Title: Evaluating neuronal, synaptic, and network function in stem cell models of neural development and disease

Authors: H. B. HAYES, S. A. CHVATAL, D. C. MILLARD, M. CLEMENTS;
Axion BioSystems, Georgia, GA

Abstract: Induced pluripotent stem cell (iPSC) technology has allowed complex human biology to be reproduced *in vitro* at high throughput scales. Further, advances in genetics and proteomics have accelerated neural disease-in-a-dish models, while 3D cell preparations, such as organoids, have enabled models that better recapitulate human development. To optimize, validate, and utilize complex *in vitro* neuronal models, it is critical to characterize the function of neurons, synapses, and networks over relevant time courses. Here, we present data supporting the use of label-free, multi-well microelectrode array (MEA) technology as an efficient approach for reliable, repeated quantification of cellular and network function across development and in disease. First, the Maestro multi-well MEA system (Axion BioSystems) was used to characterize human iPSC-derived cortical organoid function across 10 months *in vitro.* Organoids exhibited increasingly complex spiking activity over time, with network events becoming more frequent. Local field potentials were also compared to electroencephalograms from premature neonates, revealing that the development of complex network oscillations in cortical organoids mimic and predict the network dynamics of early human brain development. In addition, we also validated two human iPSC disease-in-a-dish models. In a model of Dravet syndrome, patient-specific hiPSC-derived neurons were tracked for 36 days *in vitro*. Dravet syndrome cultures exhibited significantly higher mean firing rate, network burst duration, and network burst density compared to wild type controls, reflecting an epileptic phenotype. In a model of Fragile X syndrome, hiPSC-derived neurons exhibited reduced FMR1 mRNA and FMRP expression compared to isogenic controls. Reduced expression corresponded to increased neural activity after DIV21. The disease phenotype was reversed with addition of FMR1 mRNA or co-culture with control neurons, both in a dose-dependent manner. By bringing human biology to a dish, hiPSC-derived neurons deliver biologically-relevant models for studying neural development and disease. The Maestro multi-well MEA platform enables label-free chronic tracking of neural network function ideal for validating neuronal models and developing novel therapeutics.

Title: A quasi-physiological microfluidic blood-brain barrier model for brain permeability studies

Authors: *A. BHALERAO[1], B. NOORANI[2], L. CUCULLO[3];

Abstract: Microfluidic-based organ-on-a-chip technology allowed for developing a new class of in-vitro BBB models that recapitulates many hemodynamic and architectural features of the brain microvasculature not attainable in conventional two-dimensional platforms. Herein we describe and validate a novel microfluidic BBB model that closely mimics the one in situ. Induced pluripotent stem cell (iPSC) derived BMECs were co-cultured with juxtaposed primary human pericytes and astrocytes to enable BBB-specific characteristics such as low paracellular permeability, efflux activity, and osmotic responses. The permeability coefficients of [$^{13}C_{12}$] sucrose and [$^{13}C_6$] mannitol were assessed using a highly sensitive LC-MS/MS procedure. The resulting BBB displayed continuous tight junctions' patterns, very low permeability to mannitol and sucrose, and quasi-physiological responses to hyperosmolar opening and treatment with a p-glycoprotein inhibitor as demonstrated by a decreased BBB integrity and increased permeability of Rhodamine 123, respectively. Astrocytes and pericytes on the abluminal side of the vascular channel provided at large the environmental cues necessary to form very tight barrier and extend its long-term viability for time-course studies. In conclusion, our novel multi-culture microfluidic platform showcased the ability to replicate a quasi-physiological brain microvascular, thus enabling the development of a highly predictive and translationally relevant BBB model.

Abstract: The maturation of human pluripotent stem cell (hPSC)-derived neurons follows the timing of human brain development, requiring extensive periods of culture before the emergence of adult-like function. This prolonged in vitro maturation presents a major challenge to stem cell-based models and treatments of neurological disease. We designed a high-content imaging assay based on morphological and functional readouts in hPSC-derived cortical neurons to reveal underlying pathways and to identify chemicals capable of accelerating neuronal maturation. Probing a library of 2688 bioactive drugs, we identified multiple compounds that drive neuronal maturation including regulators of chromatin remodeling and calcium signaling. By performing combinatorial assays of screen hits, we designed a cocktail of four small molecule that triggered maturation across all tested phenotypes, including measures of synaptic density, electrophysiology and transcriptomics. Remarkably, this drug cocktail was also effective in promoting the maturation of 3D cortical organoids and spinal motor neurons, and improved aspects of functional maturity in non-neural lineages such as melanocytes and pancreatic beta cells. These results demonstrate that the maturation of hPSC-derived cell types can be promoted by pharmacological intervention and suggests that some of the mechanisms controlling the timing of human maturation are shared across lineages.

Title: Neuronal and synaptic maturation in long-term cultures of human iPSC-derived neurons generated by transcription factor-based rapid differentiation

Authors: *W. LIN[1], S. YAMADA[1], H. WATANABE[1], Y. KAWASHIMA[1], Y. SEKINO[2];
[1]Biomed. Business Ctr., Ricoh Company, Ltd., Kawasaki-shi, Japan; [2]Dept. of Chem. Pharmacol., The Univ. of Tokyo, Tokyo, Japan

Abstract: Rapid differentiation methods based on the transient expression of neurogenic transcription factors allow an efficient and scalable generation of neurons from human induced pluripotent stem cells (iPSCs), thus emerging as a promising strategy for regenerative medicine and disease modeling. However, characterizing the degree of cell-type specificity and maturity in these transcription factor-induced neurons remains a challenge.
To examine the maturation process in iPSC-derived neurons, we performed a time-course evaluation of neuronal marker expression and of electrophysiological properties in cultures maintained for 3 months after induction of differentiation. Rapid elongation of neurofilament-positive neurites was observed as

expected from the first week of culture. Measurement of electrical activity with a microelectrode array (MEA) system showed spontaneous firing and generation of synchronous network bursts at 1 month of culture, which suggests that multiple neurons start connecting to each other. Immunocytochemistry showed the concomitant formation of MAP2-positive dendrites and expression of presynaptic vesicle markers, which then increased significantly over time after 2 to 3 months of culture. We further evaluated the subcellular localization of drebrin, an actin-binding protein involved in the morphology and dynamics of excitatory dendritic spines. Drebrin clusters were shown to develop along MAP2-positive dendrites at late culture stages. This indicates for the first time that iPSC-derived neurons generated by the rapid differentiation method can reach dendritic spine maturation required for neuroplasticity and response to excitotoxicity.
Transcriptome analysis by RNA sequencing (RNA-seq) also confirmed the increase of neuronal markers over time. Moreover, the expression patterns of several markers of brain development suggested that our iPSC-derived neurons undergo a transition from an immature neuron profile to a more mature cortical deep layer profile. Our results suggest that iPSC-derived neurons continue maturation after the initial differentiation period, by following hallmarks of development including establishment of neurotransmission and synaptogenesis. Optimizing iPSC-derived neuron cultures for synapse maturation would prove useful for the development of *in vitro* models that are physiologically relevant to higher brain functions and cognitive disorders.

Title: Chemically defined substrates in a ready to use format that promote differentiation, accelerated maturation and neurite extension of multiple neuronal subtypes for screening applications

Authors: W. RICHARDS, J. ZIMMERMANN, *S. VISURI, C. LEBAKKEN;
Stem Pharm, Inc, Madison, WI

Abstract: Human neural cells manufactured from induced pluripotent stem cells (iPSCs) hold great promise for modeling neurodevelopmental disorders, screening for potential risks from environmental toxins and as cell replacement therapies. However, most protocols require the use of complex, animal derived substrates that need to be prepared prior to cell plating and introduce variability to culture and

assay workflows. We have developed chemically defined substrates employing norbornene-functionalized polyethylene glycol and synthetic peptides that can be applied to cell culture surfaces, dehydrated, packaged, sterilized, and stored ready for re-hydration and use. We employed Design of Experiment (DOE) methodology utilizing Box-Behnken response surface modeling to screen for formulations that promoted viability, cell adhesion, desired morphology, and accelerated maturation of cortical glutamatergic and motor neurons or differentiation to glutamatergic neurons. These formulations were tested for compatibility with other commercially available iPSC-derived neurons including GABAergic neurons and transcriptionally induced excitatory neurons. Transcriptional profiling utilizing bulk RNASeq analysis was performed comparing neural cultures on the substrates to those cultured on standard substrates including charged polymers (poly-lysines) or animal-derived substrates (PLO-Laminin or Geltrex). Cells cultured on Stem Pharm's hydrogel substrates demonstrated an increase in transcription of gene ontology sets expressing extracellular matrix proteins, cell adhesion molecules, neuron projection guidance and cell-substrate adhesion in day seven samples and enhanced cell differentiation, migration, signaling at the cell periphery and vesicles at day fourteen. The pre-plated substrates reduce time for experimental preparation, reduce the substrate complexity, eliminate ethical considerations of animal-derived substrates, and improve assay metrics when applied to screening campaigns.

Abstract: Regenerative medicine offers the unrealized potential to reverse brain aging. However, endogenous neural stem cell (NSC) function declines with age of unclear mechanisms. Here, we developed a single cell computational drug screening technology to reinstate NSC activity, neurogenesis, and cognition in older mice through mimicking younger NSC programs. “Revealing Origins and Ontological Targets (ROOT)” first reconstructed single cell transcriptomes in cell-lineage pseudotime and identified transcriptomic signatures (TS) that define age-related NSC activity loss. ROOT then screened 1309 clinically relevant small molecules for their ability to recapitulate the TS gene networks mediating NSC activity. Three of the top 5 prioritized compounds reactivated NSCs from quiescence within middle-aged mice. Among them, Sulindac Sulfone (SS) further proved to sustain NSC proliferation, expand the NSC pool, increase neurogenesis, and improve cognitive function. We thus demonstrate the utility of a new single cell pharmacogenomics platform by revealing unexpected neural stem cell capacity for regenerative medicine.

Title: Reprogramming Human Adult Fibroblasts into GABAergic Interneurons

Authors: *A. BRUZELIUS, S. KIDNAPILLAI, D. OTTOSSON;
Lund Univ., Lund, Sweden

Abstract: Somatic cells such as human fibroblasts can be converted into mature and functional neurons termed induced neurons (iNs) through the process of over expressing ectopic neuronal conversion factors. Direct reprogramming of human fibroblasts into iNs is emerging as a promising technology to acquire patient- and disease-specific neurons for disease modeling and drug screening applications. Direct

reprogramming approaches has allowed human fetal fibroblast to be converted into a variety of subtypes, including dopaminergic, cholinergic, spinal motor and serotonergic neurons. However, conversion of adult fibroblasts into iNs remains challenging as there appears to be an intrinsic blockade of neuronal fate commitment pathways. We have applied methods for direct reprogramming of adult skin fibroblasts using REST inhibition to promote successful conversion and combined it with GABAergic interneuron fate determinants to successfully generate induced GABAergic interneurons. GABAergic interneurons are highly relevant for cognitive impairments and brain disorders such as Alzheimer's, Parkinson's diseases, schizophrenia and autism. Our results showed that we can obtain induced GABAergic interneurons from adult fibroblasts in 21 days of culture with a high survival of cells using different conversion factor cocktails. Moreover, we could detect subtype specific interneurons; calbindin and calretinin within our cultures of iNs. Despite the difficulty to convert adult fibroblasts into functional neurons in vitro, we could detect immature action potentials along with inward and outward sodium channels using whole-cell patch-clamp technology further indicative of a successful neuronal conversion.

Title: Directed differentiation of medium spiny neurons using an inducible transgenic technology 'MADR'

Authors: *P. LINESCH, N. KOBRITZ, A. YANG, H. PARK, D. PACHECO, V. B. MATTIS, J. J. BREUNIG;
Board of Governors Regenerative Med. Inst., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: A technique to direct stem cell differentiation would be a novel therapy for replenishing lost neurons in neurodegenerative diseases, such as Huntington's Disease, and would allow us to study pure populations of specific cell types in vitro. By transiently expressing a mixture of key developmental transcription factors using an inducible transgenic system, preliminary results indicate we can directly differentiate neurons. Using an inducible cocktail of transcription factors (CTIP2 and DLX2) responsible for the differentiation of Medium Spiny Neurons (MSNs), we believe we can control the identity of cells and directly reprogram them into MSNs. A transgenesis method developed by the Breunig Lab called 'MADR', Mosaic Analysis with Dual recombinase-mediated cassette exchange, uses two recombinase (Cre & FlpO) to integrate a donor DNA cassette between lox and flox sites (Kim GB, 2019 *Cell*). The donor cassette we created has two parts; a constitutively active side expressed under the mouse's CAG promoter and a doxycycline (DOX) inducible tet-on element to express genes of interest; currently MSN transcription factors CTIP2 and DLX2, as well as BCLXL, miR-9 & 124, and our reporter SMFP-MYC-bright. We have successfully validated nucleofection *in vitro* and *in vivo* using mTmG mice, primary

mouse neural stem cells (NSCs), and human iPSCs. Primary mouse NSCs displayed a morphological change resembling a neuronal cell type and IHC and genomic analysis are underway. Future directions will be to culture iPSCs into an organoid with a mixed population of inducible plasmids to make a complex mixed organoid culture. Postnatal electroporation allows the MADR system to be transfected into mice at postnatal day 1-2. At this age, the Radial Glia progenitors lining the ventricle are transfected and any daughter cells contain the inserted cassette. The mice are aged for 21 days and then administered food containing doxycycline for various time points spanning 3 days to 6 months. Around day 15 post dox, neuronal looking projections begin to be seen in SMFP-MYC-bright positive cells and between 1 - 2 months, large amounts of reporter positive projections are seen in the striatum. The correct timing of DOX is being examined but preliminary data suggests short term administration results in the differentiation of immature neurons. If MADR can tightly control directed differentiation, it could be used in cell culture models examining the complex relationship between difficult to isolate and culture neuron cell types. Additionally, this technology would be key for transplant studies in neurodegenerative disease to replenish lost cell types.

Title: Intranasal oxytocin reduces facial affect misrecognition between disgusted and angry faces in adults with autism spectrum disorders

Authors: *T. OKADA[1,2], Y. UNO[2,3];
[1]Dept. of Developmental Disorders, Natl. Inst. of Mental Health, Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Tokyo, Japan; [2]Dept. of Child and Adolescent Psychiatry, Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [3]Dept. of Psychiatry, Yokohama Psycho-Developmental Clin., Yokohama, Japan

Abstract: Objectives Administration of intranasal oxytocin (OXT) was reported to enhance the ability to recognize emotional facial expression in autism spectrum disorders (ASD). However, the whole picture of enhancements in six basic facial affect recognition and their relationship with improvements in social impairments remain unclear. Methods This study is conducted in male adults with ASD who participated in randomized controlled trial (RCT) of intranasal oxytocin (Mol Psychiatry, 2020) at Nagoya University Hospital. 24 male adults with ASD were randomly assigned to OXT and placebo groups. They were administered OXT (24 unit, twice a day) or placebo for seven weeks. In open trial following the RCT, all participants were administered OXT for six weeks. Benton Facial Recognition Test and facial expression

recognition task were examined for all participants at three time points (baseline, after randomized controlled trial, after open trial). This study protocol was approved by the Ethics Committee of the Nagoya University Graduate School of Medicine, and this study was funded by Japan Agency for Medical Research and Development (AMED) and Grants-in-Aid for Scientific Research (KAKENHI). Results OXT does not influence on the identifications of unfamiliar faces. Although the correct response rates for angry and disgusted faces after RCT are higher than those at baseline only in OXT group, it does not reach the significance level. After the open trial, patients recognized more accurately angry faces (p < 0.01) and disgusted faces (p < 0.05) than baseline. In error analysis, the misrecognition of angry for disgusted faces (p < 0.05) and misrecognition of disgusted for angry faces (p < 0.01) reduced after OXT administration. These effects are not significantly correlated with reduction in severity of social impairments. Discussion Although both anger and disgust are negative emotions, they were followed by different aggressive expressions to the others. Misrecognition between disgusted and angry faces was also reported in delinquents (Child Adolesc Psychiatry Ment Health. 2009). Oxytocin reduces misrecognition of negative facial emotions in ASD, and it may be the neuropsychological background for improvements associated with social disturbances. This hypothesis should be examined in larger samples in future.

