1 or Piezo2 and it did not have major effects on the cortical actin or tubulin cytoskeleton. TMEM120A expression alone did not result in the appearance of mechanically activated currents above background. In addition, TMEM120A and Piezo2 expression in DRG neurons overlapped, and siRNA mediated knockdown of TMEM120A did not decrease the proportion of slowly adapting mechanically activated currents, but resulted in an increased proportion of rapidly adapting currents. Our data do not support TMEM120A being a mechanically activated ion channel, and identify it as a negative modulator of Piezo2 channel activity.

Title: Effects of glutamate on extracellular H+ in retinal slices of tiger salamander.

Authors: B. K. TCHERNOOKOVA[1], M. A. KREITZER[2], *R. MALCHOW[1];
[1]Univ. of Illinois at Chicago, Chicago, IL; [2]Biol., Indiana Wesleyan Univ., Marion, IN

Abstract: Glutamate is thought to be the main excitatory neurotransmitter in the vertebrate retina. Powerful uptake systems are responsible for removing extracellular glutamate and terminating its effects on neuronal activity which in turn prevents excitotoxicity. We had previously shown that extracellular glutamate induces changes in extracellular H+ flux from isolated retinal Müller cells of the tiger salamander using self-referencing H+-selective electrodes. Here, we show that extracellular glutamate also induces changes in extracellular H+ from retinal slices from tiger salamander when self-referencing microelectrodes are positioned just over the outer plexiform layer (OPL). Recordings were made in a solution containing 1 mM HEPES as a pH buffer and without the added application of bicarbonate. Application of 300 μM glutamate induced a pronounced transient extracellular alkalinization followed by a sustained extracellular acidification. The glutamate uptake blocker DL-*threo*-β-benzyloxyaspartic acid (DL-TBOA) decreased the aklalinization induced by application of glutamate but not the acidification. When slices were bathed in the AMPA receptor blocker CNQX, a compound known to inhibit glutamate-

induced depolarization of second order retinal neurons, glutamate still induced an extracellular alkalinization, but the subsequent acidification event was diminished. We have previously shown that extracellular acidifications from isolated Müller cells as well as from retinal slices in response to extracellular ATP are mediated by the activity of purinergic receptors located on retinal Müller glial cells. Interestingly, the use of the P2 receptor blockers PPADS and suramin attenuates the acidification event following glutamate application, suggesting a potential role of purinergic signaling in the glutamate-induced changes in extracellular H+. The differential modulation of the biphasic response to extracellular glutamate suggests that different mechanisms govern the glutamate-induced alkalinization and acidification events, with the alkalinization likely being mediated by glutamate transporter activity and the acidification requiring activation of non-NMDA glutamate receptors.

Title: Regeneration and functional ERG recovery in a mouse glaucoma model after treatment with an alpha7 nicotinic acetylcholine receptor agonist

Authors: *D. M. LINN[1], J. B. SPITSBERGEN[2], S. E. WEBSTER[2], C. L. LINN[2];
[1]Biomed. Sci., Grand Valley State Univ., Allendale, MI; [2]Biol. Sci., Western Michigan Univ., Kalamazoo, MI

Abstract: Eyedrop application of the selective α7nAChR agonist, PNU-282987, has been shown to induce bothneurogenesis and regeneration of retinal neurons in adult mammals. In this study, experiments wereperformed to evaluate structural and functionality recovery after PNU-282987 treatment in glaucoma-induced mice. Both sexes of mice (between 3 and 6 months) were injected with 1.2M hypertonic saline intothe episcleral vein to induce scarring and increase IOP. After the procedure, mouse eyes were treated oncedaily using eye drops containing 1mM PNU-282987/1mg/ml BrdU and weekly ERGs from light-adaptedanimals were recorded. At different time points, animals were euthanized, and retinas were removed,processed immunocytochemically with antibodies against BrdU and Thy 1.2, counterstained with DAPI,and viewed and analyzed using a Nikon confocal microscope. Hypertonic saline injections elicited asignificant increase in intraocular pressure four weeks post injection (an average of 15.8 mmHg ±1.2)compared to an average of 11.2 mmHg (±1.8; $p<0.05$) measured from the same animals before theprocedure. Induction of glaucoma also significantly reduced the cell density of Thy1.2+ RGCs by anaverage of 28.31% (±1.5; $p<0.05$) four weeks after injection. To assess the regenerative potential of PNU-282987, injected animals were treated with BrdU alone or with PNU-282987/BrdU. In the injected micetreated only with BrdU, no BrdU+ cells appeared despite an average loss of 30.88% (±3.4; $p<0.05$) RGCs.However, after agonist treatment following saline injection, Thy1.2/BrdU+ neurons

appeared in the GCL.After 7 days of agonist treatment, PNU-282987 significantly reduced the loss of Thy1.2+ cells associatedwith the glaucoma procedure to an average of only 12.4% (±0.8; $p<0.05$) compared to the near 30% averagethat are typically lost. Light-adapted ERG recordings from saline-injected mice exposed to PNU-282987for 3 weeks had a-wave amplitudes comparable to controls. However, significant increases in the b-waveamplitudes were recorded after glaucoma-induced animals were treated with PNU-282987 for 3 weeks byan average of 57% (±5; $p<0.05$). Peak oscillatory potentials (OP1, 2 and 3), that represent inner retinalactivity, all increased after inducing glaucoma by an average between 30 - 81% (± 14; $p<0.05$) due to PNU-282987 application. Lastly, the amplitude of the photopic negative response, which represents ganglioncell activity, significantly increased by an average of 78% (±12; $p<0.05$) after PNU-282987 treatment in
glaucoma induced animals. These are the first experiments to demonstrate regeneration and functionalrecovery in a glaucoma model using an α7 nAChR agonist.

Title: Early diabetes-induced changes in retinal output neurons

Authors: *B. N. EBBINGHAUS, C. M. SORENSON, N. SHEIBANI, M. HOON;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Diabetes is a prevalent condition world-wide which often leads to visual impairment, a condition known as diabetic retinopathy. Retinal ganglion cells (RGCs), the output neurons of the retinal circuit undergo cell death during advanced stages of diabetic retinopathy with diabetes-induced vascular changes in the retina contributing to this process. Changes in RGCs prior to cell-death are not yet fully understood. In this study, we determined the impact of a short duration of hyperglycemia on RGC structure, function, and connectivity. We used a murine model (Ins2 Akita/+) of diabetes which spontaneously develops hyperglycemia at four weeks of age. We focused our analyses on the six-week time point (2 weeks after onset of hyperglycemia) and on four ‘alpha’ RGC subtypes that have been well-characterized in the mouse retina. We confirmed that RGC loss had not yet commenced at the time point of our analyses. Biolisitic transfections and immunohistochemistry were used to ascertain RGC morphology and synaptic distribution (excitatory and inhibitory) across RGC types. Single cell electrophysiology was used to determine RGC light response profiles. Interestingly RGC morphology and synaptic density was altered in a type-specific and region-specific manner. We also determined vascular density in the inner retina and found specific alterations at the time-point of our analyses. Thus, the early impact of diabetes is restricted to particular retinal circuits with certain subtype(s) of retinal output neurons being more susceptible to early diabetes-induced perturbations.

Title: An investigation of retinal and choroidal vasculature across the menstrual cycle using Swept-Source Optical Coherence Tomography

Authors: *M. E. WRIGHT[1], L. TERRY[2], S. DAVIES[1], A. CROFTS[1], J. J. STEVENTON[1], K. MURPHY[1];
[1]Cardiff Univ. Brain Res. Imaging Ctr. (CUBRIC), [2]Sch. of Optometry and Vision Sci., Cardiff Univ., Cardiff, United Kingdom

Abstract: Oestrogen has a neuroprotective effect against conditions such as dementia and glaucoma. One possible mechanism is oestrogen's vasodilatory influence on the cerebrovascular system. Considering the variation in oestrogen across a menstrual cycle, we hypothesise that changes in oestrogen hormone levels across the monthly cycle influence blood flow in both the brain and the eye.
With the increasing availability of Optical Coherence Tomography Angiography (OCT-A) for measuring retinal vasculature in clinical research, substantial changes in OCT-A derived metrics over a healthy cycle may effect clinical results. This study aims to investigate the influence of different menstrual cycle phases on retinal and choroidal vasculature using swept-source Optical Coherence Tomography (SS-OCT) and OCT-A.
The right eyes of 6 healthy, menstruating females (age mean[SD]= 22.0[2.3]; intraocular pressure mean[SD]= 12.6[3.2] mmHg; visual acuity mean[SD]= -0.1[0.1]) were tested during the early follicular (EF; day 1-4), late follicular (LF; day 10-12), and mid-luteal (ML; day 20-22) phase of their menstrual cycle. All sessions took place at the same time of day, after a fasting period of 4-6 hours. Due to the ongoing pandemic, not all participants have yet completed every phase (EF= 3; LF= 4; ML= 3).
3D macula scans were taken using a SS-OCT (Triton; TOPCON [Great Britain] Medical Limited, Newbury, UK). Choroidal thickness (inner and outer macula) was estimated by the instrument. OCT-A software in the same device was utilised to take a $3mm^2$ scan and measure retinal vascular density (superficial and deep layers); this was calculated using the ratio of vessels to non-vessels of the binarized image across a 2mm diameter ROI (centred on the fovea).
Qualitatively, choroidal thickness was thinner during the EF phase for inner (EF mean[SD]= 309.8[10.0] μm; LF mean[SD]= 329.1[56.9] μm; ML mean[SD]= 339.2[60.3] μm) and outer macula regions (EF mean[SD]= 288.3[18.8] μm; LF mean[SD]= 294.9[40.5] μm; ML mean[SD]= 302.4[44.4] μm). Vascular density was relatively stable across menstrual cycle phases for both the superficial (EF mean[SD]= 27.6[3.8]; LF mean[SD]= 27.1[2.0]; ML mean[SD]= 27.2[2.6]) and deep layers (EF mean[SD]= 33.1[4.5]; LF mean[SD]= 32.4[4.5]; ML mean[SD]= 33.3[3.4]).
These preliminary results suggest that OCT-A derived measures of retinal vascular density, in both

superficial and deep layers, are relatively stable throughout the menstrual cycle. The choroidal layer, however, appears thinnest during the EF phase, which mirrors the point of lowest oestrogen across the cycle and may provide a window into measuring cerebrovascular health.

Title: Lipid metabolilizing genes modulate anti-vegf response in age related macular degeneration

Authors: *A. ANAND[1], K. SHARMA[2], R. SINGH[3], S. SHARMA[5], N. K. SHARMA[4];
[1]Dept. of Neurology, P.G.I.M.E.R, Chandigarh, India; [2]Neurol., [3]Opthalmology, [4]neurology, PGIMER, Chandigarh, India; [5]statistics, panjab university, Chandigarh, India

Abstract: Age related macular degeneration is a multifactorial disease. SNPs in certain genes have been associated with the disease. Wet form of the disease is treated by intra-vitreal administration of anti-VEGF injections . The response to the treatment varies among individuals depending upon unknown factors. In this study we have investigated the association between genetic variation and anti-VEGF response in AMD patients. For this study 78 AMD patients were recruited from Advanced Eye Centre, PGIMER Chandigarh. Details of Anti-VEGF treatment was noted for each patient. Blood sample was collected from the patients for isolation of serum and DNA. Retrospective record of administration of Anti-VEGF therapy was consulted for 11 patients. SNP genotyping (rs920915), LIPC (rs920915) and APOE (rs769449), pro-angiogenic genes including ADAMTS9 (rs6795735) and TIMP3 (rs5749482), regulatory genes e.g. B3GALTL (rs9542236), IER3 (rs3130783), HTRA1 (rs11200638) and SLC16A8 (rs8135665, monocarboxylic transporter protein) was done using Taqman assays and ELISA was used to estimate their proteins in Serum.We found that Alcohol intake and previous cataract surgery were modulators of Anti-VEGF response. B3GALTL and LIPC variants were associated with Anti-VEGF response in Indian AMD patients. Homozygous ‘CC’genotype of LIPC variant show enhanced expression of regulatory (HTRA1, B3GALTL and IER3), monocarboxylic transporter protein SLC16A8, and LIPC levels. We also found that APOE levels increased in patients with successive VEGF injections. The results show significance of lipid metabolizing molecules (including APOE and LIPC) in AMD which can influence the Anti-VEGF outcome in AMD patients.

Title: Structure-function relationships in the Brown Norway rat streptozotocin-induced diabetic retinopathy model

Authors: *I. LELYTE[1,2], M. CERRADA-GIMENEZ[3], A. GHOSH[4,5], Z. AHMED[1], G. KALESNYKAS[3], S. KAJA[6,4];
[1]Inst. of Inflammation and Ageing, Univ. of Birmingham, Birmingham, United Kingdom; [2]R&D Division, Experimentica Ltd, Vilnius, Lithuania; [3]R&D Division, Experimentica Ltd, Kuopio, Finland; [4]R&D Division, Experimentica Ltd, Forest Park, IL; [5]Grad. Program in Biochem. and Mol. Biol., [6]Ophthalmology and Mol. Pharmacol. & Neurosci., Loyola Univ. Chicago, Maywood, IL

Abstract: The rat streptozotocin-induced model for diabetic retinopathy (DR) remains the most-commonly used experimental paradigm for drug discovery, as it recapitulates many of the complex phenotypes seen in patients. Advances in *in vivo* ocular imaging provide an opportunity to study early pathological processes in this model and to establish structure-function relationships. We recently performed a systematic literature review that included 662 records of preclinical STZ studies from the past 10 years. Of those, only one study was performed in pigmented rats, specifically Brown Norway (BN) rats. The BN strain is widely used in ocular drug discovery and the presence of pigmentation allows for the detection of potential confounding pharmacologic effects due to melanin binding. This highlights an urgent need for structure-function analysis of DR phenotypes in BN rats. BN rats (male, 3-4 months old) received two IP injections of STZ (65 mg/kg in citrate buffer, pH 4.5). Glucose levels and body weight were monitored twice per week. Rats were followed *in vivo* for 8-12 weeks by vitreofluorophotometry (VFP; OcuMetrics, Inc.), flash electroretinography (fERG; Diagnosys LLC), and spectral domain-optical coherence tomography (SD-OCT; Leica Microsystems, Inc.). Ocular tissues were collected for quantification of acellular capillaries and pericyte loss using trypsin digested retinal whole mounts, Evan's Blue (EB) extravasation assay and biomarker analysis. Majority of the rats developed hyperglycemia (>16 mmol/l) week 1 post-STZ ($p < 0.001$). Hyperglycemic rats presented significantly reduced body weight gain compared to the naïve rats by day 7 ($p < 0.001$). VFP showed mild progressive retinal leakage by week 3 post-STZ, which was statistically significant by week 5 ($p < 0.01$). fERG showed decreased photoreceptor responses by week 6 with increased latencies ($p < 0.05$). Inner retinal thickness measured by SD-OCT decreased by week 8-9 ($p < 0.001$). Pericyte ghosts increased significantly in diabetic animals compared to naïve rats ($p < 0.05$). EB levels in the retina showed a statistically significant increase, suggesting presence of blood-retinal barrier rupture. Our data demonstrate that the BN strain reproduces the known hallmarks of diabetic retinopathy, as seen in albino rat strains. Detailed analysis of the structure-function relationship in the BN rats reveal changes consistent with significant progressive pro-angiogenic vascular changes and retinal degeneration starting as early as

4 weeks post-STZ induction. The pigmented BN STZ model for DR offers unique opportunities for drug discovery.

Title: Characterizing early onset vision loss in the childhood neurodegenerative disease, Mucolipidosis type IV.

Authors: *N. CUBBAGE, M. PAMONAG, R. CISTULLI, M. T. WALKER;
Biol., James Madison Univ., Harrisonburg, VA

Abstract: Purpose: In this study we are testing to identify the mechanisms that underlie photoreceptor function loss and cell death in Mucolipidosis type IV (MLIV). MLIV is a lysosomal storage disorder, which are the greatest causes of childhood onset neurodegeneration. MLIV results from loss of function mutations in the Mcoln1 gene that encodes the lysosomal cation channel (Trpml1). Loss of Trpml1 function has been shown to disrupt cellular autophagy and phagocytic activity, which contributes to the progessive motor neuron cell death in MLIV. In the retina it is not clear why the light response of photoreceptors in MLIV are sensitive to the loss of this lysosomal channel Trpml1. In many retinal degenerative diseases regardless of the genetic origin, retinas show some disruption in rhodopsin expression and trafficking that results in decreased photoresponse and increased photoreceptor death. We hypothesize that functional defects in photoreceptors of $Mcoln1^{-/-}$ mice is due to a disruption in trafficking of photoreceptor proteins across the connecting cilium of rod and cone cells. Methods: We use

electroretinogram recordings to measure age-dependent changes in photoreceptor activity in 4 and 6 week old mice. We also measure changes in photoreceptor protein expression and localization in the mouse retina. Results: Our results show an early decline in rod photoreceptor activity beginning between 4 and 6 weeks old. At low scotopic light intensities, Mcoln1$^{-/-}$ mice have a decreased A-wave latency. At 6 weeks these mice show a significant decrease in A-wave amplitude. This decline in light activation is accompanied by a 60% decrease in total rhodopsin in Mcoln1$^{-/-}$ retina. In our analysis of retinal proteins we discovered that Mcoln1$^{-/-}$ retinas also show a significant loss of the cilia forming protein BBS4. Mcoln1$^{-/-}$ mouse photoreceptors show morphological defects in the outer segment and disruption of rhodopsin translocation. Conclusion: Our data suggests that in addition to the disruption in autophagy, the loss of Trpml1 in photoreceptors also has a secondary effect on the expression and trafficking of phototransduction proteins across the primary cilium leading to functional loss and eventual cell death.

Abstract: The blood-retinal barrier (BRB) has two components: inner and outer barrier. The neurovascular unit of the retina and tight junctions between endothelial cells play key roles in the inner BRB. Choroid, the most highly vascularized tissue of the eye, is the major components of the outer BRB and provides oxygen and nourishment to the retina, which is crucial for maintaining visual function. Retinal and choroidal blood vessels come in different morphologies and have distinct organotypic characteristics that enable them to execute tissue-specific functions. In this study, we investigated molecular and functional differences between primary human retinal endothelial cells (HRECs) and human choroidal endothelial cells (HCECs) in terms of angiogenic and vasculogenic properties, permeability, and transcytosis. We performed tube formation assay, cell migration assay, in vitro permeability assay, microfluidic sprouting assay, and transcriptome analysis. HRECs showed higher proliferation and migration activity than HCECs, but the tube formation ability did not show a significant difference. HCECs displayed earlier sprouting angiogenesis but the overall speed was faster and more stable in HRECs under angiogenic stimuli. HRECs expressed higher tight junctional proteins than HCECs, but the transcytosis related genes were more in HCECs. Angiopoietin-2 and Tie2 were predominantly expressed in HRECs, but VEGF receptors were higher in HCECs. PDGFs were not

different between HRECs and HCECs despite the pericytes coverage is less in choroidal blood vessels. Our data indicate that HCECs is a quiescent endothelium but can be stimulated under the angiogenic environment, and have a specialized transcriptome for trans-endothelial molecular transport. In conclusion, retinal and choroidal blood vessels constitute two distinct BRBs under the endothelial heterogeneity: The outer BRB, size-selective barrier with vascular transcytosis for metabolic support, and the inner BRB, forming tight barriers, composes organotypic vasculature and maintains homeostasis in the eye.

Title: Neurogenesis and Functional Recovery of Adult Retinal Neurons in Mice using an Alpha7 nAChR Agonist after Blast Exposure

Authors: J. SPITSBERGEN, ***C. LINN**;
Biol. Sci., Western Michigan Univ., Kalamazoo, MI

Abstract: Eyedrop application of the selective α7 nicotinic acetylcholine receptor agonist, PNU-282987, has been shown to induce both neurogenesis and regeneration of retinal neurons in adult mammals. The objectives of this research include: 1) examination of the cellular and functional damage associated with ocular blast exposure, 2) evaluation of structural and functional recovery post PNU-282987 treatment. The hypothesis that application of PNU-282987 causes regeneration of new neurons in a blast damaged retina that leads to recovery of retinal function was evaluated using electroretinogram (ERG) recordings. Ocular blast damage was induced in adult mice (3-8 months old; both sexes) after exposure to a single blast of 35 psi to the left eye. Blast exposed mice were treated bilaterally daily, with an eyedrop containing 1mM PNU-282987 and/or 1mg/mL BrdU, post-blast for 4 weeks. Blast exposure of 35 psi caused a significant loss of cells in all retinal layers (15 to 40% compared to unblasted eye) after 4 weeks. Immunohistochemical analysis demonstrated BrdU incorporation in all layers of the retina in blast exposed mice treated with PNU-282987/BrdU eyedrops for 7 days. Agonist treatment induced an average of 15% (+/- 5) BrdU+ cells in the GCL, 25% (+/- 8) BrdU+ cells in the INL and 17% (+/- 5) BrdU+ cells in the ONL (n=5). ERG recordings were taken from untreated animals, from animals treated with PNU-282987 for 4 weeks only and from animals exposed to blast followed by 4 weeks of PNU-282987 treatment. Light adapted ERG recordings from blast exposed mice had significantly decreased a-wave (8.39 microvolts +/- 3.9) and photopic negative response (PhNR) (9.2 microvolts +/- 2.2) amplitudes as compared to recordings taken from the same mice prior to blast exposure (*n=5, p<.05*). Animals treated with PNU-282987 for 4 weeks showed a significant increase in a-wave (5.27 microvolts +/- 2.1**)**, b-wave (35.4 microvolts +/- 10.5) and PhNR (10.12 microvolts +/- 1.4) amplitude (*n=5, p*<.05). Under blast

exposed conditions, PNU-282987 alleviated the change of ERG waveform caused by blast, but it was not significant after only 4 weeks. (*p<0.07).* These are the first experiments designed to address recovery of functional changes in the retina after blast exposure using an α7 nAChR agonist.

Title: Sensitivity of the pattern electroretinogram to variations in central dopamine in humans: A systematic review

Authors: M. CUPP[1], H. JAMSHED[1], T. PRUITT[1], ***M. J. WENGER**[2];
[1]Psychology, [2]Psychology, Cell. & Behavioral Neurobio., The Univ. of Oklahoma, Norman, OK

Abstract: Iron deficiency, even in the absence of anemia, has negative effects on cognitive performance, including working memory, selective attention, and other functions mediated by dopaminergic communication. Animal models of iron deficiency have documented negative effects of iron deficiency on D1 and D2 receptors, as well as on dopamine transporter. Directly measuring central dopamine levels in humans involves invasive techniques, including exposure to radiation or spinal puncture. Both animal studies and human studies have suggested that the pattern electroretinogram (PERG) may be a useful indirect approach to measuring central dopamine levels. The PERG is a non-invasive and economical method of measuring the function of retinal dopaminergic cells, and it has been suggested that the magnitude and latency of the PERG may be proportional to central dopamine levels. When measured in response to periodic patterns (e.g., checkboards or square-wave gratings), the PERG consists of a rapid negative deflection (the a-wave) followed by a larger positive deflection (the b-wave) and a set of oscillatory potentials. The present systematic review sought to determine the strength of the evidence in favor of the PERG is an indirect measure of central dopamine levels in humans. Eligibility criteria for inclusion in the systematic review included a focus on human participants, with varying dopamine levels such as occurs in patients with Schizophrenia, Parkinson's Disease, and ADHD, or studies in which dopamine levels were manipulated psychopharmacologically, published in English. Excluded were articles containing participant populations with glaucoma, depression, addictive drug use, or studies that did not include measurement of the PERG. Five databases were used for article search and selection. Articles were manually cross-examined for duplicates and excluded. Each abstract was reviewed by three judges before being included. A total of 28 conditions across 11 studies provided data for the analysis. We analyzed the standardized difference of the means (using Cohen's d) for the latency and amplitude of the b-wave and found the average difference between low and high dopamine conditions was 0.793 for latency and 1.029 for amplitude. This suggests the utility of the PERG as an indirect and noninvasive

measure of central dopamine and highlights its potential in understanding the mechanisms by which iron deficiency produces cognitive impairments in humans.

Title: Characterization of sensory driven intrinsic iris constriction in mammals

Authors: *M. WALKER, R. CISTULLI, S. CHAMBERS;
Biol., James Madison Univ., Harrisonburg, VA

Abstract: Purpose: The iris is the essential retinal protective muscular tissue in the eye that controls the amount of light entering the eye. Iris muscle activity is driven by neurological input in response to changes in ambient light. A subset of photosensitive retinal ganglion cells (ipRGCs) provide the principal pathway for all light input to the olivary pretectal nucleus which directs the neuronal input to drive iris constriction via the oculomotor nerve. In most vertebrates except primates, the iris has been shown to also have an intrinsic light response. It has been shown that in murine mammals, melanopsin is required to initiate this light response, but it is not clear how the signal is transmitted between cells across the iris tissue. Pharmacological inhibition experiments suggest that gap junctions are required to transmit the intrinsic signaling between cells across the iris. We have tested in iris for the expression and localization of connexin proteins that form that form intercellular gap junction channels. We hypothesize that in the intrinsic iris light response, gap junctions are required to propagate constriction across the tissue. Methods: We have designed an *ex vivo* culture assay to measure the light dependent mouse intrinsic iris construction. We used RT-PCR and immunohistochemistry to demonstrate connexin expression and localization, respectively. Results: We found that enucleated eyes show light-driven constriction independent of CNS input. We found that the enucleated eye does not dark adapt after light driven constriction has occurred. When we isolate the anterior region of the eye in culture the tissue can be dark-adapted and light-activated multiple times. Our tests of connexin expression in mice indicate the expression of Connexin 36 (Gjd2) in the iris. Immunohistochemistry with Connexin 36 antibody also shows expression in mouse and rat iris both show gap junction expression. Conclusions: Our results show that the intrinsic iris light responses in intact eye suggests that there is some inhibitory signal preventing the iris from dilating once activated. Once the iris is separated from the posterior eyecup, it can repeat multiple cycles of construction and dilation. Finally our expression and localization results suggest that Connexin 36 is involved in forming intercellular gap junction channels in the iris.

Title: Given that large receptive fields are so important for face recognition, is their activity affected by the local visual context of a face?

Authors: *S. SAHA[1], I. BIEDERMAN[2], R. MELTZER[3];
[1]Computat. Neurosci., [2]Neuroscience, Psychology, [3]Neurosci., USC, Los Angeles, CA

Abstract: Large receptive fields (r.f.s) in the first cortical visual stage (V1), critical for face recognition, enable the coding of subtle, ineffable metric variations of a face to yield unique configurations, distinguishing otherwise highly similar faces (Xu et al., 2014). Later face-selective areas, e.g., FFA, retain the V1 Gabor-like coding characteristic (Yue et. al, 2006). However, the large r.f.s, particularly those centered at the face's edges, would be affected by the face's local visual context, raising the question as to how accurate face recognition can be achieved independent of the local context. We assessed how the context affected face matching performance in a match-to-sample task that presented three similar computer-generated faces in a triangular display with a sample face on top and two test faces on the bottom, one of which matched the sample while the other was the foil (Figure 1). Independently varied was whether the faces' edges were blurred and if the adjacent context was empty (Fig. 1A) or populated with straight or curved contours (Fig. 1B) to provide noise to the large r.f.s extending past the faces' edges. Blurring a face's edges and adding adjacent contours produced a small but significant increase in mean correct reaction times (RTs) but had no effect on error rates, with the greater RT increases for curved compared to straight contours, consistent with Yue et al.'s (2011) finding that FFA shows more sensitivity to curved than to straight contours. The magnitude of the interference produced by the local context could be limited by attentional "shrink wrapping" as documented by Moran and Desimone (1985) in the r.f.s in V4, such that V1 cells may "shrink wrap" around a face's edges. How that modulation may be achieved is a problem that awaits resolution.
Figure 1. Stimuli from two illustrative trials where the sample is the upper face, the "match" to sample is the lower-left test face, and the "foil" is the lower-right test face. In trial A), the "foil" and "match" have no local contours or blur. In trial B), the "foil" and "match" have local curved contours and all three faces are blurred.

Title: Distributed responses to visual categories in ventral temporal cortex become more similar across individuals during childhood development

Authors: *M. NORDT[1], J. GOMEZ[2], V. S. NATU[1], A. A. REZAI[1], D. FINZI[1], H. KULAR[1], K. GRILL-SPECTOR[1];
[1]Dept. of Psychology, Stanford Univ., Stanford, CA; [2]Princeton Neurosci. Institute, Princeton Univ., Princeton, NJ

Abstract: Ventral temporal cortex (VTC) contains distinct distributed representations to visual categories, which have a reproducible representational similarity across adult participants. However, it is unknown if representational similarity matrices (RSMs) become more or less similar across individuals during childhood development. Here we examined this question using longitudinal functional magnetic resonance imaging in 29 children. Children were initially 5-12 years old and were scanned on average 4.4±1.9 times over the course of 1-5 years. During scanning, children viewed images of 10 ecologically-relevant categories including faces, bodies, limbs, words, places, and objects while performing an oddball

task. We computed the RSM of distributed responses to these 10 categories in each functional session for lateral and medial VTC partitions in each hemisphere. Individual RSMs, which contained category information, were then compared across participants. We compared the similarity among RSMs (excluding the diagonal) across participants as a function of age, partition, and hemisphere. Results reveal that inter-participant-similarity among RSMs was higher in right compared to left VTC, and in medial compared to lateral VTC (Fig. 1). Interestingly, in lateral VTC inter-participant-similarity also increased with age. That is, distributed VTC responses to visual categories become more similar across individuals as they grow older. This developmental effect was independent of the temporal signal to noise ratio (tSNR) and is unaffected when excluding sessions that are outliers based on motion, task performance during scanning, or category reproducibility. These results suggest that shared visual experience may lead to more similar category representations in VTC with different levels of similarity across individuals in lateral versus medial, and left versus right VTC.

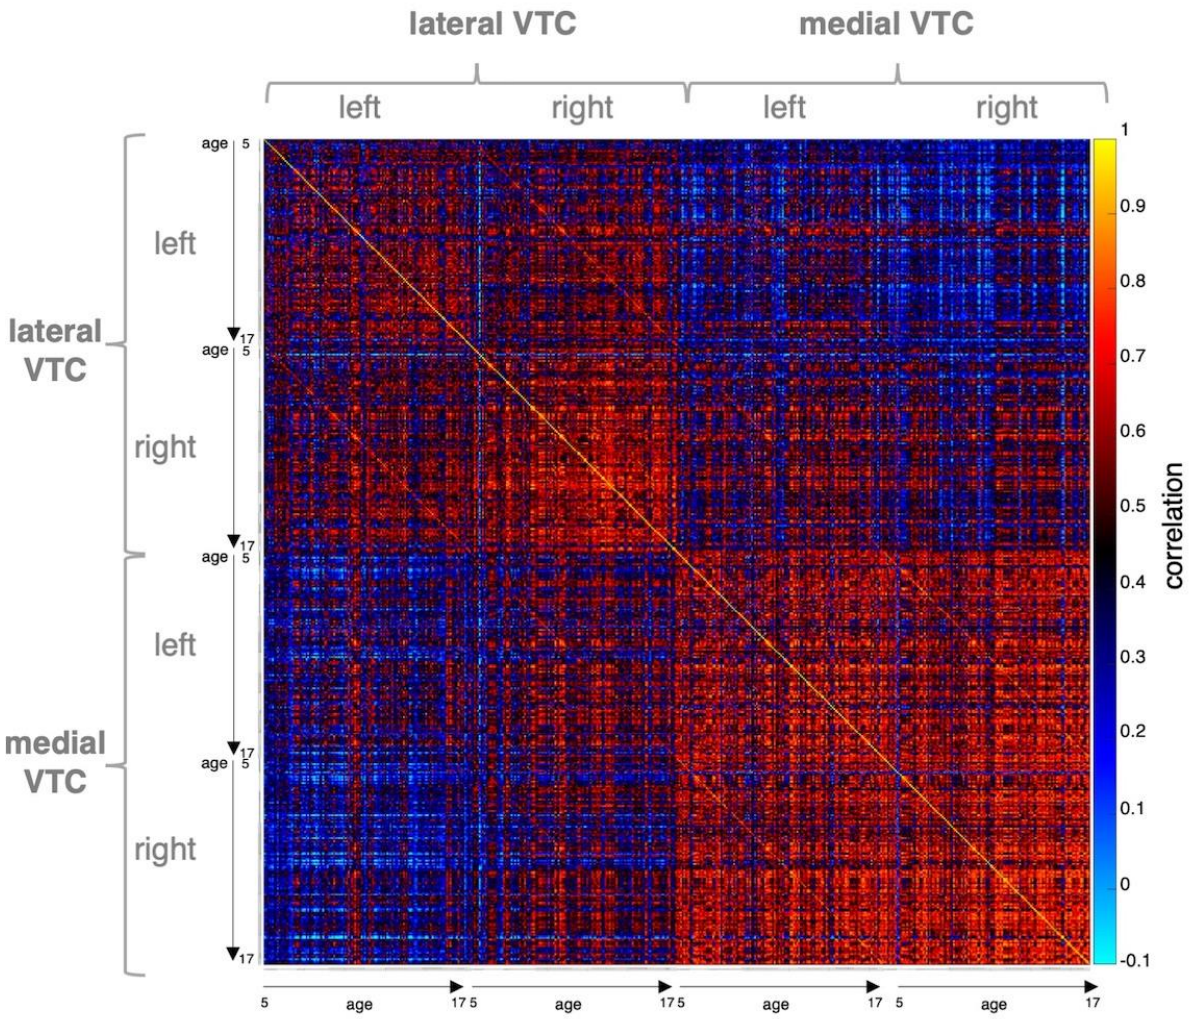

Fig. 1. Development of inter-participant-similarity among representational similarity matrices (RSM) in ventral temporal cortex (VTC). Each cell in this matrix represents the correlation (see color bar) between the lower triangle of RSMs of two sessions (n=128 sessions, 29 children ages 5-17, 18 female). The individual RSM represents the similarity between distributed representations to the 10 categories shown in the experiment (adult faces, child faces, bodies, limbs, words, numbers, cars, string instruments, corridors, houses). The inter-participant-similarity matrix is organized first by age, then by hemisphere, and finally by VTC partition (see notations on the left).

Title: Face representation under partial occlusion in the inferior temporal cortex

Authors: *J. NOROOZI[1,2], M.-R. ABOLGHASEMI-DEHAQANI[3], E. REZAYAT[2], A. SHAHAMATI[2]; [1]Dept. of Physiol., Fac. of Med. Sciences, Tarbiat Modares Univ., Tehran, Iran, Islamic Republic of; [2]Sch. of Cognitive Sci., Inst. For Res. In Fundamental Sci., Tehran, Iran, Islamic Republic of; [3]Sch. of Electrical and Computer Engineering, Col. of Engin., Cognitive Systems Laboratory, Control and Intelligent Processing Ctr. of Excellence (CIPCE), Tehran, Iran, Islamic Republic of

Abstract: One prominent feature of biological visual systems, including our own, is the ability to recognize objects independent of various transformations, such as location and orientation. One of the most dramatic of these transformations is occlusion: While a massive body of previous studies focuses on the representation of occluded objects, only a few studies aimed to address how the challenge of partial occlusion is resolved in our brain. To fully understand how the neural system resolves occlusion, the representation of the occluded object, the occluder items, and their relationship should be distinguished. We examined the inferotemporal (IT) neural responses of macaque monkeys viewing partially occluded faces to address this. The two aspects of occlusion, including type and face identities, vary independently in the stimulus set. We directly addressed the representation of occlusion by investigating how the network of IT neurons process both occluder and occluded objects over time. We applied a combination of encoding and decoding methods to the single and population of recoded neural data to explore the role of the IT cortex in occlusion processing. We found an earlier distinguished representation of occluded **as opposed to** occluder **objects** in IT neurons. Responses of IT neurons to occluded against occluder objects are prominent. While the representation of occluder objects is mainly enhanced in the late time compare to the early time of IT neurons. These observations suggest that the other areas have played an essential role in occluded processing in the IT cortex. The greater cognitive demand of partially occluded object recognition hinted at the contribution of higher-order areas. Together, these results suggested evidence exists for effective feedback originating from the PFC or other areas to the IT cortex during the representation of occlusion.

Title: Interactions between amygdala and cortex during face presentation at fixation and in the periphery

Authors: *K. D. RANA, M. SARGEANT, J. TAUBERT, L. G. UNGERLEIDER, E. P. MERRIAM; Lab. of Brain and Cognition, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Face processing is considered a function relegated to central vision. Supporting this notion are the behavioral observations that human participants tend to fixate on faces. On the other hand, it has also been shown that emotional faces are easily detected in the periphery, and the amygdala is engaged during the presentation of these peripheral faces. These findings suggest that some information about faces can be extracted from the periphery. Our goal was to investigate the functional communication between the amygdala and cortex while manipulating the screen location of faces, relative to fixation. To accomplish this, we measured brain activity using magnetoencephalography scanning during a task in which three images (size: 6 degrees across) were simultaneously presented to the observer, one image at fixation, flanked by two images 8 deg to the left and to the right of fixation. The images could either be a triplet of an object, face, and scene, or one of the aforementioned categories along with two noise images. The noise images were generated by phase-scrambling the images from the other categories. Decoding spectrotemporal activity revealed a bias for centrally-presented stimuli in the temporal lobes, which is consistent with the known central bias of the ventral visual pathway. In the amygdala, however, it was possible to decode between all stimulus locations with theta-band activity, supporting findings that it can discriminate peripherally presented faces. We used the weighted phase lag index measure to track the functional communication in the theta band between the amygdala and the cortex. We found significant theta-band connectivity between the amygdala and prefrontal cortex from 400 ms to 900 ms after stimulus onset. Our results show a delayed engagement between amygdala and prefrontal cortex in the theta band. This suggests a role of amygdala-prefrontal cortex communication in the conscious awareness of visual stimuli with greater socio-emotional meaning.

Title: Dynamic visual feature binding of face and body when perceiving emotional expression

Authors: *M. SARGEANT, K. D. RANA, J. TAUBERT, L. G. UNGERLEIDER, E. P. MERRIAM; Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: While both face and body expression are involved in the perception of emotion, their interaction is not fully understood. We investigated how face and body expression are integrated to influence emotional judgments. How do face and body expressions interact to influence the perception of emotion? What is the temporal evolution of this integration? To answer these questions, we conducted a behavioral experiment in which participants evaluated the emotional expression of images created by

joining faces and bodies. Face and body images were either emotionally congruent, with matching expressions (e.g., fearful body, fearful face), or emotionally incongruent, with unmatched expressions (e.g., fearful body, angry face). Each trial began when participants placed their mouse cursor at a fixed point at the bottom of the screen. The face and body composite image was then presented at fixation. Participants indicated their emotion expression judgment for that face/body combination by moving the mouse to one of the two targets. The trajectory of the mouse was recorded and used to infer the expression judgment over the course of the trial. Our results show that there is a preference for facial expression when identifying emotion on incongruent trials, consistent with previous findings (Solanas et al., 2018; Van de Riet & de Gelder, 2008). Moreover, the deflection of the mouse trace relative to a straight-line trajectory revealed biases in early weighting for both faces and bodies that differed from the eventual judgment on that trial. Our results reveal the utility of using dynamic mouse position for inferring emotional judgments and demonstrate that face and body expressions are dynamically weighted when participants evaluate emotional expressions.

Title: When the whole is equal to the sum of its parts: face-body integration in macaque inferotemporal cortex - fMRI study

Authors: *Y. ZAFIROVA[1,2], D. CUI[1,2], R. VOGELS[1,2];
[1]KU Leuven, Leuven, Belgium; [2]Leuven Brain Inst., Leuven, Belgium

Abstract: Social interactions involve an exchange of information between whole agents, and yet faces and bodies are processed in different brain areas and studied mostly separately (for a review, see Freiwald et al., 2016; Hesse and Tsao, 2020). How their integration unfolds on the neuronal level is unclear. To fill this gap, we conducted 2 fMRI experiments in 2 rhesus monkeys, employing static images on brown noise ($1/f^2$) background in passive fixation task. First, we identified the areas responding more to monkeys, monkey faces (without body), and headless bodies than to matching sets of carefully controlled objects. Face and body activations followed the classical face and bodies patches in the inferotemporal cortex (IT), with the monkey ones residing mainly in overlapping and/or neighboring voxels. In the second experiment, we examined the difference in activation between whole-agent natural (with the head in its original place) and unnatural composites (head attached to a different part of the upper body). Additionally, to estimate the contribution of the parts to the activations to the whole, individual faces and

headless bodies were presented separately, at the same position they appeared in the whole-agent images. We compared the activations to the natural versus the unnatural composites with the sum of the activations to the corresponding bodies and faces in the patches activated more strongly by monkeys compared to objects (ROIs defined with experiment 1). Only monkey patches in anterior IT, at the anterior-posterior level of face patches AL and AM, showed stronger activation to the natural compared to the unnatural composites which was not accounted for by the summed face-body activations. Importantly, the activation to the natural composites equaled the summed face-body activations in anterior IT, while the activation to the unnatural ones was less than the sum of their parts. The subadditive interaction of bodies and faces for the unnatural composites agreed with the classical divisive normalization mechanisms (e.g. Zoccolan et al., 2005). Subadditive activation to the natural whole-agents was found in the extrastriate to posterior IT regions. No evidence for superadditive face-body integration was found in the temporal cortex. In sum, these fMRI data suggest different integrating mechanisms for natural and unnatural composites of bodies and faces in anterior IT.

Title: When the whole is equal to the sum of its parts: face-body integration in macaque inferotemporal cortex - Single unit study

Authors: *A. BOGNÁR[1,2], Y. ZAFIROVA[1,2], R. VOGELS[1,2];
[1]KU Leuven, Leuven, Belgium; [2]Leuven Brain Inst., Leuven, Belgium

Abstract: For successful social interactions, it is essential to exchange information between whole agents, however facial and body information are processed in different brain areas and studied mostly separately. Our study aimed to investigate the interaction between face, body, and whole-agent information in anterior inferior temporal areas of macaques. The targeted patch was identified in an fMRI study that employed the same subjects. The identified patches were activated more strongly by natural (NC) compared to unnatural (UC) composites of whole agents. In the UC stimuli, the face was attached to the wrong part of the upper body. The difference in activation between the NC and UC conditions could not be accounted for by the sum of the activations to the same faces and (headless) bodies that were part of the composites (Zafirova et al. SFN, 2021). The targeted patches were close to face patches AL and AM. We recorded 65 single units from 2 macaques during passive fixation. In the first test, we presented static images of 20 monkeys and 20 objects. The mean response to monkeys was higher than to objects. In the second test, we presented the same 20 NC and 20 UC as employed in the fMRI study. Consistent

with the fMRI activations, the mean response to NC was higher than to the UC stimuli. Based on the responses of this test, we selected 3 monkey stimuli, and manipulations of the one with the highest response was used for the present analyses. We recorded responses to conditions in which the 6 deg wide whole-agent images were centered according to the body or face and the images were mirrored along the vertical axis. Hence, the bodies and the faces were presented equally in the ipsi- and contralateral visual fields. In each condition, we presented NC and UC and the (headless) body and face stimuli that composed the NC and UC stimuli. The face and body-only stimuli were shown at the same position as in the composites. The average response was greater for the NC compared to the UC. To examine how the response to the whole-agent stimuli relates to those to the bodies and faces presented in isolation, we calculated a contrast index: [whole-agent - (body+face)] / [abs(whole-agent) + abs(body+face)] for NC and UC responses using the corresponding body and face responses. In both monkeys and conditions (images centered on bodies or faces), the mean contrast index for NC was higher than for UC. As for the fMRI data, the response to the NC stimuli was on average similar to those of the sum to the body and face responses, while the response to UC was smaller than the summed responses. These data suggest different integrating mechanisms for NC and UC in anterior inferotemporal cortex.