Title: Empathy and sociability across the subclinical autism spectrum

Authors: *T. P. WALFORD, S. M. HAIGH;
Univ. of Nevada, Reno, NV

Abstract: Difficulties in social communication is a key characteristic of Autism Spectrum Disorder (ASD). As ASD is a spectrum, the characteristics that define the diagnosis of autism can be seen to a more subtle degree in the general population. This study focuses on a measure of social cognition (friendship quality) and a measure of cognitive style (ability to empathize) to assess their relationship with autism-related symptoms. One hundred participants (76% female, 23% male and 1% non-binary or 3rd gender with an age range of 18-51 and a median of 19) were recruited and completed the Autism Quotient (AQ; to quantify the autism-related symptoms), the Friendship Questionnaire (FQ; a measure of relationships, friendships and interaction), and the Empathy Quotient (EQ; to measure the ability to regulate emotions and interpret emotional cues during social interactions). This study examined the mediation effect of EQ on the relationship between AQ and FQ. The direct relationship between AQ and FQ indicated that a higher AQ predicted worse friendship quality (b=-1.12, SE=0.25, p<.001). Higher AQ also predicted poorer ability to empathize (lower QE score; b=-1.11, SE=0.16, p<.001). When EQ was

accounted for, the effect of AQ on friendship quality was reduced, but still significant (b=0.42, SE=0.15, *p*=.007), suggesting that both autism-related traits and the ability to empathize independently impact friendship quality. These findings indicate that similar deficits in social cognition exist in the general population and are related to subclinical autistic symptoms.

Title: Restrictive and Repetitive Behaviors in children with Autism Spectrum Disorder, and amygdala subnuclei involvement

Authors: *D. SEGUIN, A. HENNESSY, S. CORREA, J. MARTINEZ-TRUJILLO, R. NICOLSON, E. G. DUERDEN;
Western Univ., London, ON, Canada

Abstract: Introduction: Restrictive and repetitive behaviors (RRBs) are a diagnostic criteria for autism spectrum disorder (ASD). These heterogenous behaviors can include motor stereotypies such as hand flapping, and restrictive play. Some forms of RRBs, like stereotypic movements, are thought to be linked to anxiety, and may serve as a self-soothing mechanism. The amygdala is a key structure involved in regulating emotion and controlling inhibitory behaviors. Our study aimed to investigate whether RRBs in children with ASD are associated with amygdala subnuclei development and whether this relationship is modified by anxiety. Methods: A total of 123 children underwent an MRI scan,44 (34M) children with a diagnosis of ASD, and 79 (38M) typically-developing (TD) children. Children were aged 5-10 years old (mean=7.98, SD=1.45 yrs). Parents completed the Child Behavior Checklist (CBCL), the Autism Screening Questionnaire and the Screen for Child Anxiety Related Disorders (SCARED). RRBs were measured using the subscale of the CBCL. We extracted the amygdala subnuclei volumes using FreeSurfer.Statistical Analyses: To examine whether RRBs were associated with amygdala subnuclei volumes and parent-reports of anxiety, a general linear model (GLM) with RRB total score as the dependent variable and amygdala subnuclei volumes, diagnosis (Dx), CBCL-Anxiety/Depression subscale scores, and SCARED-P scores were predictor variables, adjusting for gender, age, scan site, and total cerebral volume (TCV). Results: Children's RRB scores were significantly higher in children with ASD (p<.001). Child's gender (p=.003), age (p<.001), left anterioamygdalaoid area (AAA) volume (p=.006), left central subnuclei volume (p=.008), left medial subnuclei volume (p<.001), right accessory basal (AB) subnucleus volume (p=.008) and right medial nucleus volume (p=.002) were all significantly associated with increased RRBs. Neither anxiety measures were associated with RRBs. An interaction analysis found significant main effects of diagnosis on left AAA volumes (F 1,113)= 6.81, p=.010) and

right AB volumes (F(1,113)=7.40, p=.008). Autistic males had larger volumes, and autistic females had smaller volumes for these nuclei.Conclusion: Left AAA and right AB subnuclei, regions crucial for sensory information related to anxiety and fear processing, were significantly larger in children with higher levels of repetitive behaviors. These amygdaloid subregions may be key influencers of repetitive behaviors in children with ASD.

Abstract: Introduction: The economic impact of risk factors and pathologies present in pediatric patients today has been increasing, which is worrying for our health system. Preserving health through proper monitoring of child development on a regular and regular basis will allow early detection of warning signs with respect to alterations in the normal development of the human being. With this in mind, the present research aimed to know the factors inherent to stress and anxiety in children of a Public Hospital in Pachuca, Hidalgo, especially related to Neurodevelopmental Disorders; which will allow identifying primary elements for prevention and mitigation of the increase in health expenses that this population group represents. A non-experimental, observational, non-participant descriptive method was used with a sample of 150 children who were invited to manipulate a haptic device combined with computer software, while their degree of stress was measured with the NASA-TLX Protocol. Among the results we found that 49 were female, 101 males, aged between 4 to 17 years; A peculiar characteristic of the sample is that the patients were receiving rehabilitation, however, at least 70% of the study participants had a mental load that reflected stress in NASA-TLX (6 items) when undergoing rehabilitation therapy. The Spence test (44 items) was also applied to measure anxiety, where it was found that the prevalence of generalized anxiety was 48%. For all the above, we can conclude those pediatric patients, even with

neurodevelopmental disorders are capable of performing tasks with haptic devices; However, the mental burden and anxiety that this brings them, together with their physical therapies in the Public Institution does not exempt them from suffering emotionally, which opens a window of opportunity to support them from disciplines such as Nursing, Psychology, and Neuroscience

Title: Association between autism-related gene CNTNAP2 polymorphism and subthreshold autism spectrum disorder in Japanese children

Authors: *Y. SHIOTA[1,2], T. HIROSAWA[2,3], M. KIKUCHI[3], S. YOKOYAMA[2];
[1]1.United Grad. Sch. of Child Development, Osaka University, Kanazawa University, Hamamatsu Univ. Sch. of Medicine, Chiba Univ. and Univ. of Fukui, Kanazawa, Japan; [2]Kanazawa Univ., Kanazawa, Japan; [3]Kanazawa Univ. Hosp., Kanazawa, Japan

Abstract: Subthreshold autism spectrum disorder (ASD) is a subclinical condition that shows less prominent autistic traits than fully diagnosed ASD. As children with subthreshold ASD are recognized as typically developing (TD) but often have difficulties in social adaptation, it is important to develop biomarker(s) to detect subthreshold ASD in TD children. However, no specific marker has been available, so far. Therefore, we studied genetic polymorphisms associated with autistic traits in TD children and as well as in children with ASD. One of them, the rs2710102 in the *CNTNAP2* gene encoding contactin-associated protein 2 showed significant association with ASD (Alarcon *et al.*, 2008) and higher AQ scores (Bai *et al*., 2019). Hence, the present study was focused on single-nucleotide polymorphism (SNP) of rs2710102. The subjects consisted of 77 Japanese children with ASD (49 boys, 18 girls, aged 38-98 months) and 57 TD children (34 boys, 23 girls, aged 38-98 months); informed consent/assent was obtained from each subject and parents. This study was approved by the Kanazawa University Hospital ethical committee. The ASDs diagnosis was given according to the Diagnostic and Statistical Manual of Mental Disorders (4th edition) (American Psychiatric Association, 2000) using the Diagnostic Interview for Social and Communication Disorders (Wing et al., 2002) or the Autism Diagnostic Observation Schedule-Generic (Lord et al., 2000). To assess the participants' intelligence and social reciprocity, we used the Japanese version of the Kaufman Assessment Battery for Children (K-ABC) and the Social Responsiveness Scale (SRS), respectively. In parallel,
genomic DNA was extracted from the buccal mucosa and subjected to genotyping by real-time PCR. Linear regression models were applied to estimate K-ABC and SRS-T scores based on the participants' condition (i.e., TD vs ASD), genotype, and interaction between condition and genotype; *p*-values less than 0.05 were considered statistically significant. As a result, we detected a significant difference

between genotypes and conditions [χ^2 (2) =6.56, p =0.038]. There was no significant difference in age and sex between conditions. When a co-dominant model was assumed, TD children with A-carriers (AA + AG) showed higher SRS total T-scores [t (55) = 2.11, p =0.039] and lower simultaneous processing scale scores [t (55) = -2.19, p =0.032] than GG homozygotes. These results suggest that the A-allele of rs2710102 could be useful in detecting subthreshold ASD.

Title: Image registration-based high resolution diffusion MRI in the human brainstem in autistic and non-autistic children

Authors: J. GUERRERO-GONZALEZ, N. ADLURU, G. KIRK, S. KECSKEMETI, O. J. SURGENT, D. DEAN, III, A. L. ALEXANDER, ***B. TRAVERS**;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Diffusion weighted magnetic resonance imaging (dMRI) of the brainstem is technologically challenging, especially in young children with autism. This hinders access to high resolution images, which are desirable for improving the ability to study brainstem structures. Furthermore, increasing the resolution at the acquisition level may be limited by low signal-to-noise ratios from small voxels as well as other hardware constraints. Head motion in young children may additionally affect image quality. To address these challenges, we implement a method for reliably increasing spatial resolution in dMRI that hinges on accurate geometric distortion correction and high fidelity image registration between dMRI and motion-corrected anatomical MPnRAGE images (Kecskemeti et al., 2016; Kecskemeti & Alexander, 2020). Data used in this work consists of dMRI data (1.8 mm voxels, corrected using FSL's Topup) and T1-weighted MPnRAGE anatomical data (1 mm voxels) acquired from 154 autistic and non-autistic children (ages 6-11 years-old). Within each subject, dMRI and MPnRAGE data were spatially aligned in the MPnRAGE space permitting a further reliable increase in resolution of the dMRI scan. Then, estimation of tensors and fiber orientation distributions were carried out in the up-sampled space. Figure 1 shows the advantages of this processing, including sharper details in the brainstem, which may prove useful for improving accuracy in locating white and gray matter structures. Indeed, with this approach we achieved exquisite spatial alignment between the dMRI track density images and Sitek et al.'s (2019) histology-based delineations of brainstem auditory nuclei.

Title: Defining Neurophysiological Subgroups in Autism Spectrum Disorder using Resting-State Connectivity

Authors: *A. M. BUCH[1,2], L. GROSENICK[2], P. VERTES[3], J. SEIDLITZ[4,5], S. KIM[2], C. LISTON[2]; [1]Cornell Univ. / Weill Cornell Medic Neurosci. Col., New York, NY; [3]Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom; [4]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [5]Child and Adolescent Psychiatry and Behavioral Sci., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Autism Spectrum Disorder (ASD) describes a diverse group of neurodevelopmental disorders encompassing a wide range of clinical impairments. The two core symptoms that define ASD are social communication impairments and restricted and repetitive behaviors, and there is a wide range of cognitive and language abilities. How distinct neurobiological substrates give rise to differing clinical symptoms in subsets of ASD patients is unknown. Using a large, publicly available neuroimaging dataset comprising resting state functional magnetic resonance imaging (rsfMRI) scans from N=299 subjects with ASD and N=907 neurotypical controls, we identified three latent dimensions of functional brain network connectivity that predict individual differences in ASD symptoms and behaviors. We show that patients with ASD can be grouped into distinct neurophysiological subgroups based on patterns of dysfunctional connectivity and clinical behaviors. In this cohort, functional connectivity features were extracted from rsfMRI data, regularized canonical correlation analysis was used to identify associations between connectivity features and behavioral data, and ASD subjects were clustered along these dimensions. Cross-validation analyses showed high stability in the brain-behavior dimensions, with replicable clusters in held-out data. Next, we integrated neuroimaging data with gene expression data from the Allen Human Brain Atlas, and found that within each subgroup, ASD-related functional connectivity was explained by regional differences in the expression of distinct gene sets that were enriched for ASD-associated genes (SFARI database) and different molecular associations. In sum, our results identify discrete ASD subgroups associated with specific ASD behaviors and neurophysiological signatures, and these different forms of ASD implicate distinct genetic mechanisms. The results of this study suggest a promising new approach for understanding the neurobiological substrates of ASD.

Title: Joint Analysis of Shared Familial Psychiatric and Genetic Characteristics for Synthetic Phenotypes: Application to Autism Spectrum Disorder

Authors: K. PASKOV[1], ***N. T. STOCKHAM**[2], D. WALL[3];
[1]Biomed. Informatics, [2]Neurosciences IDP, [3]Pediatrics, Stanford Univ., Stanford, CA

Abstract: The genetic architecture of complex psychiatric disorders has remained elusive despite the rise of national-scale genomic and phenotypic databases and tens of thousands of cases and controls. In the field of Autism Spectrum Disorder (ASD) recent work by Warrier,V et al. (2019) demonstrate the genetic dissociation of social and non-social ASD-associated traits in larger populations, implying that the social and non-social traits in ASD may actually reflect distinct genetic etiologies. Parsing the genetic architecture of complex diseases will likely require analysis of more specific phenotypes than simply case/control status. However, it is extremely difficult apriori to define a psychiatric phenotypic measure that captures a relevant genetic effect. Moreover confirming that a proposed trait does reflect an underlying genetic effect typically requires twin studies that may be cost-prohibitive or simply infeasible. To address this difficultly we have developed a computational method that leverages nuclear family-based Identity-by-Descent (IBD) statistics to create synthetic phenotypes that are consistent measures of genetic variation. This method can be applied using full or half siblings, and furthermore this IBD approach avoids confounding by environment and population substructure, thereby recovering a key advantage of twin studies. We demonstrate this method on the Autism Genetic Resource Exchange (AGRE), the Simons Simplex Collection (SSC), and the Simons SPARK cohorts for ASD. We recapitulate the twin-analysis heritability estimates of the subdomains of the Autism Diagnostic Interview Revised (ADIR) and the Social Communication Questionnaire (SCQ) in each cohort. Instead of attempting to find a genetic basis for an already defined psychiatric phenotype, this work uses genetic and familial information directly to define synthetic psychiatric phenotypes. This approach is cost-effective, only requiring inexpensive genotyping arrays as available from consumer vendors and small families. Furthermore, by avoiding the confounding factors of population substructure and environment this IBD method permits the analysis of large heterogeneous populations. In this work we emphasize simultaneous analysis of genetic IBD and phenotype as a complementary approach to the current paradigm of searching for causal genetic variants for a given disorder; we focus instead on the study of causal mechanisms that explain shared familial psychiatric phenotypes through shared genetic architecture.

Title: SLC17A9 is likely a resident ER/Golgi protein rather than a vesicular protein based on colocalization analyses and phylogenetic analysis of protein trafficking motifs.

Authors: *G. JENSEN[1], *G. JENSEN[2], A. DOS SANTOS[2], E. ABBASI[2], J. YANG[2], L. GASTALDELLO[2], S. RAYNER[2], D. POBURKO[2];
[2]Biomed. Physiol. and Kinesiology, [1]Simon Fraser Univ., Burnaby, BC, Canada

Abstract: BACKGROUND: Purinergic signaling is essential for neurogenesis, neuroglial communication, and neuropathic pain perception. The vesicular nucleotide transporter (SLC17A9/VNUT) is an important player in ATP release, as it is needed to load vesicles with ATP. While vesicular glutamate, acetylcholine and norepinephrine transporters are found on small synaptic vesicles, VNUT does not typically colocalize with these markers in mammalian models. It is unclear if it localizes to synaptic vesicles or another membrane bound organelle. There is little imaging data to show VNUT localizing to such vesicles. In central and peripheral nerves of rats and mice, VNUT does not colocalize with VGLUT or VMAT2. In glial cells and epithelial cells, VNUT is reported to be found in lysosomes rather than small vesicles. METHODS: We compared the primary sequence of VNUT between chordates ranging from cartilaginous fish to snakes using regex search tools in R to assess whether VNUT contains C-terminal dileucine and tyrosine motifs that are essential for synaptic vesicle localization of SLC17A5-8 and SLC18A2-3. We also conducted blob-based, epifluorescence colocalization analyses of VNUT with markers of synaptic vesicles (Syt1, Syt2, Syt5, SV2a, Synapsin), active zones (ELKS1), lysosomes (LAMP1), ER and Golgi in Neuro2A neuroblastoma cells, along with A7r5, HeLa and HEK293 cells using both antibodies and fluorescent protein conjugated marker proteins. RESULTS: Across species, VNUT has high variability in the length and primary sequence of the N-terminus and S6-7 cytosolic loop. The C-terminus is shorter than other vesicular transporters and is highly conserved between phylogenetic Classes. Dileucine and tyrosine-based motifs are absent in sharks and mammals but appear in sauropods. We found a C-terminal KDEL-like sequence (HEDL) that is unique to mammalian VNUT. We assessed colocalization as the fraction of regions of interest (ROIs) for a reference marker (e.g., VNUT) with a nearest neighbor marker whose center was within the ROIs border. VNUT colocalization with vesicle markers and lysosomal markers ranged from ~10-30%, only slightly above colocalization of randomized ROIs. In contrast, EGFP-VNUT is highly colocalized with mTagBFP2-ER-5 and mDsRed-Golgi-7 expression constructs (>70%). CONCLUSION: Mammalian VNUT seems to lack canonical, vesicle-localization motifs, while endogenous and exogenous VNUT localize mainly to the ER and Golgi. This localization suggests that vesicular release of ATP may rely on vesicles acquiring ATP at the Golgi or axonal Golgi outposts rather than being loaded by a pump on the vesicle membrane.

Title: In silico studies of spontaneous purinergic neurotransmission on urinary bladder smooth muscle with special reference to overactive bladder

Authors: *C. MAHAPATRA[1,2], R. MANCHANDA[3];
[1]Indian Inst. of Technol. Bombay, Mumbai, India; [2]Cardiovasc. Res. Inst., Univ. of California San Francisco, San Francisco, CA; [3]Indian Inst. of Technol. Bombay, Mumbai, India

Abstract: The overactive bladder (OAB) syndrome, which is characterized by a sudden urge to urinate, has substantial negative effects on physical, social, and emotional functioning. A plethora of clinical and experimental studies have supported the association of OAB with elevated frequency of spontaneous action potentials (sAP) in urinary bladder smooth muscle (UBSM) cells. The spontaneous purinergic neurotransmission (SPN) evokes spontaneous excitatory junction potential (sEJP) to initiate sAPs in UBSM cells. Information on how these sEJPs modulate the shape and time course of sAPs is sparse because of underlying complexities in the experimental setup. An in-silico investigation of the UBSM cell is established to advance our understanding of the electrophysiological basis of sAP modulation because of SPN. The UBSM cell membrane is described as an equivalent electrical circuit comprising a membrane capacitance connected in parallel with several variable conductances representing nine ion channels. This model has incorporated voltage-gated Ca^{2+} (T - type and L- type) channels, three voltage-gated potassium (Kdrs, Kdrf and Ka) channels, and two calcium-dependent potassium (BK and SK) channels. The ion channels are biophysically detailed and validated with experimental data. Multiple UBSM cells are connected via gap junctions to investigate the propagation of sEJP from one cell to another cell. The purinergic synaptic conductance profile is comprising a sum of two exponentials and defined by synaptic conductance, maximum synaptic conductance, and time constant for both rising and decay phases. The resting membrane potential (RMP) is set at ─50mV by balancing the depolarizing currents and repolarizing currents through various ion channels. The AP is characterized by rising (depolarizing) phase, falling (repolarizing) phase, and presence of an after-hyperpolarization (AHP) or after depolarization (ADP) phase. The AP with lower synaptic conductance (0.0001 μs) shows ─10mV of AHP and a slow rise in the depolarization phase. However, the AP with higher synaptic conductance (0.0002 μs) shows 5mV of ADP and a fast rise in the depolarization phase. It is observed that L-type Ca^{2+} channel is essential for AP generation in an isolated cell. However, the activation of both L-type and T-type Ca^{2+} channels is essential for AP generation in cells with propagated sEJP. As the maximum synaptic conductance is directly proportional to the amount of purinergic neurotransmission, an important implication of our simulation result is that the shape and time course of sAPs are purely neurogenic. Therefore, a moderate dose of antipurinergic drugs will be beneficial to treat OAB.

Abstract: The purinergic transmitter ATP (adenosine 5'-triphosphate) plays an essential role in both the central and peripheral nervous systems, and the ability to directly measure extracellular ATP in real time will increase our understanding of its physiological functions. We developed an ultrasensitive GPCR Activation–Based ATP sensor called $GRAB_{ATP1.0}$, with a robust fluorescence response to extracellular ATP when expressed in several cell types. This sensor has sub-second kinetics, ATP affinity in the range of tens of nanomolar, and can be used to localize ATP release with subcellular resolution. Using this sensor, we monitored ATP release under a variety of in vitro and in vivo conditions, including primary hippocampal neurons, a zebrafish model of injury-induced ATP release, and LPS-induced ATP-release events in individual astrocytes in the mouse cortex measured using in vivo two-photon imaging. Thus, the $GRAB_{ATP1.0}$ sensor is a sensitive, versatile tool for monitoring ATP release and dynamics under both physiological and pathophysiological conditions.

Title: Novel VNUT-pHluorins and the GRAB-ATP sensor reveals that VNUT can support ATP release despite being localized to the ER/Golgi in N2a and A7r5 cells.

Authors: L. GASTALDELLO[1], J. YANG[1], *D. POBURKO[1,2];
[1]Biomed. Physiol. and Kinesiology, [2]Ctr. for Cell Biology, Develop. and Dis., Simon Fraser Univ., Burnaby, BC, Canada

Abstract: BACKGROUND: Purinergic signaling by ATP plays important roles in neurogenesis, neuroglial communication, neuropathic pain perception, and diverse roles outside of the nervous system. ATP can be released by vesicular mechanisms and pannexin channels, and the vesicular nucleotide transporter (VNUT/SLC17A9) is widely accepted to mediate the loading of secreted vesicles with ATP. The fusion of pHluorins, pH-sensitive GFPs, into lumen facing domains of transporters for neurotransmitters like glutamate and catecholamines provided valuable tools to study the regulation of vesicle release and recycling. We aimed to create a VNUT-pHluorin to better understand the regulation of vesicular ATP release. METHODS: We used the CCTOP server and comparison with SLC17A5 (sialin) and SLC17A6-8 (VGLUT1-3), to predict VNUT's 12 transmembrane domains and insert superecliptic pHluorin into the s1-2, s7-8 and s11-12 loops of rat VNUT (NM_001108613.1) and s3-4 loop of a mouse-codon optimized human VNUT (NM022082). We also fused the s1-2 loop of VGLUT-pHluorin into VNUT's s1-2 loop, and we made a red VMAT2-pHuji. To visualize ATP release we used the Li Lab's GRAB-ATP. Constructs were expressed in mouse Neuro-2a (N2a) and rat smooth muscle A7r5 cells. RESULTS: We assessed surface localization and the pH of pHluorin-containing organelles by changing external pH or puffing NH4Cl or sodium butyrate onto cells. The s3-4, s7-8 and s11-12 pHluorins localized to a neutral (pH 7.0-7.5), diffuse organelle, likely the endoplasmic reticulum (ER). The s1-2 and VNUT::VGLUTs1-2 pHluorins localized to ER and a perinuclear locus with a pH ~6.5 that colocalized with a RFP-labelled Golgi marker. Small acidic puncta were seen in A7r5 cells, but not in N2a cells. Depolarization (105 mM KCl) and hypotonic stress (0.5x imaging buffer), but not ionophores (A23187, ionomycin), stimulated ATP release as seen with GRAB-ATP, but failed to cause VNUT-pHluorin externalization. A second, but not initial, release of ATP was blocked with the VNUT inhibitor clodronate (5 µM, 5 hr). By comparison, VMAT2-pHuji largely localized to small, mobile acidic (pH 5.5-6.0) vesicles that were externalized on some cells, but were not released upon stimulation of the cells. CONCLUSION: VNUT's s1-2 loop is the optimal position for a lumen-facing pHluorin. VNUT seems to be an ER/Golgi resident protein that poorly traffics to acidic vesicles in N2a and A7r5 cells. Clodronate's inhibition of a second bout of ATP release suggests that VNUT-dependent loading of vesicles occurs at the Golgi and or Golgi outposts, rather than at the site of release and recycling, which would be a paradigm shift in our understanding of vesicular ATP release.

Title: Differential modulation of acetylcholine signaling on anterior and posterior paraventricular thalamic neurons

Authors: *Q. YE, X. ZHANG;
Psychology, Florida State Univ., Tallahassee, FL

Abstract: Paraventricular nucleus of thalamus (PVT) connects brain structures such as the brainstem, zona incerta, and the hypothalamus to the nucleus accumbens and the amygdala for the regulation of the motivated behaviors including feeding and drug addiction. Both glutamatergic and GABAergic neurotransmissions have been recently studied for the modulation of PVT neurons and the control of food intake. However, it remains unknown whether other neurotransmitters also regulate feeding by modulating the activity of PVT neurons. Although the midbrain-originated cholinergic axons have been found in PVT, little is known about the function and modulation of cholinergic signaling in PVT. In this study, we used slice patch-clamp recordings to functionally characterize the effects of acetylcholine (ACh) on PVT neurons. We found that 60% of anterior PVT (aPVT) neurons were excited by ACh, 23% were inhibited, and the rest (17%) were nonresponsive. The ACh-induced excitation was mimicked by the nicotinic acetylcholine receptor (nAChR) agonist nicotine and blocked by the nAChR antagonist mecamylamine in 67% of ACh-excited neurons. However, the selective alpha7 nAChR antagonist methyllycaconitine (MLA) produced little effect on ACh activation of aPVT neurons. In contrast, ACh inhibited 70% of posterior PVT (pPVT) neurons and the inhibitory effect was blocked by the muscarinic acetylcholine receptor (mAChR) antagonist atropine, indicating mAChRs contribute to ACh inhibition of pPVT neurons. The remaining pPVT neurons were excited (8%) by ACh or had no response. Together, these preliminary data suggest that ACh excites aPVT neurons by activating nAChRs but inhibits pPVT neurons via binding to mAChRs. In future studies, we will study how PVT is functionally innervated by midbrain ACh projections and whether the differential modulation of ACh on aPVT and pPVT regulates food intake using optogenetics and virus-based neural circuit mapping.

Title: Striatal fiber photometry reflects primarily non-somatic activity

Authors: *A. LEGARIA[1], B. YANG[3], B. AHANONU[4], J. A. LICHOLAI[5], J. G. PARKER[6], A. V. KRAVITZ[2];
[1]Washington Univ. in St. Louis, Saint Louis, MO; [2]Washington Univ. in St. Louis, St. Louis, MO; [3]Physiol., Northwestern Univ., Chicago, IL; [4]Univ. of California-San Francisco, San Francisco, CA; [5]Brown Univ., Providence, RI; [6]Dept. of Physiol., Northwestern Univ. Feinberg Sch. of Medicin, Chicago, IL

Abstract: Calcium recording via fiber photometry is commonly used as a proxy for recording population neuronal activity in vivo, yet the biological source of the photometry signal remains unclear. Here we used simultaneous in vivo extracellular electrophysiology and fiber photometry in the striatum, along with endoscopic 1-photon and 2-photon calcium imaging in mice, to investigate the electrophysiological correlates of fiber photometry recordings. We found that fiber photometry transients correlate only moderately (r2 ~ 0.3) with spiking activity. Furthermore, we found that in both 1-photon and 2-photon calcium imaging, fiber photometry has a very strong correlation with changes in non-somatic calcium, but only moderate correlations with changes in somatic calcium.

Title: Noradrenaline innervation and alpha receptors in the primate mediodorsal and pulvinar thalamic nuclei

Authors: *I. PÉREZ-SANTOS[1], N. PALOMERO-GALLAGHER[2,3,4], K. ZILLES[2,4,5], C. CAVADA[1];
[1]Univ. Autónoma de Madrid, Madrid, Spain; [2]Res. Ctr. Jülich, Jülich, Germany; [3]RWTH Aachen Univ., Aachen, Germany; [4]Heinrich-Heine-University, Düsseldorf, Germany; [5]JARA-BRAIN, Jülich-Aachen Res. Alliance, Jülich, Germany

Abstract: The mediodorsal (MD) and pulvinar nuclei are the two main primate Higher Order nuclei. In the macaque brain, they are within the most densely innervated by NA and display high alpha adrenoceptor concentrations. The purpose of this study is to compare the patterns of NA innervation and adrenoceptors in the macaque and human MD and pulvinar nuclei. NA axons in the human thalamus were revealed by immunostaining against the noradrenaline transporter and mapped with the software Neurolucida®. The alpha adrenoceptors were analyzed by Quantitative autoradiography using the following ligands: [3H]-Prazosin to reveal alpha-1 receptors, [3H]-RX-821002 to reveal whole alpha-2 adrenoceptor population, and [3H]-UK-14,304 to reveal high-affinity state alpha-2 adrenoceptor. The distributions of axons and receptors were compared to previously published data from macaques. The human MD had a moderate NA innervation, with the highest densities in the medial and ventral regions. Within the human pulvinar complex, the oral pulvinar nucleus (Pul O) had the highest NA innervation; the medial pulvinar (Pul M) showed moderate densities of NA axons, and the lateral and inferior pulvinar (Pul L, Pul I) displayed low NA axon densities. Regarding alpha-1 adrenoceptors, the highest densities were present in the dorsal and medial regions of MD, and in the medial regions of Pul M. alpha-2 receptor concentrations were highest in Pul I. Pul O showed high alpha-2 receptor revealed by [3H]-RX-821002 but rather low revealed by [3H]-UK-14,304 suggesting that this nucleus has a low proportion of high-affinity alpha-2 receptors. Overall, the distributions of NA axons and alpha adrenoceptors in the human MD and pulvinar nuclei are similar to those in macaques, but some differences are present: alpha-1 receptor concentrations are higher in macaques than in humans, and the high-affinity alpha-2 receptor concentrations in the Pul O are higher in macaques.

Title: Serotonergic IL-1R1 modulates serotonin transporter activity and impacts neuronal activity after LPS in a sex-dependent manner

Authors: *P. GAJEWSKI-KURDZIEL[1], A. TILLMAN[1], N. L. BAGANZ[2], M. J. ROBSON[3], N. QUAN[2], R. D. BLAKELY[2];
[1]Biomed. Science, Charles E. Schmidt Col. of Med., Florida Atlantic Univ. (FAU), Jupiter, FL; [2]Stiles Nicholson Brain Inst., Florida Atlantic Univ., Jupiter, FL; [3]Div. of Pharmaceut. Sciences, James L. Winkle Col. of Pharm., Univ. of Cincinnati, Cincinnati, OH

Abstract: Dysfunction of serotonin (5-HT) producing and/or responsive circuits is believed to support the expression of behaviors observed in neuropsychiatric disorders including depression, autism, and schizophrenia. The presence of elevated inflammatory cytokines in subjects with mood disorders and the significant comorbidity of neuropsychiatric disorders with chronic inflammatory conditions suggests a commonality in the manifestation of these conditions. However, exact relationships remain ill-defined, leaving a gap in the development of mechanism-based treatments. Inflammatory cytokines impact multiple aspects of neural signaling, but neuronal expression of cytokine receptors has not been extensively characterized. We and others have shown that 5-HT neurons of the raphe express high levels of the receptor for IL-1β (IL-1R1). Interestingly, mRNA studies suggest a non-uniform expression of IL-1R1 throughout distinct raphe subregions, suggesting discrete 5-HT circuits contribute to the behavioral output of CNS IL-1β. We have shown in mouse brain synaptosomes that activation of the peripheral innate immune system as well as direct exposure to IL-1β rapidly increases the activity of the presynaptic 5-HT transporter (SERT), a key protein for the control of extracellular serotonin availability and signaling. Here we report the use of multiple approaches to validate the actions of serotonergic IL-1R1 on SERT function and search for evidence of circuit-specific sensitivity to serotonergic IL-1R1 activation. Using a transgenic approach to knockout serotonergic IL-1R1, we show that the ability of peripheral LPS treatment to stimulate SERT in midbrain synaptosomes is lost. Consistent with these findings, high-speed chronoamperometry in hippocampal CA3 reveals that local IL-1β speeds up 5-HT clearance. Additionally, serotonergic IL-1R1 activation is in part responsible for the ability of peripheral immune activation to modulate neuronal activity of distinct regions innervated by 5-HT neurons. In these studies, we find distinct sex-dependent differences in the role of serotonergic IL-1R1 in LPS induced cFos production in areas including septum and lateral habenula. We are currently using retrograde tracing to confirm the projection of IL-1R1 expressing 5HT neurons to these sites and hypothesize that the changes in activation observed represent circuit level contributions of serotonergic IL-1R1 to the ability of peripheral immune activation to drive behavior. Altered signaling by these circuits may support neuropsychiatric disorders which may be testable through human brain imaging approaches and remediable by immunosuppressive treatments.

Title: The Protobiotic Lactobacillus reuteri Preferentially Synthesizes Kynurenic Acid from Kynurenine

Authors: *F. M. NOTARANGELO, A. E. FOO, K. V. SATHYASAIKUMAR, R. SCHWARCZ; Psychiatry, Maryland Psychiatric Res. Ctr., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The gut-brain axis is increasingly understood to play a major role in a variety of neuropsychiatric disorders. Of special interest, studies in germ-free and antibiotic-treated rodents have revealed that intestinal bacteria can regulate cognitive functions in the host. Separate studies showed that metabolites of the kynurenine pathway (KP) of tryptophan degradation, and specifically the neuroactive KP metabolite kynurenic acid (KYNA), may link gut dysbiosis with cognitive impairments (Dehhaghi et al., 2019). *Lactobacillus (L.) reuteri*, a common and well-studied probiotic bacterium which is present in many mammals including humans, may play a special role in this context (e.g. Marin et al., 2017; Verbeek et al., 2021). We showed in a pilot study that newly produced KYNA can be readily recovered in the extracellular compartment after *L. reuteri*, suspended in Hank's Balanced Salt Solution, was incubated at 37°C with KYNA's immediate bioprecursor L-kynurenine. Interestingly, however, exposure to L-tryptophan did not generate KYNA. *De novo* synthesis of KYNA increased in a linear fashion with bacterial concentration (up to 10^8 CFU/ml), L-kynurenine concentration (up to 1 mM) and time (up to 3 hours) (Foo et al., 2019). Using the same experimental conditions (mostly 10^8 CFU/ml, 100 µM kynurenine, 3 hour incubation), we now examined the characteristics of L-kynurenine metabolism in greater detail. In line with studies in mammalian tissues, L-kynurenine readily entered the cultured cells, newly formed KYNA was promptly and essentially quantitatively released into the extracellular milieu, and KYNA neosynthesis was effectively blocked by either of two selective inhibitors of mammalian kynurenine aminotransferase II (PF-048559989 and BFF-122). However, in marked contrast to processes that are well-established in mammals, kynurenine uptake was *not* affected by tryptophan, leucine or other substrates of the large neutral amino acid transporter LAT-1 (all at 5 mM). Moreover, kynurenine was only minimally converted to 3-hydroxykynurenine and not at all to anthranilic acid, i.e. along the two other branches of the mammalian KP, and KYNA neosynthesis was *not* reduced by co-incubation with millimolar concentrations of presumed competitive enzyme substrates (α-aminoadipate and glutamine). Taken together, these results demonstrate substantive differences between bacterial and mammalian KP metabolism. Extrapolation to bacterial species other than *L. reuteri*, and especially possible implications for the effects of bacterial L-kynurenine metabolism on physiology and pathology in the host brain, are currently under investigation in our laboratory.