Abstract: Neurons in the human medial temporal lobe (MTL) that are selective for the identity of specific people are classically thought to encode a person's identity invariant to visual features (e.g., skin tone, eye shape). However, it remains largely unknown how visual information from higher visual cortical areas is translated into a semantic representation of an individual person. Here, we show that some MTL neurons are selective to multiple different face identities on the basis of shared visual features that form clusters in the representation of a deep neural network trained to recognize faces. Contrary to prevailing views, we find that these neurons represent an individual's face with feature-based encoding, rather than through association with concepts. The response of feature neurons did not depend on face identity, race, gender, or familiarity; and the region of feature space to which they are tuned predicted their response to new face stimuli. Our results provide critical evidence bridging the perception-driven representation of facial features in the higher visual cortex and the memory-driven representation of semantics in the MTL, which may form the basis for declarative memory.

Title: Microstructurally and functionally distinct fusiform face area(s) in over 1000 participants

Authors: X. CHEN[1], B. J. PARKER[2], Z. ZHEN[1], ***K. S. WEINER**[2];
[1]Beijing NormalUniversity, Beijing, China; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: Determining how visual categories are represented in the brain continues to be a highly debated topic with many different proposed theories. Theoretical debates aside - for example, the ever-popular arguments between modular vs. distributed processing, as well as the role of expertise - there is great interest in cortical networks selective for faces across species. In humans, the Fusiform Face Area (FFA) is a widely studied functional region that is causally involved in face perception. Even though the extended field has been studying the FFA for over two decades, we still lack answers to foundational questions regarding the structure and function of the FFA from a large (N>1000) group of participants. To fill this gap in knowledge, we quantified anatomical and functional features of fusiform face-selective regions in 1080 participants included in the Human Connectome Project (HCP) with a four-fold approach. First, we manually identified fusiform face-selective regions (4,221 in total) in all 2,160 hemispheres to determine incidence rates regarding how often a participant will have 0, 1, or 2 FFAs in a large group of participants for the first time. Second, we extracted macroanatomical (cortical thickness) and microstructural (myelination) features of each region. Third, we quantified functional features (face selectivity and functional connectivity fingerprints) of each region. Fourth, we examined the similarity in spatial patterns of each anatomical and functional feature between pairs of monozygotic (MZ) and

dizygotic (DZ) twins included in the HCP dataset. This approach revealed four main findings. First, ~2/3 of individuals have two FFAs that are macroanatomically, microstructurally, and functionally distinct. Second, pFus-faces/FFA-1 is more face-selective than mFus-faces/FFA-2, and the two regions also have distinct functional connectivity fingerprints. Third, pFus-faces/FFA-1 in the posterior FG is cortically thinner and more heavily myelinated than the more anterior mFus-faces/FFA-2. Fourth, face-selective patterns within each region were more similar in MZ than DZ twins and more so than anatomical gradients of thickness and myelination. Altogether, we show that fusiform face-selective regions are microstructurally and functionally distinct in over 1000 participants for the first time. As we share our areal definitions with the field, future studies can perform novel multimodal analyses that leverage the rich multimodal HCP dataset to explore how anatomical and functional features of these regions relate to cognitive and behavioral metrics also acquired in each participant.

Title: Stimulation of gamma motor neurons in vitro using optogenetics

Authors: R. MANDAWE[1], A. KAREKAL[1], S. K. BYRI[1], D. CHELINE[1], A. OCCIANO[1], S. ORTIZ[1], S. HOCHMAN[2], *K. WILKINSON[1];

Abstract: Gamma motor neurons innervate the intrafusal fibers of the muscle spindle and control muscle spindle length and sensitivity of the muscle spindle afferents. It is challenging to independently stimulate the gamma motor neurons without also recruiting the alpha motor neurons that control the force generating extrafusal fibers. Optical stimulation in mice expressing the blue light gated Channel rhodopsin 2 (ChR2) in motor neurons led to alpha motor neuron recruitment from small to large diameter with increasing optical intensities (Llewellyn, et al., 2010). We hypothesized that gamma motor neurons, which are smaller than alpha motor neurons, will be recruited first in mice expressing ChR2 in ChAT positive motor neurons. The extensor digitorum longus muscle and sciatic nerve were dissected and placed in a tissue bath with oxygenated synthetic interstitial fluid. The sciatic nerve was attached to an extracellular suction electrode that recorded muscle spindle afferent activity. We used a light guide to deliver blue LED light (470nm; 0.5mW-5 mW) to the end of the nerve. We found that lower levels of optical stimulation recruited the gamma motor neurons as evidenced by an increased muscle spindle afferent firing rate. Higher optical intensities recruited alpha motor neurons to produce a twitch muscle contraction. Blocking neuromuscular transmission with alpha bungarotoxin blocked both the LED-induced twitch contractions and increases in muscle spindle afferent firing, eliminating the possibility of

direct optical recruitment of muscle spindle afferents. In some muscle spindle afferents with baseline firing, higher frequencies of optical stimulation led to greater increases in afferent firing rates as expected. Gamma motor neuron stimulation could recruit muscle spindle afferent firing in units that only fired during stretch, however, the recruitment was not always predictable and long lasting changes including the development of baseline firing was sometimes observed. Some of the variability we observed could be due to variable recruitment of dynamic and static gamma neurons or to the recruitment of alpha motor neurons which counteracted the gamma motor neuron induced stretch of the muscle spindle. We predict that a gamma motor neuron specific driver for ChR2 expression will decrease variability and are currently testing mice with ChR2 expression in Npas1 expressing cells, a recently identified gamma motor neuron marker (Blum, et al., 2021). The ability to stimulate gamma motor neurons in vitro will be valuable for studying gamma motor neuron function and screening for intrafusal fiber dysfunction in disease models.

Title: Nucleus Ambiguus Neurons Controlling Swallowing

Authors: *T. COVERDELL, S. ABBOTT, J. CAMPBELL;
Univ. of Virginia, Charlottesville, VA

Abstract: Difficulty swallowing, or dysphagia, affects 1 in 25 adults in the United States annually and is a common complication of neurological conditions in the elderly. Neurological dysphagia can often lead to life-threatening conditions, such as infection, malnutrition, dehydration, choking, and aspiration pneumonia. Thus, there is a great clinical need to understand the neural control of swallowing and how to target its dysfunction. The nucleus ambiguus (nAmb), a region of the hindbrain that provides parasympathetic input to the pharynx, larynx, esophagus, lungs, and heart through the vagus nerve, mediates many different important functions, including swallowing, speech, respiration, and cardiac function. The nAmb's importance in swallowing has been studied; however, little is known about the cellular organization of the nAmb, including whether there are functional subtypes of neurons that may specifically control the esophageal and pharyngeal phases of swallowing. To address these questions, we characterized nAmb neurons based on their transcriptome-wide mRNA expression, anatomy, and ability to control swallowing muscles. Our single-cell transcriptomics analysis of 235 nAmb neurons pointed to three molecularly distinct nAmb neuron subtypes (differentially marked by the genes *Crhr2*, *Vipr2*, and *Tbx3*), which we validated and anatomically mapped by in situ detection of marker transcripts. Of note, the Crhr2 nAmb subtype was found predominantly in the rostral, "compact" nAmb, raising the possibility

that they were esophageal motor neurons. In contrast, the Vipr2 nAmb subtype was found in the caudal, "loose" nAmb, suggesting that they may instead provide pharyngeal/laryngeal control. To test these hypotheses, we used marker-driven genetic technology to label the axon projections of Crhr2 nAmb and Vipr2 nAmb neurons and imaged them in optically cleared esophagus and upper throat samples. Our results show that Crhr2 nAmb neurons project to the esophagus, whereas Vipr2 nAmb neurons innervate the upper esophageal sphincter. Furthermore, optogenetic stimulation of the cell bodies of Crhr2 and Vipr2 nAmb neurons under anesthesia activated swallowing-related muscles of the mouth and upper airway. Focal stimulation of the esophagus caused contractions only in Crhr2 nAmb neurons targeted mice. No change in heart rate or breathing were observed during stimulation of either Crhr2 or Vipr2 nAmb neurons. Together, these studies characterize the genetic, cellular, and functional organization of brainstem neural circuits for swallowing.

Title: Tau from no Tau: Temporal dynamics of Na^+ pump mediated memory traces

Authors: *O. F. MEGWA[1], L. M. PASCUAL[1], S. R. PULVER[2], A. A. PRINZ[1];
[1]Biol., Emory Univ., Atlanta, GA; [2]Sch. of Psychology and Neurosci., Univ. of St Andrews, St Andrews, United Kingdom

Abstract: Na^+ / K^+ ATPases (Na^+ pumps) mediate long-lasting, dynamic ion currents that provide a neuronal memory of previous activity than can last tens of seconds. The mechanisms controlling the dynamics of cellular memory are not well understood and can be counterintuitive. For example, long-lasting memory traces can arise from Na^+ pumps that instantaneously respond to Na^+ concentration changes in the absence of an explicit pump activation time constant. Here, we use computational modelling to examine how pump dynamics without time constants shape cellular memory traces.
In modelling a *Drosophila* larval motor neuron, we incorporated a Na^+ pump, a dynamic intracellular Na^+ concentration, and a dynamic Na^+ reversal potential. The pump current $I_p = I_{p,max} / \{1 + \exp[(NaH - Na)/NaS]\}$ is an S-shaped function of internal Na^+ concentration (Na) with three parameters: maximal pump current ($I_{p,max}$), half-activation concentration (NaH), and a slope factor (NaS) that determines the pump's sensitivity. This model does not include an explicit time constant *Tau* of pump activation. The pump shapes neuronal dynamics by generating an electric current due to an efflux of Na^+ ions and influx of K^+ ions while also changing the intracellular Na^+ concentration and thereby the Na^+ reversal potential. We find that despite the absence of an explicit *Tau*, the pump produces after-hyperpolarizations (AHPs) following bursts of action potentials that can last for multiple seconds, matching experimental data. This

‘*Tau* from no *Tau*’ arises from the interaction of the pump current, membrane currents and the Na^+ dynamics. The AHP duration depends on both parameters NaH and NaS. NaH primarily controls AHP amplitude and NaS controls the AHP duration. More vigorous spiking produces larger amplitude AHPs, but also - counterintuitively - reduces AHP duration. We further show that after the AHP - when the electrical effect of the pump has largely subsided - cellular excitability is still altered, suggesting a cellular memory for previous activity that is not driven solely by changes in membrane potential. This memory trace arises from interactions of the pump with membrane conductances and Na^+ concentration dynamics without slow molecular signaling cascades.
We conclude that even in the absence of an activation time constant *Tau*, Na^+ pumps can encode cellular memories of spiking dynamics. Our work provides testable predictions for physiologists and has implications for understanding information processing in neural networks and the neural control of animal behavior.

Title: Persistent and hyperpolarization-activated inward currents shape fast and slow motoneuron recruitment during postnatal development

Authors: *S. A. SHARPLES, G. B. MILES;
Univ. of St Andrews, St Andrews, United Kingdom

Abstract: The fine control of movement is a prerequisite for complex behaviour and is mediated by the orderly recruitment of slow and fast motor units. The size principle was initially proposed to account for orderly recruitment; however, motoneuron size is a poor predictor of recruitment amongst functionally defined motor unit subtypes. While intrinsic properties of motoneurons are key regulators of motoneuron recruitment, the underlying currents involved are not well defined.
Whole-cell patch-clamp electrophysiology was deployed to study intrinsic properties, and the underlying currents, that contribute to the differential recruitment of fast and slow motoneurons (n = 261). Motoneuron subtypes were identified based on repetitive firing latency in response to a square depolarizing current pulse at rheobase. Motoneurons were studied during the first three postnatal weeks in male and female mice to identify key properties that establish orderly recruitment and contribute to the emergence of fine motor control during this period.
Data revealed that fast and slow motoneurons are functionally homogeneous during the first postnatal week and are recruited based on size, irrespective of motoneuron subtype. The recruitment of fast and slow motoneurons becomes staggered during the second postnatal week due to the differential maturation

of passive and active properties, particularly persistent inward currents (PICs). PICs measured in voltage clamp were larger and activated at a more depolarized voltage in fast compared to slow motoneurons. Subsequent blockade of either NaV1.6 channels with 4,9-anhdrotetrodotoxin (200 nM; n = 22) or L-type calcium channels with nifedipine (20 uM; n = 16) reduced PIC amplitude; however, only blocking NaV1.6 depolarized PIC activation voltage, which translated to an increase in recruitment current.
The current required to recruit fast motoneurons increases further in the third postnatal week, despite no additional changes in passive properties or PICs. This further staggering of recruitment currents reflects development of a hyperpolarization-activated inward current (Ih) in fast motoneurons that is active near resting membrane potential. Subsequent blockade of the resting Ih with ZD7288 (10 uM; n = 21) led to a decrease in the recruitment current and increase in the medium afterhyperpolarization of fast but not slow motoneurons.
Our results suggest that motoneuron recruitment is multifactorial, with recruitment order established during postnatal development through the differential maturation of passive properties and sequential integration of persistent and hyperpolarization-activated inward currents.

Title: Understanding motor sequence generation across spatiotemporal scales

Authors: *A. D. ELLIOTT[1], R. VUONG[1], S. ROY[1], H. SHROFF[2], B. WHITE[1];
[1]NIH/NIMH, Bethesda, MD; [2]NIBIB, NIH/NIBIB, Bethesda, MD

Abstract: Behaviors are produced from a fixed set of neuromuscular connections, yet the brain produces a variety of movements for routine tasks and large number of adaptable responses to external stimuli. Neuromodulators and sensory feedback are two components known to tailor the activity of central pattern generators to adapt motor output to desired goals, though mechanistic detail of these processes remains limited. To investigate these processes, we have been studying a behavioral paradigm in *Drosophila* called the pupal ecdysis sequence in which motor activity can be monitored at single-muscle resolution while manipulating neuromodulatory and sensory input (Elliott et al, eLife, 2021). In this paradigm, sensory input plays a role in initiating behavior, individual movements are determined by a syllabary of co-active muscles, and certain syllables are sensitive to regulation by neuromodulators. Notably, the activity of individual muscles is recruited stochastically. This raised the question of how neuromodulators and sensory input differentially regulate motor output from the CNS. We hypothesize that these inputs operate in equilibrium to balance feedback from the moving body and output from central pattern generators. To test this hypothesis, we have built a custom lightsheet microscope that permits the effects of acute neuromodulatory and sensory manipulations on neural activity to be monitored at single cell resolution. We find that activation of specific proprioceptive inputs and neuromodulator-expressing cells causes distinct changes in motor output. To identify motor neurons that are sensitive to sensory input, we

have generated an expression atlas with lightsheet data aligning neuroanatomical markers and somata of subsets of motor neurons. We are currently measuring motor neuron calcium activity during fictive behavior both in an excised CNS and in a semi-intact fillet preparation that maintains sensory and motor neuron connections and registering the live data to our atlas to tease out which motor neurons are sensitive to sensory input. Our studies promise a detailed description of the regulatory roles played by neuromodulators and sensory neurons in shaping the output of the central pattern generators for an elemental behavioral sequence.

Title: Does Estrogen Influence Fatigue Outcomes in Transcranial Direct Current Stimulation?

Authors: *J. R. DETERS, A. C. FIETSAM, C. D. WORKMAN, T. RUDROFF;
Dept Hlth. & Human Physiol., Univ. of Iowa, Iowa City, IA

Abstract: Transcranial direct current stimulation (tDCS) research is prone to high inter- and intra-subject variability, with approximately 50% of subjects not responding to tDCS or showing effects contrary to the expected response (e.g., inhibition after anodal stimulation). Biological sex may contribute to the marked inconsistency of results across the tDCS literature, possibly due to sex hormones that fluctuate significantly more in women than men. One of the main female sex hormones, estradiol (E2), has been found to endogenously increase cortical excitability. Therefore, administering anodal tDCS when estradiol is high might lead to overexcitation of the target area. Overexcitation may interfere with normal activation patterns in the cortex, thus resulting in decreased performance after tDCS administration. Accordingly, the aim of this study was to assess potential differences in leg muscle fatigability after tDCS administration when E2 was high versus when E2 was unknown. Twelve healthy young (aged 19-34) eumenorrheic women performed an isokinetic fatigue task (FT) after receiving 20 min of 4 mA anodal tDCS over the dominant leg M1 during the phase characterized by the highest E2 levels (late follicular). Subsequently, the subjects were age-matched from a previous study utilizing the same stimulation parameters in which hormone levels were not measured. A torque-derived fatigue index (FI) was calculated from the 40-repetition FT as follows: ([mean of first five reps-mean of last five reps]/mean of first five reps) *100. A higher FI represents a greater difference in torque output between the beginning and the ending of the FT, indicating an increase in fatigability. The results of this comparison revealed higher FI values when E2 levels were evaluated (i.e., the FT was performed when E2 levels were known to be high) versus when E2 was not measured (E2: 64.1 ± 7.77%, No E2: 52.4 ± 15.32 %; $p = 0.03$). Increased fatigability when E2 was high compared to when it was not evaluated indicates that E2 levels may alter functional outcomes in tDCS studies. E2 enhances excitability via increased concentration of glutamate, while tDCS induces excitation through downregulation of GABA levels. Thus, if tDCS is applied when endogenous cortical excitability is already upregulated via high E2 levels, overexcitation

may result in increased muscle fatigability. Importantly, differences in FI values in this study underscore the need to consider sex hormone levels as potential variables. Therefore, including methods for menstrual cycle phase identification into subject evaluations beforehand are critical to addressing the issue of variability in future tDCS studies.

Title: Personal Protective Equipment Alters Leg Muscle Fatigability Independent of Transcranial Direct Current Stimulation or Sex

Authors: *A. C. FIETSAM, J. R. DETERS, C. D. WORKMAN, A. L. COOPER, T. RUDROFF; Univ. of Iowa, Iowa City, IA

Abstract: In response to the COVID-19 pandemic, the use of personal protective equipment (PEE) has increased. However, mandating subjects to wear PPE during vigorous exercise might independently influence the fatigue outcomes in transcranial direct current stimulation (tDCS) studies. Sixteen young healthy subjects (8 females, age range: 20-26) wore PPE during an isokinetic fatigue task (FT) in conjunction with sham, 2 mA, and 4 mA tDCS conditions. The subjects were age- and sex-matched to sixteen subjects who did not wear PPE in our previous pre-pandemic study, in which right knee extensor fatigability significantly increased under these same conditions. A torque-derived fatigue index (FI-T) was calculated as: ([mean of first five reps - mean of last five reps]/mean of first five reps)*100 and a work-dervied fatigue index (FI-W) was calculated as: (total work performed in the last half of the FT/total work performed in the first half of the FT)*100. The results indicated that FI-T was higher (PPE: 60 ± 10%, No PPE: 50.4 ± 6.7%; $p = 0.01$) and FI-W was lower (PPE: 55.2 ± 10%, No PPE: 62.6 ± 5.1%; $p = 0.04$) for the right knee extensors in the sham condition, indicating greater performance fatigability in the PPE study compared to the No PPE study when stimulation was not applied. Additionally, there were no differences in knee extensor fatigability or muscle activity (EMG) between sham, 2 mA, or 4 mA tDCS in the PPE study, which contrasted with the results of the No PPE study. Therefore, a ceiling effect might have already been reached during the sham condition, which then resulted in the null effects of applying 2 mA and 4 mA tDCS and the significant contrast with the No PPE study. These results may also be influenced by the pandemic-altered research environment (i.e., both subjects and researchers wearing PPE) and psychological factors (e.g., anxiety). Moreover, there were no differences in the FI-T, FI-W, or average EMG of the right knee extensors in the PPE study when the responses between males and females were compared. Thus, PPE worn by subjects and researchers might have a detrimental effect on fatigue outcomes in tDCS studies irrespective of stimulation intensity or the sex of the subject.

Title: Map kinase signaling is required for complement-associated clearance of synaptic inputs from injured motoneurons

Authors: *E. ASGHARI ADIB[1], J. SHADRACH[2], B. A. PIERCHALA[2,3], C. COLLINS[1];
[1]Molecular, Cell. and Developmental Biol., [2]Biol. & Material Sci., Univ. of Michigan, Ann Arbor, MI;
[3]Anatomy, Cell Biol. and Physiol., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Innate immune responses via the complement system and activated microglia have been found to direct the loss of synapses in both developmental and disease conditions. A major outstanding question in the field has been to understand how and why some synapses but not others are marked for clearance by complement; in particular, what are the cell-intrinsic mechanisms within neurons that lead to such marking? Our findings have implicated a neuronal kinase in triggering complement-associated synapse loss. Our study has focused on the loss of upstream excitatory inputs from axotomized motoneurons (MNs) following peripheral nerve injury (PNI). Termed 'synaptic stripping', this form of synapse loss is one of the oldest documented forms of microglial-associated synapse loss (Blinzinger K, Kreutzberg G. 1968) while the role of microglia in synaptic stripping has been debated (Alvarez FJ et al. 2020) prior studies have reported a critical role for complement component C3 (Berg A et al. 2012). We found that the deposition of the initiating factor C1q is dramatically induced around injured MN cell bodies following PNI, and that the Dual Leucine Zipper Kinase (DLK) is required cell autonomously in injured MNs for the activation of complement and associated microglial responses to PNI in the spinal cord. DLK is previously known as an axonally localized kinase the regulates multiple responses to nerve injury, including degeneration of the distal axon and the ability of the proximal axon to regenerate (Asghari Adib et al. 2018) MAP Kinase signaling downstream is thought to be mediated retrogradely through axons, placing DLK as an attractive upstream regulator of multiple responses to axonal damage. The activation of complement, innate immunity and synapse loss is a new role for DLK. However, it is consistent with an overarching role for DLK in promoting structural plasticity in the nervous system, enabling adaptive responses to axon damage. We are currently pursuing the mechanism, following a RiboTag approach that has identified genes strongly regulated by DLK in injured MNs following PNI.

Title: Early-life stress may delay puberty in both sexes and alter corticosterone response to acute stress in males

Authors: *A. G. GIBSON[1], S. M. MOENTER[2];
[1]Neurosci. Grad. Program, [2]Mol. & Integrative Physiology, Intrnl. Medicine, and Obstetrics and Gyne, Univ. of Michigan, Ann Arbor, MI

Abstract: Both chronic and acute exposure to stress can alter the neuroendocrine regulation of reproduction. Adverse childhood experiences (ACEs) have profound consequences for physiological development and are important social determinants of health. In humans, ACEs can alter reproductive outcomes including age at menarche, engagement in risky sexual behaviors, and fertility. Early-life stress can also shape the way each physiologic system responds to stress in adulthood, promoting either resiliency or susceptibility to later stress. Adult stress has been independently demonstrated to disrupt fertility. We tested if a mouse model of early-life stress, the limited bedding and nesting (LBN) paradigm, altered reproductive development and the response of adults to an acute stress. CBA dams were crossed with B6 sires expressing GFP under control of the gonadotropin-releasing hormone (GnRH) promoter. Second litters were used to decrease pup loss. Litters were reared under standard conditions (STD) or the LBN paradigm from postnatal days (P) 4 to 11. Dam mass did not differ with treatment from P4 to weaning at P21 (p=0.57). Mean litter mass was the same for STD and LBN litters on P4 (p=0.11). In contrast, at the end of the LBN paradigm on P11, LBN-exposed offspring had a transiently lower body mass (p<0.001) that resolved by P21 (p=0.62). We monitored age at vaginal opening and first estrus in females or at preputial separation in males as external indicators of puberty. There was no difference in age at vaginal opening (p=0.27, n=32 STD, 29 LBN), but there was a trend for delayed first estrus in LBN offspring (p=0.06, n=29 STD, 29 LBN). Preputial separation was delayed by LBN (p=0.01, n=15 STD, 25 LBN). To test if LBN confers susceptibility or resilience to adult stress, we used an acute, layered, psychosocial stress (ALPS) paradigm that disrupts the preovulatory luteinizing hormone (LH) surge when given on the morning of proestrus. In preliminary studies, there was a trend for LBN to reduce the corticosterone response to ALPS in adulthood in male offspring (3-way interaction, p=0.06 n=4 STD-CON, 3 STD-ALPS, 6 LBN-CON, 6 LBN-ALPS). There were no treatment effects on baseline corticosterone levels (ps>0.999). ALPS treatment increased corticosterone in both STD and LBN groups (p<0.001). The interaction may stem from LBN blunting corticosterone response to ALPS (mean±SEM: 392±16.5 ng/mL STD-ALPS, 263±35.4 LBN-ALPS, p=0.22); animal numbers need to be increased to confirm this. Other future work will test the hypothesis that LBN female offspring are less susceptible to the effects of ALPS on corticosterone and that this renders them resilient to acute stress disruption of the LH surge.

Title: Early-life resource scarcity environment alters maternal care and impacts offspring visual development trajectory and physical growth in two strains of inbred mice

Authors: C. BECERRA[1,2], F. DELGADO[1], L. F. PACHECO-OTALORA[1], *G. E. PARDO[1];
[1]Lab. de Investigación en Neurociencias, Univ. Andina del Cusco, Cuzco, Peru; [2]Univ. Nacional de San Antonio Abad del Cusco, Cuzco, Peru

Abstract: Background. Early experiences, especially those related to impaired mother-infant interactions, impact the infant's neuronal and behavioral maturation. Recently, the early-life exposure of mice litters to the limited bedding nesting material (LNB) paradigm has been shown to reduce body weight and delay the eye-opening in offspring of both sexes, suggesting the critical role of early mother-infant experiences on the maturation of the visual system and somatic growth. To understand whether genetic factors also influence these changes, we exposed litters of mice from two inbred strains with phenotypic differences in stress susceptibility (C57BL/6NCrl and BALB/c) mice LBN paradigm. Then, we compare the dams maternal care profile and somatic growth and maturation of the visual system of the offspring. **Methods**. The maternal behavior of control and LBN dams was evaluated on 3 to 9 pups' days of life. During the postnatal day (PND) 2 to 9, a group of litters of both strains were exposed to the LBN protocol. From PND 10 to PND 22, pups of each litter were weighed daily and examined to verify the occurrence of eye-opening. **Results**. We found that LNB stress during PND 3-9 altered the maternal care profile of mice two strains differently. C57BL/6NCrl dams exposed to LNB significantly increased the presence in the nest, the exits from the nest (sorties), and nest-building behaviors. In contrast, BALB/c dams exposed to LBN increased the presence in the nest just during PND 5-7 with no changes in the sorties or nest-building behaviors. LNB exposed pups, for both strains, had their eye-opening occurring progressively between PND 12 and 21, although, for the BALB/c strain, this process began and ended earlier than for the C57BL/6NCrl strain. Exposure to the LBN protocol delays eye-opening in both strains, although significantly impacting the C57BL/6NCrl strain, which considerably delays the start and end of eye-opening, mainly in females. Likewise, exposure to the LBN protocol decreases body weight in the offspring of both strains, specifically during the periods PND 10-12 and PND 19-22, with a more significant impact on females of the C57BL/6NCrl strain. **Conclusions**. These data show that although both strain dams have slightly different maternal behavior profiles, both seem to deal differently with exposure to the LBN protocol. Exposure to an early adverse environment can alter specific neural circuits' trajectory and maturation rate in the genetic background sex-dependent manner of the offspring. These results can contribute to understanding individual variations in the long-term effects of stress in early life.

Title: Early life adversity potentiates adult response to acute threat: A brain-wide imaging and behavior study

Authors: T. W. USELMAN[1], R. E. JACOBS[2], *E. L. BEARER[1,3];
[1]Dept. of Pathology, Univ. of New Mexico Hlth. Sci. Ctr., Albuquerque, NM; [2]Zilkha Neurogenetic Inst., USC Keck Sch. of Med., Los Angeles, CA; [3]Biol. and BioEngineering, Caltech, Pasadena, CA

Abstract: Adverse childhood experiences increase vulnerability later in life to stress-provoked mental illnesses, such as anxiety/depression and substance use disorders. How these experiences shape the brain in ways that lead to such disorders remains a mystery. Brain-wide imaging of neural activity in the adult raised with or without early life adversity (ELA) holds promise of finding clues. Longitudinal manganese-enhanced magnetic resonance imaging (MEMRI) provides a methodology to follow brain-wide neural activity dynamics over time in awake-behaving animals. Mn(II) delivered systemically is enters active neurons through voltage-gated calcium channels throughout the brain over 22-26h. Behavior is recorded in our custom arena during Mn(II) uptake. We capture an image of normal exploration at 22h, and then expose mice to predator odor (TMT, 2,3,5-Trimethyl-3-thiazoline), a naturalistic acute threat, and reimage at 26h (Uselman et al, 2020). Here we apply MEMRI paired with behavior to investigate ELA effects on responses to TMT in normally reared (n=12) and maternally deprived mice (n=24, ± ELA). Dams with newborn pups were deprived of adequate bedding from day P2-P9, which induces elevated cortisol in the pups (Rice et al., 2008). At 10 weeks of age, mice ± ELA were subjected to our paired behavior-MEMRI longitudinal procedure for both acute and delayed responses. After imaging, mice are sacrificed, brains perfusion-fixed and serial sections stained by immunohistochemistry. MEMRI images were skull-stripped, spatially co-registered, and intensity normalized. To measure the degree of activity and relationships between brain regions we performed statistical parametric mapping (SPM), segmentation of 110 brain regions, cross-correlation analysis, and Louvain community detection. Predator stress increased defensive/avoidance behavior for both groups ($p<0.05$, Tukey-Adjusted), attesting to the expected effect of the TMT. Basal neural activity of ELA mice resembled that of acute fear in normally reared mice, with increased activity in the basal forebrain and hindbrain. Additionally ELA resulted in decreased correlations of Mn(II) accumulations between brain segments, which fragmented further after acute threat. Staining for the norepinephrine transporter revealed clumping of distal projections, suggesting that neural activity dynamics could be due in part to ELA's effect on development of the noradrenergic system. Together our data find that ELA disrupts the arborization of noradrenergic projections and fragments neural activity in both basal state and during acute threat. Supported by NIMH RO1MH096093.

Title: Effects of a maternal high-sucrose diet on fetal rat brain development

Authors: *D. R. SEIB, G. V. KACHKOVSKI, G. S. RUTLEDGE, H. W. CHEN, T. S. BODNAR, H. R. PRICE, A. C. COLLIER, K. K. SOMA;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Consumption of sucrose (table sugar) is high in much of the world. The effects of a maternal diet high in sucrose on the placenta and fetal brain remain unknown. In rats, maternal consumption of sucrose at a human-relevant level has effects on the mother's physiology and steroids, as well as long-lasting and sex-specific effects on the adult offspring's brain and behavior. In mothers, there are metabolic effects of sucrose intake, such as impaired glucose tolerance, increased liver lipids, and increased adipose inflammation. In mothers, sucrose intake also decreases corticosterone levels in the blood but not in the brain. In the adult male offspring, preference for a high-sucrose and high-fat diet increases due to maternal sucrose intake. Maternal sucrose intake also increases motivation for sugar rewards in a progressive ratio task in adult male offspring. In adult female offspring, corticosterone levels increase in the blood and brain as a result of maternal sucrose intake. In this study, we investigated the underlying mechanisms of the observed behavioral and endocrine effects in the adult offspring. Here, we examined cytokines and anti-inflammatory steroids in the placenta, amniotic fluid, and fetal blood and brain. In our model, we feed rat dams either a high-sucrose diet (26% of kCal) or an isocaloric, matched, control diet (1% sucrose) 10 weeks prior to and during gestation. At embryonic day 19 (E19), we collected maternal blood, placenta, amniotic fluid, fetal blood, and fetal brain. We use Palkovits punch to microdissect the placenta and fetal brain. Next, we use a liquid chromatography-tandem mass spectrometry (LC-MS/MS) assay, which is highly precise and specific, to measure multiple steroids (e.g. corticosterone, estrone, allopregnanolone). The method is highly sensitive, and we can measure neurosteroids in multiple regions of the fetal brain (e.g. prefrontal cortex, nucleus accumbens, hypothalamus, hippocampus). Moreover, we will examine steroidogenic enzymes and cytokines in the fetal brain and placenta. We will also examine neuronal proliferation, microglia and tyrosine hydroxylase immunoreactivity in the fetal brain. Current data show that maternal high sucrose diet leads to a 60% increase in dehydrocorticosterone (inactive metabolite of corticosterone) and a 100% increase in aldosterone in the dam's serum and amniotic fluid. Testosterone and androstenedione were significantly higher in the amniotic fluid of male fetuses than female fetuses. Ongoing experiments will examine how a maternal high sucrose diet affects brain development possibly by increasing inflammation.

Title: Adolescent Stress Confers Resilience to Traumatic Stress in Adulthood: Role of the Prefrontal Cortex

Authors: *N. NAWREEN[1], E. M. COTELLA[1], R. D. MOLONEY[2], S. E. MARTELLE[3], K. M. OSHIMA[4], P. LEMEN[5], J. NIBLACK[5], R. JULAKANTI[5], M. FITZGERALD[5], M. L. BACCEI[7], J. P. HERMAN[6];

Abstract: Stress during adolescence is usually associated with psychopathology later in life. However, under certain circumstances, developmental stress can promote an adaptive phenotype, allowing individuals to cope better with adverse situations in adulthood, thereby contributing to resilience. The aim of the study was to understand how adolescent stress alters behavioral and physiological responses to traumatic stress in adulthood. Sprague Dawley rats were subjected to adolescent chronic variable stress (adol CVS) followed by single prolonged stress (SPS) in adulthood. One week after SPS, animals were tested for acquisition, extinction, extinction recall and reinstatement of auditory-cued fear conditioning, with neuronal recruitment during reinstatement assessed by Fos expression. Patch clamp electrophysiology was performed to examine physiological changes associated with resilience. We observed that adol CVS blocked SPS-induced impairment of extinction learning (males) and enhancement fear reinstatement (both sexes). SPS effects were associated with a reduction of infralimbic (IL) cortex neuronal recruitment after reinstatement in males and increased engagement of the central amygdala in females, both of which were also prevented by adol CVS. We explored the mechanism behind reduced IL recruitment in male rats by studying the intrinsic excitability of IL pyramidal neurons. SPS reduced excitability of IL neurons and prior adol CVS prevented this effect, indicating that adolescent stress can impart resilience to the effects of traumatic stress by modification of IL output in males. Overall, our study suggests that prior stress exposure can limit the impact of a subsequent severe stress exposure in adulthood, effects that are mediated by sex-specific modification of infralimbic and amygdala signaling.

Title: Intracerebroventricular infusion of corticosterone in neonatal mice

Authors: *H. BAJAJ[1], M. X. LI[1], K. M. GRAY[2], J. E. HAMDEN[3,4], M. SALEHZADEH[3,4], S. MCERLANE[5], K. K. SOMA[1,3,4];

Abstract: Early life stress (ELS) has profound effects on brain development and function. Stressors activate the hypothalamic-pituitary-adrenal (HPA) axis, resulting in increased glucocorticoid (GC) secretion from the adrenal glands into the blood. Low GC levels in early life are crucial for normal neurodevelopment, and high GC levels lead to increased neuronal death and dendritic atrophy. Recent evidence suggests that, in early life, the brain can locally produce GCs, independently from the adrenal glands. Current ELS paradigms use manipulations that elevate circulating GC levels, such as maternal separation, endotoxin exposure, and systemic corticosterone administration (p.o., i.p. or s.c.). No study has delivered corticosterone directly to the developing brain. Here, we developed a simple and robust technique to administer corticosterone directly to the neonatal brain via a single intracerebroventricular (ICV) infusion into a lateral ventricle. Local anesthetic (lidocaine) was applied to the scalp of male and female postnatal day 5 (PND5) C57BL/6J mice. After 8 minutes, we administered 2 µL of either sterile saline (vehicle control) or corticosterone (5, 10, 15, or 45 ng/mL) (n=8/group) with a single ICV infusion. After 2.5 hours, we collected the brain, whole blood, and liver. Corticosterone concentrations were assessed via liquid chromatography tandem mass spectrometry (LC-MS/MS) in microdissected brain regions, whole blood, and liver. With higher doses of corticosterone, brain levels of corticosterone increased, whereas peripheral levels of corticosterone remained low. This study provides a novel paradigm to administer corticosterone directly to the brain without general anesthesia, which is a potent stressor. Our paradigm can be used to specifically manipulate levels of corticosterone, or other neuromodulators, in the brain of neonatal mice.

Title: Functional connectivity at term equivalent age predicts frequency of neonatal intensive care unit procedures in infants born very preterm using machine learning.

Authors: *K. M. COOK, J. DE ASIS-CRUZ, J.-H. KIM, N. ANDESCAVAGE, S. K. BASU, A. J. DU PLESSIS, C. LIMPEROPOULOS;
Children's Natl., Washington, DC

Abstract: Compared with full-term infants, Extreme and Very Preterm (EPT/VPT) infants born <32 gestational weeks (GW) are at increased risk of long-term motor, cognitive, and neuropsychological disorders, including autism, ADHD, and schizophrenia. The third trimester is a critical period for cortical development and the prematurely ex-utero neonatal intensive care unit (NICU) environment, which includes sensory overload and frequent stressful procedures (e.g., heel pricks, nasogastric tube placements, and catheterizations), is a putative contributor to the long-term neurodevelopmental sequelae of EPT/VPT survivors. To further address the role of NICU stress on brain connectivity at term equivalent age, we performed resting state fMRI at mean 39 GW in 62 EPT/VPT-born infants with no/minor brain injury. Using functional connectivity between 90 anatomically defined ROIs, we utilized linear support vector regression (SVR) to predict the total number of NICU stressful procedures (mean = 118.79, range = 55-197) between birth and term equivalent age. First, 20% of the sample (n=12) was withheld to perform feature selection through elastic net regularization, reducing the total number of connections to 122 (~3% of the original 4005). Subsequently, the remaining 80% of the data were split into 1,000 random 70%-10% (n=44/6) training-test sets. A separate SVR model was then trained for each split using 10-fold cross validation. Mean test accuracy across splits was $r = 0.646$ with a RMSE of 29.81 (20% of the range). Importantly, although there is a strong correlation between GW at birth and the number of NICU procedures ($r = -0.48$, $p < 0.001$), our SVR model was unable to reliably predict age at birth ($r = 0.09$, RMSE = 2.39) suggesting that we successfully isolated features sensitive to NICU stress, not those simply those related to GW at birth. The 122 edges were then characterized, calculating the mean model beta weights for across all 1,000 procedure prediction models. Across edges, 72 (60%) exhibited a negative relationship between connectivity strength and procedure number - heavily represented in the right inferior temporal gyrus and left precentral gyrus, paracentral lobule, and supplemental motor area. Positive relationships between connectivity and procedure number were observable in the fusiform gyrus and orbital frontal regions. Our results support the notion that NICU stress exposure is associated with altered functional brain connectivity in EPT/VPT infants at term age, independent of gestational age at birth, and may implicate mechanistic precursors to developmental deficits.

Title: Guanfacine acts upon BNST alpha2a adrenergic heteroreceptors to increase calcium activity in a pro-reinstatement circuit-specific manner

Authors: *J. A. BROWN[1,2], A. Y. JIN[1,2], S. W. CENTANNI[3,2], M. N. BEDENBAUGH[3,2], R. B. SIMERLY[3,2], D. G. WINDER[3,2];
[1]Pharmacol., [2]Vanderbilt Ctr. for Addiction Res., [3]Mol. Physiol. and Biophysics, Vanderbilt Univ., Nashville, TN

Abstract: Guanfacine, an alpha2a-adrenergic receptor (α_{2a}-AR) agonist, decreases anxiety associated with drug withdrawal and reinstatement behavior, but its mechanisms of action are unknown. We recently found that α_{2a}-ARs also play a role in driving reinstatement of drug seeking behavior, potentially through activation of the bed nucleus of the stria terminalis (BNST). We have shown that guanfacine activates and inhibits cells in the BNST and has pro-reinstatement effects. Here, we investigated the activity and circuitry of BNST cells activated by guanfacine, termed "guansembles". We applied a Fos-TRAP (*T*argeted *R*ecombination in *A*ctive *P*opulations) approach and validated this as a viable method to investigate guansembles by finding that repeated exposure to guanfacine activates overlapping cell populations. We combined this Fos-TRAP approach with cre-dependent GCaMP fiber photometry to record *in vivo* calcium dynamics in guansembles following exposure to guanfacine and during restraint stress. Guanfacine and restraint stress increased and decreased neuronal activity in guansembles, respectively. The effect of restraint stress on guansembles attenuated over time with repeated restraint. Next, we paired Fos-Trap with a cre-dependent PKA sensor, FLIM-AKAR, and used fluorescence lifetime photometry (FLiP) to record from guansembles *in vivo* to test the hypothesis that guanfacine regulates cAMP signaling in these cells. Results suggest that guanfacine inhibits PKA signaling in guansembles, consistent with activation of a Gi-coupled GPCR. We also observed a decrease in PKA signaling during acute restraint stress. To investigate the neural circuits in which guansembles participate, we utilized a FosTrap-guided retroviral rabies tracing approach to explore the monosynaptic connections onto BNST guansembles. Using tissue clearing and light sheet microscopy, we visualized and quantified BNST guansemble afferents. This approach revealed multiple areas including regions of the thalamus, hypothalamus, and the striatum. These results support guanfacine's activation of pro-reinstatement circuitry. Overall, this study identified Fos-TRAP as a viable method to study guansembles. Our *in vivo* neuronal activity studies support the hypothesis that guanfacine has an excitatory post-synaptic signaling effect on neuronal activity. Our tracing studies revealed guanfacine activation in a potentially novel pro-reinstatement circuit. Understanding the microcircuitry involving BNST guansembles has the potential to uncover the regulatory mechanisms underlying stress-induced reinstatement and α_{2a}-AR agonists as an effective therapeutic.