Title: Quantifying the information capacity of synapses in hippocampal area CA1 and DG in rat

Authors: *M. SAMAVAT[1], T. M. BARTOL, Jr.[1], C. BROMER[1], D. D. HUBBARD[2], D. C. HANKA[2], M. KUWAJIMA[2], J. M. MENDENHALL[2], P. H. PARKER[2], W. C. ABRAHAM[3], K. M. HARRIS[2], T. J. SEJNOWSKI[1];

Abstract: The substantial variability of synapse sizes motivated us to measure the precision and calculate the information capacity of spine head volumes (SHVs) that are known to have high correlation with synaptic strength. Three-dimensional reconstructions from serial section electron microscopy (3DEM) of dendrites in rat hippocampal area CA1 and dentate gyrus (DG) were analyzed. Motivated by our earlier study (Bartol et al, eLife 2015) we expanded and enhanced our protocol to overcome a limitation in the earlier study. The eLife work assumed that spines sharing the same dendrites and same axons (SDSA) would be most similar in activation histories, and thus synaptic strength. The CV between SDSA SHVs was computed to give the separation of peaks with an overlap of 31% between consecutive Gaussians spanning the range of SHVs for the SDSA pairs. Here we used information theory plus non overlapping clustering to determine the number of discrete clusters formed, based on all of the SHVs without overlap. The median CV of the SDSA pairs was used to determine the borders of each bin. The new analysis of all 288 SHVs in the prior CA1 cube revealed 24 distinguishable clusters of synaptic strength and entropy of 4.1 bits per synapse. New results show that the DG synapses are less precise than the CA1 synapses with a value of 5 and 6 distinguishable clusters and entropy of 2 and 2.05 bits for 30 min and 2 hours control synapses, respectively. Production of LTP increased the precision and boosted the number of distinguishable clusters of SHV to 10 at 30 min and 8 at 2 hours. In addition, the entropy of SHV increased relative to controls by 1 bit at 30 min and 0.7 bit at 2 hours post induction of LTP. Using the new protocol revealed that the KL divergence distance [H(P,Q)-H(P)] between the distribution of SHV clusters (P) and uniform distribution of states (Q) for the 2 hours LTP was less than half of the control condition. These findings imply that learning moves distributions of SHVs toward a more uniform distribution with maximum information.

Title: Effects of direct current stimulation on synaptic plasticity in a single neuron

Authors: *F. FARAHANI[1], G. KRONBERG[2], H. V. OVIEDO[1], L. C. PARRA[1];
[1]The City Col. of New York, New York, NY; [2]Mount Sinai, New York, NY

Abstract: Background: Transcranial direct current stimulation (DCS) has lasting effects that may be explained by a boost in synaptic long-term potentiation (LTP). We hypothesized that this boost is the result of a modulation of somatic spiking in the postsynaptic neuron. Previous studies with population activity provided only indirect evidence for this hypothesis. To test this directly, we record somatic spiking in a postsynaptic neuron during LTP induction with concurrent DCS. **Methods**: We performed whole-cell patch-clamp recordings at the soma of individual CA1 pyramidal neuron. LTP was induced with theta-burst stimulation (TBS) applied concurrently with DCS. To test the causal role of somatic polarization, we manipulated somatic polarization via somatic current injections. We also used a computational multi-compartment model of a CA1 pyramidal neuron that captures the effect of electric fields on membrane polarization and activity-dependent synaptic plasticity. **Results**: TBS-induced LTP was enhanced when paired with anodal DCS as well as depolarizing current injections. In both cases, somatic spiking in the postsynaptic neuron during the TBS was increased, suggesting that evoked somatic activity is the primary factor affecting LTP modulation. However, the boost of LTP with DCS was less than expected given the increase in spiking activity alone. In some cells, we also observed DCS-induced spiking, suggesting DCS also modulates LTP via induced network activity. The computational model reproduces these results and suggests that they are driven by both direct changes in postsynaptic spiking and indirect changes due to network activity. **Conclusion:** DCS enhances synaptic plasticity by increasing postsynaptic somatic spiking, however, we also find that an increase in network activity may limit this enhancement.

Title: Experimental model for high-resolution imaging and manipulation of endogenous AMPA receptor surface mobility during synaptic plasticity and behavioural adaptation

Authors: *A. M. GETZ[1], M. DUCROS[2], C. BREILLAT[1], A. LAMPIN-SAINT-AMAUX[1], S. DABURON[1], U. FRANÇOIS[1], H. ZIEGER[1], A. NOWACKA[1], M. FERNÁNDEZ-MONREAL[2], F. LANORE[1], M. SAINLOS[1], E. HOSY[1], Y. HUMEAU[1], D. CHOQUET[1,2];
[1]IINS, Bordeaux, France; [2]Bordeaux Imaging Ctr., Bordeaux, France

Abstract: Regulation of surface synaptic receptor content by reversible diffusing-trapping tunes synaptic function, in particular during experience-dependent plasticity and behavioural adaptation. However,

experimental approaches to track and modify receptor movements in integrated experimental systems are limited. Exploiting AMPA-type glutamate receptors (AMPAR) as a model system, we used CRISPR-Cas9 genome editing to generate a knock-in mouse line expressing the 15 amino acid biotin acceptor peptide tag (AP) on the extracellular N-terminus of GluA2 (AP-GluA2). Labelling specificity of AP-GluA2 containing AMPAR is achieved by the directed expression of biotin ligase (BirA), which selectively biotinylates the AP tag. Target-specific introduction of BirA allows the use of monovalent or tetravalent avidin variants (monomeric StreptAvidin (mSA) or NeutrAvidin (NA)) to respectively monitor or manipulate the surface mobility of endogenous AMPAR containing biotinylated AP-GluA2. Due to their small size, mSA (~3 nm) and NA (~6 nm) efficiently target membrane proteins in confined synaptic domains and organized brain tissue. This AP tag modification does not perturb GluA2 protein expression or localization, AMPAR channel function, synaptic physiology, or animal behaviour. We built a Lattice Light Sheet microscope and added a custom photostimulation module, where we performed FRAP imaging in organotypic hippocampal slices to measure the mobility dynamics of endogenous AMPAR. Using fluorophore-conjugated mSA, we found that AMPAR in CA1 stratum radiatum are highly mobile at extrasynaptic sites and more confined at synaptic ones. NA immobilized AMPAR and arrested surface mobility in both domains. Crosslinking of surface AMPAR by NA precluded the expression of LTP at CA3-CA1 synapses in acute slices, and in vivo delivery of NA into the CA1 region by implanted cannula blocked the formation of contextual fear memory. This knock-in mouse model represents a new genetic labelling strategy that enables target-specific measurement and control of the mobility dynamics of endogenous cell surface proteins in integrated experimental systems. For studying AMPAR dynamics, this system opens new possibilities to explore as-yet unanswered questions regarding the molecular links between synaptic plasticity and behavioural learning. With the CRISPR-Cas9 revolution in targeted genome engineering, this methodology can be adapted for the study of a large variety of synaptic proteins, with broad implications for advancing our understanding of brain organization and function.

Title: Glun3a-containing nmda receptors limit long-term potentiation in the adult ventral hippocampus

Authors: *E. HURLEY, B. MUKERJEE, J. ADUNDO, F. NAFAR, L. FANG, M. PARSONS;
Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: The dorsal and ventral hippocampus (DH and VH) are dramatically different structures. The DH is involved in cognition and undergoes robust synaptic plasticity, while the VH functions in emotional processing and exhibits poor plasticity. N-methyl-D-aspartate receptors (NMDARs) assemble as functionally diverse heterotetramers with essential roles in synaptic plasticity. Incorporation of the GluN3A subunit into NMDARs delays synapse maturity, opposes synaptic plasticity and alters conventional NMDAR properties. GluN3A-containing NMDARs have reduced sensitivity to magnesium (Mg^{2+}) and reduced calcium (Ca^{2+}) permeability. The GluN3A subunit was initially thought to be important in development, as expression is nearly eliminated in the adult brain. In agreement with recent reports, we show that GluN3A remains elevated, particularly in extrasynaptic locations, in the adult VH and not the DH. Despite GluN3A persistence, VH spines matched the maturity level observed for the DH. As presynaptic and postsynaptic GluN3A-NMDARs can facilitate glutamate release and blunt Ca^{2+} permeability, respectively, we performed real-time glutamate and calcium imaging experiments to further understand the consequences of GluN3A persistence in the adult VH. Compared to the DH, the VH accumulated more glutamate during afferent stimulation yet exhibited less NMDAR-mediated Ca^{2+} influx. We hypothesized that prolonged GluN3A expression acts as a brake on VH synaptic plasticity. Indeed, in wild type (WT) mice, long-term potentiation (LTP) was significantly lower in the VH compared to the DH. In contrast, GluN3A knockout (KO) mice exhibited strong VH LTP that exceeded the magnitude of LTP in the DH. Whole-cell patching of CA1 pyramidal neurons revealed an increase in glycine-induced currents in the WT VH. In addition, the Mg^{2+} sensitivity was significantly reduced in the WT VH. Together these results conclude that the VH has a higher number of GluN3A-containing NMDARs that assemble as functional GluN1/GluN3A excitatory glycine receptors and GluN1/GluN2/GluN3A containing glutamate receptors with reduced Mg-sensitivity. In sum, our data show that GluN3A persistence limits VH plasticity in adulthood, perhaps to serve a protective role to prevent overexcitation of anxiety and fear circuitry.

Title: Multiple pathways of store-driven calcium signaling shape the long-term dynamics of CA1 excitatory synapses

Authors: *S. NADKARNI[1], V. JALTARE[1,3], G. MAHAJAN[2];
[1]Biol., [2]Indian Inst. of Sci. Educ. and Res. Pune, Pune, India; [3]Col. of Engin. Pune, Pune, India

Abstract: A transient increase in the calcium concentration in dendritic spines drives activity-dependent long-term synaptic plasticity, which is believed to be a substrate for enduring information storage. While

calcium entry through NMDA receptors is a primary source for this calcium, additional pathways of calcium, associated with the endoplasmic reticulum (ER), are also likely involved in this process. Interestingly, the expression of both IP3 and ryanodine receptors (RyRs) is observed in the ER of predominantly large dendritic spines. The distinct biophysical properties of these receptors (calcium signaling through IP3 receptors can be slow and long-lasting, while RyRs respond in short and quick bursts of calcium) raises fundamental questions on the range of attributes bestowed to the spine by various sources and sinks of calcium. To address this gap in understanding, we developed a computational model of calcium signaling in an ER-bearing dendritic spine. We investigated the consequence of a wide range of physiological activity patterns on the induction of plasticity. Our model accurately captures the interplay among various components regulating calcium exchange between the cytosol, the ER, and the exterior. We show that 1) the differences in the kinetic profiles of the IP3 and RyR channels produce distinct effects on the rate-dependent plasticity profile, and 2) the store-operated calcium entry (SOCE) is involved during induction of both LTD and LTP when local depletion of the ER is taken into account. We further extend our model to include a biophysical description of receptor-trafficking-based structural plasticity to examine the scaling of calcium signaling with changing spine volume in the presence of the ER store. Altogether, results from the model provide a context for experimental findings and predict a considerable physiological impact of the ER store on the dynamic range of synaptic plasticity. When synapses of variable sizes were simulated, our results show that the presence of both IP3 and RyR receptors ER ensures effective and efficient use and re-use of synapses for storing information in the patterns of synaptic connection strengths.

Title: The role of beta-actin mRNA localization at single dendritic spines during structural long-term potentiation

Authors: *J. SHIM[1], H. AHN[1], B. LEE[1], H. MOON[2], H. CHOI[1], H. PARK[1];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: mRNA localization and local translation in dendrites and axons are required for spatiotemporally efficient gene expression. A synaptic stimulus can induce localization of mRNA and local protein synthesis. Such stimulus-induced synaptic plasticity underlying learning and memory is represented in the form of long-term potentiation by spine volume changes. To investigate the physiological role of beta-actin mRNA localization in dendritic spines, we employed two-photon glutamate uncaging and glycine induced chemical LTP to stimulate dendrite spines. Hippocampal neurons cultured from the MCP × MBS knock-in mice in which all endogenous beta-actin mRNAs are

fluorescently labeled were used for live-cell imaging of beta-actin mRNA. Our results suggest that localization of beta-actin mRNA has a strong correlation with structural LTP process. This study sheds a light on the implication of beta-actin mRNA localization and local translation for LTP in neurons and their role in long-term memory formation.

Title: Lack of tau in hippocampal CA1 neurons - what is altered?

Authors: N. D. MONTEIRO ABREU, N. I. TRUSHINA, M. HRYNCHAK, M. RIEROLA-CARRERA, K. TULVA, *R. BRANDT, L. BAKOTA;
Neurobio., Osnabrück Univ., Osnabrück, Germany

Abstract: Alzheimer's disease is a progressive brain disorder that slowly destroys memory and thinking skills, and eventually the ability to carry out the simplest tasks. One of the key molecules that has been linked to the disease is the microtubule-associated protein tau since it is a principal component of the neurofibrillary tangles, which are present in neurons of the diseased brain. However, it is unknown how a protein that is primarily located in the axon shaft is involved in a disease that is believed to have a synaptic origin. In this regard, the function and morphology of CA1 neurons from tau knock out (tauKO - B6.129X1-Mapt^{tm1Hnd}/J) male mice were studied. Analysis of potential functional alterations in synaptic transmission was performed by microelectrode array (MEA) system. Induction of LTP by high-frequency stimulation (HFS) leads to a higher potentiation of the population spikes and fEPSP in 12-months-old tauKO mice. Interestingly, 3-months-old tauKO mice lose the ability of a potentiated response in the *stratum radiatum* over time, but not at the site of the generation of the action potential. To understand the potential reason for these differences, both the length and distance of axonal initial segments (AIS) were analyzed, revealing that tauKO mice generally have shorter AIS and in particular, AIS in the hippocampi of the 3-months-old mice are located further away from the soma than in control mice. The signal propagation down the dendritic branch appears unchanged in 12-months-old mice, because no difference was found in the length of dendrites or branching number between the two genotypes. However, tauKO mice at that age are possessing a higher fraction of mushroom spines on their dendrites. On a molecular level, mass spectrometry data showed that in 12-months-old tauKO mice the amount of $GABA_A$ receptor subunit is decreased. The data indicate that tau has a complex effect on synapse function, which is dependent on the developmental stage of the animals. This is of particular importance because current therapeutic strategies aim to reduce tau level in the brain of diseased patients.

Abstract: Long-term potentiation (LTP) and depression (LTD) are mechanisms of inherent synaptic plasticity of neurons and support the storage and recovery of memories in the mammalian brain. The ability to potentiate a synapse long-term is a model for long term memory formation. Our previous work has shown that the anti-apoptotic protein Bcl-xL not only prevents apoptosis, but also potentiates long-term synaptic responses. Here, we present that Bcl-xL is required for changes in ATP synthase stoichiometry that in turn induce dramatic changes in ATP levels in hippocampal neurons during LTP stimulation and progression. Using fluorescence imaging with a FRET based ATP construct (ATeam) in live hippocampal neurons, we find that LTP induction causes a sharp decrease in ATP levels followed by a persistent long-term increase in ATP production, suggesting that intense synaptic stimulation causes neuronal ATP synthase to become metabolically more efficient. In agreement with this, the later increase in ATP levels is associated with decreases in oxygen consumption by single neurons, with maturation of dendritic spines and with insertion of AMPA receptors into the plasma membrane. The LTP-associated increase in ATP levels and maturation of dendritic spines is blocked by application of Bcl-xL specific inhibitors and by inhibition of mitochondrial ATP synthase activity. Bcl-xL and ATP synthase inhibition also prevent LTP-induced increase in surface glutamate receptor insertion. During LTP, components of the ATP synthase are synthesized. This causes a change in stoichiometry of the ATP synthase, decreasing the ratio of free membrane-bound c-subunit to assembled ATP synthase. The increase in ATP production efficiency results in localized ATP production required for CAMKII and AMPA-serine 845 phosphorylation. The latter phosphorylation events are prevented by Bcl-xL inhibition and by ATP synthase inhibition. In hippocampal slice recordings, inhibition of Bcl-xL impairs early stage LTP and prevents late stage LTP. Our findings suggest that long-term changes in mitochondrial efficiency brought on by activity-dependent Bcl-xL translocation to mitochondria are required for LTP and shed light upon the role of mitochondrial metabolic plasticity in acute induction and long-term maintenance of learning and memory formation. If such mitochondria-dependent metabolic changes fail to occur, synaptic dysfunction and neurodegeneration may ensue.

Title: $Ca_v1.3$ calcium channels are simple linear amplifiers of firing activity in DA SN neurons

Authors: *J. SHIN[1], L. KOVACHEVA[1], D. THOMAS[2], S. STOJANOVIC[1], C. A. PALADINI[3], G. GEISSLINGER[2], J. STRIESSNIG[4], J. ROEPER[1];

[3]UTSA Neurosciences Inst., UTSA, San Antonio, TX; [4]Pharmacol. and Toxicology, Univ. of Innsbruck, Innsbruck, Austria

Abstract: Studying the role of Cav1.3 channels in dopamine neurons of the substantia nigra pars compacta (DA SN) and its potential relevance in the context of neuroprotection in Parkinson disease has been complicated due to the lack of selective pharmacological targeting. We combined on-cell, whole-cell and perforated patch-clamp recordings of labelled and identified DA SN neurons in acute slice preparations of 8 - 12 weeks old C57BL6/N wildtype and Cav1.2 $DHP^{-/-}$ knockin mice. In the latter, only Cav1.3 channels are sensitive to dihydropyridines (DHP) like isradipine, while the DHP binding site of Cav1.2 has been rendered non-functional by mutagenesis. We demonstrate that in vitro autonomous pacing is amplified by Cav1.3 channels with a linear gain of about 30% of the intrinsic baseline frequency. The Cav1.3 gain was unaffected by somatodendritic D2 autoreceptors or the presence of DHP-sensitive Cav1.2 channels in wildtype mice, suggesting a universal role of Cav1.3 channels as a rate-dependent linear amplifier in DA SN neurons. To characterize Cav1.3 channel function across the entire dynamic firing range of DA SN neurons observed in vivo (ca. 1-50 Hz), we utilized the dynamic-clamp technique for evoking these frequencies via in silico NMDAR conductances. By using 300 nM isradipine, we demonstrated that Cav1.3 channels linearly amplified firing frequencies across the entire range selectively in lateral DA SN neurons. We also evaluated clinically relevant (3 - 10 nM) concentrations of isradipine in vitro in a similar fashion. These low nanomolar concentrations partially reduced lateral DA SN firing across the dynamic range by about 25%, consistent with incomplete Cav1.3 channel inhibition. We then tested whether in vivo firing of lateral DA SN neurons was selectively reduced by 25% upon systemic application of isradipine (3 mg kg-1) as predicted by our in vitro experiments. Our in vivo recordings confirmed these predictions for lateral DA SN neurons and also demonstrated that medial DA SN neurons were not affected in vivo by clinically relevant concentrations of israpipine. Our study demonstrated that Cav1.3 channels function as linear amplifiers of autonomous pacemaking and selectively boost firing frequency in vivo across the entire dynamic firing range of lateral DA SN neurons. We also show that targeting the highly vulnerable DA neurons in the lateral SN with DHPs in the clinical concentration range is feasible and might be applicable in Parkinson Disease.

Title: R and T-type Ca2+ channels underlie persistent firing in LEC III pyramidal neurons

Authors: *C. LIN, M. M. OH, J. F. DISTERHOFT;
Physiol., Northwestern Univ., Chicago, IL

Abstract: Persistent firing in LEC III has been shown to underlie associative learning and memory (Fuster, 1972, Lin et al, 2020). However, the mechanisms that underlie this phenomenon are yet to be determined. There have been many candidates, including Ca2+-activated nonselective cation (CAN) channels (Fraser and MacVicar, 1996; Tahvildari et al, 2008), Ether-a-Go-Go Related Gene (ERG) channels (Cui and Stowbirdge, 2018), transient receptor potential canonical (TRPC) channels (Arboit et al, 2020), voltage-gated Ca2+ channels (Fraser and MacVicar, 1996, Tahvildari et al, 2008), and persistent Na+ currents (Zylberberg and Stowbridge, 2017).
Although the channels that underlie persistent firing are still unknown, Ca2+ seems to be an important component of the mechanism (Tahvildari et al, 2008, Lin et al, 2020). We have determined that the R/T-Types, but not L-type voltage-gated Ca2+ channel contribute to persistent firing in LEC III pyramidal neurons. Application of Ni2+ (a blocker of R/T-type channels) eliminates the afterdepolarization (ADP) and plateau potential (PP) that underlies persistent firing and prevents firing. Application of nimodipine (blocker of L-type Cav1.2 channels) and isradipine (blocker of L-type Cav1.3 channels), however, had no effect on the ADP or persistent firing.
Future experiments will continue to determine the specific contributions of R vs. T-type channels and the overall role that these channels play in eliciting persistent firing.

Title: Dominant role of calcium and calcium-dependent potassium channels in regulating complex spike bursting in a heterogeneous population of CA3 pyramidal neuron models

Authors: *R. ROY[1], R. NARAYANAN[2];
[1]Indian Inst. of Sci., Bengaluru, India; [2]Indian Inst. of Sci., Bangalore, India

Abstract: Complex spike bursting (CSB) is a characteristic neuronal signature exhibited by hippocampal CA3 pyramidal neurons. Although complex burst patterns have been implicated in place cell formation and in inducing synaptic plasticity, assessment of the heterogeneities in the ionic mechanisms underlying CSB generation in CA3 pyramidal neurons remains unexplored. In this study, we employed an unbiased stochastic search algorithm (involving 11 ion channels and 14 parameters) to generate a heterogenous population of morphologically realistic CA3 pyramidal neurons models that accounted for their ion-channel kinetics, gating properties, and associated heterogeneities. We validated 12,000 stochastically generated models against 11 signature electrophysiological intrinsic measurements, and found 236 valid models. These valid models were endowed with broad distributions of underlying parameters showing weak pair-wise correlations. We found two functional subclasses of valid models, intrinsically bursting (IB; n=67) and regular spiking (RS; n=169), which exhibited two distinct clusters in the parametric space with both linear (PCA) and non-linear (t-SNE) dimension reduction analyses. As the clustering was predominantly along the first principal component, which aligned with the parametric axes for calcium and calcium-activated conductances, we tested if those parameters were different between the two subpopulations. We found the N-type calcium (CaN) conductance to be significantly higher and the small-conductance calcium-activated potassium (SK) conductance to be significantly lower for IB neurons compared to RS neurons. We then triggered CSB in all 236 models by subjecting them to 5 different kinds of inputs, and observed considerable heterogeneity in their propensity for exhibiting CSB. Quantitatively, these models manifested heterogeneities in the 3 characteristic signatures of CSBs: (i) amplitude difference between the first and the last action potential within the CSB; (ii) sub-threshold ramp voltage; and (iii) CSB rate with 4 consecutive pulse-current inputs. Finally, we employed virtual knockout analyses involving 7 voltage- and/or calcium-dependent channels as well as NMDA receptors, and showed that synergistic interactions among several ion channels regulated CSB. Of these different ion channels and receptors, we found dominant roles for NMDA receptors as well as CaN and SK channels in regulating CSBs across models. Together, our analyses unveil the expression of ion-channel degeneracy in CA3 pyramidal neurons and emphasize the dominance of calcium and calcium activated potassium channels in the emergence of CSB.

Title: Neuromodulation-dependent correlation levels in neuron ion channel expression result from a competition between passive and active membrane properties.

Authors: A. FYON, *G. DRION;
Univ. of Liège, Liege, Belgium

Abstract: Neurons and circuits are subject to significant changes in their firing activity and responsiveness to external inputs via neuromodulation (Marder, 2012). Many nervous system functions depend on reliable neuromodulation, yet the physiological properties of neurons that are targeted by neuromodulators are often highly variable (Grashow et al., 2009 ; Marder et al., 2014). In this work, we use conductance-based neuron models to investigate the mechanisms by which neuromodulation can be reliable in variable neurons by tuning correlations in ion channel expression. We show that the correlations required for reliable neuromodulation depends on the type of variability in neuron intrinsic properties. Variability in neuron passive properties such as input resistance results in correlations whose slope is affected by neuromodulation state. Variability in neuron active properties such as voltage-gated channel densities results in correlations of constant slope that are translated by neuromodulation state. As a result, the global correlation level in neurons that are variable in both passive and active properties will appear strongly correlated when correlations due to both variability types are aligned, i.e. when they are of similar slope, and appear to decorrelate as neuromodulation state varies due to a misalignment of correlation slopes.

Title: Ion channel dynamics contribute to altered excitability in a genetic model of Angelman Syndrome

Authors: *A. PRATT[1], C. MALLOY[2], D. A. HOFFMAN[3];
[1]Eunice Kennedy Shriver Natl. Inst. of Child Hlth. an, Chevy Chase, MD; [2]Mol. Neurophysiol. and Biophysics, Natl. Inst. of Hlth. Office of Intramural, Bethesda, MD; [3]NIH, Bethesda, MD

Abstract: Angelman Syndrome (AS) is a rare neurodevelopmental disorder that causes delayed development and a predisposition to seizures, among other neurological phenotypes. Loss-of-function mutations in the maternal allele of Ube3a, the gene that encodes for E3A ubiquitin ligase, is known to be the cause of this condition. Our group sought to investigate how Ube3a impairment leads to an increased prevalence of seizures and behavioral phenotypes associated with this condition. To model AS, heterozygous knockout (KO) of Ube3a was employed and its effect on pyramidal cell excitability in the CA1 of the mouse hippocampus was examined. Firing property recordings revealed dampened basal excitability at hyperpolarized membrane potentials in the KO group. Reduced excitability was primarily due to increased inter-spike interval duration at the beginning of current steps under the hyperpolarized condition. Interestingly, no difference was observed in excitability between groups at resting membrane potential. Differences in ion channel dynamics in the hyperpolarized state suggest that membrane potential contributes to differences in ion channel availability between groups.

Abstract: Eliezer Cartagena-López, Katherine Cordero Padilla, Héctor G. Marrero Hernández, Yolimar Romero Estremera and Cristina Velázquez-MarreroAbstract:Research has identified the large conductance voltage- and calcium-activated channel (BK) as va key regulator of neuronal excitability genetically associated to behavioral alcohol tolerance in invertebrates. Similarly in mammals, decreasing BK channel alcohol sensitivity by knocking out its 4 subunit leads to increased alcohol voluntary consumption in mice. Sensitivity to ethanol at the molecular level is characterized by acute potentiation of channel activity. However, different isoforms of the BK channel show variations in alcohol sensitivity and are differentially distributed on the plasma membrane surface in response to prolonged exposure, also known as persistent alcohol tolerance (PMT). miRNA targeting of alcohol-sensitive isoforms coupled with active internalization of BK channels in response to ethanol are believed to be key in establishing homeostatic adaptations that produce persistent changes within the striatum. These mechanisms may operate independently, with the same end point of increasing the representation of alcohol insensitive BK channels or interact to orchestrate and optimize these persistent adaptive changes at the translational and trafficking level of regulation. In our current study we have designed and expressed cDNA constructs containing sequences for two important BK channel isoforms and created stably transfected cell lines expressing both; STREX and ZERO. These isoforms differ in their sequence by a 53 amino acid cassette in the C-terminus region present in STREX and absent in ZERO. This uniquely confers STREX with an insensitivity to acute alcohol exposure. The cDNAs where further designed to include a GFP-tag for in-vivo studies and contain differing 3'UTR regions to explore the role of miR-9 expression on protein translation for both isoforms. Our results indicate significant effects correlating miR-9 exposure to BK channel internalization in the absence of translational regulation supporting the link between miR-9 and Wnt/beta-catenin signaling in the internalization of BK channels during molecular alcohol tolerance.

Title: The sodium leak channel Nalcn contributes to pacemaking activity of dopaminergic neurons

Authors: *D. E. COBB-LEWIS[1], Z. M. KHALIQ[2];
[1]The Natl. Institutional Inst. of Health, NINDS, The George Washington University, The Natl. Ins, Bethesda, MD; [2]NIH/NINDS, Bethesda, MD

Abstract: Dopaminergic neurons fire spontaneous action potentials in a rhythmic, pacemaker fashion, setting tonic dopamine levels in the basal ganglia. Alterations to tonic dopamine levels are associated with

Parkinson's disease, depression, and schizophrenia. Past work has suggested that a sodium leak conductance may be the largest contributor to pacemaking in dopaminergic neurons, but the molecular correlate of this conductance remains a matter of debate. Here we investigated the contribution of the sodium leak channel, NALCN, to spontaneous pacemaker activity of dopaminergic neurons. Using calcium imaging to monitor action potential firing, we found that the vast majority of control dopaminergic neurons fire spontaneously (85.95%) at low rates (1.71 Hz, n=242) both in the ventral tegmental area (VTA) and substantia nigra (SNc). Similarly, using electrophysiology we found 91.59% of dopaminergic neurons in the SNc fire spontaneously (2.85 Hz, n=107). By contrast, dopaminergic neurons in the VTA lacking expression of NALCN were largely quiet (80.73%, n=192) in calcium imaging experiments. We conducted additional electrophysiology experiments to determine the effect of acute manipulation of NALCN on spontaneous firing. Consistent with previous work in hippocampus showing that NALCN is potentiated in low external calcium, we found that pacemaking was increased (+178.8%) in low calcium but not in the presence of Gd3+, a non-specific blocker of NALCN. Additionally, we found that Co2+, another non-specific blocker of NALCN, significantly reduced pacemaking (-51%) while Gd3+ had no effect. Because pacemaking is known to involve multiple conductances, including L-type calcium (LCa) and hyperpolarization-activated (IH), we tested the unique contribution of NALCN to spontaneous firing by blocking these conductances. While pacemaking was not significantly affected by LCa and IH antagonists, the addition of Gd3+ significantly reduced firing (-79.3%). Thus, we have identified NALCN as a novel ionic contributor to the robust pacemaking process of dopaminergic neurons.

Title: Ensemble computational models of mouse thoracic sympathetic postganglionic neurons simultaneously tuned across neurophysiological modalities

Authors: K. PUSULURI[1], Y. LI[2], S. HOCHMAN[2], *A. A. PRINZ[1];
[1]Dept. of Biol., [2]Dept. of Physiol., Emory Univ., Atlanta, GA

Abstract: Thoracic sympathetic postganglionic neurons (tSPNs) regulate downstream effector targets including vasomotor and thermoregulatory systems by receiving, integrating, and transforming synaptic inputs from preganglionic neurons in the spinal cord [1]. The mechanisms underlying tSPN excitability changes, such as may occur after spinal cord injury (SCI), can be studied by understanding the biophysical properties of tSPNs, their integrative capacity, and recruitment principles.
A conductance-based computational model of mouse tSPNs was previously described in [1]. The current study presents ensembles of tSPN models tuned to individual neurons to effectively describe experimental

recordings simultaneously across different electrophysiological modalities, including voltage-clamp (VC) step and ramp, as well as current clamp (CC) protocols. The maximal conductances, decay time constants, and other kinetic properties of relevant ion channels based on previously studied mRNA profiles in tSPNs are determined. The dynamics of transient currents via Na^+ and A-type K^+ channels are modeled using VC step protocol data, further separated by the application of the Na^+-channel blocker tetrodotoxin. Various long-lasting currents (delayed rectifier K^+, M-type K^+, Ca^{2+}-dependent K^+ etc.) are separated based on their characteristic dynamics seen under VC ramp protocol, and their aggregate under VC step protocol. Using data from CC recordings, all channel properties are also simultaneously tuned to match the passive and firing properties of the cells in response to current injections. We included a model of electrode resistance and capacitance [2] to separate experimental artifacts from ion channel dynamics and to describe the voltage-dependent delays observed in the onset of Na^+ currents under VC step protocol. Future work will employ these ensemble tSPN models to study systematic differences between genetically identified subpopulations and the mechanisms of putative homeostatic plasticity engaged to maintain excitability after lost central drive as seen after high level SCIs.