Title: Determining the role of BNST GluN2D expression in active coping bouts during repeated restraint stress

Authors: *M. A. DOYLE, J. A. BROWN, G. J. SALIMANDO, D. N. ADANK, D. G. WINDER; Vanderbilt Univ., Nashville, TN

Abstract: Alcohol use disorder (AUD) is a chronic, relapsing disease that is highly comorbid with anxiety and depression. These states of negative affect experienced during withdrawal are hypothesized to drive alcohol seeking and relapse behavior. The bed nucleus of the stria terminalis (BNST) is a brain region responsible for the integration of negative affect and alcohol-related behaviors, and it has been implicated in stress-induced ethanol seeking in rodent models. Our lab recently identified a significant decrease in BNST mRNA transcript expression of the NMDAR subunit GluN2D (*grin2d*) during protracted withdrawal from chronic ethanol in female mice, a timepoint at which these animals display increased anxiety- and depressive-like behaviors. Consistent with these data, mice lacking GluN2D show basal increases in anxiety- and depressive-like behaviors. Notably, our lab has shown that BNST knockdown of GluN2D is capable of inducing this phenotype, suggesting a role for BNST GluN2D-containing NMDARs in regulating negative affect; however, it remains unknown if GluN2D expression is capable of modifying behavioral responses during stressful stimuli. As coping strategies in response to stressors have been linked to stress susceptibility, we sought to characterize the effect of constitutive GluN2D knockout on active coping bouts measured during a repeated restraint stress paradigm in male and female mice. EthoVision and DeepLabCut were used to analyze movements. We found a significant Sex x Genotype interaction in both the total duration of time spent in active coping bouts and the average duration of these bouts, with a trend in total bout counts. Current work in the lab focuses on characterizing protein level changes in GluN2D expression, with preliminary data suggesting that BNST GluN2D levels may be decreased following acute and repeated restraint stress in male but not female mice. In parallel, ongoing studies seek to use pharmacological approaches to better define the potential implication of changes in active coping bouts. Future directions aim to characterize the role of GluN2D expression in the interaction of chronic ethanol exposure and stress, as preliminary data suggest that GluN2D constitutive knockout mice exhibit a deficit in BNST short term potentiation following chronic intermittent ethanol exposure. Together, given the restricted CNS expression of this subunit, exploration of GluN2D control of stress circuit actions may lead to a novel therapeutic target to consider in AUD treatment.

Title: Zebrafish pallial eversion demystified: Lhx5- and vGlut2a-driven GFP-expressions in zebrafish identify missing links to the mammalian amygdala

Authors: *T. MUELLER;
Kansas State Univ., Manhattan, KS

Abstract: The telencephalon zebrafish, a carp-like (cyprinid) teleost fish, shows an outwardly-grown (everted) morphology, that looks very different from inwardly grown (evaginated) forebrains of mammals. For more than a century, comparative neurologists have struggled to explain how the everted forebrain can be compared with those of mammals in terms of homology and evolution. Some classical studies on the teleostean forebrain suggested that radial glia orientation and tela attachment sites speak in favor of a simple eversion process resulting in a telencephalic topology that is incomparable at large to the mammalian situation (Nieuwenhuys 2009). Likewise, recent fate mapping and genetic birth dating studies (Furlan et al. 2017) in zebrafish supported a simple outward-in pallial organization similar to those of classical studies and in support of the increasingly popular yet wrong idea that the teleostean/actinopterygian telencephalon strongly deviates from the prosomeric organization of tetrapods (Yamamoto, Bloch, and Vernier 2017).
Here, I will present results of a larger scale analysis of the distribution of molecular architecture versus *vGlut2a*- and *lhx5*-driven green fluorescent protein (GFP) expression in adult transgenic reporter lines in comparison to GFAP, which labels radial glia and their processes (Porter and Mueller 2020). The detailed analysis of these molecular expression patterns let us discover the missing evolutionary links between the evaginated and everted telencephalon ground plan allowing us to determine the true nature of major pallial and subpallial territories with respect to their homologies in tetrapods. Specifically, we identified previously overlooked parts of the thalamic eminence (EmT) and a subnucleus of the medial amygdala, which we called the posterior medial amygdala/rostral EmT (MeAp/EmTr). What is more, based on our analyses of both radial glia distribution and the tela attachment sites in relationship with the olfactory pallial divisions, we explained the topology of the everted telencephalon and re-defined pallial, subpallial, and EmT derivatives of the extended olfactory amygdala and in adult zebrafish. The results show that the teleostean telencephalon is the result of a complete and complex eversion. At large, our results indicate that a prosomeric amygdala ground plan as well as a homolog to the mammalian isocortex evolved in a common ancestor of teleosts and tetrapods.

Title: Cortical granularity shapes the organization of afferent paths to the amygdala and its striatal targets in nonhuman primate

Authors: *A. C. MCHALE[1], Y. T. CHO[2], J. L. FUDGE[1];
[1]Del Monte Inst. for Neurosci., Univ. of Rochester Med. Ctr., Rochester, NY; [2]Yale Univ., New Haven, CT

Abstract: The prefrontal cortex (PFC) and insula, amygdala, and striatum form interconnected networks that drive motivated behaviors. We previously found a connectional trend in which the relative granularity of the ventromedial and orbital PFC/insula predicted afferent connections to specific regions of the basal nucleus, and also the topography of efferent connections in amygdalo-striatal paths, in the same animal (Cho et al 2013). To further interrogate the relationship between cortex, amygdala, and striatum, and to better define the 'limbic (amygdala-recipient) striatum', we conducted tract tracing studies in two cohorts of primates (*macaque fasicularis;* Male n = 12, Female n = 1, mean weight = 4.46 kg, mean age = 4.9 years; Cohort 1: n = 8 animals & 11 total injection sites; Cohort 2: n = 6 animals & 6 total injection sites). We used an analytic strategy based on a cortical granularity index to define the topography of cortico-amygdalo-striatal (indirect) and cortico-'limbic' striatal (direct) paths originating in the entire PFC and insula. Using a quantitative approach, we found that the level of cortical granularity predicts the complexity and location of projections to both the basal nucleus of the amygdala and striatum. Remarkably, 'cortical-like' basal nucleus subdivisions also followed these rules in their projections to the striatum, defining the 'limbic' striatum. The ventral basal nucleus was the 'foundational' input, with progressively more dorsal basal nucleus regions gradually adding inputs as the 'limbic striatum' extended caudally. In both 'direct' and 'indirect' paths to the 'limbic' striatum, agranular cortices formed a 'foundational', broad projection, and were joined by inputs from progressively more differentiated cortices. Together, the 'indirect' and 'direct' paths follow consistent rules dictating projection strength and complexity to their striatal targets. Within this general rule, subtle differences in the indirect and direct paths were found. In cortico-amygdalo-striatal paths (indirect), we found that agranular cortices consistently dominate amygdala inputs to the striatum; in contrast, cortical (direct) inputs to these 'limbic' (amygdala-recipient) striatal sites create gradual shifts in connectivity fingerprints, with differences along the rostro-caudal axis of the 'limbic' striatum.

Title: Localization and contribution of basal forebrain GABAergic input to the basolateral amygdala

Authors: T. TUNA[1], T. BANKS[2], M. STROUD[2], S. S. NAIR[2], *G. UNAL[1];
[1]Bogazici Univ., Istanbul, Turkey; [2]Univ. of Missouri, Columbia, MO

Abstract: Basal forebrain (BF) GABAergic neurons from the medial septum selectively target GABAergic interneurons of the hippocampus, contributing to the excitability of the principal neurons (PNs). This projection is key for the generation of hippocampal theta oscillations (4-12 Hz), which correlate with hippocampal forms of learning and memory. There is a similar BF GABAergic projection to the basolateral amygdala (BLA) with unclear electrophysiological and functional role. We hypothesize that BF GABAergic projections carry out a similar neuromodulatory function in all of their target limbic structures by regulating local network activity via phase-dependent disinhibition of the principal cells. To test this hypothesis, we localized BLA-targeting BF cell groups by retrograde tract-tracing, and revealed their molecular profiles by fluorescent immunohistochemistry in male Wistar rats. The densest retrograde labeling was observed in the horizontal diagonal band (hDB), ventral pallidum (VP) and substantia innominata (SI) nuclei. We observed BLA-projecting parvalbumin (PV)-immunopositive or calbindin (CB)-immunopositive putative GABAergic neurons in the VP. The PV+ subgroup consisted of 5% of the retrogradely-labeled VP neurons and 12% of its PV cell population, whereas the CB+ subgroup was about 13% of the labelled neurons and 10% of the VP CB population. Anterograde tract-tracing with PHA-L suggest that both groups target putative GABAergic interneurons in the BLA. To shape and complement ongoing in vivo electrophysiological experiments, we developed a 1000-cell biophysical BLA model by incorporating tested properties of an earlier hippocampal network model (Hummos & Nair, 2017). Single cell models were created for PNs as well as PV+, somatostatin+, and calretinin+ BLA interneurons. The afferents comprised of excitatory thalamic/cortical inputs, rhythmic BF GABAergic projections, and modulatory BF cholinergic input introduced at three different states (low, baseline and high). Synaptic communication was modeled with AMPA, NMDA, $GABA_A$, and $GABA_B$ currents. To mimic the aforementioned phase-dependent disinhibition, 90% of the BF GABAergic input was given to the PV+ interneurons while 10% was directed to the PNs. As hypothesized, local theta oscillations arise when both the cholinergic and the GABAergic input from the BF are present in addition to the excitatory thalamic/cortical input. Following the case in the hippocampus, removing the cholinergic or the GABAergic BF input alone decreases the BLA theta power. The oscillation ceases completely when the GABAergic input is cut together with either the cholinergic or the thalamic/cortical input.

Title: Activation of lateral parabrachial nucleus pituitary adenylate cyclase-activating polypeptide afferents in the bed nucleus of the stria terminalis increases anxiety-like behavior

Authors: *M. N. BOUCHER[1], S. K. MORIARTY[1], E. B. KOTLER[1], M. R. RICE[1], V. MAY[2], S. E. HAMMACK[1];
[1]Psychological Sci., Univ. of Vermont, Burlington, VT; [2]Dept Neurolog. Sci., Univ. of Vermont Col. of Med., Burlington, VT

Abstract: In order to improve treatments for stress-related psychiatric disorders it is important to understand the neural circuitry underlying emotional behavior. The bed nucleus of the stria terminalis (BNST) has been long studied for its role in many stress related pathologies, such as anxiety, pain, depression, and addiction. Our prior work has demonstrated that pituitary adenylate cyclase-activating polypeptide (PACAP) receptor activation in the BNST is both necessary and sufficient for many of the behavioral consequences of chronic stress, as well the stress-induced reinstatement of cocaine seeking behaviors. While the BNST contains local PACAP-expressing neurons, a major source of afferent PACAP is the lateral parabrachial nucleus (LPBn), and we have previously shown that excitotoxic lesioning of the LPBn substantially decreased PACAP immunostaining in the BNST. Here, we used chemogenetic techniques to selectively activate LPBn PACAP afferents in the BNST. We injected AAV2.hSyn.DIO.hM3D(Gq).mCherry, Cre-dependent AAVs containing excitatory designer receptors exclusively activated by designer drugs (DREADDS), into the LPBn of PACAP-IRES-Cre mice. Immediately before behavioral testing, CNO was infused directly into the BNST. We found that after selective activation of LPBn PACAP afferents in the BNST, mice spent significantly less time in the open arms of the elevated plus maze compared with controls, while total locomotor activity was not affected. These results indicate that activation of PACAPergic LPBn projections to the BNST may play an important role in producing anxiety-like behavior. On-going studies are examining whether the anxiogenic effect of LPBn PACAP afferent activation is dependent on BNST PACAP receptor activation.

Title: The role of noradrenergic signaling from the solitary nucleus to the central amygdala in post-trauma threat responses and autonomic function

Authors: *C. E. STELLY[1], K. J. ANDERSON[1], A. M. HALL[1], J. P. FADOK[2], J. G. TASKER[3]; [2]Psychology and Tulane Brain Inst., [3]Cell and Mol. Biol., [1]Tulane Univ., New Orleans, LA

Abstract: After traumatic stress, a subset of individuals develop pathological changes in behavior and autonomic function. Norepinephrine (NE) signaling is implicated in the pathophysiology of post-traumatic stress; however, studies have focused primarily on one of two sources of NE projections, the locus coeruleus. The solitary nucleus (NTS) also provides noradrenergic innervation to subcortical structures, including the central amygdala (CeA), a key brain region for generating behavioral and autonomic responses to threat. Persistent fear responses that interfere with daily activities and hyperarousal are dissociable outcomes of trauma. We employed two stress paradigms to model these respective outcomes in mice and examine the contribution of noradrenergic NTS projections. Persistent, generalized fear was elicited with discriminative fear conditioning. In this paradigm, fear cues suppressed ongoing reward-seeking, and this conditioned suppression effect increased in magnitude and generalized to neutral cues over several weeks. Hyperarousal was elicited by a single traumatic footshock followed by repeated, brief exposures to a distinct but associated 'reminder' context. In this paradigm, a subset of mice (50%) displayed a sensitized acoustic startle response and an increased resting heart rate. To test the necessity of the NTS-CeA projection for these outcomes, Gi-DREADDs were expressed selectively in noradrenergic NTS neurons and activated by local agonist infusion in the CeA.

Title: Melanocortin 4 receptor stimulation prevents antidepressant-associated weight gain in mice caused by long-term fluoxetine exposure

Authors: *M. J. ORTUNO ROMERO[1], M. SCHNEEBERGER PANE[2], A. ILANGES[2], F. MARCHILDON[2], K. PELLEGRINO[2], J. M. FRIEDMAN[2], P. DUCY[1];

Abstract: Contrasting with the predicted anorexigenic effect of increasing brain serotonin signaling, long-term use of selective serotonin reuptake inhibitors (SSRIs) antidepressants is correlated with body weight gain. This adverse outcome increases the risk of transitioning to obesity and interferes with treatment compliance. We show that orally administered fluoxetine (Flx), a widely prescribed SSRI, increases body weight by enhancing food intake in healthy mice at two different time points and through two distinct mechanisms. Within hours, Flx decreases the activity of a subset of brainstem serotonergic neurons by triggering autoinhibitory signaling through the serotonin Htr1a receptor. Upon longer treatment, Flx blunts serotonin Htr2c receptor expression/signaling, decreases the phosphorylation of Creb and Stat3 and dampens the production of pro-opiomelanocortin (POMC)/alpha-melanocyte-stimulating hormone (α-MSH) in hypothalamic neurons, thereby increasing appetite. According with the fact that α-MSH suppresses appetite by signaling through the melanocortin 4 receptor (Mc4r), exogenous stimulation of Mc4r by co-treating mice with Flx and lipocalin-2, an anorexigenic hormone signaling through this receptor, normalizes appetite and body weight. Flx and other SSRIs also inhibit CREB/STAT3 phosphorylation in a human neuronal cell line suggesting that these non-canonical effects could contribute to the weight gain observed in long-term users of SSRIs. By defining the molecular basis of the long-term SSRIs-associated weight gain our study proposes a therapeutic strategy to counter it.

Title: Decreases in DNA 5-hydroxymethylation within the hypothalamus control weight gain in a sex-specific manner during the development of obesity

Authors: *T. MCFADDEN[1], M. MUSAUS[2], K. FARRELL[1], A. SALAUATOVA[2], H. DURAISWAMY[3], T. J. JAROME[4];

Abstract: Obesity affects about 34% of the U.S. population and is a major contributing factor associated with health risks such as cancer, heart disease, and diabetes. Understanding the neurobiology of obesity is

crucial for responding to the etiology of this disease. The hypothalamus is responsible for controlling food intake and numerous studies have observed altered hypothalamic gene regulation in obesity models. However, little is known about the mechanisms controlling persistent changes in gene expression in the hypothalamus during obesity. Epigenetic mechanisms, such as DNA methylation, serves as powerful mechanisms of persistently controlling gene transcription throughout the lifetime of the individual. Yet little is known about whether hypothalamic DNA methylation changes contribute to the development of obesity. Here, we found that rats fed a high fat diet over the course of 7 weeks gained more weight per gram of food compared to rats that were fed standard rat chow with the overall percentage of weight gain being significantly higher in females than males. For DNA methylation levels, we found that male, but not female, rats fed a high fat diet had decreased global levels of DNA 5-hydroxymethylation (5-hmC), a potent transcriptional activator, within the hypothalamus. Importantly, correlational analyses revealed that within the hypothalamus of the male, but not female, rats fed a high fat diet there was an inverse relationship between body weight and DNA 5-hmC. This indicates that as DNA 5-hmC levels decreased, bodyweight increased. Consistent with this, only 3 weeks of exposure to the high fat diet, which was not sufficient to cause abnormal weight gain, decreased 5-hmC levels in the hypothalamus of male rats, suggesting that the decreases in DNA 5-hmC preceded significant weight gain. CRISPR-dCas9-VP64 mediated increases in expression of the DNA 5-hmC enzymes (*Tet1/2/3*) in the hypothalamus slowed weight gain in male rats fed a high fat diet relative to control injected animals, which resulted in a lower percentage of bodyweight gained over 7 weeks on the high fat diet. Conversely, CRISPR-dCas9-KRAB mediated reductions in the *Tet1/2/3* enzymes did not artificially stimulate weight gain in male rats fed a standard chow diet, suggesting that reductions in hypothalamic DNA 5-hmC contribute to, but are not sufficient to cause, abnormal weight gain. Collectively, these results indicate that decreases in hypothalamic DNA 5-hmC likely facilitate weight gain during the development of obesity in a sex-specific manner. Current experiments are underway to determine whether altered DNA 5-hmC occurs at genes that specifically regulate appetite.

Title: Does clozapine induce “hunger” in rats trained to discriminate between 2 and 22 hours food deprivation?

Authors: *S. D. PETIT, G. E. GROSLAND, E. K. CEDARBLOOM, K. D. NORMAN-KLATT, A. M. VIGIL, D. C. JEWETT;
Univ. of Wisconsin - Eau Claire, Eau Claire, WI

Abstract: In humans, weight gain is a side effect of several atypical antipsychotics. The underlying mechanism behind this effect is unclear. Previous work has demonstrated that clozapine often, but not always, increases food intake in rats. Clozapine also increases rodents' motivation to acquire food under a progressive ratio schedule. The current study investigated whether clozapine would induce discriminative stimulus effects similar to "hunger". Eleven male, Sprague-Dawley rats were trained to discriminate between 22 hrs of food deprivation and 2 hrs of food deprivation in a two-lever, operant choice task. Following 2 hrs food deprivation, rats were trained to emit 15 responses (FR 15) to the right lever to earn a 45 mg food pellet. Left lever presses were punished with 8 sec of darkness under the FR 15. Training sessions lasted until subjects earned 10 food pellets or 15 min elapsed. Under 22-hrs deprivation conditions, the contingencies were reversed (left lever presses were reinforced with food delivery, and right lever presses resulted in 8 seconds of darkness). Discrimination acquisition was defined as 80% or greater condition appropriate responding for 8 out of 10 consecutive sessions. After acquiring the discrimination (mean = 76, SEM = 6 sessions), subjects were food deprived for 2 hrs and administered clozapine (1.0-5.6 mg/kg, s.c.) or vehicle (30% DMSO; 1.0 ml/kg, s.c.). The discriminative stimulus effects of food deprivation and response rates were assessed every 15 min for 2 hrs. During these 5 min test sessions, 5 food pellets could be earned and lever presses toward either lever were reinforced under the FR 15. Clozapine (1.0-3.2 mg/kg) did not alter either the discriminative stimulus effects of 2-hr deprivation or lever-pressing rates. Clozapine (5.6 mg/kg) significantly decreased lever pressing rates and significantly increased 22-hrs deprivation-appropriate responding. Approximately 50% of rats selected the lever associated with 22-hrs food deprivation following 5.6 mg/kg clozapine. These data suggest that clozapine may increase food intake by inducing "hunger-like" discriminative stimulus effects.

Title: Hypothalamic orexin/hypocretin neurons mediate behavioural effects of dietary non-essential amino acids

Authors: *P. VISKAITIS[1], C. GARAU[2], M. ARNOLD[1], L. T. JENSEN[3], L. FUGGER[4], D. PELEG-RAIBSTEIN[1], D. BURDAKOV[1];
[1]ETH Zurich, Schwerzenbach, Switzerland; [2]Univ. of Leicester, Leicester, United Kingdom; [3]Aarhus Univ., Aarhus, Denmark; [4]Univ. of Oxford, Oxford, United Kingdom

Abstract: Dietary macronutrients can exert distinct physiological and behavioural consequences via direct or indirect effects on the brain. While a huge body of research exists detailing sensing pathways and outcomes of many nutrients, relatively little is known about such effects of non-essential amino acids

(nAAs). Hypothalamic hypocretin/orexin neurons (HONs) are prospective nAA in vivo sensors and/or mediators of nAA behavioural/physiological effects due to unique HONs' membrane properties and their roles in control of behaviour, metabolism and feeding. Specifically, it was suggested that HONs promote feeding, while their suppression by ingested calories mediates negative feedback control of feeding. However, the natural activity dynamics of HONs during intragastric nutrient absorption and metabolism remain unknown. To investigate the role of HONs in gut-brain communication, here we combined genetically-targeted neural manipulations and recordings with deep learning-assisted classification of post-ingestive behavioural effects. We show that intragastric infusions of nAAs, but not isocaloric glucose, rapidly activate HONs, suppress feeding and evoke exploratory behaviours in mice. We demonstrate that this non-canonical post-ingestive HON activation is crucial for the nAA-induced shift from feeding to exploring, because genetic ablation of HONs abolishes, while optogenetic activation of HONs recapitulates the nAA-induced behavioural switch. Collectively, these results uncover a previously unsuspected role of post-ingestive HON activation in the suppression of feeding, and identify a neural mechanism explaining behavioural differences between isocaloric nutrients.

Title: The satiating benefits of low-intensity exercise on high-fat feeding behavior

Authors: *J. CORDEIRA, E. HOEGLER;
Biol. and Envrn. Sci., Western Connecticut State Univ., Danbury, CT

Abstract: We previously showed that voluntary wheel running in mice for 30 minutes per day reduced weekly intake of very high-fat diet (VHFD). Here, we aimed to further characterize the benefits of voluntary exercise on high-fat feeding behavior. We provided mice with VHFD *ad libitum* and either an open or locked running wheel for 30 minutes daily. We measured food intake (amount) and meal structure (number, size, frequency and duration) during the 12-hour light (inactive) and dark (active) periods. We also assessed exercise intensity by measuring blood lactate levels before and after wheel running. Wheel running reduced VHFD intake significantly and exclusively during the light period, through reductions in meal size and duration. Meal number and inter-meal intervals were unchanged. Interestingly, these results depended on mice being fed freshly thawed VHFD daily, which stimulated overeating. Exercise had no benefit after VHFD was several days old (during weekly food replacement). Blood lactate levels before and after wheel running were not different. Altogether, results indicate that low-intensity exercise reduces overconsumption of palatable, VHFD by enhancing satiation during the inactive period. Since inactive-period feeding is especially obesogenic, understanding the mechanisms

underlying enhanced satiation from exercise may help in the treatment or prevention of diet-induced disease. Our work also identifies food quality/spoilage as a potentially confounding variable in experiments using VHFD.

Abstract: Endocannabinoids (eCB) are neuromodulatory lipid signalling molecules known to regulate the activity of mesolimbic dopamine neurons of the ventral tegmental area (VTA) to support reward-motivated behaviour. Alpha/beta-hydrolase domain 6 (ABHD6) is a post-synaptically localized serine hydrolase that degrades the eCB 2-arachidonoylglyerol, controlling its accumulation and signalling actions at cannabinoid type 1 receptors in a physiological range. We previously established a substantial role for ABHD6 in the nucleus accumbens (NAc) on body weight regulation and food-motivated behavior, however the contribution of VTA ABHD6 on to energy balance and the rewarding effects of food remained unknown. We assessed ABHD6 expression in the VTA using RNAscope in situ hybridization, observing expression of ABHD6 within both TH-expressing neurons and non-TH-expressing cells. To test the role of neuronal ABHD6 on feeding and metabolism, ABHD6 was conditionally deleted in neurons via adeno-associated virus microinjections to the VTA delivering Cre (or GFP control) under the control of a synapsin promotor in adult male ABHD6-LoxP mice to generate ABHD6^{VTA-KO} mice. Four weeks after surgery, mice (n=6-10/group) were subjected to a 22 hr fast with refeeding responses on chow diet, with no significant differences observed between groups. In addition, weekly body weight and cumulative food intake was measured over a 6-week period on chow diet, with a significant group main effect and group x time interaction (2-way ANOVA) showing increased food intake in ABHD6^{VTA-KO} mice. Thereafter, mice were subjected to metabolic cages for measurement of energy expenditure, respiratory exchange ratio (RER), and ambulatory locomotor activity, where

ABHD6^{VTA-KO} mice were found to have significantly reduced RER during the dark cycle. Mice were then switched to a high-fat diet (60% kcal from fat) with body weight and food intake measured weekly for 12 weeks, with no differences in body weight or food intake observed. Following this, metabolic measures were recorded via CLAMS on high-fat diet, with significantly reduced ambulatory activity during the light cycle in ABHD6^{VTA-KO} mice. To examine food-motivated behaviour, a separate group (n=8-10/group) mice were trained on an operant task to earn high-fat/high-sugar pellet food rewards. Mice were tested in a progressive ratio operant task before and after a fast, with no differences observed between genotypes. These results illuminate the influence of ABHD6 in the VTA on energy balance, and contrast with its significant impact in the NAc, a region innervated by VTA neurons, on body weight regulation and reward-directed behaviors.

Title: Effects of maternal hyperglycemia associated with snack intake on offspring high-protein, high-fat and high-sugar diets preference

Authors: *G. V. SILVA[1], M. G. MARTINS[1,2], G. P. OLIVEIRA[1,2], A. G. CRUZ[1,2], L. P. RODRIGUES[1], B. C. WOODSIDE[3], A. C. I. KISS[1,2];
[1]Dept. of Structural and Functional Biol., São Paulo State Univ., Botucatu, Brazil; [2]Grad. Program in Gen. Physiol., Inst. of Biosciences, Univ. of São Paulo (USP), São Paulo, Brazil; [3]Ctr. for Studies in Behavioral Neurobio., Concordia Univ., Montreal, QC, Canada

Abstract: Abnormalities in maternal metabolism or nutrition can increase human and rodent offspring susceptibility to develop obesity and metabolic disorders. There is ongoing interest in the role of offspring macronutrients preference play in this scenario. Since brain circuits involved in feeding behavior starts developing during pregnancy, those conditions may impact offspring food preference. Previous studies have shown that maternal nutrition may influence offspring food preference. Additionally, maternal hyperglycemia can change offspring food intake. However, the effects of their association on offspring food preference have not been explored yet. Therefore, the present study aimed to evaluate the effects of maternal hyperglycemia associated with snack intake on offspring food preference. In order to achieve this goal, initial and sustained food preference to high-protein, high-sugar, and high-fat diet (HPD, HSD, and HFD, respectively) in infant and adult offspring from normo- or hyperglycemic dams, that received

only chow or chow plus snacks, was evaluated. Sprague-Dawley rats were mated and on pregnancy day 0 (PD0) were divided in two groups: dams fed with regular chow or regular chow plus snacks. Snacks were comprised of potato chips and 1.5% sucrose solution and were offered from PD0 until lactational day 14. On PD7, half of dams from both groups were rendered hyperglycemic by streptozotocin intraperitoneal injection (STZ, 35mg/Kg). Thus, four experimental groups were obtained: Control (n=15), Control-Snack (n=12), STZ (n=12), and STZ-Snack (n=12). Dams gave birth naturally and litters were culled to 8 pups (4 males and 4 females). HPD, HSD, and HFD preference were evaluated in female and male offspring on infancy (PND30) and adulthood (PND75). On the test day, 3 males and 3 females from each litter were housed on individual cages and fasted for 12 hours. Food preference was then evaluated by offering two different kinds of powdered diet: regular chow vs HPD, HSD, or HFD. Fasting animals were given access to both diets in the early dark phase of the cycle, and food intake was assessed 1, 12 and 36 hours later. Food preference was determined as the percentage of consumed modified diet in relation to the total amount consumed of both diets (regular chow plus modified diet). In general, infant animals exhibited a lower preference to all modified diets than adults. Offspring from hyperglycemic dams exhibited a lower preference to HSD and HFD diets, while offspring from snack-fed dams exhibited a lower preference to HPD. No effects of their association were observed. We concluded that maternal hyperglycemia and snack intake impaired offspring food preference.

Title: Differential Effects of Mitragynine and Morphine on Unconditioned Food and Water Intake

Authors: *J. D. ZUARTH GONZALEZ[1], F. LEON[2], M. MOTTINELLI[2], C. R. MCCURDY[2], T. HIRANITA[1], G. DE LARTIGUE[1], L. R. MCMAHON[1];

Abstract: Amidst the current opioid public health crisis, compounds of interest have emerged in efforts to tackle the opioid epidemic. Kratom (Mitragyna Speciosa) and associated commercial products are used to self-treat a plethora of ailments including pain and opioid dependence. Among various constituents in kratom, mitragynine is the primary alkaloid. In vitro studies show that mitragynine binds to opioid receptors (e.g. Obeng et al, 2020). Studies showing in vivo opioidergic activity of mitragynine are lacking. The aim of the current study was to characterize the effects of mitragynine on unconditioned intake of food and water and compare to those of the opioid agonist, morphine. Methods: 24 male Sprague-Dawley rats received morphine or mitragynine (each, 1.78, 5.6, 17.8, 56 mg/kg, IP) while ad

libitum intake of food and water was constantly monitored using an automated system beginning at dark onset. A separate group was used to testthe pretreatment effects of opioid antagonist, naltrexone. Results: Both morphine and mitragynine showed a biphasic dose effect on food, in which low doses increased food intake, whereas higher doses decreased food intake. Both hyperphagic and hypophagic effects of morphine were reversed by naltrexone but only the hyperphagic effects of mitragynine were antagonized by naltrexone. Interestingly, morphine monotonously decreased water intake, however, the trend for mitragynine was to increase water intake. Conclusion: These data suggest that opioidergic signaling mediates the hyperphagic effects of mitragynine but hypophagia induced by the high dose of mitragynine might recruit other receptors populations. Naltrexone was ineffective reversing the adipsic effects of morphine and mitragynine, which suggests that a non-opioid mechanism is involved for fluid intake.Supported by National Institute on Drug Abuse grants UH3 DA048353 and R01 DA047855.

Title: Dopamine and GABArelease from combinatorial neurons in the zona incerta play distinct but complimentary roles in threat response behavior

Authors: Z. D. BRODNIK[1], J. A. MIRANDA-BARRIENTOS[2], S. ZHANG[3], M. MORALES[4];

Abstract: While the notion that neurons signal by releasing one unique neurotransmitter is widely accepted, we and others have provided evidence that neurons may co-release multiple neurotransmitters. Tyrosine hydroxylase (TH) positive neurons in the ventral tegmental area have been shown to release the inhibitory neurotransmitter GABA. However, in contrast to GABA neurons distributed throughout the brain, VTA TH-GABA neurons do not have the capability to synthesize GABA utilizing the enzyme glutamic acid decarboxylase (GAD) and lack the GABA vesicular transporter (VGaT). By brain mapping of cellular co-expression we identified a subpopulation of TH-GAD-VGaT neurons in the zona incerta. Based on these anatomical findings, we designed up a multidisciplinary approach to determine the role of zona incerta TH-GAD-VGaT neurons in behavior. (1) By viral based tract tracing and immuno-ultrastructural analysis, we found that axon terminals from these neurons contained both TH- and VGaT-proteins. (2) By ex vivo fast scan cyclic voltammetry and electrophysiology, we found that TH-VGaT axon terminals indeed released both dopamine and GABA. (3) By in vivo fiber photometry, we found that zona incerta TH cells preferentially respond to threatening stimuli. (4) By chemogenetics, we found that

excitation of zona incerta TH neurons suppressed threat response behaviors while their inhibition enhanced threat response behaviors. (5) By viral based CRISPR knockout strategy, we found that specific GABA signal ablation from TH-GABA neurons increased the rate of at which threat response behaviors are initiated. In contrast, specific dopamine signal ablation from TH-GABA neurons increased the duration threat response behavior bouts. In summary, we demonstrated that the zona incerta contains neurons that co-release dopamine and GABA, and provide evidence indicating that the release of these two neurotransmitters from the same neuron play distinct but complementary roles in gating the expression of active threat response behaviors.

Title: Lateral habenula topographic distribution of afferents from ventral tegmental area and entopeduncular nucleus dual glutamate-GABA neurons

Authors: *S. ZHANG[1], H.-L. WANG[2], B. LIU[3], M. F. MORALES[4];
[1]Natl. Inst. of Health, Natl. Inst. on Drug Abuse, IRP, Baltimore, MD; [2]IRP/NIDA/NIH, Baltimore, MD; [3]NIH/NIDA, Baltimore, MD; [4]Cell Neurobiol Res. Br., IRP, NIDA, NIH, Baltimore, MD

Abstract: For decades, it has been thought that glutamate and GABA neurotransmitters are released by distinct neurons. However, by immuno-electron microscopy (immuno-EM), we previously demonstrated that within the lateral habenula (LHb) about 53% of the total population of axon terminals co-express transporters for the vesicular accumulation of glutamate (VGluT2), and for the vesicular accumulation of GABA (VGaT). We had found that single $VGluT2^{+}VGaT^{+}$ axon terminals can simultaneously establish asymmetric and symmetric synapses with postsynaptic non-overlapping glutamate AMPA and $GABA_A$ receptors. By immuno-EM and immunoprecipitation analysis of confirmed LHb purified vesicles, we haven't detected coexistence of VGluT2 and VGaT at the vesicular level. From these ultrastructural and molecular findings, we had concluded that the dual $VGluT2^{+}VGaT^{+}$ terminals have two distinct pools of vesicles for accumulation and release of glutamate or GABA (for electrophysiology evidence, see Miranda-Barrientos et al., SfN 2021). We previously established that LHb $VGluT2^{+}VGaT^{+}$ axon terminals are derived from both the ventral tegmental area (VTA) and the entopeduncular nucleus (EPN). In this study, we simultaneously mapped LHb distribution of VTA-axons and EPN-axons from dual $VGluT2^{+}VGaT^{+}$ neurons. To selectively target $VGluT2^{+}VGaT^{+}$ neurons, we crossed VGluT2::Cre mice with VGaT::FlpO mice and injected INTRSECT viral vectors AAV-DJ-Cre_{ON}/Flp_{ON}-ChR2-eYFP in VTA and AAV-DJ-Cre_{ON}/Flp_{ON}-ChR2-mCherry in EPN. To validate the specificity of the mice and vectors, we

examined the expression of both VGluT2 and VGaT mRNAs in VTA-eYFP$^+$ neurons and EPN-mCherry$^+$ neurons. We detected co-expression of VGluT2 and VGaT mRNAs in 87.5 ± 2.6% of VTA-eYFP$^+$ neurons and 84.8 ± 1.8% of EPN-mCherry$^+$ neurons. At the axon level by confocal microscopy mapping, we found that while VTA-eYFP$^+$ axons and EPN-mCherry$^+$ axons had distinct LHb rostro-caudal distributions, there was some overlapping. At the axon terminal level, by quadruple immunofluorescent confocal microscopy, we established that 92.9 ± 2.5% of VTA-eYFP$^+$ axon terminals and 90.9 ± 3.0% EPN-mCherry$^+$ axons terminals co-expressed VGluT2- and VGaT-proteins. We further determined that the VTA and EPN axon terminals were segregated throughout the LHb, even in those areas in which axons from VTA and EPN overlapped, and confirmed that single axon terminals from VTA-eYFP$^+$ and EPN-mCherry$^+$ axons established each asymmetric and symmetric synapses. We concluded that glutamate and GABA release from VTA and EPN VGluT2$^+$VGaT$^+$ axons regulate the activity of distinct subpopulations of LHb neurons.

Title: Neuropeptide Plasticity Underlying Cue Dependent Aversive Learning

Authors: *T. FRANCIS[1], A. BELILOS[1], C. SANDERS[1], G. SCHOENBAUM[2], M. MORALES[1]; [1]Integrative Neurosci. Res. Br., [2]Cell. and Neurocomputational Systems Br., NIH/NIDA IRP, Baltimore, MD

Abstract: Predictive environmental stimuli guide animal behavior and promote survival. Response to these stimuli require motivational brain circuits facilitated by valence and salience. The core subregion of the Nucleus Accumbens (NAc), an integration center for motivated behavior, responds to salient cues, irrespective of valence. However, the cellular and synaptic mechanisms that underlie NAc core salience processing have not been explored. Previously, we found release of substance P, a neuropeptide released by salient aversive stimuli, in the NAc core, promotes cell-type specific long-term potentiation (LTP) of excitatory transmission on dopamine 2 (D2) receptor expressing medium spiny neurons (MSNs). This LTP requires cholinergic signaling. Therefore, we aimed to test the hypothesis that NAc core substance P plasticity, via cholinergic signaling, is required for aversive learning. To test this, we used a Pavlovian fear conditioning paradigm where a cue (white noise) is paired with an aversive stimulus (footshock). In corroboration with our hypothesis, electrophysiological signatures of LTP on NAc core D2-MSNs were only observed in mice that underwent cue-footshock pairing and not the cue alone. Systemic pharmacological antagonism of the substance P receptor or conditional knockout of this receptor from

cholinergic neurons in NAc core neurons led to a strong suppression in the learned association compared to saline injected mice or mice without the knockout. These results suggest substance P release and plasticity may be facilitating aversive learning. Next, to determine the role of D2-MSN activity in this behavior, we suppressed learning by repeatedly playing the cue prior to pairing of the cue with the footshock. This procedure significantly diminished the salience of the cue and decreased expression of the activity marker c-fos selectively in NAc core D2-MSNs. Furthermore, optogenetic inhibition of D2-MSNs reversibly prevented cue recall compared to non-inhibited viral controls, suggesting D2-MSN activity is required for the recall of cues predicting shocks. Finally, using an acetylcholine sensor to monitor NAc cholinergic signaling *in vivo*, our preliminary findings indicate dynamic cholinergic signaling is required for aversive conditioning. Together, these results suggest NAc core substance P and cholinergic signaling drives plasticity that is required for learning about cues predicting aversive outcomes. This work unveils an undiscovered role for the NAc in salience processing and aversive learning which may underlie related symptoms in anxiety and mood disorders such as post-traumatic stress disorder and behavioral depression.

Title: Lateral habenula glutamate and GABA releasing properties from dual glutamate-GABA axon terminals

Authors: *J. MIRANDA-BARRIENTOS[1], I. CHAMBERS[2], S. ZHANG[3], B. LIU[1], H.-L. WANG[4], M. F. MORALES[5];
[1]Natl. Inst. on Drug Abuse, Baltimore, MD; [2]Natl. Inst. on Drug Abuse, baltimore, MD; [3]Natl. Inst. of Health, Natl. Inst. on Drug Abuse, IRP, Baltimore, MD; [4]IRP/NIDA/NIH, Baltimore, MD; [5]Cell Neurobiol Res. Br., IRP, NIDA, NIH, Baltimore, MD

Abstract: Neurons that utilize either glutamate or GABA as signaling molecules are widely distributed in the brain and have been studied for decades. However, we and others have recently demonstrated that the lateral habenula (LHb), a brain region activated by aversive stimuli and related to negative motivational states, contains axon terminals that release glutamate and GABA. These glutamate-GABA releasing axon terminals are originated from neurons that co-express the vesicular glutamate transporter 2 (VGluT2) and the vesicular GABA transporter (VGaT) ($VGluT2^+$ $VGaT^+$ neurons) located in both ventral tegmental area (VTA) and entopeduncular nucleus (EPN). In this study, we determined the LHb glutamate-GABA releasing properties from VTA and EPN inputs. To selectively target expression of channel-rhodopsin in $VGluT2^+$ $VGaT^+$ neurons, we crossed VGluT2::Cre mice with VGaT::FlpO mice and injected

INTRSECT viral vectors in the VTA or EPN of these dual transgenic mice. By patch-clamp electrophysiology, we found that LHb activation of VGluT2^{+} VGaT^{+} inputs, from VTA or EPN, produced monosynaptic excitatory postsynaptic currents (EPSCs) blocked by CNQX, and monosynaptic inhibitory postsynaptic currents (IPSCs) blocked by Bicuculline. By current-clamp recordings, we found that LHb activation of VGluT2^{+} VGaT^{+} inputs from VTA produced inhibition of LHb neurons due to higher amplitude of GABA mediated currents. In contrast, LHb activation of VGluT2^{+} VGaT^{+} inputs from EPN produced activation of LHb neurons due to higher amplitude of glutamate mediated currents. By stimulation of LHb VGluT2^{+} VGaT^{+} inputs from the VTA or EPN at different frequencies, we found frequency-dependent steep decline in glutamate release with a sustain release of GABA. Moreover, by pharmacological blocking of calcium channels with conotoxin, we found a 40% decrease in glutamate release without affecting GABA release, indicating that N-type calcium channels partially mediates glutamate release, but not GABA release. In summary, by the selective targeting of dual glutamate-GABA neurons, we demonstrated (1) LHb glutamate and GABA release from VGluT2^{+} VGaT^{+} inputs from both VTA and EPN neurons, (2) LHb neuronal inactivation by local activation of VTA VGluT2^{+} VGaT^{+} inputs, and LHb neuronal activation by local activation of EPN VGluT2^{+} VGaT^{+} inputs, and (3) different mechanisms for GABA and glutamate release. Collectively, these electrophysiological and pharmacological findings support the notion that glutamate and GABA are packed in independent synaptic vesicles.This study was supported by the Intramural Research Program of the National Institute on Drug Abuse.

Title: Feeding behavior is modulated by an inhibitory pathway from the Substantia Nigra pars reticulata to the Dorsal Raphe

Authors: *M. F. BARBANO, H.-L. WANG, I. CHAMBERS, M. MORALES;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: The Dorsal Raphe nucleus (DR) is a major source of the neurotransmitter serotonin, and has been implicated in the processing of emotions, stress, anxiety, depression, and motivation. In addition to serotonin neurons, the DR has dopaminergic, GABAergic, glutamatergic and peptidergic neurons. We had previously demonstrated that DR-glutamatergic neurons expressing the vesicular glutamate transporter 3 (VGluT3) play a role in reward. However, it is currently unclear the type of neurons involved in the regulation of DR-VGluT3 neurons. To investigate the sources of monosynaptic inputs to

DR-VGluT3 neurons, we used a rabies-virus-based-*trans*-synaptic retrograde tracing strategy and identified the Substantia Nigra pars reticulata (SNr) as a major source of putative monosynaptic inputs to DR-VGluT3 neurons. Given that most neurons in the SNr are GABA neurons expressing the vesicular GABA transporter (VGaT), we used VGaT:Cre mice to express channelrhodopsin (ChR2) in the SNr. By *ex vivo* electrophysiological recordings of DR neurons, we found that GABA release from SNr neurons differentially modulate DR serotonin, VGluT3 and GABA neurons (Chambers et al., SfN 2021), indicating that SNr GABA neurons provide a major inhibitory input to different DR neuronal subpopulations. To evaluate the behavioral consequences of DR optical stimulation of SNr GABA inputs, we prepared ChR2-eYFP, Halo-eYFP and eYFP mice that we tested in two tasks: free-feeding or an instrumental task for food. We found that DR photoactivation of SNr GABA terminals elicited voracious food intake in food-sated mice, without increasing motivation for food reward. In contrast, DR photoinhibition of SNr GABA terminals did not modulate free-feeding behavior, but decreased motivation for food reward in a progressive ratio test. Collectively, these findings indicate that the modulation of feeding behavior by SNr GABA neurons projecting to DR is effort-sensitive. We next determined the extent to which DR photoactivation of SNr GABA terminals could block lithium chloride (LiCl)-induced taste devaluation. In this test, we presented mice with palatable novel food pellets and immediately after the feeding session injected them with LiCl. Next day, we measured food intake in response to DR photostimulation of SNr GABA terminals and found that food intake did not change in ChR2-eYFP mice, but significantly decreased in eYFP mice. We conclude that GABAergic neurotransmission from the SNr to DR neurons plays a role in feeding behavior, throughout a mechanism that involves the regulation of DR glutamatergic neurons.

Title: Substantia Nigra inputs to the Dorsal Raphe preferentially target glutamatergic neurons

Authors: *J. MIRANDA-BARRIENTOS, **I. O. J. CHAMBERS**, M. F. BARBANO, H.-L. WANG, S. ZHANG, B. LIU, *M. MORALES;
IRP, NIDA, NIH, Baltimore, MD

Abstract: The Dorsal Raphe (DR) is a brain structure known for containing serotonergic neurons that express Tryptophan Hydroxylase (TPH, for the synthesis of serotonin) and the Serotonin Transporter (SERT, for the uptake of serotonin). In addition to serotonin neurons, the DR has dopaminergic, glutamatergic, GABAergic and peptidergic neurons. We had previously demonstrated that both DR-glutamatergic neurons expressing the vesicular glutamate transporter 3 (VGluT3) alone or in combination with serotonergic markers (TPH or SERT) provide major glutamatergic inputs to dopamine neurons within the ventral tegmental area. In addition, by a rabies-virus-based-*trans*-synaptic retrograde tracing strategy, we identified the Substantia Nigra pars reticulata (SNr) as a major source of putative

monosynaptic inputs to DR-VGluT3 neurons (Barbano et al., SfN 2021). In this study we used *ex vivo* electrophysiological recordings to determine the connectivity between inputs from the SNr and DR-SERT, DR-VGluT3 and DR-GABAergic neurons. For the *in vivo* tagging of DR neurons, we did intra-DR injections of a Cre-dependent viral vector (AAV1-DIO-eYFP) to express enhanced yellow fluorescent protein (eYFP) into the DR of three Cre-dependent transgenic mouse lines (SERT::Cre, VGluT3::Cre and VGaT::Cre mice), and in the SNr of the same mice we injected a viral vector (AAV1-CaMKII-mCherry-ChR2) to express channelrhodopsin in SNr neurons and corresponding inputs to DR. While we detected inhibitory postsynaptic currents (IPSCs) within all DR subpopulations of tagged neurons in response to photoactivation of SNr inputs, these responses had differential properties among the DR neuronal subpopulations. We detected IPSCs in about half of the tagged SERT neurons (47.6%), about one third of tagged VGaT neurons (30.4%), and in most of the tagged VGluT3 neurons (81.0%). In addition, we found that the amplitude of IPSCs was different among each of the subpopulations of DR neurons, -5.4 pA to -95.1 pA ($\bar{x}$ = -20.22 pA) for SERT tagged neurons, -8.5 pA to -248.7 pA ($\bar{x}$ = -77.85 pA) for VGaT neurons, and -11.4 pA to -467.2 pA ($\bar{x}$ = -125.82 pA) for VGluT3 neurons. The identified diverse range of amplitude of IPSCs within each subpopulation of tagged neurons indicates further heterogeneity within DR neurons, which is likely to include neurons co-expressing more than one neurotransmitter, for instance serotonin and glutamate, serotonin and GABA, etc. We concluded that neurons from the SNr provide a major inhibitory input to the DR that preferentially synapses on glutamatergic neurons expressing VGluT3.

Title: Pnoc neurons in the extended amygdala encode and are necessary to explore anxiogenic environments

Authors: *M. M. ORTIZ-JUZA[1], R. L. UNG[1], R. A. ALGHORAZI[1], A. L. RING[1], G. VELAZQUEZ-HERNANDEZ[1], J. RODRIGUEZ-ROMAGUERA[2];
[1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Univ. Of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Anxiety disorders are often defined by rapid and amplified arousal responses to stimuli and environments. The bed nucleus of the stria terminalis (BNST), a component of the extended amygdala, is

involved in regulating anxiety states. We recently showed that prepronociceptin-expressing neurons in the BNST (*Pnoc*^{BNST} neurons) encode arousal responses during presentation of motivationally salient stimuli (Rodriguez-Romaguera et al., 2020). The role of *Pnoc*^{BNST} neurons in encoding anxiety-like behaviors is unknown. We sought to understand how response dynamics of *Pnoc*^{BNST} neurons encode anxiogenic environments in mice. To visualize activity of *Pnoc*^{BNST} neurons we used head mountable miniature microscopes in freely moving mice exposed to the elevated plus maze (EPM). Population activity of *Pnoc*^{BNST} neurons increased when mice explored the open arms of the EPM. Further analysis on individual *Pnoc*^{BNST} neurons revealed three different types of response patterns: 1) neurons that were excited in the open arms, 2) neurons that were inhibited in open arms, and 3) neurons that did not change activity across arms. We also found that the activity of neurons that were excited in the open arms correlated with distance to the edge of the open arms, with increased activity as mice approached the edge of the open arms. Our data indicate that *Pnoc*^{BNST} neurons encode anxiogenic environments. To test if *Pnoc*^{BNST} neurons are necessary for mice to engage with anxiogenic environments, we selectively inhibited them in the EPM using optogenetics only when mice were in the open arms (real time EPM). Photoinhibition of *Pnoc*^{BNST} neurons decreased the amount of time spent in the open arms, demonstrating that *Pnoc*^{BNST} neuronal activity is necessary for mice to explore anxiogenic environments. In contrast, photoactivation of *Pnoc*^{BNST} neurons in the real time EPM did not alter time in the open arms, suggesting that *Pnoc*^{BNST} neuronal activity is not sufficient to increase exploration of anxiogenic environments. We previously showed that *Pnoc*^{BNST} neurons track arousal responses to motivationally salient stimuli, and our new findings indicate that activity of these neurons are also necessary to engage with anxiogenic environments. Taken together, our data suggest that perhaps *Pnoc*^{BNST} neurons regulate the arousal responses that are necessary for animals to explore anxiogenic environments.

Chapel Hill, Chapel Hill, NC; [4]Anesthesiol. and Pain Med., Univ. of Washington, Seattle, WA; [5]Shenzhen Inst. for Advanced Technologies, Shenzhen, China

Abstract: Motivational states consist of behavioral and physiological components controlled by multiple brain regions. An integral component of this neural circuitry is the bed nucleus of the stria terminalis (BNST), a part of the extended amygdala. We recently found neurons in the BNST that express the gene prepronociceptin (*Pnoc*^{BNST} neurons) modulate rapid changes in physiological arousal upon presentation of motivationally salient stimuli (Rodriguez-Romaguera et al., 2020). This was accomplished by combining pupillometric assessment in combination with *two-photon* calcium imaging in head-fixed animals, in which we observed that *Pnoc*^{BNST} neuronal responses directly correspond with rapid increases in pupillary size when mice are exposed to both aversive (TMT predator odor) and rewarding (peanut oil) odors. However, how dynamics of *Pnoc*^{BNST} neurons encode behavioral responses to the same motivationally salient stimuli remains unknown. We therefore employed calcium imaging in freely moving mice using head mountable miniature microscopes. We injected Cre-dependent calcium indicator GCaMP6s in *Pnoc*-IRES-Cre mice to visualize activity of individual *Pnoc*^{BNST} neurons when exposed to either TMT or peanut oil in their home cage. Population activity of *Pnoc*^{BNST} neurons was higher when mice were exposed to TMT, as compared to peanut oil. Furthermore, activity of individual *Pnoc*^{BNST} neurons correlated with proximity to odor source when mice were exposed to TMT, but not peanut oil. Our data suggest that *Pnoc*^{BNST} neurons preferentially encode relative location of aversive odors. Next, we tested if optogenetic manipulation of *Pnoc*^{BNST} neurons modulates time spent near TMT and peanut oil. Photoinhibition of *Pnoc*^{BNST} neurons decreased the amount of time spent in the odor zone when mice were exposed to TMT, but not peanut oil, indicating that *Pnoc*^{BNST} neuronal activity is necessary for mice to explore aversive odors. In contrast, photoactivation of *Pnoc*^{BNST} neurons did not alter time in the odor zone for either odor, suggesting that *Pnoc*^{BNST} neuronal activity is not sufficient to increase time spent near motivationally salient odors. Taken together, our data indicate that *Pnoc*^{BNST} neurons are necessary to explore aversive odors. We previously showed that *Pnoc*^{BNST} neurons encode for arousal responses to motivationally salient odors, and these new findings indicate activity of these neurons are specific to engage with aversive odors.

Title: Post-conditioning lesions to the perirhinal cortex impairs fear extinction to a discontinuous conditioned stimulus.

Authors: D. GONZALEZ MAGANA, N. A. VANG, R. A. K. PUREWAL, *S. C. FURTAK;
Dept. of Psychology, California State Univ. Sacramento, Sacramento, CA

Abstract: The perirhinal cortex (PER) is a medial temporal lobe structure involved in learning and memory. The PER receives both unimodal and polymodal sensory information, which make this region well positioned to associate and process stimulus information. The PER has been examined in tasks that involve processing of visual stimuli, such as delay non-match to sample, object recognition and more recently in fear memory paradigms. Studies focused on the role of the PER in fear memory specifically have tested whether the PER supports fear learning to stimuli that require unitization across modality, features or time for representation. In the current study, we assess whether excitotoxic lesions to the PER post-conditioning affect retrieval of the fear memory or extinction memory to a continuous or discontinuous white light conditioned stimulus (CS). Based on the stimulus unitization hypothesis of the PER, we predicted that the PER should be necessary for fear learning to the discontinuous CS but not the continuous CS. Male Spraque-Dawley rats (280-420 g) were assigned to one of four groups based on CS type (continuous vs discontinuous) and surgery type (lesion vs sham). The fear extinction paradigm consisted of three phases: fear acquisition, extinction training, and extinction retrieval. Animals underwent surgery three days after fear acquisition, then ten days later returned to the conditioning chamber for extinction training and extinction retrieval, which occurred on two consecutive days. Results showed that animals with damage to the PER had significant deficits, indicated by reduced freezing levels, during retrieval of the fear memory in the extinction training phase of the behavioral paradigm to both the continuous and discontinuous CS compared to their sham control groups. The next day during retrieval of the extinction memory (extinction retrieval), significant differences in freezing levels were observed between lesion and sham groups in the discontinuous CS groups but not in the continuous CS group. This study supports previous research suggesting the PER is a part of a wider system of structures engaged in fear learning and further supports a role for the PER in stimulus unitization in fear-related tasks.

Title: Dynamics of Coordinated Neural Activity in the Infralimbic Cortex - Nucleus Accumbens Shell Circuit during Conditioned Negative Affect and its Extinction

Authors: *J. E. DOUTON, M. M. BORCHLEWICZ, R. M. CARELLI;
Psychology and Neurosci., Univ. of North Carolina, Chapel Hill, NC

Abstract: The disruption in hedonic processing is associated with many psychiatric illnesses and can lead to maladaptive behaviors. For example, the prevalence of negative affect during withdrawal in substance use disorders can promote relapse. In depression, negative affect drives the aversive emotional state that can result in suicide. Thus, it is critical to understand the neural mechanisms that modulate hedonic processing, whose disruption can lead to such aversive affective states. Taste reactivity (TR) is useful to study objective hedonic behaviors. TR analyzes pleasant (positive affect) and aversive (negative affect) stereotypic oromotor expressions elicited by rats when sapid stimuli are intraorally infused, allowing to infer the affective state of the rat. Moreover, TR is used to study conditioned aversive states such as Lithium Chloride (LiCl) conditioned taste aversion (CTA). Using these methods, corticolimbic circuits have been shown to play a vital role in hedonic processing. In rats, the projections from the infralimbic cortex (IL) to the nucleus accumbens shell (NAcSh) are involved in the suppression of negative affect. The goal of this study was to characterize the role of these regions in the development and extinction of a conditioned aversive state. To this end, adult male Sprague Dawley rats (n=8) were subjected to CTA. The rats were exposed to 30 intraoral infusions (IO, 1 inf/min) of 0.15% saccharin followed by an IP injection of LiCl (0.3M). After two days of recovery, rats experienced 5 IO extinction trials with the same saccharin solution (30 inf, 1 inf/min). Finally, on the last day, rats were intraorally infused with a bitter quinine solution to study responses to a natural aversive tastant. In this experiment, in vivo electrophysiological methods that record simultaneous neural oscillations of local field potential (LFPs) allowed us to study synchronized oscillatory dynamics and assess functional connectivity between the IL and the NAcSh during the task. Preliminary data show that the development of a conditioned aversive state reduced IL-NAcSh synchronous activity, manifested as a reduction in overall coherence between these regions. Specifically, oscillations observed in the naïve state at the beta (16-20 Hz) and high gamma (80 Hz) frequency bands were affected. In addition, these changes were reverted to preconditioning levels after 3 days of extinction training. Interestingly, quinine infusion did not alter functional connectivity between the IL and NAcSh. Collectively, the data indicate that the IL-NAcSh circuit may modulate conditioned aversive states that recover in extinction, but not innate aversive states (i.e., quinine).

Abstract: Fear is a central emotion guiding the behavior of animals and people. Fight, flight or freezing are understood as reactions to threatening situations. The brain circuits related to the perception of a threat and the behavioral expression of fear have been studied extensively (Tovote, Fadok, and Lüthi 2015; Silva, Gross, and Gräff 2016; LeDoux and Brown 2017). Here we designed a behavioral apparatus that used head-fixed mice and in a controlled fashion presented an ostensibly innately threatening stimulus, a live rat, to the mouse. Mice had to decide whether to forage (lick a lick tube), flee (walk backward pushing the predator away), or freeze. During a trial, mice walked on a treadmill. The movement of the treadmill was linked to the movement of a reward tube and linked to the movement of a potential threat, a rat. Our results suggest that in a head-fixed condition where mice forage for a reward the innate expression of flight and freezing behavior is suppressed. Mice were invariably focused on obtaining the reward; they did not attend to the presence of the potential predator. We compared these results to the outcome of various behavioral tests in freely moving mice. Naïve, untrained mice with free access to water were used to examine their response to looming stimuli (Yilmaz and Meister 2013), rat odors (Murata et al. 2019), and the presence of a live rat (Yang et al. 2004). The results from these experiments showed a diverse behavioral phenotype, which included a small but significant number of mice (25-40%, tested in 12 mice) expressing fear in response to the looming stimulus, and avoidance or place preference in response to the presence or odor of a rat. Our work suggests that the expression of "innate fear" is context-dependent.

Title: Corticostriatal control of defense behavior in mice induced by auditory looming cues

Authors: *Z. LI[1], J. WEI[1], G. ZHANG[1], J. HUANG[2], B. ZINGG[3,4], X. WANG[3], H. TAO[1], L. I. ZHANG[1];

Abstract: Animals exhibit innate defense behaviors in response to approaching threats cued by the dynamics of sensory inputs of various modalities. The underlying neural circuits have been mostly studied in the visual system, but remain unclear for other modalities. Here, by utilizing sounds with increasing (vs. decreasing) loudness to mimic looming (vs. receding) objects, we find that looming sounds elicit stereotypical sequential defensive reactions: freezing followed by flight. Both behaviors require the activity of auditory cortex, in particular the sustained type of responses, but are differentially mediated by corticostriatal projections primarily innervating D2 neurons in the tail of the striatum and corticocollicular projections to the superior colliculus, respectively. The behavioral transition from freezing to flight can be attributed to the differential temporal dynamics of the striatal and collicular neurons in their responses to looming sound stimuli. Our results reveal an essential role of the striatum in the innate defense control.

Title: Chronic Social Defeat Stress Leads to Over-Generalized Fear: A Role for Impaired Safety Learning and Disrupted Communication Between the Amygdala and Prefrontal Cortex

Authors: *I. S. GRUNFELD[1], L. E. DENHOLTZ[2], I. NAHMOUD[3], A. V. AUBRY[6], S. HANIF[4], S. DATTA[7], S. CHATTARJI[7], N. S. BURGHARDT[4], E. LIKHTIK[5];

Abstract: Chronic stress leads to the generalization of fear to non-threatening cues, a key symptom in numerous psychiatric disorders. We previously showed that in the absence of stress, successful discrimination of threatening and non-threatening cues is associated with suppression of the basolateral amygdala (BLA) by the medial prefrontal cortex (mPFC). In contrast, BLA activity is not under mPFC control during fear generalization. Here, we used the chronic social defeat stress (CSDS) model to investigate the contribution of the BLA and mPFC to stress-induced fear generalization in 129 Sv/Ev

mice. We found that 10 days of CSDS decreased dendritic spines in the prelimbic (n=3 mice) and infralimbic (n=4 mice) subregions of the mPFC relative to non-stressed controls (n=3 mice/group, $p<0.0001$). In contrast, CSDS enhanced consolidation of cued fear memory (n=18-19/group, $p<0.001$) and increased the expression of the immediate-early gene Arc in the BLA during fear memory retrieval ($p<0.05$), supporting differential effects of chronic stress on these brain regions. We then tested the effects of CSDS on discrimination learning using an auditory differential fear conditioning task, in which one tone was paired with a shock (CS+) and a second tone was unpaired (CS-, 2kHz and 8kHz, counterbalanced). The majority of non-stressed animals successfully discriminated between the tones (n=14/19, 73.69%), freezing at least 10% more to the CS+ than the CS-. However, the majority of stressed mice generalized their fear to the CS- (n=11/17, 64.7%), freezing similarly to the two tones. To investigate whether this might reflect an effect of stress on safety learning, mice were trained on a salient safety learning task, where the presence of a 1-sec light and a 30-sec tone signaled absence of shock. Whereas non-stressed controls reliably decreased freezing during the safe tone (n=10, $p<0.05$ compared to pre-tone), the CSDS group failed to do so (n=11, $p>0.05$). Preliminary analyses of local field potential recordings reveal that the safety cue evokes a theta (4-12 Hz) oscillation in the BLA of control mice ($p<0.05$), but not defeated mice. We conclude that chronic stress differentially impacts the mPFC and BLA and alters theta-range communication in this circuit during periods of explicit safety, potentially diminishing the ability to discriminate between threatening and non-threatening cues.

Title: The role of claustral circuits in observational threat

Authors: *H. JUNG[1], J. HEU[1], A. D. HUBERMAN[1,2,3,4];
[1]Dept. of Neurobio., [2]Dept. of Ophthalmology, [3]Wu Tsai Neurosciences Inst., [4]BioX, Stanford Univ. Sch. of Med., Stanford, CA

Abstract: The selection of appropriate defensive strategies is essential for survival and is evolutionarily conserved among humans and animals. This process involves rapid evaluation of severity of the threat stimuli and proper decision for defensive strategies to pursue. These defensive responses are also apparent when the threat stimuli are detected through indirect experience, mainly through observation, but *how the brain links this observational threat to subsequent behaviors remains poorly understood*. Here we use a combination of behavioral, calcium imaging, and chemogenetic approaches to investigate the neural correlates underlying observational threat. First, by developing a novel visually-driven behavioral paradigm, we demonstrated that freezing is the significant responsive behavior of mice during

observational threat. Next, by analyzing neural activity of the early-immediate gene c-Fos throughout the brain, we identified that *the claustrum showed increased activity in response to observational threat*. In vivo calcium imaging also revealed that the increased activity observed in the claustrum precedes a freezing response during observational threat. Finally, by chemogenetically manipulating the claustral circuits, we demonstrated that visual information on the threat stimuli is transmitted from the basolateral amygdala (BLA) to the claustrum and that this information is critical for selecting appropriate defensive responses to observational threat. This study provides a new model for investigating the social transmission of threat and illuminates a central role of claustral circuits in visual threat perception. This novel function of the claustrum and its circuits may underlie a fundamental role in modulating defensive systems to both physical and social threats in health and disease.

Abstract: Major depression disorder (MDD) is a chronic debilitating disorder of largely unknownetiology. Protein kinases are essential components of cellular signaling pathways. Alteredexpression and activity of a number of protein kinases have been implicated in thepathophysiology of MDD. However, less is known about how kinase-kinase interactionsare dysregulated in MDD and how perturbation of these complex kinase networks affectsdownstream biological processes. Using the Pamgene kinome peptide array platform, weexamined serine/threonine protein kinase activity in cortical excitatory neuronsdifferentiated from induced pluripotent stem cells (iPSCs) from subjects diagnosed withMDD (N=5) and corresponding controls (N=5). Neurons from an MDD patient with a 4-bpmutation in the disrupted in schizophrenia 1 (DISC1) gene and from sporadic MDD caseswere assayed. Array data was analyzed using Kinome Random Sampling Analysis(KRSA) to identify kinases with significantly altered activity. In MDD-DISC1 neurons wefound a global downregulation of kinase activity. Using KRSA analysis we identifiedkinases like extracellular signal-regulated kinases, protein kinase G, and protein kinaseA (Z score ≥±4) that were differentially represented in MDD-DISC1 neurons compared tocontrol. Conversely, there was a global upregulation of kinase activity in sporadic MDDneurons. KRSA analysis identified myotonic dystrophy protein kinase, protein kinase A,and c-Jun N-terminal kinases (Z score>=±3) as differentially represented in sporadic MDDneurons. Our data provide new insights into kinase network abnormalities in MDD.Further

exploration of kinase interaction networks and biological pathways affected by
altered kinase activity in MDD-DISC1 and MDD-sporadic neurons will also inform ourunderstanding of the dysregulated molecular mechanisms involved in cellularhomeostasis and neuronal function that could be underlie MDD pathophysiology.

Title: Reduction in left frontal alpha oscillations by transcranial alternating current stimulation in major depressive disorder is context-dependent

Authors: J. RIDDLE, M. L. ALEXANDER, C. E. SCHILLER, D. R. RUBINOW, F. FROHLICH; Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Left frontal alpha oscillations are associated with decreased approach motivation and have been proposed as a target for non-invasive brain stimulation for the treatment of depression and anhedonia. Indeed, transcranial alternating current stimulation (tACS) at the alpha frequency reduced left frontal alpha power and was associated with a higher response rate than placebo stimulation in patients with major depressive disorder (MDD) in a recent double-blind placebo controlled clinical trial. In this current study (NCT03449979), we aimed to replicate successful target engagement by delineating the effects of a single session of bifrontal tACS at the individualized alpha frequency (IAF-tACS) on alpha oscillations in patients with MDD. 84 participants were randomized to receive verum or sham IAF-tACS. Electrical brain activity was recorded during rest and while viewing emotionally-salient images before and after stimulation to investigate if the modulation of alpha oscillation by tACS exhibited specificity with regards to valence. In agreement with the previous study of tACS in MDD, we found that a single session of bifrontal IAF-tACS reduced left frontal alpha power during the resting state when compared to placebo. Furthermore, the reduction of left frontal alpha oscillation by tACS was specific for stimuli with positive valence. In contrast, these effects on left frontal alpha power were not found in healthy control participants. Together these results support an important role of tACS in reducing left frontal alpha oscillations as a future treatment for MDD.

Title: Chronic treatment with the selective GSK-3 inhibitor SB16763 induces antidepressant-like effects in the IFN-alpha model of neuroinflammation: a behavioural and molecular study

Authors: *D. FELICE[1], A. FREEBURN[1], J. KEALY[1], B. GARRONE[2], C. MILANESE[2], F. P. DI GIORGIO[2], C. K. CALLAGHAN[1], M. BIANCHI[1];
[1]Ulysses Neuroscience, Trinity Col., Inst. of Neurosci. (TCIN), Lloyd Inst., Dublin, Ireland; [2]Global R&D External Innovation, Angelini Pharma S.p.A., Rome, Italy

Abstract: Glycogen synthase kinase-3 (GSK3) activity has recently been linked to mood disorders. The first evidence was that GSK3β is a target of the mood stabilizer lithium. Recent studies strongly support GSK3β inhibitors as potential therapeutic approaches for mood disorders. Chronic Interferon-alpha (IFN-α) administration in the rat represents a new back translational preclinical model of neuroinflammation. The model was ideated from the observation that patients undergoing IFN-α treatment often report neuropsychiatric side-effects. IFN-α is commonly used in the treatment of cancer and hepatitis. Furthermore, a subpopulation of patients with major depressive disorder (MDD) exhibit increased levels of peripheral inflammatory markers suggesting a chronic inflammation status. Here, we use the IFN-α model to investigate the effects of chronic treatment with the GSK3β inhibitor SB216763 on behaviour, adult hippocampal neurogenesis as well as BDNF and inflammatory biomarkers in hippocampus, medial-prefrontal cortex (mPFC) and plasma. The effects of treatment with SB216763 were compared to the selective serotonin reuptake inhibitor (SSRI) fluoxetine. Male Wistar rats (3mth, n=14 per group) were injected with recombinant human IFN-α (170,000 IU/kg, 3 times per week for 3 weeks) or saline (0.9%). After IFN-α, rats underwent chronic treatment (14 days) with SB216763 (2 mg/kg or 10 mg/kg; *ip*) or fluoxetine (FLX, 10 mg/kg, *po*) or vehicle. Rats were tested in the forced swim test (FST) and elevated plus maze (EPM). Following testing, hippocampal brain tissue was harvested and processed by flow cytometry for analysis of neurogenesis. Hippocampal, mPFC and plasma samples were analysed for changes in cytokines and BDNF levels by MSD assay. Data were analysed by ANOVA and Fishers LSD pairwise comparisons.SB216763 was similarly efficacious as FLX in FST and EPM, recovering IFN-α induced deficits which was associated with increased hippocampal neurogenesis. Chronic SB216763 or FLX treatment recovered IFN-α-induced decrease in mPFC BDNF levels. Only FLX treatment recovered IFN-α-induced decrease in plasma BDNF levels. Neither SB216763 or FLX treatment recovered IFN-α-induced decrease hippocampal BDNF levels. Chronic treatment with SB216763 or FLX rescues IFN-α induced increase in IL-6 levels in the mPFC and plasma, and recovered IFN-α induced increased TNFα in the hippocampus and mPFC. These data validate IFN-α treatment in the rat as a back translational model of neuroinflammation and depression and demonstrates the antidepressant-like effects of SB216763.

Title: The endogenous neurosteroid (3α,5α)3-hydroxypregnan-20-one (3α,5α-THP, allopregnanolone) moderates toll-like receptor (TLR) inflammatory signaling with sex differences and relevance to postpartum depression (PPD)

Authors: *I. BALAN[1], R. MEEKER[2], G. BOERO[3], R. PATTERSON[4], H. KROHN[4], S. MELTZER-BRODY[4], T. K. O'BUCKLEY[3], A. L. MORROW[1];
[1]Psychiatry, Pharmacol. and Bowles Ctr. for Alcohol Studies, [2]Neurol., [3]Bowles Ctr. for Alcohol Studies, [4]Psychiatry, UNC Sch. of Med., Chapel Hill, NC

Abstract: Depression is associated with activation of both TLR4 and TLR7 inflammatory pathways and their downstream inflammatory mediators. We recently discovered that 3α,5α-THP inhibits MyD88-dependent but not TRIF-dependent TLR pro-inflammatory signal activation and the production of cytokines/chemokines through its ability to block TLR-MyD88 binding in the alcohol-preferring (P) rat brain and the mouse macrophage RAW264.7 cell line. Here, we examine the effect of 3α,5α-THP on cultured human macrophages, derived from both males and females and examine whether Brexanolone (Brex; a proprietary form of 3α,5α-THP) treatment of postpartum depression (PPD) involves the inhibition of TLR4 and TLR7 activation. Human macrophages cultured from peripheral blood mononuclear cells of male and female healthy subjects (3-5/group) were treated with lipopolysaccharide (LPS, 1 μg/ml, 24h) or imiquimod (IMQ; 30 μg/ml, 24 h) alone or with 3α,5α-THP (1 μM) and examined for TLR pathway activation as defined by the expression of cytokines/chemokines and activated (phosphorylated) transcription factors. 3α,5α-THP inhibits the LPS-activated TLR4 signaling pathway assessed by elevations of TNF-α (30%/males and 60%/females), MCP-1 (50%/males and 100%/females) and pCREB (70%/males and 100%/females) in the cells derived from both males and females ($p<0.05$, Two-way ANOVA). In contrast, 3α,5α-THP, inhibited the IMQ-activated TLR7 signal assessed by elevations of IL-6 (100%), IL-1β (80%) and pIRF7 (70%) in macrophages cultured from female ($p<0.05$, Two-way ANOVA), but not male ($p>0.05$, Two-way ANOVA) subjects. In patients with PPD, whole

blood collected before and after (60 h) Brex infusion was treated with LPS (10 µg/ml, 4h) or IMQ (30 µg/ml, 4 h) and cell lysates were examined for levels of TNF-α, IL-6 and IL-1β. Both LPS and IMQ caused a significant ($p<0.05$, Two-way ANOVA) increase in the levels of TNF-α (24%/IMQ and 23%/LPS), IL-6 (85%/IMQ and 94%/LPS) and IL-1β (60%/IMQ and 80%/LPS) in blood cells collected before Brex infusion. Blood cells collected after Brex infusion were completely insensitive to LPS and less sensitive to IMQ as defined by the levels of TNF-α, IL-6 and IL-1β ($p<0.05$, Two-way ANOVA) when compared with cells collected before Brex infusion. The data indicate a strong inhibition of inflammatory signaling following Brex infusion. Furthermore, the therapeutic potential of 3α,5α-THP is more promising in female than male subjects and involves modulation of pro-inflammatory MyD88-dependent TLR signaling pathways resulting in diminished TLR signal activation in human immune cells. This mechanism likely contributes to the therapeutic effects of Brex in PPD patients.

Abstract: A recent CDC report suggests that 30.2% of adults aged >18 years report experiencing some type of depressive disorder (Vahratian et al., 2021). While treatments for major depressive disorder (MDD) alleviate symptoms, these are often impeded by factors such as unwanted side effects, time needed to generate a therapeutic response (weeks to months), as well as forms of depression that are treatment resistant (TRD). By contrast, fast-acting antidepressants, such as scopolamine or ketamine, act on the order of hours to days and are effective in patients with TRD (Jaffe et al., 2013 and Krystal JH, 2007). Although scopolamine is a non-selective muscarinic acetylcholine receptor (mAChR) antagonist, its antidepressive effects are mediated by the M1 receptor isoform (M1) as evidenced by knockout and pharmacological data (Witkin et al., 2014). Scopolamine (and ketamine) act on layer 5 pyramidal neurons in the medial prefrontal cortex (mPFC), antagonizing inhibitory neurons, resulting in enhanced excitatory, transmission. Concomitantly, BDNF release and spine density are also enhanced. Together, these effects likely contribute to scopolamine's antidepressive effect (Wohleb et al 2017). Because scopolamine does not selectively target the M1 receptor, clinical dosing is associated with adverse events common to all non-selective muscarinic antagonists. We have identified and characterized an M1 selective, brain penetrant, small molecule antagonist, PIPE-307. Similar to scopolamine, we show that PIPE-307: 1) shows efficacy in the forced swim test, 2) increases mEPSC amplitude in pyramidal neurons in the

mPFC, 3) increases dendritic spine density, and 4) enhances BDNF levels. We further show that M1 protein is present on GABAergic interneurons. Together, these data suggest that (like scopolamine) PIPE-307 may be beneficial as a fast-acting antidepressant, but with an improved tolerability profile.

Title: Hippocampal Transcript Expression of Extracellular Adenosine Generating Pathway Genes in Major Depression

Authors: *D. SINCLAIR[1], S. ASAH[2], H. PANTAZOPOULOS[4], R. E. MCCULLUMSMITH[2], S. M. O'DONOVAN[3];
[1]Univ. of Toledo Col. of Med. Neurosci. & Neurolog. Disorders, Toledo, OH; [3]Neurosci., [2]Univ. of Toledo, Toledo, OH; [4]Neurobio. and Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Major depressive disorder (MDD) is a debilitating disease that is characterized by low mood, anhedonia, impaired cognitive function, sleep difficulties and appetite disturbances. It is a serious neuropsychiatric illness that affects approximately 20% of the population over the course of a lifetime. Efforts to develop new treatments are stymied by our limited understanding of the pathophysiology of depression. Epidemiological, clinical and animal model data suggests significant perturbation of the adenosine system in MDD. However, the pathways that regulate extracellular adenosine availability have yet to be studied in the human brain in this disorder. We used qPCR to assay transcript expression of adenosine metabolism pathway genes (GFAP, ADORA1, ADORA2A, ENTPD1, ENTPD2, ENTPD3, ENT1 and ADA) in the hippocampus from subjects diagnosed with MDD, MDD and substance use

disorder (SUD), SUD and a non-psychiatrically ill control group (n=20/group). Since SUD is highly comorbid with MDD, analyzing both groups will offer insight regarding MDD specific changes in adenosine generating pathways. Subjects were matched for age, sex and postmortem interval (PMI). Relative concentrations of the transcripts of interest are calculated with comparison to a standard curve made with dilutions of cDNA from a pooled sampling of all the subjects. Values for the transcripts of interest are normalized to the geometric mean of B2M, β-actin, GAPDH and PPIA. We hypothesize that the expression of targets involved in pathways that generate extracellular adenosine and the expression of adenosine receptors will be dysregulated in the hippocampus in MDD. These findings will improve our understanding of adenosine system dysfunction in MDD and offer novel insight into the pathophysiology of this serious mental illness.

Title: Connectivity based identification of candidate repurposable drugs in Major Depression using DrugFindR

Authors: *E. A. BATES, A. S. IMAMI, X. ZHANG, R. MCCULLUMSMITH, S. O'DONOVAN; Neurosciences, Univ. of Toledo, Toledo, OH

Abstract: Major depressive disorder (MDD) is a serious mental health disorder that affects millions of people in the United States. Many patients who experience MDD are resistant to available antidepressant treatments and there is a pressing need to develop novel therapies for this debilitating disorder. DrugFindR is an R Shiny application created to identify candidate repurposable drugs from the Library of Integrated Network-Based Cellular Signatures (LINCS). Extensive MDD transcriptome data is available on public databases, making entirely computational analyses more accessible and reliable. Here, we utilize DrugFindR to identify potential candidate repurposable drugs for the treatment of MDD. For this analysis, gene signatures are obtained from publicly available RNAseq datasets (GSE102556) generated from postmortem brain tissue from male and female subjects with MDD and non-psychiatrically ill controls. Following a standardized RNAseq analysis pipeline, a quantile approach is used to determine the optimal log fold change threshold for gene expression for each brain region (DLPFC, NAC, VMPFC) in the dataset. Simultaneously, LINCS signatures for known antidepressants (fluoxetine, escitalopram, sertraline, venlafaxine, moclobemide, amitriptyline) are identified and grouped based on mechanism of action (SSRI, SNRI, MAOI-A, tricyclic). Finally, using signature-based connectivity analysis, DrugFindR identifies chemical perturbagens that are highly discordant (<-0.321) with the disease gene signatures (i.e. reverse the MDD gene signatures) and highly concordant (>0.321) with known antidepressant signatures. The identified candidate repurposable drugs have significant discordant signatures across multiple different cell lines in LINCS and are FDA approved. This study utilizes the extensive repository of

chemical perturbagen signatures available in LINCS to identify novel candidate drugs that may be explored for the treatment of MDD in male and female subjects. This study addresses a pressing need in neuropsychiatric research and provides a computational basis for future clinical applications. Future studies will examine the utility of the identified drugs in vivo.

Title: Manipulating reward sensitivity using reward circuit-targeted transcranial magnetic stimulation

Authors: *J. RYAN[1], J. J. POULIOT[2], G. HAJCAK[2,1], D. E. NEE[2];
[1]Dept. of Biomed. Sci., [2]Dept. of Psychology, Florida State Univ., Tallahassee, FL

Abstract: The mesolimbic reward circuit is important for learning and motivation, and dysregulations of the reward circuit are prominent in anhedonic depression. Specifically, depression has been linked to diminished activation to rewarding stimuli and follows animal studies relating dopaminergic reductions in the reward circuit to reduced reward motivation. Non-invasive interventions that can selectively target the reward circuit may hold promise for the treatment of anhedonia, a core symptom of many individuals who exhibit treatment resistant depression. Modern transcranial magnetic stimulation (TMS) interventions have not directly targeted reward circuitry, and have shown mixed results for long-term treatment of anhedonic depression. Thus, we utilized a novel TMS intervention for modulating the reward circuit. 34 healthy individuals participated in a cross-over controlled study targeting the reward circuit or a control site (M1 or S1) with intermittent theta-burst stimulation (iTBS), an excitatory form of TMS. Individual reward circuit targets were defined based upon fMRI functional connectivity with the ventral striatum (VS), yielding targets in the rostromedial prefrontal cortex (rmPFC). The rmPFC is a novel site for TMS depression treatment, but has shown strong connectivity with the VS, an area that is otherwise unable to stimulate directly with TMS. This methodology follows previous TMS literature showing the ability to alter downstream activation through stimulation of cortical areas exhibiting high co-activation with subcortical targets. Reward circuit functioning was assessed at baseline using fMRI, and reward circuit modulation was assessed using an event-related potential referred to as the reward positivity (RewP), which has been shown to reliably track reward sensitivity, and depression risk and course. A well-established gambling paradigm was used to determine reward circuit functioning and to elicit the RewP following iTBS. Relative to control-iTBS, rmPFC-iTBS enhanced the RewP. These effects were most pronounced in individuals with reduced VS fMRI activation at baseline. These data provide promising evidence that that the reward circuit can be modulated by rmPFC-iTBS and amenability to such

modulations are most effective on individuals with reduced reward circuit function. This provides the first step towards a novel non-invasive treatment of anhedonic symptomology commonly seen in depression and other disorders of the reward circuit.

Title: Differential acute and chronic effects of subcallosal cingulate cortex deep brain stimulation for treatment-resistant depression

Authors: S. ALAGAPAN[1], S. HEISIG[2], A. C. WATERS[2], A. VEERAKUMAR[3], M. OBATUSIN[2], T. J. NAUVEL[2], A. CROWELL[3], P. RIVA POSSE[3], R. J. BUTERA[1], H. S. MAYBERG[2], C. ROZELL[1]; [1]Georgia Inst. of Technol., Atlanta, GA; [2]Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Emory Univ., Atlanta, GA

Abstract: Subcallosal cingulate deep brain stimulation (SCC DBS) has shown effectiveness in treating patients with treatment-resistant depression (TRD). However, inter-individual variability in recovery trajectory as well as intra-individual variability in clinical symptoms hinders systematic adjustment of stimulation parameters. To overcome this limitation, we aim to identify electrophysiological markers of symptom recovery as well as response to stimulation from longitudinally collected local field potential (LFP) recordings. LFPs were acquired weekly during the first 6 months of therapeutic SCC stimulation using implanted pulse generators with data acquisition capabilities (Medtronic Activa PC+S). We used a neural network classifier to differentiate the beginning and the end of the 6-month period using spectral features extracted from LFPs. We used a novel tool, generative causal explainer (GCE), to identify 'spectral discriminative factors (SDCs)' that identified the feature changes that explained the classifier performance. We used separate classifiers to differentiate facial features extracted from videos of clinical interviews taken concurrently. The classifier based on LFP was able to differentiate the early and late stages of DBS treatment (Area under ROC curve: 0.91 ± 0.05, accuracy: 0.78 ± 0.09). GCE analysis revealed increases in alpha, beta and gamma band power contributed to the classifier performance. However, beta band power exhibited a decrease initially. Using the SDCs decoded from GCE in the intermediate period between the beginning and end of the 6 months, we identified distinct transitions which coincided with, or preceded transitions identified from individualized facial features (Kendall tau = 0.89, p = 0.04). In addition, SDCs responded to changes in stimulation dose. The results suggest long-term effect of stimulation that accompanies clinical recovery is distinct from acute effect of stimulation.

In addition, SDCs may serve as biomarkers to augment clinical decision-making and as potential control signals in closed-loop DBS.

Title: Sex-specific profiles of m6A RNA methylation in the brain of individuals with Major Depressive Disorder

Authors: *H. MITSUHASHI[1], Z. AOUABED[3], P. DANTHI[3], C. NAGY[2,3], G. TURECKI[1,3];
[1]McGill Univ., Montreal, QC, Canada; [2]Neurosci., McGill Univ., Verdun, QC, Canada; [3]Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Introduction: Major Depressive Disorder (MDD) is twice as prevalent in females than males, and mounting evidence suggests that it may be driven by sex-specific molecular mechanisms. Recent gene expression studies have revealed a small overlap between differentially expressed genes (DEG) in male and female MDD. Moreover, these DEGs are enriched in synaptic regulation in males, whereas they are enriched in immune response in females, suggesting a sex-specific mechanism in MDD. However, little is known about how molecular mechanisms lead to sex differences in MDD. Epigenetic mechanisms, which are altered in response to environmental factors, are known to be involved in the pathophysiology of MDD. Similar to these epigenetic modifications, RNA modifications have emerged as a dynamic and crucial mechanism in the post-transcriptional regulation of gene expression in recent years. Among the 150 known RNA modifications, N6-methyladenosine (m6A) is the most abundant and reversible RNA modification in mammalian messenger RNA (mRNA). Emerging evidence suggests that m6A plays an important role in the brain, including neurogenesis, and memory and learning. Moreover, recent studies have linked m6A to molecular and behavioral responses to stress, making it an important candidate regulator of stress-related psychiatric disorders, including MDD. This project aims to investigate the landscape of m6A in the human brain and to identify changes that may occur in the context of MDD. **Methods:** We optimized a low-input m6A-seq method for human postmortem brain tissue and showed that the m6a-peaks are enriched in the known m6A GRACH motif and near 3'UTR and stop codon as suggested by the previous study. The ventromedial prefrontal cortex was obtained from male and female MDD and healthy control subjects to investigate the role of m6A in MDD. We performed m6A-seq and RNA-seq to investigate m6A at transcripts levels and the impact of m6A on gene expression. **Results:** We identified ~25,000 m6A peaks in the human brain, and these peaks were enriched in genes related to neuronal and synaptic regulation. Moreover, our results show a distinct m6A

profile in MDD and control, with a little overlap between males and females. **Conclusion:** Our results show sex-specific transcriptional profiles in MDD as suggested by the previous studies, and how epitranscriptomic regulation could regulate these different molecular mechanisms. Our research will help us understand the role of m6A in psychiatric disorders and will serve as a much-needed example of sex-specific analysis in MDD.

Title: Symptom improvement is not associated with white matter changes in women with premenstrual dysphoric disorder under selective progesterone receptor modulator treatment.

Authors: *E. KALTSOUNI[1], X. GU[1], E. COMASCO[1], I. SUNDSTRÖM POROMAA[2];
[1]Neuroscience, Sci. for Life Lab., [2]Women's and Children's Hlth., Uppsala Univ., Uppsala, Sweden

Abstract: Approximately 5-8% of reproductive women suffer from premenstrual dysphoric disorder (PMDD) which is characterized by severe cyclic mood symptoms emerging in the luteal phase of the menstrual cycle. Impaired cortico-limbic function is related to the affective symptoms experienced in the luteal phase in PMDD, likely due to maladaptive neural response to ordinary hormonal fluctuations. The aim of this study is to employ tract-based spatial statistics (TBSS) to evaluate the microstructural integrity changes of white matter (WM) tracts in women with PMDD after selective progesterone receptor modulator (SPRM) treatment compared with placebo. Diffusion tensor imaging (DTI) data were acquired from 35 women that underwent brain scanning during the luteal phase of the menstrual cycle, before and after a three-month treatment with SPRM or placebo. Reporting of PMDD symptoms severity was done through self-reports using the Daily Record of Severity of Problems, while liquid chromatography - tandem mass spectrometry was used for the measurement of gonadal hormone levels. Whole brain and region of interest TBSS analyses were performed to assess time by treatment interaction effects on WM microstructure by integrating multiple DTI metrics including fractional anisotropy, mean diffusivity, radial diffusivity, and axial diffusivity. No significant treatment effects emerged from the permutation-based non-parametric analyses. Analyses on the relationship between hormonal level over time and changes in white matter are ongoing. Additionally, ongoing correlation analyses are being performed to further investigate the relationships between changes in DTI metrics over time and symptom improvement. These preliminary results suggest that white matter alterations may not contribute to the

improvement of mental symptoms observed after selective progesterone receptor modulator treatment in women with PMDD.