Title: Distinct roles of beta and gamma bursts in the mouse basolateral amygdala-medial prefrontal cortex circuitry in the presence of a predatory robot

Authors: *J. KIM[1,3], H.-B. HAN[2,4], S. CHO[1], J. CHOI[5,6];
[1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Korea Inst. of Sci. and Technol., Seoul City, Korea, Republic of; [3]Kyung Hee Univ., Seoul, Korea, Republic of; [4]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [5]Korea Inst. of Sci. and Tech. (KIST), Seoul, Korea, Republic of; [6]Univ. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Oscillatory activities in the basolateral amygdala (BLA) are known to regulate emotion-related behaviors with the medial prefrontal cortex (mPFC). Several studies on the rodent BLA have reported that transient oscillations at the high beta (~25 Hz, beta bursts) and low gamma (~40 Hz, gamma bursts)

frequency range emerge during the emotion- or reward-related situations. However, whether the beta and gamma bursts have similar or different neuronal contexts is unclear. To characterize the functional roles of the beta and gamma bursts in the BLA-mPFC circuit, we examined their relevance to mouse behaviors by introducing a predatory robot in the open field arena. To classify the behavioral states, we used the dynamic parameters of the position data to classify the response of the mice towards or their interactions with the robot (e.g., attack, escape, freeze, avoid, etc.). We observed that the BLA-mPFC circuit predominantly displays both beta and gamma bursts in a significant level compared to the baseline. However, the moments during which these bursts occurred showed discrepancy: while most of the beta bursts were associated with the executive behaviors, the gamma bursts didn't show such behavior-specificity. Rather, the gamma bursts occurred in an elevated manner during the situations of enhanced threat. Our observations so far concede with the recent findings and suggest the updated view of high beta and low gamma oscillations. Even the resonance frequencies are at proximate, the generative mechanisms of beta and gamma oscillations are different. The beta and gamma bursts in the mPFC and BLA may reflect distinct functional role in emotional and non-emotional cognitive processes.

Abstract: Our limited means to non-invasively modulate deep brain circuits constrain the development of new therapeutic strategies for many neurological disorders such as Alzheimer's disease (AD). Previously, we showed that periodic sensory stimulation, or sensory flicker, modulates neural activity in rodent higher cognitive regions, suggesting this approach could be a powerful non-invasive tool to modulate such circuits. However, we do not know whether this method could be used to modulate these circuits in humans, the extent of its effects across brain regions, nor the mechanism by which this stimulation affects non-sensory circuits. We studied the effects of visual and auditory flicker in humans at both the local field

potential (LFP) and single neuron level, across a comprehensive set of brain regions. To do so, we recruited treatment-resistant epileptic patients undergoing presurgical intracranial seizure monitoring with stereotactic EEG, who were not suspected to be sensitive to photic-induced seizures. Subjects were exposed to visual-only, auditory-only, and audiovisual stimulation at a range of frequencies between 5.5Hz to 80Hz, as well as to single pulses of stimulation. We show that sensory flicker increases LFP oscillations at the frequency of the flickering stimulus in higher cognitive regions such as the hippocampus and prefrontal cortex, and our data suggests that it may also modulate the activity of single neurons in such regions. We confirmed that these findings cannot be explained by electrical artifacts or volume conduction from sensory areas. Moreover, we investigated the mechanisms by which sensory flicker propagates from sensory to higher cognitive brain regions. Specifically, we tested whether sensory flicker responses result from a linear or non-linear combination of single sensory pulse responses or result from amplification of specific frequencies due to resonant properties of local or long-range circuits. Our data points to the latter as a possible mechanism by which sensory flicker modulates deep brain circuits. This is the first extensive study examining the neurophysiological response to sensory flicker at such a high spatial and temporal resolution in humans. Our results suggest that this stimulation effectively modulates circuits involved in disease, including deep circuits that are hard to target non-invasively. Finally, our data sheds light on the potential mechanism by which sensory flicker modulates such non-sensory circuits.

Title: Inter-areal coherence differences are explained by differences in gamma frequency

Authors: *J. R. DOWDALL[1,2], M. SCHNEIDER[2], M. VINCK[2];
[1]Robarts Res. Inst., London, ON, Canada; [2]Ernst Struengmann Inst., Frankfurt am Main, Germany

Abstract: Inter-areal coherence in the gamma band (30-90 Hz) has been postulated to mediate the feedforward flow of information between anatomically connected brain areas (Fries 2005, Bastos, et. al. 2015). Several studies have observed an increase in inter-areal coherence with attention, which co-occurs with a shift in the gamma peak frequency (Bosman, et. al 2012, Ferro, et. al. 2021). These frequency shifts may be a mechanism by which the attended stimulus gains preferential processing at downstream targets, yet the underlying mechanism remains unclear. To this end, we studied the role of frequency shifts and their effect on inter-areal coherence by theoretical analysis and numerical simulations using damped harmonic oscillators. We contrasted two general mechanisms through which frequency shifts can cause changes in the magnitude of coherence, namely resonance (Izhikevich, et. al. 2003) and source mixing (Buzsáki & Schomburg, 2015, Schneider, et. al. 2020). These two mechanisms make distinct and

opposite predictions on the relationship between the magnitude of inter-areal coherence and frequency shifts. Our findings have strong implications toward understanding the mechanism of coherence, the degree to which coherence reflects inter-areal communication, and the utility of coherence for quantifying the flow of the information between anatomically connected brain areas.

Title: Metastability of Down states in the cerebral cortex: dynamics and modulation

Authors: A. CAMASSA[1], A. GALLUZZI[2], M. MATTIA[3], *M. SANCHEZ-VIVES[4,5];
[1]IDIBAPS, Barcelona, Spain; [2]Inst. Superiore di Sanitá, Rome, Italy; [3]Inst. Superiore di Sanità, Roma, Italy; [4]IDIBAPS (Institut D'Investigacions Biomediques August Pi I Sunyer), Barcelona, Spain; [5]ICREA, Barcelona, Spain

Abstract: Under unconscious brain states, the cortical dynamics is dominated by a rhythm know as "slow oscillations" (SO) characterized by the alternation between periods of activity, or Up states, and periods of silence, or Down states. In this context, the Down states play a critical role for the cerebral cortex function, being responsible of resetting the system and breaking causal interactions between cortical areas. These cortical quiescent periods account for the drop of cortical complexity reported under unconscious brain states (e.g. Rosanova et al, *Nature communications* (2018) 9: 1), and as such they are key components for the understanding and characterization of the dynamics and mechanistic differences between conscious and unconscious brain states. The mechanisms underlying SOs are still under debate, so here we focused on the less-studied silent period, the Down state, and analysed the instantaneous phase and synchronization (Kuramoto order parameter) of the local field potential and multiunit activity in multielectrode recordings obtained from *in vivo* and *in vitro* cortical networks, and from a multimodular network of spiking neurons *in silico* (Capone et al. (2019) *Cereb. Cortex* 29:319). Through this multiscale exploration we identified a metastable dynamic within the Down states characterized by two phases: 1) a sustained period of high synchronization right after the Up-to-Down transition, where the collective phase behavior shows an exponential trend and high synchronization, eventually followed by 2) a second period characterized by poor network synchronization, in which the collective phase randomly fluctuates between $-\pi$ and $+\pi$. For this reason, we decided to name these stages "deterministic" and "stochastic" respectively. A large parameter space was investigated through different experimental manipulations (anesthesia levels, electric fields, alterations of excitation/inhibition, etc) in order to validate this framework, that integrates a broad range of slow oscillatory frequencies. The identification of the

metastable periods of the Down states and the possibility of inferring local and global features of network dynamics through the analytical approach used here, illustrates the value of the combined recording and analysis of LFPs and spikes, which offer insights that cannot be obtained at present by examining spikes alone (Mazzoni et al (2013) *Princ. Neural Coding* 411-430). Accordingly, we propose here a more detailed description of the Up and Down state cycle dynamics that bridges cortical properties emerging at the mesoscale with their underlying mechanisms at the microscale.

Title: Co-occurrence of hippocampal theta- and ripple-frequency rhythms in foraging rats

Authors: *P. SEENIVASAN[1], R. BASAK[2], R. NARAYANAN[1];
[1]Indian Inst. of Sci., Bangalore, India; [2]Indian Inst. of Science, Bangalore, Bangalore, India

Abstract: Brain rhythms have been postulated to play central roles in animal cognition. The occurrence of theta- and ripple-frequency hippocampal rhythms is known to be significantly dissociated with respect to both physiology and behavior. While θ-frequency (4-12 Hz) oscillations are assigned to encoding processes during exploratory behavior and rapid eye movement (REM) sleep, ripple-frequency (120-250 Hz) oscillations are linked to consolidation phenomena during non-REM sleep and wakeful rest. However, as the two oscillations are differentially expressed across hippocampal *strata*, reports of exclusivity need validation through simultaneous recordings across *strata*. Additionally, intracellular counterparts of sharp waves (dendritic plateau potentials), that occur in close association with ripples, have been observed simultaneously during θ oscillations. Motivated by these observations, we assessed their potential co-occurrence by recording hippocampal extracellular potentials from rats (n=3) that foraged in an open arena using 32-channel silicon polytrodes spanning different *strata*. We identified individual *strata* based on histology, laminar profiles of extracellular signals during sharp wave ripples (SPW-Rs), and characteristic cross-*strata* θ-phase reversal. Theta epochs and ripple events were exclusively identified from the distal *stratum radiatum/stratum lacunosum moleculare* and *stratum pyramidale* respectively, to account for their differential expression profiles. A simultaneous detection of the two rhythms from their respective *strata* was defined as a co-occurrence, termed as *θ ripple* events. Across rats, we found 10-20% of total ripples to be *θ ripples*, with the frequency of occurrence of ripples within θ epochs (median across sessions: 0.2-0.4 Hz) higher than their occurrence outside (0.1-0.2 Hz). Further, we found the magnitude of θ power during and in the vicinity of *θ ripples* to match that within

identified θ epochs. We also assessed the behavioral state of the rat during ripple events, and found a distribution of ripple kinds - e-θ, i-θ, e-nonθ, and i-nonθ, with distinctions based on physiology (θ *vs.* non-θ epochs) and behavior (exploratory *vs.* immobile), emphasizing the need to consider ripples other than the dominant i-nonθ ripples. Finally, we found that *θ ripple*s expressed a strong phase preference (range $[\pi/2,\pi]$) with respect to the θ oscillation. Together, our analyses provide direct quantitative evidence urging the need to revisit the dichotomy between the two rhythms, by demonstrating their co-occurrence during different behavioral states.

Title: The timescale and magnitude of aperiodic activity decreases with cortical depth in humans, macaques and mice

Authors: *M. HALGREN[1], R. KANG[1], B. VOYTEK[2], I. ULBERT[3], D. FABÓ[4], L. EROSS[3], L. WITTNER[5], J. MADSEN[6], W. K. DOYLE[7], O. DEVINSKY[7], E. HALGREN[8], M. T. HARNETT[1], S. S. CASH[9];

Abstract: Cortical dynamics obey a 1/f power law, exhibiting an exponential decay of spectral power with increasing frequency. The slope and offset of this 1/f decay reflect the timescale and magnitude of aperiodic neural activity, respectively. These properties are tightly linked to cellular and circuit mechanisms (e.g. excitation:inhibition balance, firing rates) as well as cognitive processes (perception, memory, state). However, the physiology underlying the 1/f power law in cortical dynamics is not well understood. Here, we compared laminar recordings from human, macaque and mouse cortex to evaluate how 1/f aperiodic dynamics vary across cortical layers and species. We report that 1/f slope is steepest in superficial layers and flattest in deep layers in each species. Additionally, the magnitude of this 1/f decay

is greatest in superficial cortex and decreases with depth. Both of these findings can be accounted for by a simple model in which transmembrane currents have longer time constants and greater densities in superficial cortical layers. Together, our results provide novel mechanistic insight into aperiodic dynamics in cortex and suggest that the timescale and magnitude of aperiodic cortical currents decrease with cortical depth.

Title: Traveling waves in the prefrontal cortex during working memory

Authors: *S. BHATTACHARYA, S. L. BRINCAT, M. LUNDQVIST, E. K. MILLER;
MIT, Cambridge, MA

Abstract: Neural oscillations are evident across cortex but their spatial structure is not well explored. Are oscillations stationary or do they form “traveling waves”, i.e., spatially organized patterns whose peaks and troughs move sequentially across cortex? Here, we show that oscillations in the prefrontal cortex (PFC) organized as traveling waves in the theta (4-8Hz), alpha (8-12Hz) and beta (12-30Hz) bands. Some traveling waves were planar while many rotated around an anatomical point. The waves were modulated during performance of a working memory task. During baseline conditions, waves flowed bidirectionally along a specific axis of orientation. Waves in different frequency bands could travel in different directions. During task performance, there was an increase in waves in one direction over the other, especially in the beta band.

Title: Opposite effects of ketamine on the generation of hippocampal sharp wave ripples: A comparison of brain slices and the whole brain.

Authors: *J. GU[1,3], S. VICINI[2], J.-Y. WU[1];
[1]Neurosci., [2]Dept Parmacology & Physiol., Georgetown Univ. Med. Ctr., Washington, DC; [3]Col. of William and Mary, Williamsburg, VA

Abstract: Ketamine is a promising, fast-acting antidepressant that act as a non-competitive NMDA antagonist. Its action on other transmitter systems (e.g., AMPA receptors, monoaminergic, cholinergic and opioid systems) have been widely noted but remain elusive.
To investigate the non-NMDA effects of ketamine, we tested ketamine on the occurrence of hippocampal sharp wave-ripples (SWRs) in mouse hippocampal slices and whole animals. SWRs are a spontaneous neuronal activity essential for memory consolidation, generated locally in the hippocampus. The generation of SWR is known to be insensitive to NMDA receptors but highly sensitive to other neurotransmitter receptor systems including AMPA, GABA, acetylcholine, dopamine, serotonin, norepinephrine, and opioids in the CA3 local circuits.
We found ketamine has opposite effects on SWRs when comparing slices and the whole brain *in vivo*. In mouse hippocampal slice, ketamine reduced the SWRs occurrence rate without affecting their amplitude. In contrast, when applied to whole animal (ip injection), ketamine increases the occurrence rate and ripple amplitude.
The *in vivo* and *in vitro* effects began to occur at a similar sub-anesthetic dose of 25-50 mg/kg and became more obvious at higher doses (100 mg/kg, 40 μM). In brain slices, high doses (200 mg/l, 80 μM) sharply reduce the occurrence rate of SWRs, yet some of the remaining SWRs continued to exhibit a high amplitude.
The *in vitro* effect is unlikely to related to the NMDA antagonism, because the effect of ketamine persisted after a complete blockage of NMDA receptors with 150 μM of AP5. We also found that manipulating AMPA, GABAa, acetylcholine, dopamine, or serotonin receptors can all change the SWR occurrence rate and amplitude, but none of them exhibited a reduction in occurrence without affecting amplitude. The effects of ketamine on SWR generation circuits will be further explored.
Our results suggest that the changes of SWR induced by ketamine *in vivo* is a combination of direct (local) and indirect effects. The indirect effects may be derived from metabolic products of ketamine and/or neurotransmitters released from other brain structures.

Title: Competing patterns of oscillatory activity in the basolateral amygdala-medial prefrontal cortex circuitry during freeze-or-flight response

Authors: *H.-B. HAN[1,2], Y. JEONG[3], J. CHOI[1];
[1]Korea Inst. of Sci. and Tech. (KIST), Seoul, Korea, Republic of; [2]Program of Brain and Cognitive Engin., [3]Bio and Brain Engin., KAIST, Daejeon, Korea, Republic of

Abstract: Confronting a predatory threat, our brain quickly evaluates relevant behavioral strategies among different types of defensive behaviors, for example, freeze-or-flight. Converging evidence suggests that bidirectional connections in mPFC-BLA circuits play key roles for defensive behaviors, however, the underlying mechanism remains largely unknown. Here, we propose the distinct rhythmic states in mPFC-BLA and their interactions support flexible switching in freeze-or-flight decision process, the rhythms of which may bridge functionally relevant neural ensembles through coherence and resonance as well. Using LFP recordings in mice, we observed the emergence of various rhythmic states in mPFC-BLA. By identifying the different types of defensive behavior manifested in a naturalistic predator-avoidance task, we found freeze-related rhythmic state (mPFC→BLA 5 Hz) and flight-related rhythmic states (BLA→mPFC 10 Hz & mPFC→BLA 30 Hz) in mPFC-BLA. The rhythmic states were not only distinctive but also mutually-exclusive; the two behavior-specific states in mPFC-BLA barely coexist, as if the behavioral states of freeze/flight do not coexist. Two flight-related rhythms also showed a functional segregation, whereas the 30 Hz represents the top-down aspect of flight behavior (e.g., refuge-oriented moving), the 10 Hz simply correlated to the speed of movement during flight. The frequency channels of rhythms match well with the characteristics of previously-reported functional networks that mPFC-BLA deploys (e.g., 5 Hz with basal ganglia, 10 Hz with hippocampus), suggesting a bridging role of mPFC-BLA during different defensive behaviors. Taken together, our results provide empirical data of mPFC-BLA exhibiting various frequency channels during defensive behaviors, and further suggest the role of oscillatory switching for flexible functional transition in the single brain circuits of mPFC-BLA.