Title: Glutamatergic and GABAerigc modulation of cognitive flexibility during rodent touchscreen reversal

Authors: *J. CHANDRASEKARAN[1], D. N. LINSENBARDT[3], J. L. BRIGMAN[2];
[2]Dept. of Neurosciences, [1]Univ. of New Mexico, Albuquerque, NM; [3]Univ. of New mexico, Albuquerque,, NM

Abstract: Executive functions, such as behavioral flexibility, allow an individual to adapt to an ever-changing environment. Impaired flexibility has been associated with multiple neuropsychiatric and neurodevelopmental disorders and understanding the mechanisms of flexibility is critical for developing effective treatment. Preclinical studies have demonstrated that the lateral orbitofrontal cortex (OFC) tracks and updates changing reward values during reversal, a well-validated cross-species task of flexibility. NMDARs are known to globally mediate learning and the ratio of NMDAR subunits GluN2A and GluN2B have been suggested to act as a gate for synaptic plasticity during learning. Loss of forebrain GluN2A impairs learning while loss of cortical GluN2B is sufficient to impair flexibility and alter coherence with the dorsal striatum (DS). It is still unknown if the 2A/2B ratio varies during stages of learning and reversal. In addition, AMPARs also play a critical role in synaptic plasticity. The membrane insertion of AMPAR depends on NMDAR activation which is essential for learning, yet the role of AMPAR subunits in reversal learning is still unknown. In addition to evidence showing the OFC tracks reward value via intra-region coherence of glutamatergic neurons, GABAergic interneurons also play a role in reversal learning. However, the role of E/I balance during reversal learning is unknown. In order to test if NMDAR and AMPAR subunit expression is critical for gating plasticity during reversal, we tested C57BL/6J male mice (n=20/group) to stages associated with learning and flexible choice. 2 hours following the beginning of the session mice were sacrificed, brains removed and immunoblotting performed to quantify the levels of NMDAR and AMPAR subunits in the synaptic fraction. To examine E/I balance during reversal, C57BL/6J mice were implanted with drivable 64 channel shank electrode (Cambridge neurotech) following discrimination. Single unit firing activity of putative pyramidal and

fast-spiking interneurons was recorded during early reversal sessions 1-4 and chance reversal (50% correct choice). Our results show a pattern of increased GluN2B expression in the DS during learning, and a subsequent increase in the subunit in the OFC during early reversal when flexibility was required. Analysis of glutamatergic and GABAergic activity in vivo revealed dynamic alteration in E/I balance during reversal. Together, these results further our understanding of the mechanisms mediating flexibility, and provide a strong foundation to develop better treatment strategies for neuropsychiatric disorders presenting with maladaptive perseveration.

Title: Increased activation of the lateral orbitofrontal cortex impairs reversal learning

Authors: *K. M. TUITE, M. GIROTTI, D. A. MORILAK;
Pharmacol., The Univ. of Texas Hlth. Sci. Ctr. At S, San Antonio, TX

Abstract: Stress-related psychiatric disorders, such as major depressive disorder and anxiety disorders, have cognitive symptoms that are not well-treated by classical antidepressants and cause major detriments to patients' quality of life. Reversal learning, a form of cognitive flexibility necessary to adapt to a changing environment, is disrupted in stress-related psychiatric disorders. The orbitofrontal cortex (OFC) is involved in reversal learning, and hyperactivity in the OFC is associated with psychiatric disorders in humans. Reversal learning in rodents is evaluated using the first three stages of the attentional set-shifting test (AST). We have previously reported that chronic stress impairs reversal learning and that inducing long-term depression (LTD) in the mediodorsal thalamus to OFC projection reverses these deficits. This indicates reducing OFC activity following stress restores reversal learning to control levels. However, we have yet to investigate OFC activity in reversal learning under baseline conditions. To address this, animals went through either the compound discrimination or reversal learning stages of AST and brains were processed for Fos immunohistochemistry. In lateral OFC, Fos induction significantly decreased following reversal learning compared to compound discrimination. Additionally, Fos expression was increased after reversal learning in the central medial thalamus (CM), an afferent to the OFC, that has yet to be implicated in reversal learning. We next tested the hypothesis that a decrease in OFC activity is necessary for successful reversal learning. We used an adeno-associated virus to deliver an excitatory (Gq) DREADD or control GFP construct into the lateral OFC under the control of the CaMKII promoter to increase activity specifically of glutamatergic neurons. Animals received injections of DREADD agonist 21 (1 mg/kg, i.p.) 20 minutes preceding reversal learning. Activating the Gq DREADD significantly impaired reversal learning, increasing trials to criterion during reversal learning as well as

regressive errors. These results suggest that preventing inhibition in the OFC during reversal learning impairs performance. Future experiments will investigate circuit-level activity in the OFC and its efferent targets and determine the potential role of the excitatory CM thalamic afferent to the OFC in reversal learning and in the effects of stress.

Title: Population dynamics of individual neurons in prelimbic and infralimbic cortices of rats in a behavioral paradigm requiring action control.

Authors: *A. PARTHASARATHY[1,2], B. J. G. VAN DEN BOOM[1,2], F. VEEN[1], N. YEE[1], I. WILLUHN[1,2];
[1]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [2]Amsterdam Universitair Medische Centra (Amsterdam UMC), Amsterdam, Netherlands

Abstract: Several psychiatric conditions, classified as impulsivity disorders, are associated with impaired inhibitory control of behavior. Such an inability to inhibit unwanted behavior is often linked to dysfunctional expression or suppression of appetitive behavior. A number of studies suggest that prelimbic (PL) and infralimbic (IL) cortices play dichotomized roles in the expression and suppression (respectively) of reward-driven actions, drug seeking, or fear conditioning. However, the neural encoding of appetitive behavior in PL and IL in the context of such behaviors is understood insufficiently. Thus, we investigated how populations of neurons within PL and IL are coordinated and collaboratively establish appetitive behavior. We recorded calcium transients from PL and IL neurons by imaging GCaMP6s activity with implantable, miniaturized fluorescence microscopes (miniscopes) in rats that performed a reward-driven go/nogo task. We observed that similar proportions of neurons in PL and IL encoded task relevant information during go (expression) and nogo (suppression) trials. To investigate the role of population activity in PL and IL, we used a dimensionality-reduction approach to compute the (neural) activity space that contains information about the animal's task-related behavior and studied the temporal dynamics within this activity space. Using this computational approach, we detected significant information about the two trial types in both PL and IL neuron populations on a trial-by-trial basis, prior to the trial-relevant behavioral response of the trial. In addition, PL and IL population activity played a role in encoding individual behavioral events, such as lever presses (the operant action in go trials). Such extraction of task-relevant information at a single-trial level provides a strong behavioral correlate that is difficult to detect using traditional population activity representations such as single-cell averaging.

Furthermore, our population-activity data demonstrate that go and nogo trials are encoded differently in PL and IL. Overall, we showed that population activity in PL and IL exhibits task-relevant information about the animal's behavior on a trial-by-trial basis. Based on these findings, we can now focus on investigating which subpopulations of neurons in PL and IL encode the aforementioned neural activity during go and nogo trials. In the long run, this line of research will help us understand how PL and IL neurons contribute to expression (go) and suppression (nogo) of action under both normal and psychiatric conditions, to which impaired inhibitory behavioral control is central.

Title: Differential projections from the five divisions of the orbital cortex to the thalamus in the rat

Authors: R. P. VERTES, S. B. LINLEY, A. K. P. ROJAS, W. B. HOOVER;
Ctr. Complex Systems, Florida Atlantic Univ., Boca Raton, FL

Abstract: Using the anterograde tracer, PHA-L, we examined projections from the orbital cortex (ORB) to the thalamus in the rat; that is, from the medial orbital (MO), ventral orbital (VO), ventrolateral orbital (VLO), lateral orbital (LO) and dorsolateral orbital (DLO) cortices to the thalamus. Overall, projections from the ORB to the thalamus were essentially restricted to central/medial regions of the thalamus, with a lack of projections to principal (or relay) nuclei of the thalamus. Although differentially innervated by each subdivision, the main thalamic targets of the ORB were: the paratenial nucleus (PT), nucleus reuniens (RE), medial and central divisions of the mediodorsal nucleus (MD), intermediodorsal nucleus (IMD), the submedial nucleus (SMT) and the rostral intralaminar nuclei (ILt). MO distributed heavily to the PT, RE and medial MD and lightly to IMD. Similar to MO, VO distributed heavily to PT and RE but unlike MO to the central rather than to the medial division of MD. VO heavily targeted ventrolateral parts of RE, including the lateral wings of RE. The projections of VLO significantly differed from those of MO and VO. There was an absence of VLO projections to the rostral thalamus including to PT and RE; the main VLO targets were SMT, central MD, anterior medial (AM) nucleus and the rostral ILt -- central medial (CEM), paracentral (PC) and central lateral (CL) nuclei. LO distributed heavily to the central MD, moderately to IMD and SMT, and lightly to PT and the rhomboid (RH) nucleus. DLO distributed heavily to PT and medial MD and moderately to IMD, RH and SMT. In summary, (1) all ORB divisions projected to MD, with notable differences across medial and central divisions of MD; (2) with the exception of VLO, all ORB divisions projected to PT; (3) projections to RE mainly arose from MO and VO; (4) projections to the intralaminar nuclei mainly arose from VLO; and (5) interestingly, there was a general absence of ORB projections to the paraventricular nucleus, and with some exceptions, to the

anterior nuclei of the thalamus. In the absence of direct projections from medial prefrontal cortex (mPFC) to the hippocampus (HF), we previously showed that RE is an important anatomical link between the mPFC and the HF (Vertes et al., 2007). In the same manner, RE appears to critically link the ORB (MO and VO) with the HF, possibly involved in relaying information on reward contingencies or behavioral adaptations from the ORB to the HF. The foregoing indicates that each of the subdivisions of the ORB exhibit a unique pattern of projections to the thalamus in the rat, which suggests that individual divisions of ORB may exert unique functional effects on thalamic or thalamocortical systems.

Title: Gamma-frequency auditory stimulation improves rule shifting in Dlx5/6$^{+/-}$ mice

Authors: *J. SHI, A. J. PHENSY, V. S. SOHAL;
Dept. of Psychiatry, Univ. of California San Francisco, San Francisco, CA

Abstract: Cognitive flexibility is critical for organisms to adapt to changing environments. Deficits in this ability are associated with neuropsychiatric disorders such as schizophrenia. We have previously shown that synchronized gamma-frequency oscillations generated by parvalbumin (PV) interneurons in the medial prefrontal cortex (mPFC) play a key role in cognitive flexibility (Cho et al. 2015, 2020), and that optogenetically enhancing this gamma-frequency synchronization in mutant mice with abnormal PV interneuron development can rescue their deficits in cognitive flexibility, measured using a rule shifting task (Cho et al., 2015, 2020). Recently, multiple studies have demonstrated the effectiveness of using gamma-frequency trains of visual and/or auditory stimuli to entrain higher-order brain regions including the mPFC and ameliorate cognitive deficits in mouse models of Alzheimer's disease (Martorell et al. 2019, Adaikkan et al. 2019). Here, we investigated the effect of gamma-frequency (40 Hz) auditory stimulation on *Dlx5/6*$^{+/-}$ mice during a rule shifting task. In this task, mice form an initial association between one cue (an odor or a textured digging medium) and the location of a hidden food reward. Upon successful learning, the association is shifted to a familiar (but previously task-irrelevant) cue belonging to the other modality (odor or texture). Gamma-frequency auditory stimulation rescued the performance of *Dlx5/6*$^{+/-}$ mice in this rule shifting task, significantly reducing the numbers of trials needed to reach a learning criterion and of preservative errors to near wild-type levels. Unlike the pro-cognitive effects of gamma-frequency optogenetic stimulation (Cho et al., 2015), these effects did not persist in the absence of additional stimulation on subsequent days of testing. We also recorded signals from genetically encoded voltage indicators expressed in mPFC PV interneurons to measure gamma-frequency synchronization. We are currently analyzing these data to identify possible circuit changes elicited by gamma-frequency auditory stimulation.

Title: Activity of Drd2-expressing neurons in the mouse medial prefrontal cortex (mPFC) during social decision making

Authors: *M. TURNER, V. SOHAL;
Univ. of California, San Francisco, San Francisco, CA

Abstract: The medial prefrontal cortex (mPFC) is a hub for many forms of cognition and decision making, and is also important for normal social behavior. Dopaminergic modulation of mPFC activity is critical for these functions, and is believed to be altered in many psychiatric conditions. Of particular interest are dopamine D2 receptors (D2Rs), which have been shown to be important for normal working memory and set-shifting in rodents, and are thought to play key roles in the pathology of schizophrenia and bipolar disorder in humans. Published work from our lab using fiber photometry showed that D2R-expressing neurons in the mPFC are preferentially recruited during social interaction in mice. Which behavioral variables these neurons might encode during social interaction, and how D2Rs contributes to this activity, remains unknown. Here, we use in vivo calcium imaging and head-mounted miniature microscopes to examine the activity of D2R+ neurons in the mPFC during the three-chamber test, which is commonly used to assay social preference and social novelty preference. To image D2R+ neurons under normal conditions (D2R-WT), Drd2-Cre+/- mice were injected with AAV2-hSyn-DIO-GCaMP6m (n = 7 mice [4M, 3F], n = 362 neurons). To explore the role of the D2R in socially recruited activity, we used a separate strategy to image D2R+ neurons and knockout the receptor (D2R-KO): Drd2f/f mice were co-injected with AAV2-EF1a-DIO-GCaMP6m and AAV8-D2sp-Cre, which expresses Cre recombinase from a D2R-specific promoter (n = 6 mice [3M, 3F], n = 345 neurons). As a comparison, a separate cohort of Drd2-Cre+/- mice were injected with AAV2-hSyn-GCaMP7f to label all neurons of the mPFC (mPFC-WT) (n = 5 mice[2M, 3F], n = 355 neurons). Interestingly, we found that the largest fraction of D2R-WT neurons had significantly increased activity specifically within the center chamber (19.43% ± 7.54% per mouse, based on comparison to shuffled datasets). Notably, , a significantly smaller proportion of D2R-KO (10.41% ± 3.51%; $p = 0.023$) and of mPFC-WT (9.88% ± 2.98%; $p = 0.022$) neurons significantly increased activity within the center chamber (One-way ANOVA [$F(2,15) = 6.294$, $p = 0.0104$] with Tukey's post-hoc). These results indicate that the D2R+ population of the mPFC is preferentially recruited in the center of the three-chamber apparatus, and that this recruitment depends on D2Rs. Given that the center chamber represents a decision point in the task, this work potentially opens new doors into the study of the cells and circuits that underlie social decision-making in mice.

Title: Prefrontal long-range inhibition exerts top-down control over hippocampal signal-to-noise and exploratory behavior

Authors: *R. MALIK, Y. LI, S. SCHAMILOGLU, V. S. SOHAL;
Dept. of Psychiatry, Univ. of California San Francisco, San Francisco, CA

Abstract: The prefrontal cortex (PFC) plays a crucial role in top-down executive control of brain activity and behavior. It is postulated that PFC communicates with several cortical and subcortical brain regions, monitoring and gating their ongoing activity, in order to exert top-down control over innate and learned behaviors. One brain region that is known to interact with the PFC is the hippocampus (HPC), a key brain region for processing spatial information, and using spatial representations to guide exploratory behavior. Multiple lines of evidence in humans, non-human primates, and rodents have suggested that PFC exerts top-down control over information processing in the HPC, particularly during exploratory behaviors. However, the circuit mechanisms mediating prefrontal top-down control remain unclear, and it is not known whether the PFC acts by transmitting specific information to the HPC or by modulating the network state and emergent circuit function. Our study addresses this major gap by revealing a novel anatomical substrate mediating prefrontal top-down control. Specifically, we have identified monosynaptic long-range GABAergic (LRG) projections from the PFC to the dorsal HPC, and have elucidated how these projections regulate exploratory behavior via actions on hippocampal neurons, microcircuits, network dynamics, and information processing. We found that PFC-HPC LRG projections preferentially inhibit vasoactive intestinal polypeptide expressing interneurons, which are known to disinhibit hippocampal microcircuits, thus representing a novel ‘doubly disinhibitory’ long-range circuit motif. Due to this specific targeting, stimulation of LRG projections increases hippocampal feedforward inhibition and reduces hippocampal activity in vivo. The net effect of these actions is to specifically enhance the signal-to-noise ratio for hippocampal representations of objects. Correspondingly, both stimulation and inhibition of PFC-HPC LRG projections affect object exploration behavior. Together, these results outline a new top-down pathway in which prefrontal LRG projections target hippocampal disinhibitory microcircuits, thereby enhancing signals and network dynamics underlying exploratory behavior.

Title: Amphetamine use and withdrawal impairs interval timing in mice

Authors: *H. R. STUTT[1], M. A. WEBER[2], N. S. NARAYANAN[3];
[2]Dept. of Neurol., [1]Univ. of Iowa, Iowa City, IA; [3]Neurol., Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

Abstract: Amphetamine dependence and withdrawal is associated with high incidences of relapse, stress hypersensitivity, and anxiety. Cognitive dysfunctions such as impaired working memory, attention, and temporal control of action may underlie these factors to drive the cycle of addiction. Further, amphetamine-related hospitalizations and overdoses are increasing, and only a few treatment options are available. Therefore, it is critical to elucidate how amphetamine abuse affects cognitive function. Interval timing, i.e. the temporal control of action, is ideally suited to investigate amphetamine-induced cognitive dysfunction as it requires processes such as working memory and attention and is dependent on dopamine in both the dorsomedial striatum and frontal cortex. Here, we investigated how amphetamine use and withdrawal in rodents impacts interval timing behavior using an operant-based timing task. This task requires the rodent to make a decision to "switch" from one response port to another based on their perception of how much time has passed. Following training, half the subjects received daily amphetamine injections (2.5 mg/kg ip.) for 14 days while the other half received equivalent volumes of saline. We observed that acute exposure to amphetamine resulted in both earlier and greater variability of switch times on average. In addition, following a 14 day period of forced withdrawal, subjects previously exposed to amphetamine were more variable on average. These results suggest that amphetamine exposure can produce changes in time perception immediately following exposure and well into withdrawal. We hypothesize that this acute and prolonged deficit in interval timing is the result of altered dopamine function in the dorsomedial striatum and frontal cortex. We will test this hypothesis using dLight, an in vivo dopamine sensor, and fiber photometry recordings before, during, and after chronic amphetamine administration. Together, these findings will provide detailed mechanistic understanding of how amphetamine use and withdrawal can negatively impact cognitive function, and may guide future studies exploring brain stimulation and pharmacological interventions for cognitive dysfunctions associated with amphetamine use and withdrawal.

Title: Sex Differences in the Effects of Chronic Stress and Prefrontal Cortical REDD1 Overexpression on Pavlovian Autoshaping Behavior in Rats

Authors: B. KURTOGLU[1], D. WHEELER[2], B. WINDSOR[1], M. SPRING[3], J. EVANS[1], D. NOWAK[1], M. MANTYCH[1], P. LAMBERTON[2], R. WHEELER[2], *J. MANTSCH[1];

Abstract: Sign tracking and goal tracking have been linked to human disease states including substance use disorders and depression. The prefrontal cortex (PFC) is important for regulating Pavlovian autoshaping behavior and chronic stress is known to produce structural and functional changes in PFC that might also contribute to disease states. In this task, a cue (the presentation of a lever) is associated with the subsequent delivery of a reward (a sucrose pellet). Rats can express the acquisition of this association by approaching the cue (sign tracking), or by anticipatory approach to the reward (goal tracking). In contrast to prior studies, chronic unpredictable stress (CUS) promoted a CS+ responding in male rats consistent with the shift to a sign tracking phenotype. In contrast, in females rats CUS produced a shift towards a goal directed behavior. Previous studies have shown that the protein REDD1 (regulated in development and DNA damage responses-1) is increased in post-mortem PFC tissue from individuals diagnosed with depression. Recently, we observed that, there is an increase in REDD1 expression and a decrease in Raptor phosphorylation, one of the key elements of the mTORC1 complex, in rat PFC after CUS, suggesting disrupted mTORC1 function. This effect was transient as it was not observed at a later time point after CUS. To determine if REDD1 overexpression is sufficient to produce changes in Pavlovian autoshaping, we used a viral vector to overexpress REDD1 in the PFC of male rats before training them in a Pavlovian autoshaping task. Similar to CUS, REDD1 overexpression produced a phenotype that was consistent with sign tracking behavior in male rats. Relative to control rats, REDD1 rats showed reduced anticipatory approach to the food (goal tracking), but enhanced approach to the cue (sign tracking). The observation that CUS and REDD1 overexpression produce sign tracking phenotypes in male rats likely has relevance for understanding a number of stress related disorders. Future research will determine whether female rats are similarly affected by REDD1 overexpression, and examine the time course of REDD1, necessity of disrupted mTORC1 for stress effects and reconcile the differences between our current and past findings.

Title: Extinction learning promotes neuroplasticity in the medial prefrontal cortex of chronically stressed rats

Authors: *S. E. BULIN, J. LIU, D. A. MORILAK;
Univ. of Texas Hlth. At San Antonio, San Antonio, TX

Abstract: Posttraumatic stress disorder (PTSD) is a serious mental disorder that affects 7-8% of the population in the USA. Our lab has established a model of cognitive behavioral intervention in rats, namely extinction therapy, which resembles prolonged exposure therapy for PTSD. Our animal model of extinction therapy ameliorates stress-induced deficits in cognitive flexibility and active coping behavior and these therapeutic effects are blocked by inhibition of the pyramidal neurons in the medial prefrontal cortex (mPFC). In this current study, we investigate mechanisms underlying the efficacy of extinction therapy involving alterations in synaptic and structural plasticity of the mPFC in chronically stressed rats. To test for changes in neuroplasticity in the mediodorsal thalamus (MDT) to mPFC pathway, previously shown to be less responsive after stress, rats were injected with the viral vector AAV5-CAMKII-ChETA-YFP in the MDT to achieve pathway specificity. 3-4 weeks after virus injections, rats underwent chronic unpredictable stress (CUS) or control treatment. Extinction or control treatment was applied 24 hrs after the end of CUS, and 24 hrs later, rats were anesthetized to record local field potentials evoked in the mPFC by stimulating in the MDT. A current-response curve was collected prior to applying optogenetic laser stimulation to induce long-term potentiation (opto-LTP). Responses were then recorded at an intensity that generated 50% maximal response at baseline for 90 minutes after opto-LTP induction. In male rats, extinction rescued stress-induced deficits in the afferent-evoked response and increased potentiation after opto-LTP ($p<0.001$). However, in stressed female rats, extinction learning had no effect on mPFC responsivity, but rescued stress-induced deficits in opto-LTP ($p<0.01$). In a separate experiment, changes in structural plasticity was examined. CUS and nonstressed rats were sacrificed 24 hr after extinction learning or tone exposure to examine changes in spine density and neuronal morphology. Images of pyramidal cells in layer II/III and layer V of the mPFC were acquired and spine density and morphology in both apical and basal dendrites were measured. 10 µm segments were analyzed every 50 µm from the soma. Quantification is ongoing.

Title: Putamen inhibition enhances flexibility in action selection in rhesus monkeys

Authors: *T. SHNITKO[1], V. CUZON CARLSON[2], K. GRANT[1];
[1]Oregon Natl. Primate Res. Center, OHSU, Beaverton, OR; [2]Oregon Natl. Primate Res. Cenetr, OHSU, Beaverton, OR

Abstract: The activity of parallel cortico-basal ganglia circuits are responsible for action selection. The associative cortico-basal ganglia circuit, that includes the striatal caudate nucleus, is critical for flexible behaviors that adapt in response to changing contingencies. In contrast, inflexible or habitual behaviors rely primarily on the sensorimotor cortico-basal ganglia circuit that includes the striatal putamen. Here we test the hypothesis that decreasing the output of the sensorimotor circuit, will bias towards the use of the associative circuit in action selection, therefore increasing behavioral flexibility. To this end, the impact of reversible putamen inhibition on performance of an attentional set-shifting task (ASST) was tested in 12 rhesus monkeys (6 females) in which Gi-DREADDs were virally expressed in the pre-commissural putamen under the human synapsin 1 promoter. The ASST was based on solving a sequence of up to 8 visual-discrimination "sets" of two geometric shapes and colors, that increased in difficulty across sets. Touching the "correct" stimuli resulted in reinforcement while touching the "incorrect" stimuli resulted in a 10-s delay to the next trial and no reinforcement. Advancing through sets was self-pacing and occurred with 12 of 15 correct trials. Sessions ended when all 8 sets were completed or 45 minutes elapsed. All monkeys were housed in the same room and given 37 daily ASST sessions simultaneously within their housing cages (task acquisition). The DREADD actuator, deschloroclozapine (DCZ, 300mg/kg) or saline was given 30 minutes prior to ASST sessions. Neither DCZ or saline injection altered performance on the well-trained ASST performance (activation was tested following 5 baseline sessions). However, following an ASST session that incorporated a sensorimotor challenge (SMC), where the visual stimuli was reduced in size to assess action selection flexibility (Shnitko et al., 2020), animals that received DCZ performed better than those that were treated with saline. Activation of Gi-DREADDs within the putamen led to animals completing more sets (DCZ = 8 sets, saline = 3 sets) as well as decreased the number of errors made (DCZ = 25±4 errors, saline = 42±10 errors). Thus, study revealed that disruption within the sensorimotor neurocircuit via putamen inhibition enhances flexibility in action selection when subjects presented with a novel aspect of a well-learned visual discrimination.

Title: Segregated Output Channels from Cerebellar Cortex to Prefrontal Cortex

Authors: *A. C. BOSTAN[1], R. P. DUM[2], P. L. STRICK[3];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Neurobiology, Ctr. for Neural Basis of Cognition, Systems Neurosci. Inst., Univ. Pittsburgh, Pittsburgh, PA; [3]Systems Neurosci. Inst., Univ. Pittsburgh Sch. Med., Pittsburgh, PA

Abstract: There is a growing recognition that the cerebellum is not only concerned with the control of movement, but also is involved in cognitive function. Indeed, it is now clear that a substantial portion of the output from the cerebellum is directed at nonmotor areas of the cerebral cortex in the frontal lobe. These same areas of the prefrontal cortex are a major source of signals back to the cerebellar cortex. We have begun to explore the mapping principles that define this cerebro-cerebellar circuitry. To do this, we injected the CVS-N2C strain of the rabies virus with the mCherry marker gene (RV-MC) into area 9L of the prefrontal cortex in a Cebus monkey. In the same animal, we injected the CVS-N2C strain with the GFP marker gene (RV-GFP) into an adjacent region of the prefrontal cortex, the PrePMd. We set the survival time to allow transport of both virus strains to infect first-order neurons in regions of the thalamus, second-order neurons in the cerebellar nuclei, and then third-order neurons (Purkinje cells [P-cells]) in the cerebellar cortex. Virus transport from either injection site infected P-cells located laterally in the posterior lobe of the cerebellum, within regions of Crus I, Crus IIa, and Crus IIp. However, the densest labeling following transport from the PrePMd injection of RV-GFP and that following transport from the area 9L injection of RV-MC displayed limited overlap. Three regions of the cerebellar cortex contained infected RV-GFP and RV-MC P-Cells: (1) the posterior bank of the cerebellar cortex in the fissure between Crus I and Crus IIa; (2) the posterior bank of cerebellar cortex in the fissure between Crus IIa and IIp; and (3) the surface of Crus IIp. Even at these sites, patches of P-cells infected by virus transport from PrePMd were interleaved with patches of P-cells infected by virus transport from area 9L. Our estimate is that the overlap in the two types of patches is less than 6%. These results along with others indicate that a relatively large region of the cerebellar cortex in the hemisphere is interconnected with areas of the prefrontal cortex. However, within this region, separate channels exist that are focused on specific prefrontal areas.

Title: Internal states guiding instrumental behaviour engage the anterior insular cortex in rats

Authors: *M. PUAUD, D. JOSHI, A. WRIGHT, V. HO, M. FOUYSSAC, D. BELIN;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Interoceptive mechanisms contribute to both, subjective states but also to guide behaviour and control executive functions. fMRI studies in humans have revealed that the posterior insula (PI) is

involved in the integration of emotional states triggered by peripherally-generated interoceptive cues, such as the increased heart rate induced by the peripherally-acting β-adrenoreceptor agonist, isoproterenol. In contrast, the anterior insula (AI) seems to mediate the utilisation of interoceptive states to make predictions about the environment and thereby to guide behaviour. We tested two hypotheses in 42 male Sprague Dawley rats (i) that rats can equally utilise peripherally- and centrally-generated interoceptive states to guide their behaviour in a drug discrimination task (DDT), and (ii) that the utilisation of interoceptive states to guide behaviour is specifically associated with functional activation of the AI. Rats were trained to discriminate between (i) different exteroceptive cues, (ii) saline and the centrally-acting $GABA_A$ receptor antagonist pentylenetetrazol (PTZ) or (iii) saline and isoproterenol. The reliance on the different cues to guide behaviour was measured and compared over a 12 min challenge session under extinction conditions. Transcriptomic correlates of PTZ discrimination were assessed by qPCR from cDNA libraries of the amygdala, the AI, PI and motor cortex M1. Discrimination was acquired at the same rate across interoceptive and exteroceptive cues, suggesting that interoceptive states are at least equally potent at guiding behaviour as salient exteroceptive stimuli. At the neurobiological level, administration of PTZ in non-trained animals resulted in an increase in mRNA levels of the cellular plasticity marker zif268 in the PI and the central (CeN), but not the basolateral, amygdala. No changes in zif268 mRNA levels were observed in the AI. In contrast, administration of PTZ in animals subsequently tested in the DDT resulted in an increase in zif268 mRNA levels in the AI alongside the PI and CeN. No changes in cellular plasticity were observed in the Motor cortex M1, thereby ruling out non-specific effect of PTZ on the activity of the brain. Together, these results show that a PI-CeN neural system is involved in the integration of the interoceptive effects of PTZ whereas plasticity in the AI is specifically recruited when animals utilise these interoceptive states to guide their behaviour.

Title: The direct and indirect pathways of the basal ganglia modulate dorsal cortical activity and future perceptual decisions

Authors: *E. H. VAN BEEST[1], M. A. O. ABDELWAHAB[1], J. L. CAZEMIER[2], C. BALTIRA[1], M. C. MAES[1], B. D. PERI[1], M. W. SELF[1], I. WILLUHN[3,4], P. R. ROELFSEMA[1,4,5];
[1]Vision and Cognition, [2]Cortical Structure and Function, [3]Neuromodulation and Behavior, Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [4]Psychiatry, Amsterdam UMC, Amsterdam, Netherlands; [5]Integrative Neurophysiol., VU Univ., Amsterdam, Netherlands

Abstract: The striatum, the major input structure of the basal ganglia, receives topographically organized neural projections from the cortex. Two complementary pathways emerge from the striatum: the direct pathway, primarily expressing dopamine D1 receptors, and the indirect pathway, primarily expressing dopamine D2 receptors. The direct pathway disinhibits the thalamus, thereby promoting activity in the thalamocortical circuit. Conversely, the indirect pathway suppresses this circuit. Here we asked how this organization modulates persistent activity related to perceptual decisions in the cortex. We unilaterally injected a virus to express an excitatory opsin in either pathway and measured behavioral responses and neural activity across the dorsal cortex in adult mice using widefield imaging. The mice had been trained to report the location of a grating stimulus with a left or right licking response. Photo-stimulating the direct pathway in “resting state” evoked activity across the dorsal cortex, specifically in visual and motor regions relevant for the task. Photo-stimulation of the indirect pathway had little effect during “resting state”. Stimulation of the direct pathway during the visual detection task evoked extra cortical activity globally and increased the number of lick-responses to the contralateral side. Stimulation of the indirect pathway evoked more ipsilateral lick-responses and a local decrease in activity in visual areas. We also included a condition in which the decision had to be postponed by 1500ms to measure persistent activity. Persistent activity, which is a neural correlate of working memory, has been observed in many different regions including cortical areas and nuclei of the basal ganglia, which may suggest that working memories are coded in a distributed manner. We tested the influence of the complementary pathways on persistent activity and found that stimulating the direct pathway before or during the delay evoked similar neuronal activity as to when a contralateral grating was presented, and promoted future contralateral lick responses. The opposite effect occurred when stimulating the indirect pathway before or during the memory delay. In conclusion, the direct and indirect pathway enable flexible modulation of cortical activity, biasing both current and future perceptual decisions. These findings support a gating function for the basal ganglia in perceptual decisions, in which cortical inputs can be reverberated by the direct pathway or terminated by the indirect pathway. Dopaminergic inputs to the striatum could play a role in balancing the decision such that rewards are optimized.

Title: Chronic intermittent ethanol exposure alters the excitability of dorsal medial striatum-projecting orbitofrontal cortex and basolateral amygdala neurons

Authors: S. NIMITVILAI-ROBERTS, D. GIOIA, J. J. WOODWARD;
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Alcohol addiction is associated with dysfunction of brain circuitry including areas of the orbitofrontal cortex (OFC) and the basolateral sub-region of the amygdala (BLA). The OFC sends strong unidirectional glutamatergic inputs into the areas of the dorsal striatum (DS), in which the medial DS (DMS) is involved in goal-directed actions while the lateral DS (DLS) is important in gating habit-like behaviors. In addition to the OFC that provides top-down control of the DS, the BLA also projects glutamatergic inputs to the DS and is reciprocally interacted with neurons in the OFC. Several studies including ours reported that chronic ethanol exposure (CIE) induces changes in electrophysiological properties of neurons within the OFC, BLA and DS. However, no studies have examined whether CIE alters the function of OFC and BLA neurons that selectively project to the DS. In this study, we injected fluorescent retrobeads into the DMS of adult mice and recorded changes in current-evoked spiking of OFC and BLA neurons from the same animals following four weekly cycles of air or CIE treatment. Consistent with our previous findings, 3-day and 7-day withdrawal from CIE exposure enhanced excitability of DMS-projecting OFC neurons, and this increase was accompanied by a reduction in the after-hyperpolarization amplitude. In contrast, neuronal spiking varied in DMS-projecting BLA neurons with a decrease in evoked firing at 3-day withdrawal followed by an increase in firing at 7-day withdrawal from CIE treatment. An enhanced excitability of DMS-projecting BLA neurons in 7-day withdrawal CIE group was accompanied by a significant increase in the action potential width, suggesting a downregulation of voltage-gated potassium channels, possibly Kv1.1. Overall, these results suggest that chronic exposure to ethanol alters neuronal excitability of DMS-projecting OFC and DMS-projecting BLA neurons in distinct ways and on a different time scale that may contribute to the impairment of emotional processing and flexible behavior observed in alcohol-dependent individuals. Title: Top down regulation of dopamine activity affects cognitive flexibility in a sex-specific manner when behaviors are well-learned

Authors: *D. BORTZ, C. FEISTRITZER, A. A. GRACE;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cognitive flexibility is the act of adjusting behavior in response to changing reward contingencies. Deficits in cognitive flexibility are pervasive and represent core, predictive features in disorders such as depression, bipolar, addiction, and schizophrenia. For example, cognitive flexibility deficit severity predicts mood symptom onset and severity in depression and bipolar. The circuitry that

regulates cognitive flexibility has been well-studied, highlighting the necessity of dopamine (DA) release and receptor activation in prefrontal cortex and striatum. These studies, however, typically measure flexibility 1-2 sessions after the initial discrimination was learned, but not after overtraining. This gap in knowledge is important because rewarded behaviors that are repeated eventually become outcome-insensitive, stereotyped habits, which coincides with a shift in related DA release patterns from ventral to dorsolateral striatum. This suggests that the circuitry underlying cognitive flexibility, particularly with regard to the regulation of DA activity, may be different as behaviors become well-learned.
Previous studies have indicated a role for the medial septum (MS) and its bidirectional regulation of ventral tegmental area (VTA) and substantia nigra (SNc) DA activity in cognitive flexibility; however, the extent of its role, particularly following overtraining, is unclear. To investigate this, we activated the MS or prelimbic cortex to MS pathway of male and female rats using DREADDs and measured their performance on an operant-based set-shifting task, following 1, 10, or 15 days of discrimination training. Rats tested following 1 day of training showed no effect of MS activation. Following 10 days of training, however, activation of the MS or the prelimbic to MS pathway significantly improved set-shifting performance, but only in female rats. Following 15 days of training, MS activation improved performance in both male and female rats. These effects were mediated by the MS's regulation of VTA and SNc DA activity, but to differing degrees based on sex. The difference in MS activation efficacy in male and female rats may be explained by learning rate during training. Female rats reached an average of >92% correct performance during discrimination training in fewer days than males, and more days at this performance criteria predicted worse performance in controls and better performance following MS activation. These data suggest that MS activation may be more effective as training increases and that this region may be a critical relay from prelimbic cortex to midbrain by which flexibility is reinstated once behaviors are well-learned.

Title: Physiology of thalamic nucleus reuniens projections to the medial prefrontal cortex in mice

Authors: *G. VANTOMME[1], G. DEVIENNE[1], A. LUTHI[2], J. R. HUGUENARD[1];
[1]Wu Tsai Neurosciences Inst., Stanford Univ., Palo Alto, CA; [2]DNF, Univ. of Lausanne, Lausanne, Switzerland

Abstract: The hippocampus, along with the medial prefrontal cortex (mPFC) and the nucleus Reuniens of the thalamus (Re) form a neuronal circuit that is essential for memory, learning and executive functions. A critical gap exists between known anatomical and behavioral aspects of this network compared to the paucity of knowledge regarding functional connectivity as governed by synaptic properties, neurotransmitter receptor content, plasticity profile and synaptic integration. This project aims to fill this knowledge gap and to study the synaptic dysfunction within the Hippocampus-Re-mPFC circuit in executive function disorders. Initial ex-vivo electrophysiological recordings showed that optogenetic activation of Re afferents in mice induced excitatory postsynaptic currents in deep layer mPFC neurons. Evoked responses showed a strong short-term depression, consistent with high release probability as observed with other higher order thalamocortical neurons. Interestingly, Re synapses on mPFC neurons showed a low NMDA/AMPA ratio and a high GluN2B and GluN2C subunit content. GluN2C-NMDARs are rarely expressed in CNS synapse, and so far mostly described in cerebellar granule cells and in thalamic relay neurons. Optogenetic activation of Re afferents also induced feedforward inhibition in mPFC neurons, and train stimulation in current-clamp induced a persistent depolarization. Altogether, these data showed that Re synapses in the mPFC of mice have the plasticity profile of driver inputs and set the foundations to study synaptic dysfunctions in the Hippocampus-Re-mPFC circuit in mouse model of executive function disorders.

Title: Fmri study of alterations of cortico-cortical connectivity in a case with damage to the medial dorsal thalamus

Authors: *K. GEIER[1,2], L. YU[2], A. KACOLLJA[2], D. MCQUIGGAN[2], J. RYAN[2,1], B. R. BUCHSBAUM[2,1], R. K. OLSEN[2,1];
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Rotman Res. Institute, Baycrest Ctr., Toronto, ON, Canada

Abstract: Introduction: The medial dorsal thalamic nuclei (MDN) are key contributors to executive processes, attention, cognitive control, working memory and components of long term memory. The MDN may act as modulators of cortical activity, coordinating regions within the prefrontal cortex (PFC), in support of these different cognitive processes. Anatomically, MDN neurons project to multiple cortical

areas so they are ideally suited to modulate communication within the cortex. Computationally, feedback within a thalamocortical network can improve the efficiency of the network.
The primary empirical evidence for a role of the MDN in cortical modulation comes from optogenetic control of the MDN in rodents which shows a causal relationship between MDN activity and contralateral PFC to PFC signaling. It is crucially important to follow up on these findings with human research as PFC development is substantially different between species.
To investigate this question in humans, we examined potential differences in cortico-cortical connectivity in an amnesia case with MDN damage due to perinatal stroke.
Methods: To assess alterations in cortical connectivity we examined background functional magnetic resonance imaging (fMRI) activity for case NC, who has a lesion affecting his left and right MDN, and for 50 healthy age-matched controls. We measured background connectivity by generating correlation matrices of activity time series based on a coarser full cortex parcellation (100 regions) and a finer grained parcellation restricted to the left and right PFC. We used univariate and multivariate (principal components analysis) techniques.
Results: Univariate results showed 5 pairs of cortical regions which showed lower background functional connectivity in case NC than healthy controls using an adjusted Crawford t-test and with false discovery rate (FDR) correction. These regions included the dorsal and medial PFC, the posterior cingulate, and precuneus which are regions known to be strongly structurally and functionally connected to the MDN. Univariate analysis for the finer grained PFC regions did not show any significant results after multiple comparisons correction.
Multivariate results revealed that there was a significant difference in the pattern of background connectivity within the PFC with lesions to the MDN, confirming the importance of the MDN in humans for PFC modulation.
Conclusion: Reductions in background connectivity in NC is consistent with findings from the rodent literature. Disorders that show MDN alterations, such as schizophrenia, may be caused in part by alterations in thalamic modulation of cortico-cortical connectivity.

Title: Subcortical Contributions to Arithmetic Procedures

Authors: *W. SABAN[1], P. PINHEIRO-CHAGAS[2], S. PIANTADOSI[3], R. IVRY[4];
[1]Univ. of California Berkeley, Berkeley, CA; [2]Stanford Univ., Stanford, CA; [3]Univ. of California, Berkeley, Berkeley, CA; [4]Univ. California, Berkeley, CA

Abstract: Humans exhibit complex arithmetic skills, often attributed to the exceptional enlargement of neocortical regions during evolution. However, the past 30 years have provided ample evidence that the functional domain of the basal ganglia (BG) and cerebellum, two ancient subcortical regions extend beyond the motor domain. Using a neuropsychological approach, we explored the contributions of these two subcortical regions to processes involved in a symbolic arithmetic operation, addition. To this end, we compared the performance of three groups of participants: Individuals with either spinocerebellar ataxia (SCA), Parkinson's disease (PD, our model of BG), and matched controls. In Experiment 1, we utilized a verification task, in which participants were required to indicate if an addition problem of three, non-identical, operands (e.g., 5+6+8=19) was true or false. We examined the practice benefits for repeated items and practice benefits for non-repeated items. For the former, we assumed the benefits would reflect the operation of memory-based processes; for the latter, we assumed the benefits would reflect facilitation in the use of algorithmic procedures required for doing arithmetic. Although the SCA and PD groups were slower than the controls, all three groups showed a similar practice benefit on the repeated items, pointing to intact memory-based learning. However, the SCA group showed attenuated practice benefit compared to the other two groups for the non-repeated items, suggesting a selective impairment in algorithm-based learning. In Experiment 2, we examined two possible components of requisite algorithmic operations, execution of the counting operation and the number of required operations. To evaluate the former, we manipulated the magnitude of the calculated sum (small vs. large); for the latter, we compared equations involving the addition of two or three single digits. The SCA group showed a selective impairment on the magnitude manipulation, exhibiting a larger slope for the function relating RT to the sum of the digits. In contrast, the PD group showed a bigger cost compared to the other two groups when adding three digits relative to two digits. This pattern of results points to a double dissociation between two procedures that are involved in symbolic arithmetic, and the involvement of two subcortical areas in these algorithmic procedures.

Title: Influence of anatomical variability on neural decoding strategies by target regions of the hippocampus

Authors: *Y. JIN[1], K. MCCLAIN[2], G. BUZSAKI[3];
[1]New York Univ., New York, NY; [2]Neurosci., NYU Neurosci. Inst., New York, NY; [3]New York University, Sch. of Med., New York, NY

Abstract: The hippocampus plays a vital role in an animal's spatial navigation, where place cells encode positional information through spiking activity. The precise spiking patterns of different place cells vary

based on their anatomical position along the septotemporal axis of the hippocampus. From the septal pole to the temporal pole of the hippocampus, the phase of local theta oscillations shifts one half cycle as the wave travels along the axis, meanwhile, the size of place fields is reported to increase. Such variability in anatomical organization may impact the information decoded by downstream readers in distal regions. To investigate where and how such impact occurs, we simulate spiking in populations of place cells with the position-theta-phase (PTP) model previously published (McClain et al. 2019). We utilize two types of decoders to quantify positional information contained in spiking activity: a canonical Bayesian firing-rate decoder and a novel Bayesian theta-phase decoder. We then compare accuracy when decoding from place cells with anatomically inspired differences in theta phase and place field width. Results suggest that the phase shift across anatomically distributed place cells does not have a significant influence on firing rate decoding accuracy, while the inclusion of larger place fields leads to reduced firing rate decoding accuracy. Additionally, theta-phase decoding is generally more accurate than firing rate decoding within equivalent populations of place cells. Further characterization of these interactions between population encoding properties and spatial information content is ongoing. By assessing and comparing different strategies for decoding from different anatomical distributions of place cells, we can find out which mechanisms are more efficient for the brain and why downstream regions may utilize one specific decoding strategy over the other. Understanding the decoding strategy of downstream regions may shed important light on the mechanisms for information transfer from the hippocampus that are necessary for spatial navigation and memory consolidation, as well as the fundamental question of what is the purpose of the existence of such anatomical variability and why does it occur during evolution.

Title: Brain wide modulation of spiking activity by hippocampal ripples

Authors: *N. NITZAN[1], R. A. SWANSON[2], G. BUZSAKI[3];
[1]New York Univ., Brooklyn, NY; [2]Neurosci., New York Univ., New York, NY; [3]New York University, Sch. of Med., New York, NY

Abstract: Sharp wave ripples (SPW-Rs) are bouts of high frequency oscillations reflecting the highest levels of synchronized activity of hippocampal pyramidal cells and interneurons. Although SPW-Rs are intrinsically generated in the hippocampus, their occurrence is known to be biased by brain-state changes and by various slower brain rhythms. In return, SPW-Rs can transiently affect the ongoing activity at numerous brain regions and this bidirectional communication has been hypothesized to play an important role in the consolidation of new memory traces. However, while numerous studies addressed the effects of SPW-Rs of individual brain areas, the brain-wide coupling to events has been difficult to study at high

temporal and spatial resolution. Here, we leveraged on publically available datasets using multiple high-density Neuropixel electrodes covering numerous cortical and subcortical brain areas as well as multiple hippocampal subdivisions to study this question (Siegle et al., 2021; Steinmetz et al 2019). We found that the majority of brain areas are differentially modulated by SPW-Rs of different anatomical origin. Moreover, we report that the timing, sign and magnitude of responses to SPW-Rs are related to the magnitude of SPW-Rs. Finally, we show that the magnitude of SPW-Rs is strongly correlated with various indicators of brain-state, suggesting brain-wide coordination of activity on multiple scales. Our findings expand on previous results from functional magnetic resonance imaging studies and suggest that SPW-R triggered responses of a given brain area are not a simple function of anatomical connectivity.

Title: Birthdate and rate of neurogenesis affect functional properties of adult hippocampal neurons

Authors: *R. HUSZAR[1], Y. ZHANG[1], H. BLOCKUS[2], G. BUZSAKI[3];
[1]New York Univ., New York, NY; [2]Columbia Univ., New York, NY; [3]New York University, Sch. of Med., New York, NY

Abstract: The hippocampus can be conceived as a uniform large single unit, in contrast to the modularly organized neocortex. In the neocortex, radially migrating excitatory neurons derived from the same progenitors form vertically organized functional columns (Angevine and Sidman, 1961; Li et al., 2012). In contrast, hippocampal neurons migrate radial-tangentially in a zigzag manner and assume the form of horizontal clusters (Kitazawa et al., 2012, Xu et al., 2014). Despite this organization, 'place cells' (O'Keefe and Nadel, 1978) representing the same or different parts of the environment are thought to be randomly distributed in the hippocampus (Redish et al. 2001). Yet, distinct anatomical and functional groups have been noted radially even within the thin hippocampal pyramidal layer (Soltesz, Losonczy 2018; Valero, de la Prida 2018), and it remains to be clarified how these functional groups relate to developmental lineage (Cavalieri et al., 2021). To address how intrauterine development affects future hippocampal function, we birthdated CA1 pyramidal neurons with in-utero electroporation over a wide range of embryonic ages, and compared their functional features in freely moving, adult mice. Neurons of the same birthdate displayed distinct connectivity, and strong coactivity during theta waves and sharp-wave ripples. Birthdated neurons joined into cell assemblies whose rate of expression scaled with the pool size of neurons that were born together. Anatomically clustered (<500μm) same-day born neurons displayed overlapping spatial representations. Overall, the wiring and functional features of CA1 pyramidal neurons reflected a combination of birthdate and the rate of neurogenesis. These observations

demonstrate that sequential neurogenesis in embryonic development shapes the preconfigured forms (Dragoi, Tonegawa 2011; Grosmark et al., 2015; McKenzie et al., 2021) of adult network dynamics.

Title: A metabolic function of the hippocampal sharp wave-ripple

Authors: D. TINGLEY[1], K. MCCLAIN[2], E. KAYA[2], J. N. CARPENTER[2], G. BUZSAKI[3]; [1]Neurosci., NYU Neurosci. Inst., New York, NY; [2]NYU, New York, NY; [3]New York University, Sch. of Med., New York, NY

Abstract: The hippocampus has been implicated in both cognitive and endocrine functions. To identify an activity pattern which may link such disparate functions, we simultaneously measured electrophysiological activity from the hippocampus and interstitial glucose concentrations in the body of freely behaving rats. We report that clusters of sharp wave-ripples (SPW-Rs) recorded from the hippocampus reliably predicted a decrease in peripheral glucose concentrations within ~10 minutes. This correlation was not dependent on circadian, ultradian, or meal-triggered fluctuations, it could be mimicked with optogenetically induced ripples in the hippocampus, but not in the parietal cortex, and was attenuated to chance levels by pharmacogenetically suppressing activity of the lateral septum (LS), the major conduit between the hippocampus and hypothalamus. Our findings demonstrate that a novel function of the SPW-R is to modulate peripheral glucose homeostasis and offer a mechanism for the link between sleep disruption and blood glucose dysregulation in type 2 diabetes.

Title: Toward monosynaptic inference by dissecting causal relationships in pairwise spike trains

Authors: *Z. SACCOMANO[1], J. PLATKIEWICZ[2], S. A. MCKENZIE[3], D. F. ENGLISH[4], A. AMARASINGHAM[5];
[1]Neurosci., City Univ. of New York, New York, NY; [2]Dept. of Mathematics, The City Univ. of New York, New York, NY; [3]Neurosci., UNM Sch. of Med., Albuquerque, NM; [4]Neurosci., Virginia Tech., Blacksburg, VA; [5]Mathematics, City Col. CUNY, New York, NY

Abstract: Can we study synapses simply by observing spike trains? Very precise (under 1 millisecond), short-latency peaks in the cross-correlogram between extracellularly-recorded spike trains are widely observed in cortex and a recent experiment used optogenetic and juxtacellular stimulation of pyramidal neurons in vivo to verify this feature as primarily monosynaptic in origin. We studied this large-scale dataset and developed biophysical models of paired neurons driven by common, nonstationary inputs that can quantitatively reproduce the observed spiking dynamics between monosynaptically-connected neurons in these data. In parallel, we developed statistical inference methods to assess monosynaptic connectivity. These methods exploit a principle of conditional inference in order to be robust to nonstationarity in the underlying dynamics, and were motivated by the causal inference question: how would fine-timescale correlations change - in a connected pair - if the monosynapse did not exist in otherwise identical statistical conditions? The methods were tested on the biophysical models and the robustness of the inference technique was examined over a large range of biophysical parameters. We found that an unbiased estimator for the monosynaptic cause, derived theoretically, works precisely in the biophysical simulations, where ground truth is available, and regardless of the specific mechanisms underlying the statistical behavior of the biophysical models. Finally, we explore how to combine spontaneous and perturbation data to develop an effective parameterization of 'causal synaptic weight,' as it relates to the probabilistic theory of necessary and sufficient causation developed in the causal inference literature.

Title: A cyclic diterpenoid has a neuroprotective effect against Gulf War Illness involved neurotoxicants

Authors: J. L. MARRERO-VALENTIN[1], S. VÁZQUEZ-ALICIA[1,2], F. G. RIVERA-MOCTEZUMA[1,3], D. PEREZ[1], P. A. FERCHMIN[4], ***N. S. SABEVA**[1];
[1]Univ. Central Del Caribe, Bayamon, PR; [2]Univ. of Puerto Rico, Bayamon, PR; [3]Polytechnic Univ., San Juan, PR; [4]Neuroprotection for Life, Carmel, IN

Abstract: Organophosphate (OP) compounds have been widely used as agricultural and household pesticides, jet engine lubricants, and warfare nerve agents. Therefore, the general population and military personnel could be exposed to OPs not only during combat or terroristic attacks but also during routine military, industrial or private activities. Delayed neuronal damage of OP intoxication is thought to contribute to neuronal death and various neurological illnesses. Gulf War Illness (GWI) is one of them. GWI is a currently untreatable multi-symptom disorder experienced by more than 250,000 veterans from the Persian Gulf War (1990-1991). The distinctive hallmark of GWI includes chronic fatigue, migraine, muscle and joint pain, gastrointestinal problems, and cognitive disturbances such as depression and anxiety. Various studies have consistently linked these symptoms to exposure to pyridostigmine, DEET, permethrin, and traces of sarin (the most commonly used nerve agent). There is no effective cure for the GWI or the chronic effect of other neurotoxicants. Our group demonstrated *ex vivo* that exposure to diisopropylfluorophosphate (DFP, a surrogate of sarin) and the above-mentioned neurotoxicants reduce the number of functionally active neurons in hippocampal slices. This loss of neuronal functionality can be reversed by the application of a 4R-cembranotrienes-diol (4R), a cyclic diterpenoid with anti-inflammatory and anti-apoptotic properties. The cembranoid is not toxic and reaches higher concentrations in the brain than plasma. We took advantage of *our ex vivo* GWI model (rat hippocampal slices) to investigate whether 4R has a protective effect on synaptic integrity and neuronal survival in the presence of DFP. We combined electrophysiological recordings with molecular analysis on acute hippocampal slices. Our results suggest that 4R protects neuronal functionality and activates AKT/PI3K cell survival pathway. Thus, this cembranoid is a promising compound to protect the nervous system against neurotoxicants.

Title: Can Transcranial Radio Frequency Stimulation Modulate Ongoing Brain Activity?

Authors: *O. YAGHMAZADEH[1], G. BUZSAKI[2];
[1]New York Univ. Neurosci. Inst., New York, NY; [2]New York University, Sch. of Med., New York, NY

Abstract: Affecting brain activity by means of external stimuli provides various possibilities for research and clinical applications. In this context, non-invasive neuromodulation techniques sit in a unique position due to their potential low level of side effects. Here we report examination of a novel non-invasive contact-less neuromodulation technique based on Radio Frequency (RF) waves searching for potential entrainment of neuronal activity, at single-cell and neural network levels, in rodent models. We apply RF stimulation at around 1GHz using commercially available patch or custom-made stub antennas. Activity of neurons in the CA1 region of mice hippocampus is recorded by the means of a miniature head-mounted 1-photon imaging system (UCLA Miniscope). This recording system permits us to collect data in a metal-implant-free manner thus avoid RF interference on the collected data. In addition, the miniscope's LED circuit is replaced by a fiber-coupled far-away LED light source to avoid additional RF-induced artifacts. Animals are head-fixed at ~4cm from the center of a patch antenna and their head is exposed to continuous-wave RF radiation at 950MHz. The RF exposure is applied in a 3s-ON 3s-OFF paradigm to avoid unsafe brain and body temperature increases. Our results, comparing stimulated and sham conditions, demonstrate that RF exposure (up to 40W of power fed into the antenna) does not affect the ongoing activity of CA1 neurons in a statistically significant manner (n = 5 mice). Nevertheless, we show that by adjusting parameters of the RF stimulation (e.g. power and duty cycle) we are able to increase the brain temperature in a controlled manner. Our MR thermometry experiments show that RF-induced temperature increase is lower at the peripheral sites than in the brain which favors for less-invasive exposure. We observed that our RF paradigm, over a period of 30 minutes, induces ~1°C increase in the brain temperature (without exceeding the physiological range). It is well established that temperature changes can affect the activity of neurons in different brain regions. Hence, we suggest that Transcranial RF Stimulation can be used (and further studied) as a novel neuromodulation technique and help expanding the spectrum of non-invasive tools for brain stimulation.

Title: State-dependent neocortical dynamics surrounding hippocampal ripples

Authors: *R. SWANSON, N. MOUSAVI, N. NITZAN, R. DE LA TORRE, J. BASU, G. BUZSAKI; New York Univ., New York, NY

Abstract: Hippocampal sharp-wave ripple (SPW-R) coupled modulation of neural activity is observed throughout the neocortex during periods of quiescence and non-REM sleep (Buzsaki 2015; Logothetis 2012), and is thought to mediate systems consolidation of multi-modal memories. However, how this dynamic coupling is spontaneously achieved across regions, and thus across spatial and temporal scales in the absence of coordinating sensory input, is unknown. Taking advantage of the high spatial and temporal

resolution of widefield calcium imaging, we develop a preparation that allows simultaneous imaging of dorsal neocortex with high-density chronic ipsilateral silicon probe recordings of the hippocampus and retrosplenial cortex, allowing us to monitor mesoscale neocortical activity during sleep surrounding hippocampal SPW-Rs. In alignment with previous studies, hippocampal SPW-Rs are robustly correlated with increased fluorescence in mouse visual and association cortices, or mouse default mode network. Taking this work further, our preparation allowed us to i. deconvolve the widefield calcium signal into putative population rate across dorsal neocortex, and ii. sleep state score mice in the head-fixed preparation with respect to natural sleep in the homecage. With this additional information, we find the majority of SPW-Rs are preceded by increased excitation in neocortex followed by a DOWN state, matching a model of neocortical NREM sleep whereby neocortex is in an excitableUP regime that exhibits noise or input-driven transient cessations of spiking activity (Levenstein 2019). Leveraging the spatial resolution of widefield imaging, we find that the depth of NREM sleep corresponds to both the degree of excitation preceding the SPW-R and degree to which the evoked DOWN state spreads along the cortical hierarchy from retrosplenial cortex to visual areas. We further find that the magnitude and spatial extent of preceding neocortical excitation is correlated with the depth of coincident sharp wave in CA1, likely reflecting the magnitude of excitatory drive from neocortex to the hippocampus. This suggests the depth of NREM sleep corresponds to more or less excitable regimes, governing the extent to which transient transitions remain local, possibly serving a homeostatic rescaling function, or propagate across the brain, providing a substrate for multi-modal reactivation.

Abstract: The spatiotemporal variety of neuronal firing patterns has no agreed upon answers or theory. Using a combined experimental and modeling approach, we show that neuronal spiking can be described by discrete modes of activity with distinct temporal properties and functional implications. We

investigated spike interval statistics of excitatory neurons from six forebrain regions and found that the majority of spikes can be attributed a neuronal "ground state" (GS) mode, characterized by irregular spiking at a cell-specific low rate (~0.1-5Hz). GS rate is lognormally-distributed and conserved across wake and sleep states. In addition to the GS mode, each neuron has a repertoire of "activated state" (AS) modes, with spiking at specific higher-rate timescales and regularity, which are common among neurons in a given region/state. AS modes correspond to temporal coordination by network and/or intrinsic cellular mechanisms and are evoked by relevant inputs. Supporting this view, we find that a probabilistic modal model of stimulus encoding better accounts for spiking in thalamic head direction cells and hippocampal place cells than a model in which neurons encode stimulus features with smoothly-varying rate. We then show that GS/AS activity is readily produced in a self-balancing network of spiking neurons, in which GS rate reflects the balance of excitation and inhibition, while AS modes reflect cellular coupling to network-specific activation patterns. We hypothesize that GS spiking reflects a default mode of balanced activity that serves to maintain a persistent backbone of neuronal dynamic, from which neurons can depart and switch transiently to a communication mode of AS spiking.

Title: Probing subthreshold dynamics of hippocampal neurons by pulsed optogenetics

Authors: *M. VALERO, G. BUZSÁKI;
NYU Neurosci. Inst., New York, NY

Abstract: The fundamental computation a single neuron performs is to integrate incoming excitatory and inhibitory inputs to decide whether to fire an action potential and feedback its activity into the network. Investigation of this synaptic computation requires access to the neuron subthreshold dynamics, whose state-of-art methodologies have remained unaltered for decades and are unrealistic for cell assemblies and behaving animals.
Here, instead of intracellular recording, we probed the membrane polarization with short depolarizing

pulses optogenetically. Using chronically implanted µLED probes (4 shanks with 3 µLED on each shank), we recorded and probed large numbers of neurons simultaneously in freely moving CamKIIα-Cre::Ai32 mice. Weak blue light pulses (20 ms), inducing firing in only a handful of nearby neurons, were delivered to each µLED in a random manner so that each site was stimulated at ~0.6 s intervals. The short duration of pulses and their sparse recurrence did not perturb the properties of the neurons. Light-sensitive neurons responded to one or more µLEDs and the spike numbers were used as a proxy for estimating relative changes of the membrane potential dynamics. Strikingly, induced spike responses gain sharply increased several-folds inside the preferred position (place fields) of the responsive pyramidal cells. These results are compatible with a tuning curve model in the CA1 pyramidal cells where excitation and the inhibition display a concerted and reciprocal relationship. When optogenetic stimulation was probed on non-place cells, majority of the putative non-place cells showed place-related activity (>65%). Both place cells and non-place cells gained information rate during optogenetic stimulation, but this gain was stronger for non-place cells. Finally, to reveal whether the CA1 network is guided by a single or multiple operation modes, we optically probed neurons around hippocampal sharp wave ripples (SPW-Rs) events. In the short time window of SPW-R, excitatory and inhibitory neurons increased in parallel. As expected, optogenetic probing of the CA1 networks showed that, in contrast to the large gain within place fields, responsivity of pyramidal cells showed a robust decrease during SPW-Rs.
We have developed a method for studying subthreshold dynamics of individual cells in chronic recordings using novel high-resolution optical stimulation as a proxy for the membrane polarization. These experiments disclosed a reciprocal interaction between inhibition and excitation along the place fields of CA1 and demonstrated that the same exact perturbation can bring about opposite responses during exploration and transient SPW-Rs.

Abstract: Synaptic communication lies at the heart of neural computation and changes in synaptic strength are thought to be the neural substrate for memory. Synaptic strength is usually equated to

changes in membrane conductance caused by the binding of transmitters released at the presynaptic terminal. Necessarily, such changes in conductance interact with other dynamical properties of the postsynaptic neuron to determine how the presynaptic spike affects the probability of postsynaptic firing. Several statistical methods have been developed to measure effective neural coupling, and these are usually benchmarked *in silico* to show convergence between the estimate and the modeled effect of the synapse on membrane conductance. Despite the growing use of these methods to characterize real synaptic interactions, it is unknown how the postsynaptic state interacts with presynaptic input to skew the statistical estimation of synaptic coupling strength. To explore these issues, we studied spike transmission in the leaky integrate and fire (LIF) neuron and developed a method to track changes in spike transmission probability over time. We modeled the postsynaptic firing rate as the sum of a leak current, synaptic input, and Gaussian noise. Synaptic input was modeled as an instantaneous increase and exponential decay in postsynaptic conductance. The maximal synaptic conductance and the standard deviation of the "background" noise varied across modeled neurons and over time. We then designed a generalized linear model (GLM) to track changes in the synaptic contribution to the postsynaptic firing rate. The model assumed a separation in time scales between rapid rate fluctuations driven by the synapse and slower fluctuations driven by an unknown and unspecified "background". As previously shown, background noise strongly diminished the spike transmission between pre- and postsynaptic neurons. This change was well captured by the GLM, as were changes in conductance between neurons and over time. We next applied the GLM to ensembles of pyramidal cell to interneuron synapses recorded in the mouse CA1 region. We found that synaptic coupling strength was dynamic with "synapsembles" or groups of synapses from different neurons whose connection strength rose and fell together. The synaptic state was strongly modulated sleep/wake state and changes in spike transmission were related to changes in the postsynaptic spike-timing coefficient of variation, which also differed across sleep state. Our findings show that modulation of postsynaptic firing rate variability could be an important control point in gating the flow of information from pre- to postsynaptic neuron.

Title: Jump the gap: action-driven remapping of the hippocampal population code

Authors: *L. GREEN[1], D. TINGLEY[1], J. M. RINZEL[2], G. BUZSAKI[1];
[1]New York University, Sch. of Med., New York, NY; [2]Ctr. Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY

Abstract: The current dominant view of the hippocampus is that it is a navigation 'device', guided by environmental inputs. Yet, a critical aspect of navigation is a series of pre-planned coordinated actions. We examined the role of action in the neuronal organization of the hippocampus by training rats to jump a gap on a linear track. Recording local field potentials and ensembles of single units in the hippocampus, we found that when rats jumped a small gap on a running track, it produced a stereotypical behavior associated with consistent electrophysiological patterns, including phase reset of theta oscillations, predictable global firing rate changes and population vector shifts of hippocampal neurons. A subset of neurons ('jump cells') were systematically affected by the act of jumping, yet were influenced by distant environmental cues. Novel place fields emerged and others were either boosted or attenuated by jumping. Thus, jumping involves an entirely different action plan for the animal to traverse the same route as without jumping, which is faithfully tracked by hippocampal neuronal activity.

Title: Extrinsic control and autonomous computation in the hippocampal CA1 circuit

Authors: *I. ZUTSHI[1], M. VALERO[2], A. FERNÁNDEZ RUIZ[3], G. BUZSAKI[4];
[1]New York Univ. Sch. of Med., New York, NY; [2]NYU Neurosci. Inst., New York, NY; [3]Neurosci. Inst., New York Univ. Med. Ctr., New York, NY; [4]New York University, Sch. of Med., New York, NY

Abstract: In understanding circuit operations, a key issue is the extent to which neuronal spiking reflects local computation or responses to upstream inputs. We addressed this issue in the hippocampus by performing combined optogenetic and pharmogenetic deafferentation and local silencing. Silencing the medial entorhinal cortex (mEC) largely abolished extracellular theta and gamma currents in CA1, without affecting firing rates. In contrast, CA3 and local CA1 silencing strongly decreased firing of CA1 neurons without affecting theta currents. Each perturbation reconfigured the CA1 spatial map. Yet, the ability of the CA1 circuit to support place field activity persisted , maintaining the same fraction of place fields, spatial information and spike theta phase relationship as in the intact mouse. Thus, the CA1 network can

support autonomous computation to support coordinated place cell assemblies without reliance on its inputs, yet these inputs can effectively reconfigure and assist in maintaining stability of the CA1 map.

Title: Phase locking of CA3 neurons to distal CA1 theta oscillations predicts nonspatial memory performance

Authors: *S.-P. KU[1], E. ATUCHA[1], N. ALAVI[2], J. L. CSICSVARI[3], M. SAUVAGE[1];
[1]Functional Architecture of Memory, Leibniz Inst. for Neurobio., Magdeburg, Germany; [2]Computat. Mol. Biol., Max Planck Inst. for Mol. Enetics, Berlin, Germany; [3]Inst. of Sci. and Technol. (IST) Austria, Klosterneuburg, Austria

Abstract: Cumulative evidence in rodents has suggested a crucial role of hippocampal theta oscillations in memory function, especially in tasks involving spatial information. Much less is known about their role in non-spatial memory, even though studies in humans indicate a crucial role within this frame. Electrophysiological and immediate-early-gene imaging evidence for a robust proximodistal functional segregation of the hippocampal subfield CA1 and CA3 has recently accumulated and suggested the existence of non-spatial and spatial subnetworks segregated along this axis: the proximal CA3 (close to the dentate gyrus)- distal CA1 (close to the subiculum) and the distal CA3-proximal CA1 subnetworks, respectively (Henriksen et al, Neuron, 2011;Nakamura et al, 2013; Beer and Vavra et al, 2018). However, the mechanisms subserving information processing within these subnetworks is still not known. Here, we focus on characterizing CA3-CA1 interactions during non-spatial memory retrieval by studying CA3 spikes phase locking to theta oscillations along the proximodistal axis of CA1 using *in-vivo* electrophysiological recordings. Rats were trained on a human to rat translational high memory demand task using odors as stimuli (Nakamura et al, 2013) upon which they were chronically implanted with tetrodes along the proximodistal axis of hippocampal CA1 and CA3 to record single cell firing and LFP. In this task, the memory for odors presented during a study phase is tested after a delay (20min) by presenting the same odors (‘old’ odors) intermixed with ‘new’ odors during a retrieval phase. Overall, theta power was enhanced during retrieval when compared to any other phases of the task and selectively enhanced in distal CA1 as opposed to proximal CA1 in trained rats but not in naïve animals, indicative of a preferential role of distal CA1 theta in non-spatial information processing. In addition, population analyses of the preferred angles of CA3 spikes showed a selective phase-locking to the peak of distal CA1 theta (not proximal CA1) for the retrieval of the ‘old’ odors. Furthermore, support vector machine analyses revealed that the classification performance of CA3 neurons phase locked to distal CA1 theta was the only one predicting performance comparable to behavioral performance. In contrast, local phase-

locking in CA1 or CA3 did not. Altogether our results show that theta oscillations might play an important role in non-spatial memory as is the case for memory based on spatial information and suggest a prominent role of the coordination of electrophysiological signals between CA3 and distal CA1 (as opposed to proximal CA1) in non-spatial memory retrieval.

Title: Age Differences in Dorsolateral Prefrontal Cortex Activity During a Novel Task Manipulating Memory Load and Logic Load

Authors: *E. STURM[1], M. MUSICH[2], D. THORNTON[2], A. S. MENDEZ COLMENARES[2], J. DUFFY[2], A. Z. BURZYNSKA[2], M. L. THOMAS[2];
[1]Colorado State Univ. Molecular, Cell. & Integrative Neurosciences, Fort Collins, CO; [2]Colorado State Univ., Fort Collins, CO

Abstract: Studies have found that older adults show increased activity in the dorsolateral prefrontal cortex (DLPFC) at higher memory loads in comparison to younger adults. This age-associated increase in activity could be interpreted as compensation for decreasing neural efficiency. However, competing theories have also been proposed (e.g., dedifferentiation and alternative strategy use). We propose that manipulating memory (concrete) load and rule (abstract) load, which engage different sub-regions of the DLPFC, can help us better interpret the meaning of changes in functional brain activity with age. To better understand these relationships, we developed a novel version of the classic Sternberg paradigm wherein we manipulated working memory load and logic load. Memory load was manipulated by parametrically increasing the number of letters to be remembered. Boolean logic complexity load was manipulated by presenting a colored test letter (i.e., blue or red), allowing disjunction (e.g., repeated or red), conjunction (e.g., repeated and red), and disjunction of two rules (e.g., repeated and red -or- new and blue). The purpose of this study was to provide initial evidence that logic load manipulations are related to differential brain activity with age. We hypothesized that older-adults will show increased activity in the DLPFC at high logic load levels Data were acquired from 29 healthy adults (M=52.9 years, SD = 23.6 years, range = 28-85, 48% female), using a Siemens 3-Tesla Skyra Magnetom system. Images were sensitive to the Blood-Oxygenation-Level-Dependent (BOLD) response using T2* weighting. Region of interest-based data were analyzed using linear regression and linear mixed-effects models. We found a significant negative association between accuracy and age on the Sternberg task ($b = -.003$; $p < .05$).

Logic load had a significant effect on activity in the right (b = .02, $p < .05$) and left (b = .02, $p < .05$) DLPFC. BOLD signal increased in both the right (b = .002; $p < .05$) and left DLPFC (b = .002; $p < .05$) with age at high logic load levels. These results suggest a promising avenue for insight into brain activity associated with healthy aging. The DLPFC showed increased activity in older adults at higher load levels in our novel task, similar to traditional working memory tasks. These results suggest a promising avenue for insight into brain activity associated with healthy aging and logic load. Further research will aim to determine whether logic load manipulations engage unique regions of the DLPFC, and where these changes reflect compensatory brain activity.

Title: A novel approach to measure exercise-induced changes in latent structural integrity of the brain in sedentary healthy older adults

Authors: S. E. POLK, *E. WENGER, M. M. KLEEMEYER, Y. KÖHNCKE, A. M. BRANDMAIER, U. LINDENBERGER, S. DÜZEL;
Max Planck Inst. For Human Develop., Berlin, Germany

Abstract: Studies investigating the effects of aerobic exercise on the aging brain have found that frontal areas, such as the anterior cingulate cortex (ACC), and temporal areas, such as the hippocampus, show more positive changes in gray matter volume in exercisers versus controls over the course of a longitudinal aerobic exercise intervention. However, use of single indicators (e.g., volume), rather than a latent factor comprising multiple indicators, is more susceptible to unreliability due to measurement error. In this study, we adopted recently developed multi-modal methods using structural equation modeling to compute a latent factor including both macro- and microstructural characteristics of gray matter to capture a more reliable, global measure of gray matter structural integrity. Estimations from three different imaging modalities were used as indicators: gray matter probability (i.e., volume), magnetization transfer saturation (i.e., demyelination), and mean diffusivity (i.e., density), in order to capture the shared variance of different imaging modalities. In this way, we modeled latent change in integrity during a six-month exercise intervention in brain regions of interest previously reported in studies using volumetric approaches. Seventy-five healthy, previously sedentary older adults (63-76 years old) completed an at-home intervention study either in an exercise group ($n = 40$) or in an active control group ($n = 35$). Exercisers showed gains in cardiovascular fitness over controls, measured pre- and post-intervention using maximal oxygen uptake (VO_2max), $\Delta\chi^2_{(df = 1)} = 5.37$, $p = .010$. We successfully established reliable

latent change score models of structural integrity with three time points (pre-, mid-, and post-intervention); notably, the right ACC showed significant inter-individual differences in change, as well as significant group differences in mean change with controls decreasing and exercisers maintaining integrity in the first three months of the intervention, $\Delta\chi^2_{(df = 1)} = 4.069$, $p = .022$. Finally, change in VO_2max was positively correlated with change in rACC integrity overall and within the exercise group in the first three months, $Z = 2.296$, $p = .011$, but not within the active control group, $Z = 1.165$, $p > .050$; this difference between groups was significantly greater than zero, $\Delta\chi^2_{(df = 1)} = 4.67$, $p = .015$. In summary, the exercise group benefited from aerobic exercise in terms of cardiovascular fitness and gray matter structural integrity in the rACC, a region that has previously shown exercise-related volumetric changes. Furthermore, those exercisers who showed greater change in VO_2max also decreased less in rACC integrity.

Title: Thicker cortex is more strongly associated with motor function than cognition in older adults

Authors: *A. M. HAMLIN, S. MITTAL, E. C. NELSON, T. A. POLK;
Psychology, Univ. of Michigan, Ann Arbor, Ann Arbor, MI

Abstract: Previous research has found that cortical thickness declines with age. While some studies have found age-related cortical thinning primarily in the frontal, temporal, and parietal association cortices, others have noted similar or greater cortical thinning in sensory and motor regions. Furthermore, individual differences in cortical thickness have been associated with both cognitive measures (e.g., fluid and crystallized intelligence, memory, and processing speed) and measures of strength and motor function. Here we examine age-related differences in cortical thickness as well as the ability of cortical thickness to predict both cognitive and motor measures in a large sample of younger (*N*=58, 18 to 29 years old) and older (*N*=81, 65+ years) adults. A high-resolution T1-weighted structural image was obtained for each participant and estimates of cortical thickness were calculated using the FreeSurfer Cortical Parcellation technique. Behavioral data included the NIH toolbox Cognition Battery, Rivermead Behavioral Memory Story Test, NIH 2-minute Endurance Walk, NIH Grip Strength Test, and a Cortical Metrics vibrotactile somatosensory task. We first performed exploratory factor analyses (EFA) on the cognitive measures and identified latent factors associated with fluid and crystallized cognition, memory, and processing speed. Likewise, we performed EFA on the sensorimotor measures and identified factors related to gross motor, fine motor, and tactile ability. Finally, we performed EFA on the regional cortical thickness measures and identified three latent factors in both the left (dorsolateral frontal, cingulate

temporal, and posterior cortex) and right hemispheres (lateral frontal, medial occipital, and posterior cortex). Associations between these cortical thickness factors and age were examined through linear regressions. We found evidence of age-related cortical thinning in all three thickness factors in both hemispheres (Bs ≥ 0.01, ps ≤ 0.013). Furthermore, within older adults almost all of the cortical thickness factors were also positively associated with gross motor function after controlling for both age and sex (Bs ≥ 0.15, ps ≤ 0.035). The positive association with strength was not region specific but was observed in frontal, parietal and occipital regions in both left and right hemispheres. In contrast, we found no significant associations between cortical thickness and any of the cognitive factors. Establishing patterns of decline in cortical thickness and their relation to behavior could help identify those at risk for age-related impairments and facilitate early intervention.

Title: Age-related differences in white matter structure-function associations, relation to bold modulation and cognitive control

Authors: T.-C. LUNG, D. A. HOAGEY, K. M. RODRIGUE, *K. M. KENNEDY;
The Univ. of Texas at Dallas, Dallas, TX

Abstract: Age-related alterations to the structure and function of the human brain are widely reported. However, the associations among brain structure, function and cognitive performance during aging remain unclear. The current study used functional clusters from a parametric difficulty modulation contrast to functionally define ROIs for diffusion-based tractography to isolate tracts connecting regions of gray matter demonstrating difficulty-related up-modulation (positive modulation, POSMOD) and down-modulation (negative modulation, NEGMOD) to spatial distance judgments. We explored the association between age-related BOLD modulation and white matter tract fractional anisotropy (FA) and examined how this association relates to executive function performance across the adult lifespan (N=161 adults (age 20-94). Deterministic tractography was conducted between all in 9 functional ROIs, including regions associated with the frontal-parietal and multiple demand networks (from POSMOD) and regions overlapping with default mode network (from NEGMOD). Tractography between these functionally-defined ROIs generated 8 tracts connecting ROIs among significant age-related POSMOD (5 tracts), NEGMOD (1 tract), and cross-connecting POS-NEG modulation regions (2 tracts). Three tracts showed significant age-related decrease in FA, one POSMOD (inferior frontal-insula U-fiber), one NEGMOD (cingulum and genu of CC), and 1 CROSS-MOD (cingulum). We next tested for structure-function

associations predicting BOLD modulation using tract FA, age, and their interactions, controlling for whole-brain FA. Among these three tracts, the NEGMOD tract (cingulum and CCgenu connecting medial orbitofrontal and precuneus) FA interacted with Age to predict negative BOLD modulation, where older adults demonstrated a weaker structure-function association. Further, an Age by FA by NEGMOD interaction was found on task-switching ability, driven by older adults with lower FA and weaker negative modulation demonstrating poorer task switching performance. The present findings highlight the importance of cingulum/CCgenu tracts in the modulation of deactivations as task difficulty increased. Further, older adults with poorer white matter anisotropy in the cingulum/CCgenu and less deactivation to difficulty exhibited poorer cognitive control than their counterparts. In this visuospatial task under increasing working memory loads, the deactivation of medial orbital frontal cortex and precuneus, and the white matter integrity of the cingulum connecting these two areas influence cognitive control in later life.

Title: White matter complexity and entropy change with age, are driven by changes in crossing fibers, and predict cognitive performance

Authors: *A. R. BENDER[1], J. PLASS[2], M. MEIRING[1], J. SATOW[1], S. DÜZEL[3], U. LINDENBERGER[3], T. A. POLK[2], S. KÜHN[3];

Abstract: Age-related changes in white matter microstructure observed via diffusion magnetic resonance imaging (dMRI) are commonly thought to reflect a loss of white matter integrity. However, recent findings show that much of the reported age-related differences in white matter are due to alterations in crossing fiber complexity. Histological evidence suggests smaller-diameter axons are preferentially sensitive to the effects of enrichment, aging and pathology. Thus, it appears that variable effects of aging on differently oriented intra-voxel fiber populations may drive concomitant changes in the spatial entropy or complexity of the diffusion signal. We hypothesized that within- and between-person variation in measures of white matter complexity and entropy (CXE) reflect the differential contributions of individual fiber populations, and that these may provide a more sensitive marker of cognitive aging. The present analyses utilized data from cognitive testing and dMRI acquired in a sample of 420 younger and older adults recruited from the Berlin Aging Study-II. We processed and analyzed dMRI data (b=1000

s/mm^2; 60 directions) using the MRtrix3 single-shell fixel-based analysis (FBA) pipeline. Using this framework, we estimated fixel measures of fiber density (FD) and fiber cross-section (FC) and voxelwise parameters of CXE, transformed to a sample-specific template. Voxelwise regressions of CXE on age, corrected for multiple comparisons, revealed widespread bilateral patterns of significant positive and negative age effects. Analysis of CXE in age-sensitive regions on demographic and cognitive measures showed strong relationships with fluid and crystalized intelligence, speeded processing, and education, even controlling for differences in age. Next, we extended the FBA pipeline to output image data for FD and FC, separately for each of the three most prominent crossing fiber populations. Using this approach, we demonstrate that differential alterations of FD and FC in crossing fiber populations drive age-associated differences in CXE, and are sensitive to differences in cognition. These findings reveal the complementary capacity of non-tensor dMRI approaches for studying relationships between white matter microstructure, cognition, and lifespan development. Moreover, the present results emphasize the need for an updated framework for analyzing and interpreting dMRI data in cognitive aging that includes measures of white matter entropy.

Title: Age-related reductions in network segregation are larger in active cognitive tasks compared to rest

Authors: L. E. HARMON, *J. D. KOEN;
Univ. of Notre Dame, Notre Dame, IN

Abstract: Older adults exhibit a decrease in the distinctiveness of neural networks and their functional specialization, a phenomenon more broadly referred to as age-related neural dedifferentiation. Previous studies have analyzed resting-state fMRI data to describe age-related differences in functional connectivity of brain networks and found that increased age is associated with decreased segregation of neural networks. Here, we leverage data from the Cam-CAN cohort to investigate if age-related reductions in large-scale network segregation differ between rest and 'active' tasks. The Cam-CAN dataset provides resting state fMRI data (n=652; eyes closed) as well as fMRI data from two 'active' tasks in which participants watch a movie (n=649) and complete a sensorimotor reaction task (n=651) for healthy adults from across the lifespan (aged 18-88 years). Using the Power et al. (2011) parcellation, we measured network segregation following the procedure of Chan and colleagues (2014) in which segregation is defined by contrasting within-network from between-network connectivity. We used a linear mixed effects model to examine how network segregation differed between the rest, movie, and sensorimotor tasks and with age (linear and quadratic terms). First, the results replicated prior findings

showing that network segregation decreased with age. This relationship was nonlinear with the rate of decrease accelerating with increasing age. Critically, we also found that the relationship between age and network segregation differed between rest and the two 'active' tasks. Specifically, age-related reductions were significantly more negative for the sensorimotor and movie tasks compared to networks derived from the (eyes-closed) rest data. This appeared to be mainly in the quadratic age term of the model, suggesting that network segregation connectivity measures derived from 'active' tasks might reveal stronger nonlinear age-trends. These analyses provide a more comprehensive view of age-related network desegregation by accounting for differing cognitive states.

Title: Age-related changes in neural-vascular coupling modulate load-induced parametric effects among younger and older adults in visual and cognitive tasks

Authors: *Y. ZHAO[1], D. H. ABDELKARIM[4], M. P. TURNER[4], J. HUTCHISON[5], D. SIVAKOLUNDU[6,7], K. WEST[2], B. P. THOMAS[8], P. LIU[9], J. SPENCE[5], H. LU[9], B. P. Sch. of Med., Baltimore, MD

Abstract: Age-related decline in the modulation of neural recruitment with increasing task demand has been observed in many studies using blood-oxygen-level-dependent signal (BOLD). We measured demand-dependent age-changes in physiological factors underlying BOLD while participants performed an in-scanner visual task and two cognitive tasks (digit-symbol-verification task; DSVT and Sternberg working memory task; SWMT). In all tasks, we parametrically increased the visual or cognitive demand. In the visual tasks, participants viewed a checkerboard that flickered at 2, 4, or 8 Hz. In DSVT, participants judged if a probe pair matched one from a key of either 1, 3, or 9 digit-symbol pairings. In SWMT, participants judged if a probe letter matched one from a previously encoded memory set of either 2, 4, or 6 letters. BOLD and cerebral blood flow (CBF) were simultaneously measured using a dual-echo sequence. Hypercapnia enabled modeling of cerebral metabolic rate of oxygen ($CMRO_2$) and the neurovascular coupling ratio (NVC). In the visual task, older adults demonstrated reduced BOLD, CBF, and NVC but equivalent $CMRO_2$ at higher load conditions, compared to younger adults. In both cognitive tasks, significant reaction time differences were observed between age groups. While younger adults

demonstrated load-dependent increases in BOLD, CBF and $CMRO_2$, older adults showed discrepancies between these measures. These results suggest that age-related decreases in NVC limit older adults' capacity to modulate neural resources in response to variations in task demand.