Title: Encoding behavioral information by dynamic reorganization of a prefrontal microcircuit

Authors: *N. FROST[1], K. DONAHUE[2], V. S. SOHAL[3];
[1]Univ. of Utah, Salt Lake City, UT; [2]Univ. of California, San Francisco, San Francisco, CA; [3]Dept. of Psychiatry, U. California, San Francisco, San Francisco, CA

Abstract: Changes in multineuron activity within the brain underlie our ability to accurately represent information pertinent to cognitive tasks. The prefrontal cortex in mice plays important roles in regulating both anxiety and social interactions. While activity is modulated during both types of behaviors, the nature by which information is encoded is unclear. We reasoned that modulation of the temporal patterning of neuronal groups into behavior-specific patterns might both contribute to specific computational processes and increase the reliability by which information might be transmitted between neurons during behavior. We utilized implanted microendoscopes to record calcium activity of prefrontal neurons as mice engaged in social and anxiety-provoking behaviors to generate multi-dimensional datasets. This allowed us to identify neurons or groups of neurons which specifically encoded features pertinent to anxiety-provoking or social behaviors. We then trained a neural network receiving input from randomly assigned subsets of real neurons from each dataset to identify specific ensembles of neurons whose activity was modulated during each behavior. We show that the activity of identified ensembles convey information that is specific for each behavior with little overlap between ensembles and different behaviors. Demonstrating that the temporal patterning of neuronal activity is critical, shuffling datasets randomly reduces the performance of our classifier to chance, whereas shuffling data in a manner that preserves correlations maintains above-chance accuracy. We reason that in neurodegenerative or neurodevelopmental disorders this temporal patterning may be altered both due to changes input or changes in the function of the local microcircuit.

Title: Evoked Potentials for Programming Dentate Nucleus Deep Brain Stimulation in Stroke Rehabilitation

Authors: *J. K. HERMANN[1], A. BORSETH[1], F. PUCCI[2,3], C. TOTH[1], O. HOGUE[4], H. H. CHAN[1], A. G. MACHADO[2,3], K. B. BAKER[1];

Abstract: Elevating excitability in cortical tissues surrounding ischemic stroke lesions is hypothesized to enhance the efficacy of motor rehabilitation through promotion of plasticity mechanisms and functional reorganization. Our group has demonstrated that chronic activation of the dentatothalamocortical pathway (DTC), via deep brain stimulation (DBS) of the cerebellar dentate nucleus (DN), enhances excitability

across widespread cortical regions. Moreover, we have shown that continuous DN DBS enhances chronic post-stroke motor rehabilitation in several rodent models of cerebral ischemia and a phase-I clinical trial in patients with post-stroke hemiparesis is currently underway. With the intent of identifying methods to predict efficacious DN DBS stimulation parameters via changes in cortical excitability, we investigated the effects of DN DBS on somatosensory evoked potentials (SSEPs) in a rodent model. SSEPs were generated in eight awake Long-Evans rats by stimulating the sciatic nerve with an implanted nerve cuff and recording cortical responses from EEG screws implanted above contralateral S1 hindlimb cortex. DBS was delivered to the rodent homologue of the DN ipsilateral to the stimulated sciatic nerve via an implanted concentric electrode. Each trial contained 5 minutes of SSEPs (DBS OFF), 5 minutes of rest, 2 minutes of DBS, and 5 minutes of SSEP concurrent with DBS (DBS ON). Peak-to-peak SSEP measurements were compared between the OFF and ON DBS conditions. Among recurring peaks in the SSEP waveforms, only the mid- and later-latency features exhibited significant elevations in peak-to-peak amplitude ratios of DBS ON to DBS OFF. When DBS was delivered at 30 Hz, peaks occurring near 16 and 21 ms after stimulation exhibited a 4.4% increase in peak-to-peak amplitude relative to DBS OFF ($p = 0.044$, Wilcoxon Signed Rank/Mixed Effects Model). When DBS was delivered at 100 Hz, peaks occurring near 16 and 21 ms after stimulation exhibited a 32.5% increase ($p = 0.018$) and peaks occurring near 21 and 36 ms after stimulation exhibited a 4.2% increase in peak-to-peak amplitude relative to DBS OFF ($p=0.003$). Elevations in SSEP peak-to-peak amplitude during DN DBS suggest that activation of the DTC pathway enhances excitability in structures generating the cortical SSEP response. Although significant, the changes in cortical excitability detected by SSEPs were modest and do not appear to be sufficiently robust to reliably predict efficacious DN DBS settings for stroke rehabilitation. Regardless, our findings expand upon the range of anatomical regions affected by DN DBS therapies.

Title: Somatostatin interneurons control critical dynamics

Authors: *T. RIBEIRO[1], M. VICTOR[1], E. GEIST[1], A. VAKILI[1], D. CHIALVO[2], D. PLENZ[1];
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Escuela de Ciencia y Tecnologia, Univ. Nacional de San Martin, San Martin, Argentina

Abstract: The critical brain dynamics hypothesis has gained a lot of attention since the seminal work of Beggs & Plenz, characterizing the so-called neuronal avalanches in 2003. Since then, criticality has been observed in a number of brain regions and spatial scales, ranging from hundreds of microns to the whole brain. Most importantly, criticality has been shown to optimize information processing, with deviations from it linked to disease states. Yet, the mechanisms employed by the brain to maintain this dynamical state are still poorly understood. One hypothesis is that the balance in excitatory-inhibitory (E-I) plays a key role. Here we study the relationship between critical dynamics and E-I balance in the visual cortex of awake mice subject to visual stimuli. We employed two-photon imaging of head-fixed mice positioned on a running wheel to infer spiking activity in neurons. Retinotopic mapping was performed to discriminate areas of the visual cortex. Viral-injection into cortical layer 2/3 resulted in robust expression of the genetically encoded calcium indicator (GECI) GCaMP7s. In order to measure effects of changes in the E-I balance, we also injected transgenic mice (PVCre, SST-Cre and VIP-Cre) with the Cre-dependent opsin ChrimsonR allowing us to optically drive those interneurons. A chronic cranial window was centered over the primary visual cortex (V1) and mice were subjected to passive viewing of drifting bars at different angles (1 s each, randomly chosen) at maximum contrast interspaced by 3 s of gray screen. During the experiment, for randomly selected trials, optogenetic drive of the opsin-expressing cells was achieved by either wide-field stimulation with a LED or individual-cell stimulation through a spatial-light modulator (SLM). At any point, mice could self-initiate locomotion. Pupil diameter was assessed continuously to measure the animal's state of arousal. More than ~150 neurons were recorded consistently in a ~450 x 450 μm area at a frame rate of ~45 Hz. We analyzed neuronal avalanche statistics in those populations with and without optogenetic drive. Avalanche dynamics as well as tuning properties changed during stimulation of SST interneurons. Furthermore, using a spatial correlation analysis recently introduced by Palmieri and Jensen, we observed deviations from the correlation structure predicted for criticality only during stimulation of SST interneurons, in line with the results obtained using avalanche statistics. We therefore conclude that the visual cortex maintains critical state dynamics and a particular E-I balance during visual processing through control of SST activity.

Title: Longitudinal quantification of neural activation in awake animals evoked by low-current intracortical microstimulation

Authors: *R. LYCKE, R. KIM, C. XIE, L. LUAN;
Neuroengineering Initiative, Rice Univ., Houston, TX

Abstract: The goal of brain-machine interfaces is to record neural activity and evoke meaningful sensations in the brain. Over the years researchers have developed tools and techniques to record and stimulate the brain with increasing spatial and temporal resolution, but stimulated sensations are often perceivably different than natural stimuli, due to classical electrical neural stimulation techniques exciting large populations of neurons rather than select neurons. Observing neural activity in response to natural stimuli, the neural activity can be quantified as ensembles of neurons activating in precise time for sensations, not synchronized bulk activations of a region. To better understand the nature of intracortical microstimulation and develop stimulation to precisely activate neural populations, our lab developed a procedure to electrically stimulate neurons paired with 2P imaging and neural recording in awake animals, quantifying the neural activation in response to stimulations of varying amplitudes and waveforms. Implanting flexible low profile Neural Electronic Thread (NET) electrodes in thy1-GCaMP6s mice, fluorescing neuronal calcium, paired stimulation and 2P imaging experiments were conducted. During experiments volumes of neural tissue was imaged, 1300 um x 1300 um x 500 um, quantifying neurons adjacent and distant from the stimulating electrode. It was observed with increasing stimulation current larger populations of neurons activated both adjacent to the stimulating electrode and at distal regions, with robust activation observed at low currents, less than 5 uA. Utilizing novel differential neural population analysis techniques, neural activation was measured in awake spontaneously behaving animals across multiple months. Investigating the activation response from neighboring electrode sites showed distinct differences in neural populations activated at varying currents. With these analysis techniques, individual neuron activation consistency was chronically quantified and longitudinal changes in the activated profiles across months were measured providing insights into the network stability of stimulated neural populations. These findings and tools to quantify the activated neural populations both define the stimulation capabilities of implanted electrodes and allow for precisely quantifying activated neuron ensembles responding to stimuli. Combing the ability to stimulate targeted populations of neurons with accurate quantifications of the neural ensembles during various external stimuli brings the field of neural engineering one step closer to artificially evoked naturalistic sensation.

Title: Acute ketamine disrupts state-dependent variation in network activity and functional connectivity in the mouse neocortex.

Authors: *R. L. OREN, C. J. BARNES, J. A. CARDIN, M. J. HIGLEY;
Dept. of Neurosci., Yale Univ., New Haven, CT

Abstract: Ketamine has emerged as a powerful experimental and therapeutic tool in understanding the links between brain activity and neuropsychiatric disorders. For example, schizophrenia is associated with profound disruptions of cognition and perception that can be mimicked by a single sub-anesthetic dose of ketamine. Schizophrenia patients also exhibit altered functional connectivity across the brain, including among primary sensory and higher-order cortical areas, that may also occur after ketamine administration. At lower doses, systemic ketamine has also been successful at relieving depression in human patients, a finding that is further supported by behavioral studies in rodents. However, the cellular and network mechanisms underlying these effects remain poorly understood. To more fully examine how administration of acute ketamine influences dynamic activity within the neocortex, we took advantage of a newly developed set of techniques for wide-field 'mesoscopic' calcium imaging in awake behaving mice able to freely move on a wheel. We imaged activity across the neocortex in mice expressing the calcium indicator GCaMP6s in either excitatory pyramidal neurons (PNs) or inhibitory parvalbumin-expressing interneurons (PV-INs). Mice received either a psychotomimetic dose of ketamine (30 mg/kg) or saline during alternating imaging sessions. We found that ketamine exerted a state-dependent effect on PNs, producing little effect during quiescence while blunting their activity during locomotion. This result was region-specific, with a few medial areas including the retrosplenial and primary motor cortices showing an increase in locomotion-induced activity after ketamine. In contrast, ketamine reduced activity in PV-INs for most areas regardless of behavioral state. Lastly, ketamine disrupted the long-range functional connectivity between cortical regions, a finding that was greater for PV-IN versus PN signals. In conclusion, our results demonstrate that acute, sub-anesthetic doses of ketamine drive significant alterations in the state-dependent patterned activity of large-scale cortical networks.

Title: State-dependent heterogeneity of cortical cholinergic and noradrenergic activity

Authors: L. N. COLLINS, J. FRANCIS, B. EMANUEL, D. A. MCCORMICK;
Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: Fluctuations in brain state, which are reflected in both behavioral state and widespread cortical activity, are likely supported by broadly projecting neuromodulatory systems. However, the extent to which specific neuromodulators operate synchronously across the brain or in a more regionally specific manner is unclear. It is possible that certain neuromodulatory systems function to provide either a global arousal signal or a more regionally, task-specific signal depending on brain or behavioral state. In this study, we examine spontaneous activity of cholinergic and noradrenergic axons in awake mice to determine the interaction between arousal state and neuromodulatory activity across the cortex. To monitor neuromodulatory activity across the cortex with cellular resolution, we use mesoscale two-photon calcium imaging, allowing for simultaneous monitoring of cortical axons separated by up to 5 mm. We confirm that activity within both basal forebrain-derived cholinergic cells and locus coeruleus-derived noradrenergic cells tracks arousal and behavioral state, providing evidence for a global arousal component for both systems. However, we find a striking decrease in global cholinergic signaling during locomotion but not whisking bouts and an increase in global noradrenergic signaling at the onset of whisking. This result suggests that during certain behavioral states these neuromodulatory systems switch from a global mode to a more regionally specific mode of neuromodulation. In addition, we characterize the activity of cholinergic interneurons in the cortex and find that approximately one third of this population of cells has arousal-linked activity. Together, our results provide evidence that cholinergic and noradrenergic neuromodulatory systems do indeed operate dynamically within the cortex, and that behavioral state is highly predictive of global synchrony in spontaneously active mice.

Title: Decoding the hippocampal oscillatory complexity to predict behaviour

Authors: *R. GOUTAGNY[1], V. DOUCHAMPS[2], D. BATTAGLIA[3];
[1]CNRS UMR7364, Strasbourg, France; [2]Psychology, Univ. of Strasbourg, Strasbourg, France; [3]INS, Univ. Aix-Marseille, Marseille, France

Abstract: Theta and gamma oscillations are believed to organise hippocampal activity. The current dominant view holds that two gamma frequency sub-bands occur at different theta phases in CA1, are produced by different generators and sub-serve different cognitive operations. Recent evidence suggested however that most individual theta cycles actually contain very diverse and complex gamma contents. We

thus aimed at exploring further this theta-gamma coupling diversity by using a new topological approach based on the detection of several individual gamma bouts per theta cycle. We applied this method to the LFPs recorded in all CA1 layers of mice performing a spatial reference memory task (n=5). These signals were filtered without a priori in a large gamma band (30-200 Hz) using an ensemble empiric mode decomposition. This revealed that gamma bursts could be found for nearly every combination of frequency, amplitude and theta-phase in all layers. Only when restricting the analysis to the theta cycles with very strong gamma bouts could we observe average patterns similar to those proposed in the dominant view and that, despite few of these cycles actually matching these averages. This suggests that the two gamma sub-band generators model might be inadequate. We propose, based on a simple computational model of two neuronal populations (excitatory and inhibitory), that each generator can produce the whole gamma spectrum but might be biased toward some frequencies by modulating the inhibitory-to-excitatory coupling. Importantly, the underlying complexity of theta-gamma coupling considered at the theta cycle timescale seems nonetheless to carry behavioural information: running speed and coarse position within the maze could be predicted by a machine learning algorithm from these seemingly stochastic properties of isolated theta cycles. In conclusion, we propose the existence of an interdependence between behaviour and the rich, complex and largely overlooked diversity of hippocampal theta-gamma oscillations that goes beyond a model with few discrete, mostly mutually-exclusive gamma types.

Title: Universal scaling in the synchronization of cortical cell assemblies

Authors: *E. CAPEK[1], T. L. RIBEIRO[1], P. KELLS[1], K. SRINIVASAN[1], S. R. MILLER[1], E. GEIST[1], M. VICTOR[1], A. VAKILI[1], D. CHIALVO[2], D. PLENZ[1];
[1]Section on Critical Brain Dynamics, Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Univ. Nacional de San Martín, Buenos Aires, Argentina

Abstract: Neuronal synchronization is fundamental to many theories on cortex function. Cortical neurons, by preferentially integrating nearby, recurrent activity with distant inputs, establish local and propagated synchrony in the form of oscillations, waves, and neuronal avalanches. These forms of synchrony benefit information processing by flexibly identifying neuronal subgroups; however, they also present with unique limitations. Oscillations emphasize phase-locked firing among neurons, yet the number of different patterns that can be phase-coded per cycle seems to be few. Waves represent compact spatial propagation, which limits their simultaneous occurrence within one region. Neuronal avalanches,

in contrast, constitute highly diverse, scale-invariant patterns of synchrony that carry attractively high information capacity. Yet, it is currently not clear whether, at the cellular level, avalanches exhibit precise unfolding of synchronization. The hallmark of neuronal avalanches has been their scale-invariant spatiotemporal statistics quantified by power laws in size and duration. When interpreted within the framework of self-organized criticality, power laws suggest a critical state of cortex that supports diverse and stable, potentially system-wide propagated synchronization. On the other hand, numerous alternative models that differ from synchronization have been proposed for the generation of power laws. In order to discriminate among generative avalanche models, a single scaling exponent χ can be calculated, which captures the relationships between the mean size of avalanches, as well as the corresponding collapse in avalanche shape for different avalanche durations. Here, we revisited the estimation of χ for neuronal avalanches using 2-photon imaging of pyramidal neurons in the cortex of awake transgenic mice. We show that the synchronization and propagation of pyramidal neuron groups exhibits the hallmark of neuronal avalanches during ongoing activity in prefrontal cortex as well as during visually evoked responses in primary visual cortex. Using temporal coarse graining, we demonstrate that $\chi = 2$ and establish a universal avalanche profile in the form of an inverted parabola. These scaling relationships are in line with recent results for LFP-based avalanches in nonhuman primates. Our findings demonstrate universal scaling of synchronized neuronal avalanches to guide the formation of cortical cell assemblies.