Title: Neurophysiological effects of longitudinal hearing aid use on auditory entrainment and speech in noise perception in older adults with age related hearing loss

Authors: *K. M. BECKER[1,2], P. VOSS[3], Z. E. MARTÍNEZ MORENO[1,2], T. LUNNER[4,5], A. LÓPEZ VALDÉS[6], S. BAILLET[1,2], E. DE VILLERS-SIDANI[1];
[1]Neurol. and Neurosurg., [2]McConnell Brain Imaging Ctr., Montreal Neurolog. Inst., Montreal, QC, Canada; [3]Cognitive Neurosci. Unit, Montreal Neurolog. Inst., McGill Univ., Montreal, QC, Canada; [4]Dept. of Clin. and Exptl. Med. (IKE), Linköping Univ., Linköping, Sweden; [5]Eriksholm Res. Ctr., Snekkersten, Denmark; [6]Cognitive Hearing Sci., Eriksholm Res. Ctr., Helsingør, Denmark

Abstract: Age-related hearing loss (ARHL) is a common feature of human aging, has been strongly linked to accelerated cognitive decline in older individuals and is the largest modifiable risk factor of developing dementia. These impairments are preceded by the maladaptive re-organization of the auditory cortex, which is thought to occur as a compensatory response to degraded auditory input. The current study posited that this remodeling profoundly hinders the dynamics of brain systems and affects the temporal synchronization of neural circuits to the rhythmic fluctuations of speech that demarcate phoneme and syllable transitions. Speech-brain entrainment is related to speech intelligibility: individuals with ARHL exhibit poor speech comprehension and reduced neural entrainment to speech audio in noisy environments. Hearing aids (HA) are often considered in interventions for preventing, attenuating or delaying the onset of cognitive decline seen in ARHL. Yet, most research has reported correlational effects, with limited insight into the causal benefits of HA. In particular, whether HA can help maintain or recover auditory entrainment remains poorly investigated. The current study aimed to delineate the longitudinal neurophysiological effects of HA on auditory entrainment and speech intelligibility. MEG recordings were acquired from a group of (N=12) older adults with ARHL before and after 3-months of HA use during a speech-in-noise detection task. Subjects were presented with sentences embedded in varying levels of background noise and asked to repeat the words they heard. Our data indicate that the HA intervention modulated the magnitude of activity in left language areas associated with speech articulation, comprehension and verbal working memory, as well as right dorsolateral prefrontal cortex

and bilateral primary auditory and premotor regions involved in attentional and inhibitory control, and acoustic processing. Moreover, these areas appeared to be differentially recruited based on behavioural task performance. Collectively, these results clarify the neurophysiological mechanisms of how HA contributes to increasing speech intelligibility in aging and open new perspectives in terms of optimizing and personalizing HA interventions based on brain signal markers.

Title: Structural and functional correlates of longitudinal memory change in a sample of cognitively healthy older adults

Authors: *A. KIDWAI[1], M. A. DE CHASTELAINE[2], M. HOU[3], M. D. RUGG[4];
[1]UT Dallas Cognition and Neurosci. Grad. Program, Richardson, TX; [2]The Ctr. for Vital Longevity and Behavioral and Brain Sci., Univ. of Texas At Dallas, Dallas, TX; [3]Ctr. For Vital Longevity, Utdallas, Dallas, TX; [4]Ctr. for Vital Longevity, Univ. of Texas at Dallas Ctr. for Vital Longevity, Dallas, TX

Abstract: Structural and functional variability in the medial temporal lobe have been proposed to correlate with individual differences in episodic memory and longitudinal memory change in cognitively healthy older adults. The entorhinal cortex in particular has been reported to be sensitive to early cortical tau accumulation and reductions in its structural integrity have been reported to be associated with memory decline. The current study implemented detailed manual tracing of the entorhinal cortex following established protocols to obtain volumetric measures from its anterolateral and posterior-medial divisions. The study cohort comprised 67 older (ages 63 - 76 yrs. at baseline), cognitively healthy adults. Participants were administered a battery of neuropsychological tests on three occasions: the second occasion one month after the first test session, and a third session three years after the first one. Structural and functional MRI data were acquired between the first two sessions. Memory component scores were derived from a principal components analysis of the neuropsychological test scores. To reduce retest effects, mean memory scores across sessions 1 and 2 served as a baseline for assessing change in memory performance at session 3. Fifty-five participants, all of whom had remained cognitively healthy, returned for the session 3 tests. None of the volumetric measures derived from the entorhinal cortex demonstrated a statistically significant relationship either with baseline memory performance or longitudinal memory change. By contrast, volume of the posterior hippocampus (which was also traced manually) correlated negatively with memory decline, as did functional activity in the anterior hippocampus obtained during an

in-scanner experimental memory test. These findings suggest that structural integrity of the entorhinal cortex does not appear to be a sensitive predictor of memory performance or longitudinal memory change in older adults at low risk of prodromal Alzheimer's Disease.

Title: Transcriptomic analysis of Aβ-tau synergy in the inferior temporal cortex of the human brain in Alzheimer's disease

Authors: *S. KWON[1], M. TIPPANI[2], A. SPANGLER[2], H. DIVECHA[2], K. MONTGOMERY[2], C. BRUCE[3], S. WILLIAMS[3], M. MAK[3], G. YU[3], J. AVALOS-GRACIA[3], T. M. HYDE[2], S. C. PAGE[2], S. C. HICKS[4], L. COLLADO-TORRES[2], K. MARTINOWICH[1,2], K. R. MAYNARD[1,2];

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by senile plaques of β-amyloid (Aβ) and neurofibrillary tangles of phosphorylated tau (pTau). Accumulating evidence suggests that Aβ and tau act in concert to orchestrate complex pathobiological events underlying AD, but their additive effect remains poorly understood. Our experiments investigate Aβ-tau synergy at the level of gene expression in inferior temporal cortex (ITC) of individuals with AD. We employed 10x Genomics Visium Spatial Transcriptomics (ST) coupled with immunofluorescence (Visium-IF) to generate a proteomic-based, spatially-resolved, transcriptomic-scale map of the human ITC in AD. Visium-IF is a next-generation ST platform in which IF staining is paired with on-slide cDNA synthesis using barcoded arrays (5000 gene expression spots/array) to retain spatial X-Y coordinates of transcript expression. For this study, brain blocks were dissected to include ITC from 3 brain donors with late-onset AD (Amyloid C/Braak III) and 1 age-matched neurotypical donor. We validated laminar patterning in each block using RNAscope in situ hybridization with Layer I and VI marker genes (*RELN* and *NR4A2*). Cryosections from each block were collected in triplicate on Visium arrays and immunostained for Aβ, pTau, MAP2 and GFAP to visualize plaques, tangles, neurites, and astroglial processes. Each section was scanned using multispectral imaging and sequenced (whole-genome and targeted gene expression using the 10X Genomics human neuroscience panel). We are executing two analysis strategies with these data to identify molecular, cellular, and morphological associations with spatially-localized Aβ and tau pathology. The first compares AD patients with the neurotypical control to identify differentially expressed genes (DEGs) between diseased and normal-aging states. The second within-subject analysis examines the local effect of plaques and tangles in the same tissue section of the AD-donors. Specifically,

after clustering by staining patterns, we compare gene expression in Visium spots with 1) no pathology, 2) Aβ only, 3) tau only, 4) Aβ/tau, using a t-distributed stochastic neighbor embedding algorithm. Gene ontology analysis defines common disease pathways associated with the identified DEGs, and spot deconvolution analysis by cellular staining helps identify cell types associated with the DEGs. With enhanced spatial and cellular resolution, our novel approach can disentangle regional heterogeneity in gene expression and refine annotation of genes and cell types that are functionally linked to AD.

Title: Single-molecule cartography of adult neurogenesis in the human dentate gyrus

Authors: *A. D. RAMNAUTH[1,4], S. C. PAGE[4], E. A. PATTIE[4], M. TIPPANI[4], T. M. HYDE[4,2,3], K. MARTINOWICH[4,1,2];
[1]Solomon H. Snyder Dept. of Neurosci., [2]Dept. of Psychiatry and Behavioral Sci., [3]Dept. of Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Lieber Inst. For Brain Develop., Baltimore, MD

Abstract: Hippocampal (HPC) neurogenesis in the dentate gyrus (DG) has been reliably documented to occur across the lifespan of many mammals, including nonhuman primates, at a high rate early in life then dropping substantially lower but still present in later life. Subsequent research has linked differential rates of adult HPC neurogenesis in these model organisms with changes to plasticity, behavior, and brain disorders. Despite decades of research, indisputable evidence of adult HPC neurogenesis in humans remains elusive and the persistence of neurogenesis throughout the entire lifespan in the human DG remains controversial. The vast majority of past studies on human brain tissue have relied primarily on antibody-based methods, such as immunohistochemistry and western blotting, which are highly sensitive to variability in post-mortem tissue processing. Another limitation of these studies is the limited age range of brain donors that were used. To circumvent these technical limitations, we are employing single-molecule RNA-based methods to probe for neurogenesis in human DG cryosections throughout the entire lifespan. Specifically, we are using the Advanced Cell Diagnostics RNAscope Multiplex Fluorescent V2 Assay to probe for candidate markers of neurogenesis at various cell development stages, ranging from stem cells to immature granule cells, in the DG of fresh frozen HPC from neurotypical donors ranging in age from infant to 70+ years. We then quantify the density of expressing nuclei, as well as co-expression

and degree of expression of neurogenesis markers in nuclei in the granule cell layer of human DG using our MATLAB package dotdotdot for nuclei and transcript segmentation. Our preliminary results show that nuclei co-expressing common markers of neurogenesis such as doublecortin (DCX), sex determining region Y - box transcription factor 2 (SOX2), and nestin (NES) are abundant in the infant DG and drop dramatically with age, but remain at detectable levels, suggesting the continuation of neurogenesis throughout the entire human lifespan. In addition, we are starting to adapt our previously used workflow of the 10x Genomics Visium Spatial Gene Expression platform to define the spatial topography of the human HPC across the lifespan. We will use the resulting dataset to explore the spatial architecture of adult neurogenesis in the human DG. The resulting analyses will be useful to describe the degree to which neurogenesis persists across the lifespan and correlated changes to the neighboring tissue.

Title: Identifying Spatial Patterns of Gene Expression and Cell-type Specificity in Human Lateral Septum

Authors: *E. A. PATTIE[1], L. A. RODRIGUEZ[1,2], T. M. HYDE[1,3,4], S. C. PAGE[1], K. MARTINOWICH[1,2,3];
[1]Lieber Inst. for Brain Develop., Baltimore, MD; [2]The Solomon H. Snyder Dept. of Neurosci., [3]Dept. of Psychiatry and Behavioral Sci., [4]Dept. of Neurol., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: The lateral septum (LS) plays a regulatory role in the processing of sensory stimuli and affective information to modulate movement, fear response, and social behavior. The LS is densely interconnected with multiple brain regions related to mood and motivation including the hippocampus, ventral tegmental area, hypothalamus, and amygdala. In rodents, septal lesions modulate anxiety-related behaviors and influence activity levels, reactivity, and behavioral disinhibition. The rodent LS is predominantly composed of GABAergic cells which abundantly express TrkB, the cognate receptor for the neurotrophin, brain-derived neurotrophic factor (BDNF). However, BDNF is supplied to the LS via projections from other BDNF-rich brain regions as LS neurons do not synthesize BDNF themselves. Dopaminergic projections from the ventral tegmental area to the LS play a regulatory role on LS neural activity, and are implicated in psychotic spectrum disorders including schizophrenia. However, the degree to which circuitry, neurochemistry, and cellular composition of the LS is conserved between rodents and humans remains unclear. To address this gap, we investigated cell-type specific and spatial patterns of gene expression in the post-mortem human LS to address convergence and divergence between humans and rodents. First, we obtained fresh frozen brain blocks, and collected cryosections from n=4 neurotypical human brain donors. Then, we used multiplexed single molecule fluorescence in situ hybridization to quantify the spatial expression patterns of *BDNF* and *NTRK2*, interneuron markers (including *GAD1*, *CALB1*, *CALB2*, and *PVALB*), and dopamine receptors in the LS. Based on *GAD1*

expression patterns, we determined that neurons in the human LS are predominantly GABAergic, as seen in rodents. We also observed an abundance of *NTRK2* expression in LS neurons, and exclusion of *BDNF* transcripts. Collectively, these results indicate many similarities in the cellular composition between the rodent and human LS. Understanding the conservation of LS circuity and cell types cross-species will allow us to more effectively translate preclinical research findings in the rodent LS to understanding human neurobiology and disease.

Title: Spatial landscape of gene expression in the human locus coeruleus

Authors: *H. R. DIVECHA[1], L. WEBER[2], S. KWON[1], A. SPANGLER[1], T. M. HYDE[1], L. COLLADO-TORRES[1], K. MAYNARD[1], S. C. HICKS[2], K. MARTINOWICH[1];
[1]Lieber Inst. of Brain Develop., Baltimore, MD; [2]Biostatistics, Johns Hopkins Bloomberg school of public health, Baltimore, MD

Abstract: The locus coeruleus (LC), a brainstem pontine nucleus, is the primary site for noradrenaline (NA) production in the mammalian brain. NA-producing cells in the LC project widely to central nervous system areas with highly divergent functions. The LC-NA system plays important roles in regulating arousal and mood, and serves an integral role in several higher cognitive functions ranging from attention to motivation to working memory. Importantly, LC cell loss is a prominent hallmark of the two most prevalent neurodegenerative disorders, Alzheimer's disease and Parkinson's disease. It is hypothesized that the ability of the LC to achieve such widely divergent function-specific neuromodulation is achieved by the existence of molecularly distinct neuronal subpopulations that retain unique anatomical and functional connectivity. While several studies have examined the molecular profile of LC-NA neurons in the rodent, gene expression signatures of cell populations in the human LC are not yet available. To address this gap, we generated a spatial map of gene expression in the postmortem human LC using the transcriptome-scale 10x Genomics Visium platform. We first localized the LC in tissue sections by using RNAscope single-molecule fluorescent in-situ hybridization for NA-expressing neuron markers including SLC6A and TH. We then applied the Visium assay to tissue sections from n=4 neurotypical control brain donors (n=2 LC sections/donor). We evaluated conservation of gene expression patterns in LC-NA neurons between mouse and human LC, using data-driven approaches to identify spatially variable genes across the LC, and investigated enrichment of genes associated with Alzheimer's and Parkinson's disease in LC cell populations. In summary, we created a spatial gene expression map for the human LC, and identified molecular profiles for LC-NA neurons in the human brain.

Abstract: The Human Protein Atlas (HPA; www.proteinatlas.org) is a public online database that provides an integrated overview of protein expression and distribution in all major human tissue types, including brain. The current version (HPA20) provides a comprehensive overview of gene and protein expression in the main anatomical structures of the mouse, pig, and human brain, by combining in-house generated and publicly available transcriptomic data. However, there is an incomplete coverage of the human brain, and several regions with key roles in brain physiology and pathophysiology have not been included. To fill this gap, a more extended analysis of these areas in a greater anatomical detail was performed. In HPA21, planned to be released in November 2021, we have included additional in-house generated RNA sequencing data, based on regional and subregional protein expression in nearly 1400 samples from more than 200 (209) human brain regions microdissected in the Human Brain Tissue Bank, Budapest. These include 11 samples from different basal ganglia, 16 thalamic and 9 from the hypothalamic nuclei, 9 samples from the hippocampal complex, 5 from the amygdala, over 70 brainstem (midbrain, pons, medulla) and from 5 cerebellar cortical and nuclear samples. From the cerebral cortex 86 areas, gyri and subregions have been studied. The HPA brain section provides gene-centric pages that give an extensive and integrated overview on protein expression across regions and subregions of the brain and allow comparison between species. Furthermore, we classify all protein coding genes based on regional distribution and co-expression, thus providing lists of genes associated to brain regions and functions. All data presented are freely accessible based on the FAIR Data Principles.

Abstract: INTRODUCTION: Tissue specific expression quantitative trait loci (eQTL) has emerged as a great tool in fine mapping to identify causal genes underlying GWAS loci for neurodegenerative diseases. The challenge however has been the lack of tissue specific eQTL data. For diseases like Amyotrophic lateral sclerosis (ALS) with spinal cord (SC) involvement wherein the single available GTEx SC eQTL dataset only captures the c-1 level of SC. We thus set out to create a rich SC eQTL dataset capturing the thoracic and lumbar regions. **METHODS:** We extracted high quality DNA and RNA from thoracic and lumbar regions of SC from 93 donors and performed whole genome sequencing to capture SNP and RNA-seq to capture mRNA expression. Stringent quality control and eQTL analysis was performed according to the Broad/GTEx eQTL pipeline. Genetic data from WGS was used for principal component (PC) analysis for ancestry. PEER factors were calculated from gene expression data to account for unknown covariates. Fast-QTL was used for analyzing cis-eQTLs (< 1Mb from TSS) and Matrix-QTL was used for analyzing trans-eQTLs (>1Mb from TSS). Both the analyses were adjusted for sex, age, 10 PCs and 30 PEER factors. Allelic log fold change (aFC) a measure for cis-eQTL effect size for the lead variant in eGenes (Genes with at least one significant eQTL) was also calculated. The aFC for overlapping eQTLs from our SC eQTL dataset was compared with that of multiple tissues from GTEx including c1-SC, cerebellum and whole blood using non-parametric Spearman Rank Correlation test. **RESULTS AND CONCLUSION:** Post QC, we retained all the 93 samples for eQTL analysis. We identified 198133 cis-eQTLs and 2248 trans-eQTLs to be significantly associated with gene expression. Of the more than 24000 expressed genes in our dataset, we identified 2345 eGenes with at least one significant eQTLs. On comparison with GTEx for overlapping eQTLs we found the spearman correlation coefficient (rho) to be 0.63, 0.49 and 0.45 with c1-SC, cerebellum and whole blood tissue respectively. The differences in correlation between tissues is indicative of the stark differences in the tissue specificity of eQTLs and further highlights the need of interrogation of tissue specific eQTLs to understand the underlying role of genetics of gene expression in diseases. In conclusion, we herein generated a rich resource of SC eQTLs which will prove to be a great resource and provide impetus in drug discovery efforts by identifying underlying mechanisms and causal genes for neurodegenerative diseases like ALS.

Title: Cellular models of fetal neurodevelopment in maternal viral infection

Authors: *R. M. DE GUZMAN, S. D. SHERIDAN, L. T. MCCREA, J. M. THANOS, J. E. HORNG, T. FU, C. M. SELLGREN, R. H. PERLIS, A. G. EDLOW;

Abstract: Background: Maternal immune activation may have deleterious effects on fetal brainmacrophages (microglia). Microglia play a key role in modulating synaptic pruning,neurogenesis, and regulation of synaptic plasticity. They also are critical mediators ofneurodevelopmental morbidity in maternal immune activation. Microglia areinaccessible during fetal life and early development and there are no surrogatebiomarkers or cellular models for *in utero* microglial priming and function that can aidin identifying neonates and children most vulnerable to neurodevelopmentalmorbidity. Two candidate cell types that could serve as a proxy for fetal brain microgliainclude fetal placental macrophages (Hofbauer cells), which share a common originwith microglia in the fetal yolk sac; and cord blood monocytes, which also may carrythe imprint of *in utero* exposures. We have previously demonstrated that clusters offetal placental macrophages share a highly conserved single cell signature with fetalbrain microglia in a mouse model.Methods: The MGH COVID-19 Pregnancy Biorepository includes banked placental cellisolates and umbilical cord blood mononuclear cells (CB-MNCs) from >500 pregnantwomen positive for SARS-CoV-2, and contemporaneous SARS-CoV-2-negativecontrols. We used our previously-validated cellular models of reprogrammed inducedmicroglial-like cells (iMGs) and synaptosome phagocytosis assay to determinewhether: (1) umbilical cord blood mononuclear cell-derived iMGs (CB-iMGs) and (2)placental villous macrophage-derived iMGs (Pl-iMGs) from SARS-CoV-2-exposed casesand matched SARS-CoV-2-negative controls can be used to model the impact ofmaternal COVID-19 on fetal brain microglia. We evaluated expression of classicmicroglial markers, iMG morphology, and function using the synaptosomephagocytosis assay.Results: We demonstrated that both CB-MNCs and placental macrophages can besuccessfully reprogrammed to create iMGs that express classic microglial markers andexhibit ramified and ameboid microglial morphology. Both CB-iMGs and Pl-iMGsphagocytosed synaptosomes *in vitro*.Conclusions: These results demonstrate the potential for both CB-MNCs and placentalvillous macrophages to serve as proxy cell types that can model the impact of *in utero*exposures on fetal brain microglia. If these cellular models correlate with

neurodevelopmental phenotypes in long-term follow-up, they could be used at birthto identify at-risk neonates exposed to varied maternal environmental or infectiousexposures, during a key developmental window when intervention may improveoutcomes.

Abstract: Single nucleus transcriptomics is a powerful tool to understand cortical cellular diversity and areal variation that underlie functional parcellation. In this study we explored regional variation across the human cortex, analyzing graded and discrete variation between areas and differences in cellular makeup of sensorimotor versus association cortices. Specifically, we analyzed over 1.2 million nuclei from 8 different cortical regions (A1, ACC, ANG, DLPFC, M1, MTG, S1, and V1) collected from 7 postmortem adult donors of both sexes. Dissociated nuclei were stained for the neuronal marker NeuN and FACS-purified to enrich for neurons and a minority of non-neuronal cells. Broad sampling across all cortical layers and regions was performed with 10x Chromium V3, with ~100,000 nuclei per region passing quality control (QC). To enrich for the sparse but distinctive and disease-relevant layer 5 extratelencephalic-projecting (L5 ET) neurons, we also generated a micro-dissected layer 5 dataset from six of the brain regions with 10x Chromium V3, with ~30,000 nuclei per region passing QC. Finally, a layer-dissected SMART-seq V4 datasets was generated for each brain region, with ~10,000 nuclei per region passing QC. Together, these three datasets provide broad cell type coverage, enrichment of rare and interesting layer 5 neuron types, and the ability to annotate cell types by their laminar distribution within the cortical column. In analyzing this rich dataset we find evidence for regional specializations of specific cell populations, especially for glutamatergic types in primary visual cortex. We also report differences in neuronal cell type proportions and explore conserved signatures of cell types across brain regions. As a result of analyzing such a large and complex dataset, we also provide a computational

framework for assessing quality control, integrating datasets across donors/modalities, and clustering/curating the datasets into cross-cortical cell type taxonomies. Analysis was performed in R with significant use of normalization, integration, and clustering functions from Seurat 3.2.2.

Abstract: Model organisms have been studied for generations to explore the cellular components and functions of different brain regions. But how comparable are mammalian model organisms to the human brain? What are the common features of organization, and how have specific brain regions, cell types and gene expression patterns changed in different lineages throughout evolution? We explored these questions by sampling primary motor cortex (M1) from the brains of multiple (n>10) mammalian species, spanning diversity that represents more than 100 million years of mammalian evolution. Using single nucleus RNA-sequencing, we compiled species-specific transcriptomic cell type taxonomies and a cross-species taxonomy of conserved cell types. Marker gene expression was well conserved across species. For example, extra-telencephalic projecting layer 5 (L5 ET) pyramidal neurons, a major source of information output in the mammalian cortex, were reliably marked by expression of *POU3F1* in every species. While marker genes were conserved across species, M1 cell type proportions diverged. For example, L5 ET neurons were less abundant in humans and great apes compared to rodents. Notably, the ratio of excitatory to inhibitory neurons in M1 across species was higher in the rodent clade compared to other

mammals, suggesting that the balance of inhibition and excitation is functionally different in the rodent cortex compared to the other species examined in this study. Brain samples were collected from adult animals of each species (at least n=2 animals per species). Nuclei were stained for NeuN and captured with fluorescence-activated cell sorting (FACS) to enrich for neurons (NeuN+) while also capturing a minority of non-neuronal (NeuN-) cells. Single nucleus libraries were generated with the 10x Chromium 3' Single Cell kit (v3.1 chemistry), and ~100,000 nuclei per species passed quality control. Datasets were analyzed in R using Seurat 3.2.2. *In situ* validation was performed with RNAScope multiplex fluorescent *in situ* hybridization and immunohistochemistry.

Title: Tools for optimizing multiplexed single-nucleus sequencing experiments

Authors: *J. MAHONEY[1], A. YANNY[3], B. P. LEVI[1], J. K. MICH[1], Y. DING[3], J. A. MILLER[3], A. TORKELSON[3], K. SMITH[3], D. HIRSCHSTEIN[3], S. BARLOW[3], N. SHAPOVALOVA[3], E. LEIN[4], R. D. HODGE[2];

Abstract: The rise of highly multiplexed single cell sequencing technologies has significantly accelerated the rate and lowered the cost of generating large sequencing datasets. However, as with every new technology, a fresh set of challenges has arisen. Here we demonstrate how class-identifying antibody panels and cholesterol modified oligo (CMO) nuclei barcoding can aid researchers in collecting more useful and meaningful data from human postmortem fresh frozen brain tissue.
Non-neuronal oligodendrocytes, although interesting, have an outsized presence in single nucleus sequencing experiments due to their relative abundance throughout the human brain, particularly in subcortical regions. Therefore, investigating the diversity of cell types within the brain can be difficult when rare cell types are overwhelmed in sequencing datasets by more populous cell classes. Many research experiments use the neuronal nuclear marker NeuN and fluorescence-activated cell sorting (FACS) to deplete non-neuronal nuclei during tissue collection. Here we demonstrate how staining with NeuN, OLIG2, and SOX2 nuclear markers can identify astrocytes, inhibitory neurons, excitatory neurons,

microglia, oligodendrocyte precursor cells, and oligodendrocyte populations. For example, using a BD FACSaria Flow Cytometer and 10x Chromium 3' Single Cell kit (v3.1 chemistry), a NeuN(+) Olig2(-) Sox2(+) FACS population is shown to be ~90% inhibitory neurons. This enrichment strategy can be incredibly powerful in applications such as generating atlases or investigating rare cell types.
One drawback to highly multiplexed sequencing platforms is the large amount of tissue required as input. CMO barcodes, commonly used for overloading 10x Chromium 3' chips, can also be used to tag and pool sparse populations of nuclei. We demonstrate how CMO barcoding facilitates snRNA-seq for samples with as few as 2,000 sorted nuclei on the 10x 3' platform.

Abstract: The outermost layer of the neocortex, layer 1 exclusively contains inhibitory neuron cell bodies as well as axons and dendrites from deeper layer pyramidal neurons and axons from other brain areas. Through synapses onto pyramidal apical dendrites and volume transmission of inhibition, these neurons are thought to play a critical role in modulation of the cortical circuit according to behavioral state. Although primarily made up of neurogliaform (NDNF+) cells, the distinct "canopy" type within that population and other distinct rarer cell types have both been identified in recent work in rodent cortex. L1 cell types in human and non-human primate have been less well characterized, although two recent studies have characterized L1 electrophysiology and morphology and identified a highly specialized type,

the “rosehip” cell. To better characterize the diversity of types in human L1, we present a comprehensive dataset of >250 neurons characterized by Patch-seq in neurosurgically resected human tissue (available at biccn.org/data). Combining transcriptomics with electrophysiology and morphology, these data allowed mapping of each neuron onto a transcriptomic cell type taxonomy. Through broad sampling of cells across L1 and adjacent layers, we characterize the morphoelectric properties of each of these L1 “t-types”, including types that maintain a distinct identity across layer boundaries.
Most L1 t-types have distinct properties, while certain transcriptomically similar types show overlap in their phenotypes. We characterized rare cell types (PAX6+) with distinctive intrinsic bursting electrophysiology, and further characterize the transcriptomic identity of the previously identified rosehip type. We also present comparisons to mouse L1 cells characterized by the same platform, according to a cross-species homology of transcriptomic types. Both mouse and human have significant physiological and transcriptomic diversity in L1, and much of this diversity is aligned across species by the homology. However, we also find distinctive t-types that break from this pattern, evidence for species specialization: the stuttering rosehip and bursting PAX6 types in human, and strongly adapting VIP types that span L1 and L2/3 in mouse. Finally, we explored potential causal factors for cross-type and cross-species differences in electrophysiology by correlations to gene expression and morphological features. Together, these results leverage advantages of the Patch-seq method to deeply characterize L1 neuronal diversity across species, demonstrating species specialization within distinct cell subclasses in human and mouse.

Abstract: Mouse excitatory cortical neurons are well-understood to be organized into layers and have distinctlong-range, inter-areal projections. Each of these layers contains a variety of cell types with differentmorphology, electrophysiology and/or molecular properties. However, it is still unknown how these celltypes integrate together to form complex cortical circuits.Recent studies have described over 30 transcriptomically-defined types (t-types) among the excitatoryneurons of mouse visual cortex. These t-types correspond to previously described cell types based ontheir gene expression, laminar location, and long-range projection subclass (determined by retrogradelabeling studies; Tasic et al., 2018). Yet the diversity of the transcriptomic types exceeds the observeddiversity of those properties.The Patch-seq method measures morphological (m), electrophysiological (e) and transcriptomic (t)properties from the same cells. Here we apply that method to describe the t- and e-properties andprecise anatomical location of >1500 cells mapped to previously defined excitatory transcriptomic types.We also describe the morphological properties of >800 of those neurons from which morphologiescould be reconstructed. With these data, we relate many t-types to well-known neuron types for thisbrain region (e.g., L2/3 intratelencephalic (IT) wide branching, L5 IT slim-tufted, L5 extratelencephalicthick-tufted (TT), and L6 corticothalamic tall, narrow neurons). We also observe less well-describedtypes, such as inverted *Car3*+ L5/6 neurons and TT *Chrna6*+ L5 neurons, each of which are associatedwith a single t-type. The *Chrna6*+ neurons had different electrophysiological properties from other TTneurons. Using all three modalities together, we define a set of integrated, morpho-electric-transcriptomic (met)-types with congruent properties.In addition, to relate long-range axonal projections to met-types and t-types, we reconstruct ~170 wholebrain morphologies of visual cortical neurons. We describe the relationship between local and long-range morphological properties, and we use morphological classifiers to integrate cell type assignmentsacross the data sets using local morphology. Finally, we validate these mappings with full morphologydata collected from neurons labeled with cell type specific transgenic tools. Together, these results helpestablish a comprehensive, integrated characterization of multimodal excitatory cell types in mousevisual cortex.

Abstract: A bottom-up approach to understanding neocortical function is to start with identifying the constituent cell types and characterize their defining properties across multiple modalities. While much progress has been made in the mouse model in this context, exploration of human brain cell types has been more challenging and hindered by the lack of tools and mature brain tissue platforms to support targeted analysis. The *ex vivo* adult human neocortical slice culture paradigm provides an opportunity to extend the use of human neurosurgically-derived acute brain slices over days to weeks, thereby enabling application of viral genetic tools. We used rapid onset AAV vectors with cell class specific enhancers to prospectively label and then target human neocortical interneurons for multimodal Patch-seq analysis. Mapping recorded neurons to a human temporal cortex taxonomy based on transcriptomic profiles confirmed the high specificity of the viral approach for marking human neocortical GABAergic neurons. Additionally, this multimodal approach allowed us to evaluate the impact of the use of genetic tools and the culture paradigm has on electrophysiological, transcriptomic and morphological features. Upon examination of specific electrophysiological features, when comparing acute versus culture paradigm, we found subtle shifts in selected features; however, when reducing these features down to 2-dimensional representation, the two datasets displayed a high degree of overlap with similar structure. We have found that there are gene expression signatures from the culture paradigm (e.g. immediate early genes, stress response genes); however, these do not preclude the ability to identify canonical cell subclass and types. Lastly, close examination into specific morphological features from matched transcriptomic types yielded similar and preserved morphologies from acute and culture preparations. The combination of these approaches provides a robust and accurate method to characterize the signature properties of genetically-defined human neuron types, including diverse neocortical GABAergic neuron types that have previously been difficult to reliably target.

Abstract: Neocortical pyramidal neurons display significant diversity within and between cortical areas and across species, and understanding this diversity is key to understanding species and areal specializations in neocortical function. Single cell/nucleus (sn)RNA sequencing now allows robust cross-species/areal comparisons by generating and aligning cellular taxonomies across areas and species, while Patch-seq methods allow morpho-electric characterization of transcriptomically-identified cells. In the current study we used Patch-seq to begin understanding cross-areal pyramidal neuron differences in non-human primate (NHP), by collecting morphological, electrophysiological, and transcriptomic data from many individual pyramidal neurons in temporal cortex (TC) and primary motor cortex (M1) brain slices from the macaque.Morpho-electric properties of NHP pyramidal neurons depended upon their laminar location, cortical region and long-range axonal projection. Similar to previous reports in human neocortex, but unlike rodent cortex, subsets of supragranular pyramidal neurons in both M1 and TC displayed prominent h-current related membrane properties. We found that Layer 5 (L5) pyramidal neurons broadly segregated into two groups with morpho-electric and transcriptomic properties aligned to rodent projection neurons: extratelencephalic (ET) neocortical pyramidal neurons with long range axonal projections outside the telencephalon and intratelencephalic neurons (IT) with axonal projections constrained to the telencephalon. To directly test whether these putative L5 ET neurons projected to subcerebral regions, we injected retrograde adeno-associated virus (rAAV) into the cervical spinal cord of three macaque monkeys to express the fluorescent protein tdTomato. Targeted recordings of labeled corticospinal neurons from ex vivo slices of M1 confirmed that these neurons exhibited ET-like morpho-electric and transcriptomic properties. Cross-areal analysis of snRNA sequencing data demonstrated substantial cross areal differences in L5 ET neuron gene expression. Similarly, L5 ET neurons in M1 possessed distinct sub/suprathreshold properties and dendritic morphology compared to those found in TC. Thus, while both TC and M1 contain neuron types homologous to those found in rodents, distinct cell-type specific ion channel gene expression, physiology and morphology emerge in the non-human primate depending upon brain region.

Title: Cross species cell types mapping of cortical inhibitory neurons to populate mouse cortex with detailed neuron morpho-electrical models.

Authors: *Y. ROUSSEL, C. VERASZTÓ, D. RODARIE, T. P. L. DAMART, M. W. REIMANN, D. KELLER, H. MARKRAM;
EPFL, Blue Brain Project, Geneva, Switzerland

Abstract: The ability of the brain to produce complex computational behavior arises from its organization and properties at the cellular level. One way to probe these principles is to study the cell type composition in its different areas. We estimated the distribution of well characterized morphological and electrophysiological neuron types (me-types) in the whole mouse cortex by converting molecularly defined cell type densities from the Blue Brain mouse cell atlas into the desired me-types. We used models from the Blue Brain Project inhibitory neurons model database to populate the cortex, enabling detailed cell modelling. However the models still lacked molecular markers which were necessary for me-type densities estimates. The conversion thus required the development of a method able to assign probable molecular markers to the desired me-types. To extrapolate this missing information, we employed an additional dataset from Allen Institute for Brain Science containing molecular identity data for mouse cortical neurons. We focused on inhibitory neurons because of their established subclassifications using molecular markers (PV, SST, VIP and Lamp5). Since data came from different animal models and from different cortical areas, we first normalized the reconstructed morphologies from both datasets using cortical layers delineation before extracting morphological features (m-features). Electrophysiological features (e-features) were extracted from recordings obtained using comparable protocols such as current steps. We then built a subspace upon a number of m- and e-features common to both data sources. We optimized the weight given to m-features relative to e-features so that mouse neurons with identical molecular markers would cluster together in the resulting subspace. We identified 13 molecularly homogeneous clusters that still merged neurons from both datasets. Finally, we probabilistically assigned a molecular identity to a me-type based on the assigned latent space clusters. The resulting mapping was then used to derive inhibitory me-types densities in the cortex. Results showed relatively comparable me-type distributions across the cortical areas with only a few exceptions in layer 6 of the orbital ventrolateral area. Finally, we validated the approach using labels common to both datasets. We believe our method to be a solid approach to compile data from different sources (e.g. mouse and rat) and extrapolate additional information from sparse data (e.g. morpho-electrical description from molecular marker).

Title: Identifying Transcriptional Regulators of Ion Channel Gene Expression using CRISPRi

Authors: *R. KIRK, S. NELSON, R. XIAO;
Brandeis Univ., Waltham, MA

Abstract: Healthy neuronal function requires balanced regulation of the relative abundance and distribution of ion channels and ionotropic receptors in the cell. Despite their well-established significance, little is known about the transcriptional mechanisms that control the expression and abundance of mRNA encoding these critical proteins. Therefore, we sought to identify candidate transcriptional regulators of ion channel genes by leveraging bulk RNA-seq and ATAC-seq data collected in parallel from several neuronal cell types throughout the adult mouse brain. Motif enrichment analysis from our data implicates the Kruppel-like factor (KLF) and Regulatory Factor X (RFX) families of transcription factors as potential novel regulators of ion channel gene expression. To test our predictions, we have developed an *in vivo* CRISPR-interference (CRISPRi)-based knockdown strategy to knock down abundantly expressed (RFX3 and RFX7) or activity-regulated (KLF6 and KLF9) members of each transcription factor family individually or in combination. By injecting neonatal Emx1-Cre;LSL-dCas9-KRAB mice with AAV9 containing guide RNA's (gRNA) targeting our genes of interest, we are able to reliably produce 90-95% knock down of up to 3 genes of interest in specific cell types with a single virus. The inclusion of a Cre-dependent fluorescent reporter in our virus allows us to sort infected cells by their fluorescence and perform RNA-sequencing to understand the effects of individual or combinatorial transcription factor knockdown(s) on the neuronal transcriptome. Furthermore, the multiplexed application of CRISPRi allows us to interrogate gene expression networks in specific cell types while overcoming or unmasking the redundancy or synergy in transcription factor function. These experiments may reveal many previously unknown targets of RFX3, RFX7, KLF6, or KLF9 in the mammalian cortex, among which are expected to be ion channel genes.

Title: Comparative evaluation of dendritic spine imaging techniques- Golgi staining and microinjection

Authors: P. ROGU[1], ***I. MOLLICONE**[1], A. LIPSHUTZ[1], R. KHAN[1], G. B. ROSOKLIJA[1], A. J. DWORK[1], G. TURI[1], M. REIMERS[3], T. SALTZ[2,4], D. DUMITRIU[1];

[1]Columbia Univ. Med. Ctr., New York City, NY; [2]Columbia Univ. Med. Ctr., New York, NY; [3]Michigan State Univ., Okemos, MI; [4]Williams Col., Williamstown, MA

Abstract: Dendritic spines are submicron-sized protrusions of the dendrite that form connections between neurons. Implicated in development, age-related memory impairment, stress response, motivation, addiction, and behavior, spines are plastic, meaning that experience affects their morphology and density. Morphological changes of spines represent changes in postsynaptic receptor expression and electrochemical potentials. There are many ways to visualize spines, including the Golgi staining method and single cell microinjection of fluorescent dyes. Golgi staining is the first technique, dating back to 1873 and remaining popular today. It involves tissue-wide analysis via mercury impregnation. This staining process takes several months, after which, spines are visualized via brightfield microscopy and analysis is conducted via manual counting. Although widely used, Golgi staining lacks control and precision, and the mechanism behind the staining is not well understood. Microinjection of fluorescent dye is a newer technique that is validated and backed by its comparability to the "gold standard" of neuroimaging: serial section transmission electron microscopy. As compared to ssTEM, microinjection technique utilizes more easily acquired resources while also being faster. Although in contrast to Golgi, microinjection requires a higher degree of technical skill and expensive imaging equipment. After microinjection of individual cells, spines are visualized via a combination of confocal microscopy and 3D reconstruction software that allows for semi-automated analysis of the spines' physical properties. In this confirmatory study, we look to compare the results between the two methods (Golgi & microinjection) within the same animals and identify where the differences in results lie. Within 8 rat brains, 2 sections containing the hippocampus were Golgi stained (n=224 dendrites) and 2 sections were microinjected (n= 282 dendrites) in the CA1 region. Using 2D Golgi staining, average density in spines/10 μm was found to be 16.99 +/- 0.35 and 11.11 +/- 0.29, as rated by two different raters. In the same rat brains, using 3D microinjection, the average density value was 41.35 +/- 0.97. Three-fold magnitude differences in the spine densities recorded between the two methods were observed. The three main sources of variance come from dimensionality (2D vs. 3D imaging), microscopy type (brightfield vs. confocal), and interrater variability. Using inconsistent techniques leads to fundamentally erroneous results in the field. Here we sought to clarify the precise magnitude and sources of differences between two commonly employed techniques in spine analysis.

Title: Time-resolved and cell-type-specific analyses of protein expression during sleep and wake in the zebrafish brain

Authors: *S. E. MILLER[1], D. A. PROBER[2], E. M. SCHUMAN[3], D. A. TIRRELL[1];
[1]Chem. Engin., [2]Biol., Caltech, Pasadena, CA; [3]Max Planck Inst. for Brain Res., Frankfurt/Main, Germany

Abstract: Humans spend nearly a third of their lives in the immobile state of reduced responsiveness and altered consciousness that we call sleep. Nevertheless, much about the function of sleep remains an evolutionary and biological mystery. Lack of adequate sleep is associated with a plethora of immediate and lasting negative effects on human health, including reduced cognitive performance, mood regulation, and motor function, as well as compromised immune response, neurological disorders, and even death. The importance of sleep is also reflected in its ubiquity, having been observed in most multicellular animals. Zebrafish, as a result of their genetic tractability, rapid development, optical transparency, diurnal sleep cycle, and ability to be used in high-throughput behavioral analyses, have emerged as a valuable model organism for dissecting the conserved genes and neural circuitry involved in sleep. However, proteomic analyses of sleep, which can uncover the molecular and mechanistic links between genes and behavior, have been relatively scarce. In this work, we used bio-orthogonal non-canonical amino acid tagging (BONCAT) to label newly synthesized proteins in larval zebrafish during defined time windows with azidohomoalanine (AHA). Labeled proteins were affinity purified for subsequent proteomic analysis via liquid chromatography-tandem mass spectrometry (LC-MS/MS). We were able to compare protein expression between larvae deprived of sleep for 48 hours with control fish to examine the proteomic signature of sleep deprivation. We are also working towards optimizing and applying recently developed BONCAT methods for cell-type-specific labeling of newly synthesized proteins for use in proteomics experiments. This version of BONCAT uses zebrafish that express a mutant methionyl-tRNA synthetase, which is capable of charging the bulkier non-canonical amino acid azidonorleucine (ANL), under the control of the neuron-specific promoter HuC. This ensures that only proteins synthesized in neurons during the time period of interest are enriched for LC-MS/MS analysis. Finally, by improving the labeling efficiency by both AHA and ANL in zebrafish, we aim to facilitate more time-resolved analysis of protein expression. This would enable, for example, labeling during shorter time windows of night or day for analysis of proteins that are differentially expressed during periods dominated by sleep or wake, respectively. Our work opens the door to further mechanistic analyses, such as through the use of genetic knockouts or mutants, of the role that differentially expressed proteins play in regulating sleep and wake in zebrafish.

Title: The Neuroscience Multi-Omic (NeMO) Archive: A repository for single-cell genomic data from the mammalian brain

Authors: *H. CREASY, S. ADKINS, S. AMENT, R. CARTER, J. CRABTREE, V. FELIX, P. GANDT, B. HERB, C. MCCRACKEN, D. OLLEY, M. GIGLIO, A. MAHURKAR, O. WHITE;

Abstract: Scalable technologies to sequence the transcriptomes and epigenomes of single cells are transforming our understanding of cell types and cell states in the mammalian brain. The Brain Research through Advancing Innovative Neurotechnologies (BRAIN) Initiative Cell Census Network (BICCN) is applying single-cell multi-omic technologies at unprecedented scale to map the cell types in the mammalian brain. In an effort to increase data FAIRness (Findable, Accessible, Interoperable, Reusable), the NIH has established data repositories to make data generated by the BICCN and related BRAIN Initiative projects accessible to the broader research community. The Neuroscience Multi-Omic Archive (NeMO, nemoarchive.org) serves as the primary repository for genomic data generated by Brain Initiative researchers. NeMO currently provides access to raw and uniformly processed transcriptomic and epigenomic data from >12 million cells in all the major regions of the mouse, human, and non-human primate brains, totaling >280 TB. The goals of the NeMO Archive are to: 1) support researchers in deposition of raw and processed data to NeMO, 2) perform uniform data processing and quality control, 3) assign all data objects and datasets a persistent NeMO identifier, resolvable through identifiers.org, 4) provide a central repository for browsing, querying and accessing genomic data through the NeMO data portal, 5) enable linking of genomic data to data generated by other experimental modalities, such as neuronal morphology, connectivity, and electrophysiology, by federating with other archives through use of common data models with standardized controlled vocabularies and ontologies, and 6) engage in outreach to understand community needs and to develop resources to meet these needs. In summary, we aim to provide a comprehensive infrastructure to enable the scientific community to access, analyze and interpret neuro-omics data, in order to advance a comprehensive understanding of cell type diversity in the mammalian brain.

Title: Nemo-scorch: data coordination for the single cell opioid responses in the context of hiv (scorch) program

Authors: *S. A. AMENT[1], M. BASU[1], R. R. CAMPBELL[1], R. CARTER[1], H. H. CREASY[1], K. DEGATANO[2], B. R. HERB[1], K. IFEONU[1], L. CHANG[1], M. GIGLIO[1], R. HERTZANO[1], M. LOBO[1], A. MAHURKAR[1], T. L. TICKLE[2], O. R. WHITE[1];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Broad Inst. of Harvard and MIT, Cambridge, MA

Abstract: Substance use disorders (SUD) and HIV, independently and as comorbid conditions, are major public health concerns. Increasing evidence suggests that cell type-specific transcriptomic alterations underlie the development and persistence of SUD and HIV. However, there remain substantial gaps in our understanding of the precise mechanisms that drive neural dysfunctions and cognitive impairments that are prevalent in both disorders. In particular, there is a need for new studies to characterize the diversity of cell types within brain regions relevant to SUD and HIV, as well as to investigate how chronic or acute exposures to addictive substances influence the states and functions of these cells. The Single Cell Opioid Responses in the Context of HIV (SCORCH) program was established in 2020 by the National Institute on Drug Abuse (NIDA), with the mission of generating resources that will enable comprehensive characterization of SUD and HIV at the single-cell level. This will be accomplished primarily through single-nucleus RNA sequencing of *postmortem* brain tissues from human donors who died with HIV and/or SUD, as well as animal models. SCORCH is an interdisciplinary effort, currently involving teams of investigators at five institutions: Yale University, the J. Craig Venter Institute, the Icahn School of Medicine at Mt. Sinai, the Broad Institute of Harvard and MIT, and the University of Maryland School of Medicine. The SCORCH Data Center (scorch.igs.umaryland.edu) is responsible for coordinating and sharing the resources generated by this program, ensuring that the data is FAIR (Findable, Accessible, Interoperable, and Reusable). We will also integrate additional HIV/SUD genomic data sets and atlases of cell types in relevant brain regions that are being produced by other researchers and consortia, with the goal of creating a comprehensive resource for the HIV and SUD research communities. This will be accomplished by extending the Neuroscience Multi-Omic (NeMO) Archive (nemoarchive.org), the NeMO/Terra cloud-computing environment (terra.bio), and the NeMO Analytics single-cell genomics visualization and analysis tools (nemoanalytics.org). Here, we will describe the rationale, design, goals, and expected outcomes of the SCORCH program.

Abstract: NeMO Analytics (nemoanalytics.org) is a web-based suite of data visualization and analysis tools, focusing on single-cell data analysis. The portal allows users to visualize multi-omic data across experiments and species side-by-side. The portal is pre-populated with thematically organized datasets. Users can also upload their own data for private or public use, utilize curated datasets from other users, or select a dataset from the vast NeMO Archive. Tools include cluster visualization based on expression/cell type, cluster comparison, identification of marker genes, comparison of marker genes across datasets and note taking. Additional tools include a workbench to perform *de novo* analysis of scRNA-seq data, visualization and analysis of spatial transcriptomics data, and visualization of epigenomic data. The platform supports visualization of datasets across species and modalities side-by-side keyed on by gene symbol. *Future* functionality will include multi-gene visualization and gene regulatory analysis and tools that allow the user to explore gene set enrichment analysis of their data. NeMO Analytics is built on the gEAR portal, an open source platform for viewing and analyzing genomics data available at github.com/IGS/gEAR and described in Nature Methods: https://rdcu.be/cndgK.NeMO Analytics aims to foster a knowledge ecosystem by supporting publications and creating “living figures” that can be explored, and the underlying data further analyzed. Our goal is to be a natural continuation of the results presented in publications and allow users to pick up the analysis where the paper left off. Further, we strive to facilitate access to data held on disparate archives and allow users to analyze this data in a common workspace. A user can then better understand their own data when added to this workspace and seen in the context of countless other studies, currently spanning more that 10 million cells.

Abstract: Single-cell transcriptome and epigenome profiling technologies have transformed our understanding of brain cell type diversity, with hundreds of cell types identified in the mouse brain by recent studies (Armand et al., 2021). However, it is challenging to comprehensively validate the statistical reproducibility and biological function of the vast number of cell types identified. Moreover, we lack objective and operable criteria to define cell type distinctions that balance between over- and under-splitting of cells to establish a consensus taxonomy of brain cell types.

Here, we develop computational methods that use multi-omic data to cross-validate cell types, and evaluate their level of over- or under-splitting. The methods build on the assumption that the cell type identity of a cell is consistently represented in its transcriptome and epigenome. Therefore, we can compare a cell's multi-modal profiles with those of its neighbors to objectively assess the validity of cell types, based on similarities and differences that are supported by both transcriptomic and epigenomic features.

We applied our methods to a multi-omic dataset from the human frontal cortex, containing 3,898 neuronal cells profiled by single-nucleus methyl-cytosine, chromatin accessibility and transcriptome sequencing (snmCAT-seq). This dataset provides high-resolution information about three modalities for each cell: DNA methylation, regions of open chromatin, and gene expression. Cluster cross-validation analysis identifies a range of 20 to 50 reliable cell types that are supported by both transcriptomes and DNA methylomes. Under- vs. over-splitting analysis reveals that splitting neuronal population into 17 major cell types under-estimated cell type diversity, with 16 types containing substantial within-cell type heterogeneity. Further splitting the 17 major types into 52 subtypes greatly reduces within-cell type heterogeneity, at a slight cost of reduced uniqueness. In addition, we benchmarked the effectiveness of several computational integration methods, using the matched transcriptomes and DNA methylomes as ground truth. All five methods we tested can reliably assign matched transcriptomes and DNA methylomes to the same major cell types (n=17; accuracy 31.0%~87.3%), while the performance decreases at the subtype level (n=52; maximum accuracy 62.6%).

As the amount of human brain multi-omics data grows, we expect our methods to be useful for objectively validating the appropriate resolution of cell types. Moreover, cross-validation will be important for identifying reliable inter-individual variability among human brain cell types.

Abstract: Background: Human *NEUROG1* gene encodes neurogenin1protein. It has an essential role as a transcription factor in neurogenesis and neuron repair. Mutations in this gene linked to many congenital and brain diseases. Method: This study used bioinformatics tools to evaluate the effects of mutations along the sequence of the gene. Genomic data has been retrieved from NCBI, GenBank, and Ensembl databases. Result: From 617 SNPs and INDels reported in the dbSNP, only four in coding has been predicted as deleterious by all software. Modeling of three-dimensional structure of NEUROG1 was generated by I-TASSER and validated by different software. Analysis of 3' UTR region showed that 8 SNPs were found to affect microRNA binding sites either by creating or disturbing them. Computational analysis has been used for the possible effects of reported SNPs on the functionality of the gene and its protein. Conclusion: This gene has been suggested as a candidate for gene therapy at genetics and epigenetics levels and\or drug design of neurodegenerative and other neurological diseases.

Title: Soft Clustering by Consensus (SoCCo) enables robust and scalable characterization and interpretation of diverse brain cell population structures

Authors: *S. GOGGIN[1], E. ZUNDER[2];
[1]Neurosci. Grad. Program, Univ. of Virgina, Charlottesville, VA; [2]Biomed. Engin., Univ. of Virginia, Charlottesville, VA

Abstract: Single cell molecular profiling technologies have enabled major advances in our ability to identify and characterize functionally important subsets of cells and their complex roles in the brain. These studies have increasingly revealed that in any given snapshot of the brain there may exist a range of cell population structures - from defined, discrete populations that align well with the canonical concept of a “cell type" to those which can be better described as complex landscapes of continuous phenotypes. Identification of meaningful population structure within a single cell dataset generally relies on some form of clustering, but these approaches are not able to robustly capture and describe this broad range of population structures. Most clustering techniques force a discrete and categorical perspective on defining cell populations, do not generalize well across datasets, and have low reproducibility in response to small changes to input data or algorithm parameters. To address the need for a method that can provide robust, generalizable, and actionable descriptions of observed heterogeneity of molecularly-defined cell population structures, we have developed a new method called Soft Clustering by Consensus (SoCCo). Our method utilizes an ensemble of clusterings to explore a wide range of data subspaces at many different resolutions, and then applies a consensus function across these ensemble members to obtain a final soft cluster membership matrix. The process of integrating information from the diverse ensemble members enables our method to capture the complex cell population structures that exist in a given single cell dataset, and the soft clustering output is able to quantitatively describe the resulting cellular landscape without forcing cells into a single discrete grouping. This approach has two further advantages - the use of data subsampling allows our method to be scalable to very large datasets, and the internal hyperparameter search and optimization removes the need for extensive manual hyperparameter tuning which contributes to the usability of SoCCo. Finally, we have also developed a fuzzy differential expression approach that enables direct interpretation of the biological complexity captured by our soft clustering outputs. We have validated our method through simulation studies and with real mass cytometry and scRNA-seq datasets. Our results demonstrate that SoCCo is more generalizable to diverse datasets, scalable to large datasets, and yields more reproducible results than current state of the art methods. SoCCo will enable effective use of powerful single cell analysis approaches by a broader community of neuroscientists.

Title: Assessing and Improving on PrediXcan's Ability to Impute Gene Expression

Authors: *J. DRAKE[1], N. TAYLOR[1], J. MARTEL[1], N. GILLESPIE[2], J. POWELL[3], N. MARTIN[4], V. VLADIMIROV[1];
[1]Texas A&M Univ., Bryan, TX; [2]Virginia Inst. for Psychiatric and Behavioral Genet., Richmond, VA; [3]Garvan-Weizmann Ctr. for Cell. Genomics, Darlinghurst, Australia; [4]QIMR Berghofer Med. Res. Inst., Herston, Australia

Abstract: Gene expression is the consequence of environmental and genetic factors, which include epigenetic regulators and interactions between non-coding and protein coding RNAs. Gene expression (GE) imputation is becoming a powerful tool to derive and test for an association between GE patterns and phenotype of interest in a much larger than previously thought sample sizes. The correlation's strength between the genetic and expression profile of a given sample can be used to calculate the genetic contribution to GE (in the form of weights), which are then used to impute GE from unrelated genotypic data. PrediXcan, among others, is a recent software for GE imputation that utilizes this relationship by using the genetic and GE data in the Genotype-Tissue Expression Project (GTEx) database. PrediXcan has gained popularity in psychiatric genetics due to its ability to circumvent the necessity of post-mortem brain tissues. However, an important question is estimating the reliability and accuracy of the imputed GE. To address this question, here, we tested the correlation between imputed and measured GE derived from nucleus accumbens of 63 subjects. Among the number of matched genes (n=975), i.e., between the GTEx database and our sample, we identified only 1.3% with Pearson correlation ≥ 0.5. To address this seemingly low number of genes with an agreement between imputed and measured GE, and to improve on PrediXcan's imputation quality, we have expanded on their work by including much larger samples (i.e., N=630) from the Brisbane Longitudinal Twin Study and utilized heritability estimates to screen for poorly performing models.

Title: Machine learning identifies metabolic clusters of IDH-wild type glioblastoma and predicts prolonged survival within the neuronal subtype

Authors: *M. ALEXANDER[1,2], J. GOODMAN[3];
[1]Yale Univ., New Haven, CT; [2]Frank H. Netter MD Sch. of Med., New Haven, CT; [3]Frank H. Netter MD Sch. of Med., North Haven, CT

Abstract: In our previous work we identified that differential metabolic pathway activation in low-grade glioma predicts prolonged patient survival. Here we test the hypothesis that differences in metabolic pathway activation would be associated with differences in survival of patients with glioblastoma

multiforme (GBM), the high-grade form brain tumors that remain associated with 100% mortality and poor survival time after diagnosis. Using expression data from all TCGA GBM studies, we estimate reaction activity scores for the cell's metabolic pathways, and cluster GBM tumors into three distinct metabolic clusters. We show that, unlike in LGG, in GBM, the metabolic clusters by themselves to not predict any differences in patient survival. However, our cluster 1 metabolic cluster is associated with higher survival within the neuronal subtype of GBM, which itself is has the shortest patient survival. We then apply a LASSO regularization survival model that allows us to include all reaction activity scores in our estimation. Using this variable selection approach, we identify expression of three catalytic units of G6P, GLUD1, GLUD2, and CSP-S to be predictive of differences in survival of GBM patients. These results are consistent with recent findings in the literature on the role of glutamate in glioma. Our results point towards development of metabolic markers of patient survival in GBM using gene expression, as well as leading to hypotheses about potential targets for treatment designed to disrupt GBM metabolism.

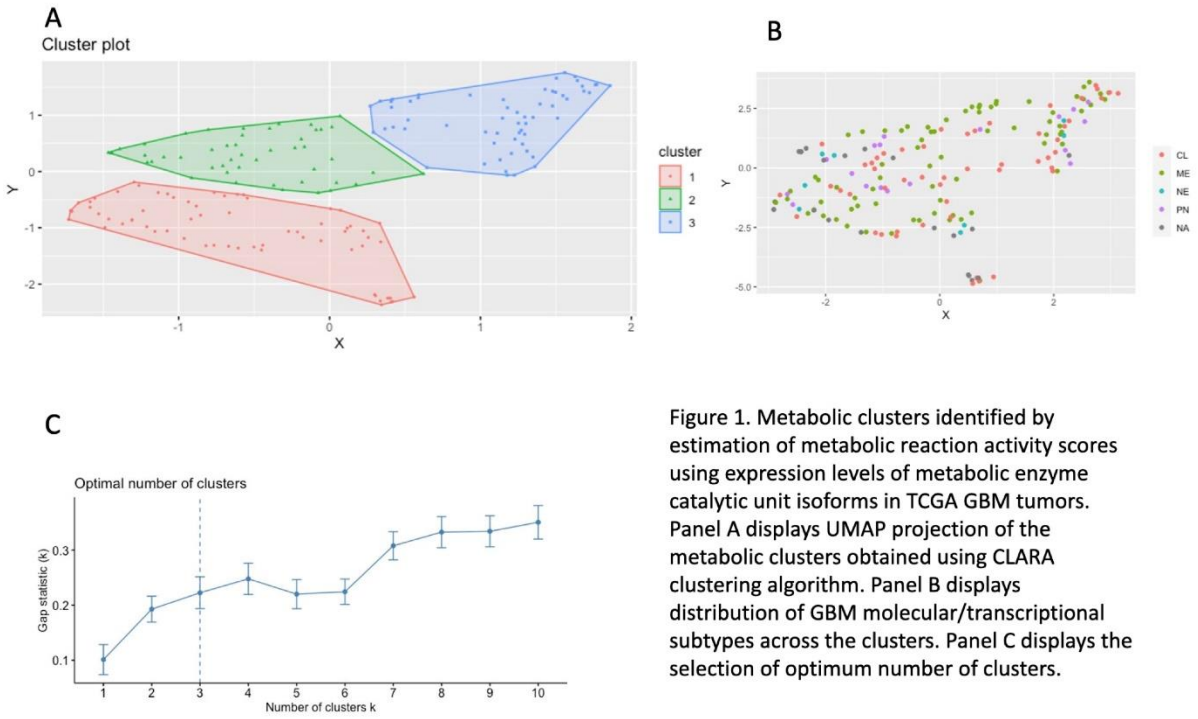

Figure 1. Metabolic clusters identified by estimation of metabolic reaction activity scores using expression levels of metabolic enzyme catalytic unit isoforms in TCGA GBM tumors. Panel A displays UMAP projection of the metabolic clusters obtained using CLARA clustering algorithm. Panel B displays distribution of GBM molecular/transcriptional subtypes across the clusters. Panel C displays the selection of optimum number of clusters.

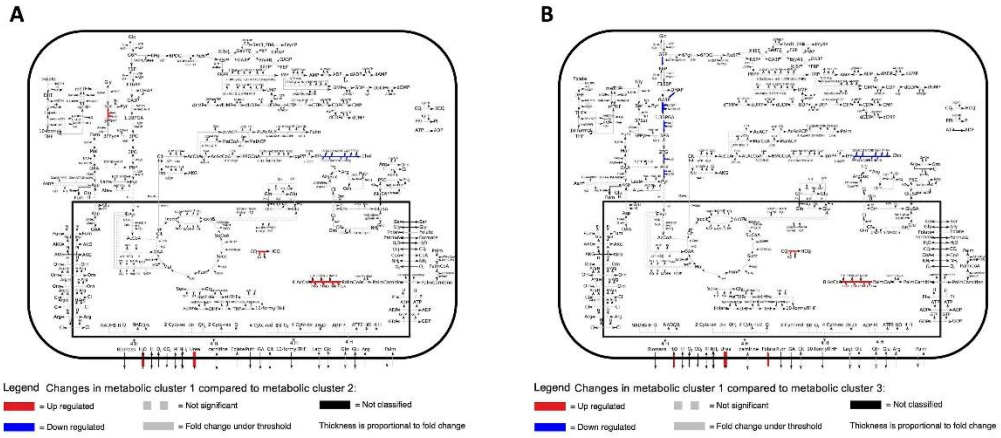

Figure 2: Differentially expressed metabolic reaction pathways estimated from RNA-Seq expression data for all GBM studies in TCGA. Panel A displays differentially upregulated and downregulated metabolic reactions in metabolic cluster 1 compared to metabolic cluster 2. Panel B displays differentially upregulated and downregulated metabolic reactions in metabolic cluster 1 compared to metabolic cluster 3.

Title: Relationship between heritability and latent dimensions of behaviour in the striatum, thalamus and globus pallidus

Authors: *N. BLOSTEIN[1], S. PATEL[3], R. PATEL[2], G. A. DEVENYI[4], S. TULLO[5], E. PLITMAN[2], M. COSTANTINO[2], R. MARKELLO[7], S. BEDFORD[8], M. CHAKRAVARTY[6];

Abstract: Introduction. Although the basal ganglia are traditionally associated with habit formation and motor control, non-motor basal ganglia loops have been found to modulate cognitive and limbic brain functions. The following study seeks to examine how latent dimensions of cognitive and emotional behaviour relate to heritability in shape measures of the striatum, thalamus and globus pallidus as a means of examining how cognition may be related to genetics.
Methods. Heritability measures were computed via a twin and non-twin sibling design, using MRI data of healthy adult twin and non-twin siblings from the Human Connectome Project (HCP; n=1086 participants; 3T; T1w; 0.7 mm isotropic voxels). Images were preprocessed using the minc-bpipe-library, and subcortical structure segmentations and vertex-wise shape measures obtained using MAGeTbrain and the CoBrA Lab subcortical atlases. OpenMx (version 2.12.2) was used to compute heritability estimates using structural equation modeling. Pyls 0.01 was used to run a partial least squares correlation (PLSC) analysis in Python 3.6.8. We obtained latent variables (LV) relating vertex-wise surface area and displacement to 30 behavioural variables related to cognition and emotion. For each significant latent variable, we adapted the Alexander-Bloch 2018 surface-based spin test to assess the significance of the correlation between vertex-wise heritability measures and LV-specific brain loadings.
Results. We found 4 significant LVs for both vertex-wise surface area and displacement. The bootstrap resampling ratios of the brain loadings had significant correlations with vertex-wise heritability measures for all 3 structures and across most LVs (Figure 1). Negative affect, emotion recognition, language processing and executive function loaded heavily onto our significant LVs.
Conclusion. The following study honed in on the understudied subcortex in order to further uncover gene-brain-behaviour interactions. We identified latent variables of behaviour whose brain patterns were significantly correlated with heritability.

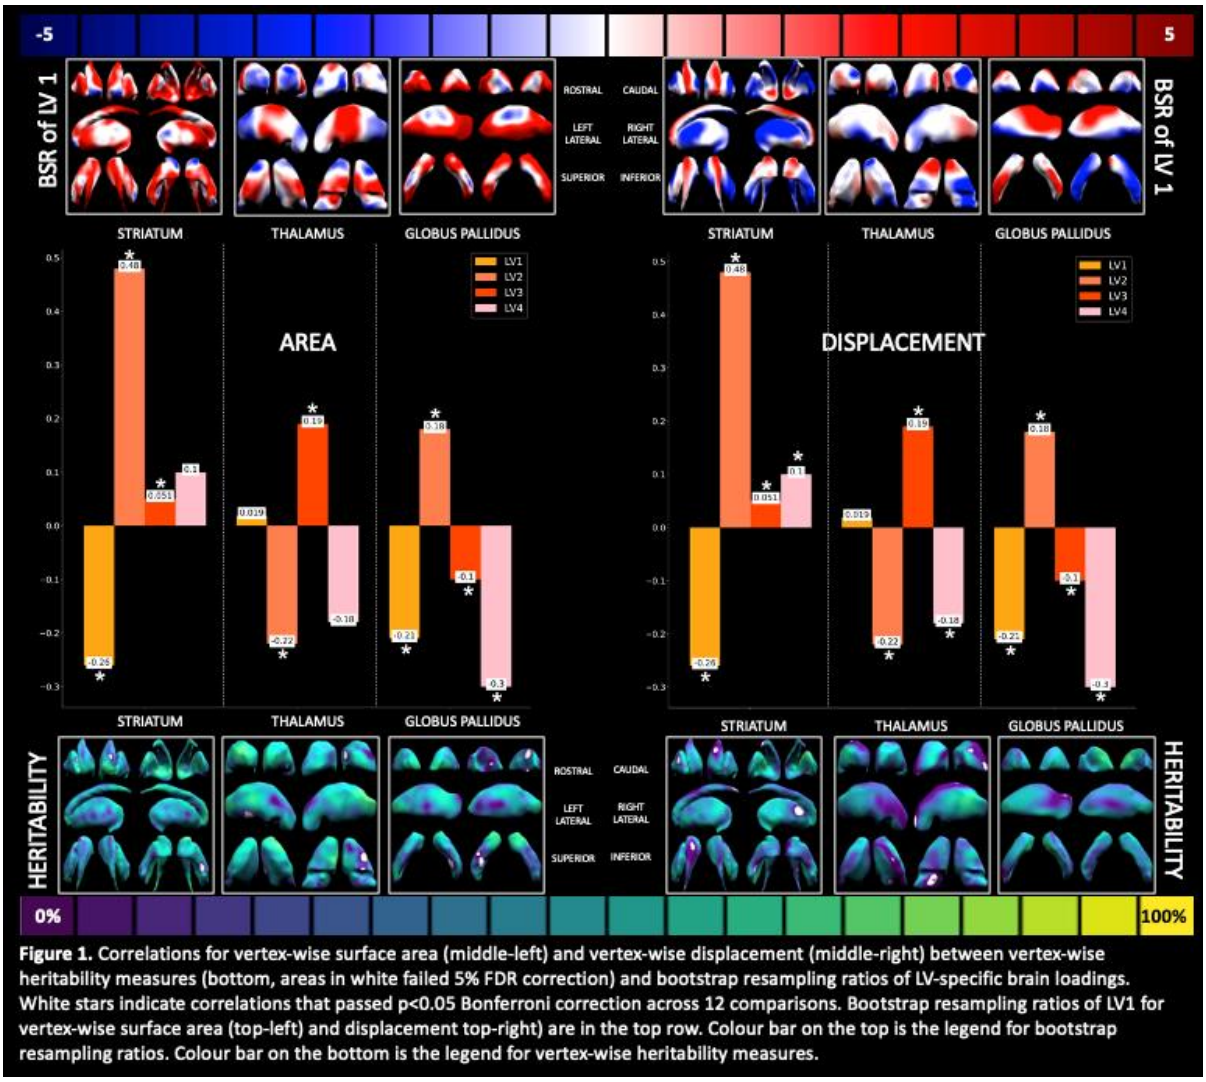

Figure 1. Correlations for vertex-wise surface area (middle-left) and vertex-wise displacement (middle-right) between vertex-wise heritability measures (bottom, areas in white failed 5% FDR correction) and bootstrap resampling ratios of LV-specific brain loadings. White stars indicate correlations that passed p<0.05 Bonferroni correction across 12 comparisons. Bootstrap resampling ratios of LV1 for vertex-wise surface area (top-left) and displacement top-right) are in the top row. Colour bar on the top is the legend for bootstrap resampling ratios. Colour bar on the bottom is the legend for vertex-wise heritability measures.

Title: Surrogate methods for robust significance evaluation of spike patterns in non-Poisson data

Authors: *P. BOUSS[1,2], A. STELLA[1,2], G. PALM[3], S. GRÜN[1,2];
[1]Inst. of Neurosci. and Med. (INM-6/ INM-10), Inst. for Advanced Simulation (IAS-6), Forschungszentrum Jülich, Jülich, Germany; [2]Theoretical Systems Neurobio., RWTH Aachen Univ., Aachen, Germany; [3]Neuroinformatics, Univ. of Ulm, Ulm, Germany

Abstract: Spatio-temporal spike patterns were suggested as indications of active cell assemblies. We developed the SPADE method [1-3] to detect significant spatio-temporal patterns (STPs) with millisecond accuracy. STPs are defined as repeating spike patterns across neurons with potential temporal delays between the spikes. The significance of STPs is derived by comparison to the null hypothesis of independence implemented by surrogate data. SPADE first discretizes the spike trains into bins of a few ms and clips bins with more than 1 spike to 1. The binarized spike trains are examined for STPs by counting repeated patterns using frequent itemset mining. The significance of STPs is evaluated by comparison to pattern counts derived from surrogate data, i.e., modifications of the original data intended to destroy potential spike correlation but under conservation of the firing rate profiles. To avoid false results, surrogate data are required to retain the statistical properties of the original data as close as possible. A classically chosen surrogate technique is Uniform Dithering (UD), which displaces each spike independently according to a uniform distribution. We find that UD surrogates applied to our data (motor cortex) contain fewer spikes than the original data. As a consequence, fewer patterns are expected and, thus, false positives may be generated. We identified as the reason for this spike reduction a change of the ISI distribution: UD surrogates are more Poisson-like than the original data which are in tendency more regular. Thus UD destroys a potential dead time and, therefore, spikes are clipped away.To overcome this problem, we studied several surrogate techniques, in particular methods that consider the ISI distribution, i.e., a modification of UD preserving the dead time, (UDD), (joint-)ISI dithering, trial shifting [4]. Another ansatz is a surrogate that shuffles bins of already discretized spike trains within a small window. We examined the surrogates for spike loss, ISI distribution, auto-correlation, and false positives when applied to different ground truth data sets. These are stationary point process models but also non-stationary point processes mimicking the statistical features of the experimental data. It turned out that trial-shuffling [4] best preserves the features of the original data and generates few false positives; we used it then for application to real data.

Title: Representation learning for neural population activity with Neural Data Transformers

Authors: *J. YE[1], C. PANDARINATH[2];
[1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Biomed. Engin., Emory Univ. / Georgia Tech., Atlanta, GA

Abstract: Neural population activity is theorized to reflect an underlying dynamical structure. This structure can be accurately captured using state space models with explicit dynamics, such as those based on recurrent neural networks (RNNs). However, using recurrence to explicitly model dynamics necessitates sequential processing of data, slowing real-time applications such as brain-computer interfaces. Here we introduce the Neural Data Transformer (NDT), a non-recurrent alternative. We test the NDT's ability to capture autonomous dynamical systems by applying it to synthetic datasets with known dynamics and data from monkey motor cortex during a reaching task well-modeled by RNNs. The NDT models these datasets as well as state-of-the-art recurrent models. Further, its non-recurrence enables 3.9ms inference, well within the loop time of real-time applications and more than 6 times faster than recurrent baselines on the monkey reaching dataset. These results suggest that an explicit dynamics model is not necessary to model autonomous neural population dynamics. Code github.com/snel-repo/neural-data-transformers.

Title: Stochasticity of Brain Rhythms

Authors: *C. HOFFMAN[1], J. CHENG[2], D. JI[2], Y. A. DABAGHIAN[3];
[1]Univ. of Texas Hlth. Sci. Center, Houston, Houston, TX; [2]Baylor Col. of Med., Houston, TX; [3]Neurol., Univ. of Texas At Houston, McGovern Med. S, Houston, TX

Abstract: The discovery of EEGs in 1930's revolutionized the field of neuroscience by providing a non-invasive tool for understanding and diagnosing physiological functions, neurological pathologies, etc. Currently, most analysis methods are based on using either instantaneous or time-averaged characteristics

of the brain waves. We propose an alternative approach that focuses on temporal patterns of brain waves over finite timescales. Specifically, we use two independent methods for quantifying structural regularity and irregularity of the recorded signals and correlate the resulting "stochasticity scores" with behavior. The first method, discovered by A. Kolmogorov in 1933, produces a λ-score that quantifies the pattern's consistency with the underlying mean behavior. The second method, introduced by V. Arnold in the 2000's, yields a β-score that measures how "structured" (e.g., periodic-like or time-clustered) the pattern is. We then analyzed subcortical EEGs recorded in the hippocampal CA1 area of mice running a U-shaped track and studied series of short sequences of their θ-peaks, γ-peaks, and Sharp Wave Ripple (SWR) events. We found that θ-stochasticity in all mice is typically low, indicating almost-periodicity of the θ-rhythm, with occasional bursts. In contrast, γ-waves and SWRs are on average stochastically unbiased, displaying a full range of patterns. Importantly, the dynamics of both λ- and β-scores for all waves are overtly coupled to the animal's behavior; particular patterns of the animal's brain waves correlate with its location, speed, and acceleration. For example, we observe γ-bursts during slow motion, and orderly, nearly periodic sequences of SWRs around food wells which we make explicit using the Dynamic Time Warping method. Overall, these results offer a novel perspective on studying the structure, the dynamics, and the functionality of the brain waves.

Title: Annolid - an instance segmentation-based multiple animal tracking and behavior analysis package

Authors: *C. YANG, M. EINHORN, T. A. CLELAND;
Psychology, Cornell Univ., Ithaca, NY

Abstract: Animal behavior is hugely complex, and the goals of behavioral analysis are correspondingly diverse. Methods of behavior quantification range from the tracking of single or multiple animals, or specific body parts of animals, to the identification of freezing, other behavioral states, interactions with objects, or the scoring of urine deposition. Such behaviors often are quantified based on video recordings, and the annotation and scoring of such recordings often are rate-limiting steps for research progression. A variety of software packages have been produced to facilitate video annotation, including a recent generation of deep learning-based pose estimation packages in which only a subset of the video frames must be explicitly scored. However, using these packages off-label for other behavior analyses has yielded mixed results; the tracking of multiple identified animals, particularly within complex or cluttered environments, has proven particularly challenging.
We present Annolid, a deep learning-based package for behavior analysis that is optimized for a range of common animal behavior assessments and requires substantially less manual frame annotation than

related packages. Uniquely, Annolid is based on instance segmentation models, and leverages overfitting to achieve robust tracking of multiple identified animals even in environments where animals may be partially or entirely obscured by environmental features or by one another. Using relatively few scored frames (tens to hundreds), we demonstrate robust behavior classification results for a wide variety of tasks, including animal tracking, body part tracking, and specialized measurements such as freezing or urine deposition. We further demonstrate successful multiple animal tracking under challenging conditions such as the partial or complete obscuring of tracked animals within visually cluttered environments. Arbitrary behaviors also can be directly recognized by the Annolid network, sometimes requiring higher numbers of scored frames; alternatively, such behaviors can be identified in post-processing analysis by the conjunction of simpler factors (such as nose location or body mask overlap). Model fitting can be performed locally or using online resources such as Google Colab. Results can be edited using our manual video scoring package Glitter2. Annolid and Glitter2 are both freely available from Github: https://github.com/healthonrails/annolid, https://github.com/matham/glitter2.

Title: How to turn a microscope into a Tesla: Leveraging artificial intelligence transfer learning for identification and quantification of novel biomarkers in microscopy images.

Authors: J. J. THEIS[1], W. M. O'KEEFFE[2], G. W. WADE[2], C. V. KING[2], K. J. LAWTON[3,2], *J. H. HARKNESS[3,2];
[1]Univ. of St. Thomas, St. Paul, MN; [2]Rewire Neuro, Portland, OR; [3]Neurosci., Washington State Univ., Vancouver, WA

Abstract: Many fields of neuroscience utilize microscopy imaging to evaluate a broad range of cell types and subcellular structures. Imaging data is crucial for evaluating experimental outcomes and inferring relationships between relevant biomarkers. With progress in imaging technology, researchers can view much greater detail from larger datasets. Unfortunately, identification and quantification of these biomarkers remains a bottleneck, often requiring significant hand annotation that is both time consuming and introduces intra- and inter-rater errors. While some automated solutions exist, these often require a great deal of user involvement to correct inaccuracies. In recent years, machine learning (ML) emerged as

an excellent solution to accurately recognize regions of interest in microscopy images. The ML training process generally requires 1000's to 100,000's+ of user annotated images. Although hand-annotation is still a large upfront time investment, it produces a highly accurate model that is useful long-term for much faster and more consistent analysis of frequently studied cell types and biomarkers. Regrettably, this method is less useful for studying novel cell types or biomarkers, with few training images available. To combat these limitations, we used a ML technique known as transfer learning, which starts with a pre-trained model of a roughly similar biomarker as a base to create a new model. With transfer learning, we are able to reduce the number of required annotated images from several 100 to a few dozen, depending on cell density. We tested this method for several novel biomarkers from our *Pipsqueak AI* machine learning database, including models that are trained to detect staining for Parvalbumin, 8-oxo-dG, c-Fos, WFA, and DAPI. Our preliminary experiments trained new deep ML models with unique user annotated datasets based on similar existing biomarkers in our database. For one such dataset containing just 28 annotated images, we achieved a 5.5% increase in accuracy (86.9% vs. 82.4%) and a 11.1% increase in precision (84.3% v.s. 75.9%) compared to the original model. Further, when comparing this new model against a model which used only the user's annotated images for training, we achieved an accuracy increase of 24.8% (86.9% vs. 69.6%). Our results indicate that this computational method will greatly reduce the time and resources needed to train accurate detection algorithms, thus broadening the reach of machine learning to novel biomarkers and smaller image sets. Overall, this technology will allow the analysis bottleneck to catch up to the current hardware advances in the field, and rapidly advance research findings across disciplines.

Title: Dendritic Spine Counter plugin for ImageJ

Authors: *M. VOLOSHIN[1], P. C. ROMERO[1], J. PARATO[2];
[1]Mighty Data, Inc., Weaverville, NC; [2]SUNY Empire State, Brooklyn, NY

Abstract: In the central nervous system, most excitatory synapses are represented as small protrusions called dendritic spines. The number of excitatory synapses on a neuron impacts overall excitability, and, on a larger scale, network activity. In diseases such as Alzheimer's Disease, Autism Spectrum Disorder, and schizophrenia, spine density is abnormal, resulting in improper brain function. Therefore, computing spine density is an important data-gathering step for many avenues of research into these disorders. Here, we have created a free ImageJ plugin, Dendritic Spine Counter, that will allow researchers and students to count spines in 2D. This plugin allows a user to submit a 2D image of stained neuronal tissue, mark a dendrite on that image for analysis, and receive an automated visually interactive list of structural features along that dendrite that are likely to be spines. The plugin operates “semi-automatically”, requiring minimal input from the user outside of specifying the dendrite to analyze. It also offers manual override options, permitting the user to directly add or remove spines. The machine vision algorithms underlying Dendritic Spine Counter were implemented using a heuristic-driven “expert system” approach, primarily employing basic image transformation functions and statistical analyses of pixel areas.

Abstract: Research has established the association between psychiatric disorders with somatic comorbidities like cardiovascular risks and type II diabetes. In this study we are interested to understand the relation of obesity (measured by BMI) in individuals with mental disorders. We investigated the relationship between Grey Matter Volume (GMV) and Body Mass Index (BMI) by the use of multivariate analyses in two large, multi-site cohorts: IXI (https://brain-development.org/ixi-dataset/) and PRONIA (https://www.pronia.eu/). We extracted age-matched mentally healthy samples from both cohorts and further selected a balanced population covering people across all BMI ranges as a discovery group. The remaining healthy individuals were retained as replication samples. Another replication sample included the PRONIA clinical patient participants (Clinical High Risk, Recent Onset Psychosis and Recent Onset Depression). We developed multivariate regression and classification models to estimate BMI labels/classes using whole-brain grey matter volume data. For the regression model, we measured the difference between neuroanatomically predicted and observed BMI (BMIgap). For the classification model, we distinguished between normal and obese individuals (Overweight (BMI ≥ 25), Obese Class I (BMI ≥ 30), Obese Class II (BMI ≥ 35) and Obese Class III (BMI ≥ 35)). We removed the effects of age, sex and site by performing a partial correlation analysis. Repeated nested cross-validation as implemented in NeuroMiner (https://github.com/neurominer-git) was used to derive and test models. Models were also externally validated using the structural GMV images of healthy controls (replication sample) and the clinical PRONIA participants. The regression model performed with an MAE of 3.3 BMI points (r=0.37; P<.001) during model discovery. The classification model identified the obese group with a balanced accuracy of 64% during model discovery. During model application, the balanced accuracy was reported to be 59% with the structural images of the patients. The study will be essential in finding out underlying important signatures of somatic comorbidities associated with psychiatric disorders.

Title: Structural design optimization of a network of springs for supplementing muscle torque during gait

Authors: *B. MALIZIA[1], M. JACOBSON[1], P. RYALI[1], M. KIM[1], C. FRIGO[2], J. PATTON[1]; [1]Univ. of Illinois Chicago, Chicago, IL; [2]Politecnico di Milano, Milan, Italy

Abstract: Commercially available exoskeletons for gait assistance and rehabilitation, implementing strategies such as gravity compensation and metabolic cost reduction, often require the use of motors and

controllers. Our research shows that it is possible to use structural optimization to arrange a network of diagonal tension elements, which act mathematically as basis functions, to reproduce the muscular torques generated during physiological walking. This network of muscle-like elastic elements, called ExoNET, is a multidimensional spring system that shifts control intelligence from software to physical hardware. The resulting device has the potential to be simple, inexpensive, customizable, and wearable. Importantly, it can deliver any desired torques to multiple joints at many operating points. Moreover, the ExoNET overcomes the need for a rigid skeleton, using the very anatomy of the human body as a rigid link. It is quick and easy to use, and hence is valuable for therapy. Here, we present Dynamic Simulations through Musculoskeletal Models that validate the results of the structural optimization. Desired kinematics and a hip-knee ExoNET model determined the necessary muscle torques, and simulations demonstrated successful walking with significantly reduced muscle torques. This study demonstrates that the active energy input from muscles can be decreased by intelligently storing and returning energy during the gait cycle. Further developments involve Human-in-the-loop optimization (HITLO), while the patient walks on a treadmill, for the design of ExoNETs. Such bio-inspired passive systems may hold promise for neurorehabilitation and human augmentation. Supported by NIDILRR 90REGE0005-01

Abstract: Advances in neural recording are presenting increasing opportunities to study neural activity in unprecedented detail, across a wide variety of neural systems and diverse behaviors. In parallel, progress in machine learning is yielding powerful computational approaches for analyzing neural population activity. In particular, latent variable models (LVMs) facilitate visualization and interpretation of complex population activity by uncovering time-varying patterns that capture the internal state of the population. Because LVMs do not strictly depend on external variables, they can be applied to diverse brain areas and behaviors. However, modeling progress is currently impeded by a lack of standardized comparisons, resulting in methods being developed and compared in an ad hoc manner. We introduce the Neural Latents Benchmark, a planned series of benchmark suites aimed at providing standardized quantitative evaluation of LVMs. We discuss challenges in comparing approaches as well as key principles and metrics that can overcome these challenges. We select co-smoothing - i.e., prediction of activity of held-out neurons - as a metric that is practical to implement and quantifies quality of inferred latent variables, yet makes only weak assumptions about the experimental task and brain area. We identify other commonly-used metrics, such as behavioral decoding and prediction of future timesteps, to serve as secondary evaluations of model quality.
Our first benchmark suite tests the broad applicability of LVMs to neural population spiking activity and consists of benchmarks that measure performance using four datasets: motor cortex during stereotyped and free-paced reaching, somatosensory cortex during reaching with perturbations, and frontal cortex during cognitive timing tasks. Each dataset poses unique modeling challenges, e.g., the need to account for a large number of behavioral conditions, unstructured trials, external perturbations, and limited behavioral correlates. For stereotyped reaching, we also include datasets of varying trial counts to evaluate LVMs on limited amounts of data. For evaluation, models must infer firing rates of both seen and unseen neurons in testing data. To ensure accessibility and standardization, we provide datasets in the Neurodata Without Borders format, host the benchmarks on the growing EvalAI platform, and offer a code package that demonstrates data preprocessing and submission. We anticipate that this benchmark suite will provide valuable points of comparison for LVM developers and users, enabling the community to identify and build upon promising approaches. http://neurallatents.github.io

Title: Direct inference of signal and noise correlations from two-photon calcium imaging data without intermediate spike deconvolution

Authors: A. RUPASINGHE[1], N. A. FRANCIS[2], J. LIU[2], Z. BOWEN[2], P. O. KANOLD[3,4], *B. BABADI[1];

Abstract: Two-photon calcium imaging has created a unique opportunity to simultaneously record the activity of large populations of neurons and thereby probe the mechanisms through which neurons collectively encode information. Accurate extraction of neuronal activity correlations from two-photon data is crucial for this purpose, yet it is largely hindered by several key limitations faced by existing methods. First, since the two-photon observations of calcium activity are temporally blurred and noisy surrogates of spiking events, estimation methods tailored for spike train analyses are not directly applicable. Secondly, although there exist well-developed techniques for spike deconvolution, they are generally biased towards obtaining accurate first-order statistics (i.e., spike timings) via spatiotemporal priors, which may be detrimental to recovering second-order statistics (i.e., correlations). Finally, even if spikes were perfectly recovered, inferring network-level features from spiking data is a challenging task due to the non-linear relation of neuronal spiking to endogenous and exogenous variables.
We address these challenges by developing a multi-tier Bayesian model to directly estimate signal and noise correlations from two-photon fluorescence observations, without requiring intermediate spike deconvolution. Signal correlations quantify the similarity of neural responses that are time-locked to repeated stimuli, while noise correlations account for the stimulus-independent trial-to-trial variability shared by neural responses, both of which are jointly estimated by our proposed method.
We demonstrate the utility of our proposed approach through theoretical analysis and applications to simulated and experimentally recorded two-photon imaging data from the mouse primary auditory cortex. Our method reliably extracts noise correlation structures that are invariant across spontaneous vs. stimulus-driven neural activity. In addition, our joint estimation of signal and noise correlations corroborates existing hypotheses regarding the distinction of their structures. While application of our proposed method to spatial analysis of signal and noise correlations in the mouse auditory cortex is consistent with existing work, it reveals novel and distinct spatial trends in the correlation structures of primary cortical layers 2/3 vs. 4. Our proposed method provides a robust and scalable alternative to existing approaches for inferring neuronal activity correlations from two-photon imaging data.