Title: Scale-free behavioral dynamics directly linked with scale-free cortical dynamics

Authors: S. A. JONES, J. H. BARFIELD, ***W. L. SHEW**;
Univ. of Arkansas, Fayetteville, AR

Abstract: Naturally occurring body movements and collective neural activity both exhibit complex dynamics, often with scale-free, fractal spatiotemporal structure. Scale-free dynamics of both brain and behavior are each associated with functional benefits to the organism. In cerebral cortex, the criticality hypothesis is often suggested to explain scale-free dynamics, but previous studies have not directly linked scale-free neural activity fluctuations with corresponding behavioral dynamics. This disconnect between the criticality hypothesis and behavior has long been a criticism of the hypothesis. Here we show that scale-free dynamics of mouse behavior and certain subsets of cortical neurons are one-to-one related. Indeed, we considered many distinct subsets of neurons and found that those with the broadest range of power-law scaling were most correlated with behavior. Surprisingly, the scale-free dynamics of these

subsets of neurons were obscured when considering the entire recorded population of neurons together. This was due to other subsets of neurons that were strongly anticorrelated with the scale-free subsets. The fluctuations of these anticorrelated subsets effectively canceled each other out, resulting in combined dynamics without scale-free fluctuations. This type of competitive critical dynamics is not explained by previous theory of critical neural systems, to our knowledge (but see adjacent poster by us for a new theory). Our results establish neural underpinnings of scale-free behavior and clear behavioral relevance of scale-free neural activity, which was previously thought to represent background noise in cerebral cortex.

Title: Winnerless competition among cortical neurons: a new theory of scale-free cortical dynamics

Authors: *J. H. BARFIELD[1], S. A. JONES[1], W. L. SHEW[2];
[1]Univ. of Arkansas, Fayetteville, AR; [2]Univ. of Arkansas Fayetteville, Fayetteville, AR

Abstract: Naturally occurring body movements and collective neural activity both exhibit complex dynamics, often with scale-free, fractal spatiotemporal structure. Scale-free dynamics of both brain and behavior are each associated with functional benefits to the organism. In the cerebral cortex, scale-free dynamics have often been explained by the criticality hypothesis, which supposes that cortical neural networks operate at the tipping point of a phase transition, between regimes of synchronous and asynchronous activity. However, previous models and theory of the criticality hypothesis do not explain some prominent recent experimental observations of scale-free neural activity (see nearby poster by us). These experiments showed that scale-free neural activity in visual cortex often occurs among certain subsets of neurons, while the population, as a whole, does not appear to have scale-free activity. This observation was attributed to strongly anticorrelated subsets of neurons whose fluctuations effectively cancel each other out, obscuring critical dynamics at the population level. Here we describe a model that can explain these observations and suggests a new type of critical dynamics not considered previously, to our knowledge. Our model is similar to winner-take-all models, previously used to study decision making. The model generates scale-free dynamics among anticorrelated subsets of neurons when it is tuned to operate at the tipping point between regimes of locked-in winner-take-all dynamics and stochastic winnerless switching. Our model offers a fresh view of the criticality hypothesis and suggests that criticality could play a role in decision making.

Title: Adrenergic signalling contributes to cardiorespiratory death after status epilepticus in an anesthetised rat model

Authors: *A. SABETGHADAM[1], H. EL BEHEIRY[2], A. EBRAHIMAMINI[3], A. PEIMANI[3], P. CARLEN[3,1];
[1]Fundamental Neurobio., Krembil Res. Inst., Toronto, ON, Canada; [2]Dept. of Anesthesia and Pain Med., [3]Biomed. Engin., Univ. of Toronto, Toronto, ON, Canada

Abstract: Background: Status epilepticus (SE) is a common neurological emergency with high mortality rate of 20% in generalized convulsive patients. We hypothesized that the peripheral cardiorespiratory complications due to activation of peripheral adrenoreceptors following seizure spread to brainstem mainly contributes to death in SE. **Methods:** We used adult male Wistar rats anesthetized with isoflurane (1.5-1.7%, mixed with 100% O2), tracheally intubated and connected to an artificial ventilator. Each animal was implanted with a cannulated bipolar stainless-steel electrode into the right hippocampal CA3 region to infuse kainic acid (KA) with simultaneous local field potential (LFP) recording. Medium-impedance glass electrodes were also implanted to record the LFPs of the left parietal cortex (PC) and the right brainstem rostroventrolateral medulla (RVLM) localized by a glutamate-related localization method. Electrocardiogram (ECG), cardiac and respiratory rates, respiratory and plasma gases (mmHg), pH, electrolyte, and glucose (mmol/l) were measured along with core temperature (°C) and cannulated arterial blood pressure (mmHg). In a separate set of experiment, animals (n=5) were pretreated with a non-selective alpha-adrenergic receptor blocker, phentolamine (10mg/kg, i.v.), 5 min before local KA infusion. **Results:** The results showed a gradual increase of blood pressure with increased rates of ventilation in the animal immediately following infusion with KA, which gradually decreased until the apnea occurred, usually within 10-15 min after KA infusion, which was always followed by asystole 5-7 min later. However, in phentolamine pretreated animals, phentolamine dose-dependently prolonged the window before animal become apneic. Also, in KA treated animals in which artificial ventilation was not successful, phentolamine could alleviate the attempted breathing period leading to animal survival. Blood pH, glucose and NE levels significantly increased after KA infusion with no significant change in the electrolyte concentrations. There was no change in the amplitude of the ECG; however there was arrythmia at the time of KA infusion which was associated with transient apnea at that time. **Conclusion:** Increased survival time and alleviated apnea was demonstrated in KA animals pretreated with a non-selective adrenergic receptor blocker, phentolamine, which is a drug of choice for the treatment of neurogenic pulmonary edema. This raises the possibility of pulmonary edema caused by adrenergic activation due to a catecholamine storm induced by brainstem RVLM activation. This process could be a potential cause of death in SE patients.

Title: Selective serotonin reuptake inhibitors and 5-HT_2 receptor agonists cause distinct, sleep-state dependent changes in postictal breathing in amygdala kindled mice

Authors: *K. G. JOYAL, A. N. PETRUCCI, M. V. LITTLEPAGE-SAUNDERS, N. A. BOODHOO, G. F. BUCHANAN;
Univ. of Iowa, Iowa City, IA

Abstract: Sudden unexpected death in epilepsy (SUDEP) is the leading cause of death in patients with refractory epilepsy. While the exact etiology of SUDEP is unclear, it is believed seizure-related respiratory failure is a major factor. SUDEP often occurs at night, possibly during sleep. Serotonin (5-HT) is implicated in SUDEP. 5-HT modulates breathing, sleep-wake, and seizure threshold and severity. We hypothesized that enhancing 5-HT tone prior seizure onset would increase postictal breathing frequency (f_R), tidal volume (V_T), minute ventilation (V_E) and breathing regularity and decrease periictal apnea. Since sleep state is implicated in SUDEP, seizures were induced during both wake and NREM sleep. 5-HT_2 receptors were targeted due to their implication in respiratory regulation and SUDEP. 16 adult (8-12 wks) male and female C57BL/6J mice were instrumented for EEG/EMG recording and implanted with a bipolar stimulating/recording electrode into the basolateral amygdala [AP: -1.3 mm; ML: -2.8 mm; DV: -4.7 mm]. After recovery, afterdischarge threshold determination, and kindling (80-380 mA; 1 s train of 1 msec biphasic square waves; 60 Hz; 2x/day), seizures were induced during wake and NREM sleep following treatment with vehicle; 5-HT_2 agonists, TCB-2 (10 mg/kg) and MK-212 (10 mg/kg); and selective 5-HT reuptake inhibitors (SSRI) citalopram (20 mg/kg) and fluoxetine (10 mg/kg), alone, or 15 min after 5-HT_2 receptor antagonists ketanserin (3 mg/kg) or RS-102221 (10 mg/kg). All drugs were given intraperitoneally 30-60 min prior to seizures. Citalopram and the 5-HT_{2C} agonist MK-212 had sleep state-dependent effects on f_R, V_T, and V_E during different postictal timepoints. Citalopram and fluoxetine eliminated ictal and postictal apneas, regardless of sleep state. MK-212 increased ictal apneas compared to vehicle when seizures were induced during NREM. Citalopram decreased breathing variability immediately after seizures compared to vehicle, but only with those induced during wake. This effect persisted when 5-HT_2 receptor antagonists were administered prior to citalopram. MK-212 decreased variability compared to vehicle in the later postictal period, regardless of sleep state. The 5-HT_{2A} agonist, TCB-2, had negligible effects on breathing compared to vehicle. Our results indicate that increasing available 5-HT and activating 5-HT_2 receptors cause distinct, sleep state-dependent changes in breathing following seizures induced in amygdala kindled mice. This suggests that the efficacy of 5-HT-enhancing

treatments on postictal breathing is sleep state dependent and that multiple serotonergic mechanisms govern recovery of eupnea in the postictal period.

Title: Extracellular field clamp can suppress generation of epileptiform activity

Authors: *M. SUBRAMANIAN, C.-C. CHIANG, D. DURAND;
Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: *Objective*: Epileptiform activity including spikes and seizures can propagate using electric fields independently of synaptic transmission. Recent studies also show that neural recruitment in epilepsy occurs in part due to electric field (ephaptic) coupling. Therefore, controlling the local electric field could suppress or cancel the generation of abnormally synchronized events. We tested the hypothesis that clamping the local extracellular electric fields can prevent the generation of epileptic spikes and seizures. *Methods*: Spontaneous epileptic spikes and seizures were induced using 4-aminopyridine in an *in vitro* experimental setup using longitudinal hippocampal slices from 4 mice. Two extracellular recording electrodes were used: R1 was placed in the cell layer at the edge of the temporal region of the hippocampal slice to detect the generation of the epileptic activity; R2 was placed in the septal region to observe the propagation of the activity along the longitudinal direction. Two stimulating electrodes S1-2 were placed outside the slice in the transverse direction at the edge of the Temporal region in line with R1. An extracellular voltage clamp system was connected to R1 and S1-2 and designed to maintain the voltage at R1 equal to zero by applying the appropriate feedback current between S1 and S2. *Results:* 4-AP induced spikes and seizures in the temporal region (R1) (focus) which were observed to propagate to the septal region (R2). The electric field produced by the applied current with the feedback circuit "on", cancelled the local extracellular electric field involved in the generation of the epileptic events as evidenced by the clamp achieving 100% suppression of both epileptic spikes and seizure events as observed by R1. No spikes or seizures were observed into the septal region with clamp was "on" at R2 showing complete suppression of epileptiform activity in this slice. Both the spikes and seizure events recovered as soon as the clamp was turned off. *Significance:* The results show that an extracellular clamp applied to a seizure "focus" can completely suppress the generation that epileptiform activity and prevent its propagation away from the focus. Although the spatial extent of the control is currently limited to the region around the recording site, this method could be effective to control seizure generation in a small known focus.

Title: Hibernation-like state presents a new approach to understanding and treating temporal lobe epilepsy

Authors: *T. M. MOKHOTHU[1], A. HIRANO[2], T. SAKURAI[2], K. Z. TANAKA[1];
[1]Okinawa Inst. of Sci. and Technol. (OIST), Okinawa, Japan; [2]Fac. of Medicine, Intl. Inst. for Integrative Sleep Med. (WPI-IIIS), Tsukuba Univ., Tsukuba, Japan

Abstract: Temporal Lobe Epilepsy (TLE) is a debilitating neurological disease with no cure. Treatments reportedly work in only two-thirds of the patients, and although much research is being done to develop more treatment lines, there is also a growing research interest focused on preventative measures to stop the disease before it becomes fully-fledged chronic epilepsy. To have effective targeted prevention strategies, we should first understand the changes in each stage of the disease progression and pinpoint the therapeutic windows. One such stage of the disease with immense potential for targeted therapy is the Latent phase, a silent/ seizure-free period between the initial insult and the first spontaneous seizure. The consensus is that this period comprises neuronal plasticity changes, aberrant gene expression, and changes in the resting-state functional connectivity between regions and hemispheres. The current study probes the question of whether the presence of a latent period is a determiner of chronic epilepsy or not. We, therefore, ask, if these processes should be stopped, could chronic epilepsy be prevented? We will pause latent period processes in the brain by inducing hibernation in mice following the pilocarpine induction of epilepsy. Using a transgenic mouse line, Qrfp-*iCre, which* expresses icre in Qrfp-expressing neurons in the hypothalamus, we can excite these neurons in a DREADD mediated paradigm, thus initiating a rapid reduction of overall metabolism, which effectively stops all action potentials and neuronal changes. We induce this hibernation-like state immediately after status epilepticus induction to artificially stop molecular, and plasticity changes typically occurring within the latent period and compare the seizure outcome through statistical analyses of spontaneous seizure onset, frequency, and severity in hibernated mice versus typical pilocarpine-induced mice with no hibernation. This experiment will allow us to evaluate whether a state of hibernation that halts the metabolic activities, which we believe governs the development of acute seizures into chronic seizures, is enough to impact the spontaneous recurrent seizures. This work will increase our understanding of the latent period and forge new research paths to further understand the mechanisms underlying epileptogenesis and expand on the timelines of intervention before chronicity.

Title: Rescue of intrinsic excitability of Lgi1-deficient CA3 neurons by recovery of Kv1.1 potassium channel.

Authors: *J. EXTREMET[1], J. RAMIREZ-FRANCO[1], L. MOLINIERES[1], N. BOUMEDINE[1], O. EL FAR[1], D. DEBANNE[2], M. RUSSIER[1];
[1]UNIS UMR 1072, Marseille, France; [2]UNIS - Umr_s 1072 - INSERM AMU, Marseille, France

Abstract: Leucine-rich Glioma Inactivated 1 (Lgi1) is a secreted glycoprotein in the central nervous system. It is targeted by auto-antibodies associated with Limbic Encephalitis (LE) and its deletion induces Autosomal Dominant Lateral Temporal Lobe Epilepsy. Accordingly, lethal epileptiform activity is observed in Lgi1 knock-out mice model (Boillot et al., 2014). It has been shown that Lgi1 deficiency leads to a decrease in axonal Kv1.1 channel density, a voltage-gated potassium channel subunit carrying I_D current that dampens intrinsic excitability and glutamate release (Seagar et al., 2017). In order to test whether Lgi1 controls intrinsic excitability through the expression of Kv1 channel-mediated I_D current, Lgi1 expression was rescued in Lgi1 KO neurons by single cell electroporation of Lgi1-encoding gene. Three days after the electroporation, the rescue of a wild-type electrophysiological phenotype was investigated. We evaluated changes in intrinsic excitability (IE) by patch-clamp recording of CA3 pyramidal neurons in current clamp. The Kv1.1-mediated I_D current were measured in voltage clamp and immunoreactivity of Kv1.1 potassium channel were quantified by immunohistochemistry to test the role of this channel in modulating the intrinsic excitability. We observed a reduction in IE and a higher sensitivity to dendrotoxin-K (DTx-K, a selective Kv1.1 subunit blocker) in KO neurons electroporated with Lgi1-encoding gene (KO/Lgi1 neurons). Restored IE was correlated to the rescue of the Kv1.1-mediated I_D current and Kv1.1 channel immunostaining at the Axon Initial Segment of KO/Lgi1 neurons. As Lgi1 is released extracellularly, we assessed its paracrine effect on IE and Kv1.1 immunostaining. We showed a partial rescue of IE in neurons adjacent to the KO/Lgi1 neurons with a change in Kv1.1 channel expression. We conclude that reintroducing the Lgi1 gene is sufficient to rescue IE in Lgi1-deficient neurons by restoring the expression of the Kv1.1 channel and that it affects IE of adjacent neurons through a paracrine effect.

Title: Gs967 reduces seizure activity in the zebrafish pentylenetetrazol model

Authors: *P. MILDER, J. MARRS, T. CUMMINS;
Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Epilepsy is a disease caused by the recurrent state of seizures, occurring due to an imbalance between neuronal inhibition and excitation (Scharfman, 2007). Thirty percent of patients with epilepsy do not respond to current anti-epileptic drug (AED) treatments, creating critical need to test current and novel AEDs to improve treatments for refractory patients. The pentylenetetrazol (PTZ) epilepsy model has been employed to test AEDs in both mammal and zebrafish models. We tested the novel AED compound GS967, which has been used in mice models and shown to be specifically effective for SCN8A epilepsy (Baker et al, 2014) and SCN2A epilepsy (Baker et al, 2018) within mice models. Due to GS967 positive efficacy in two different genetic epileptic models, we tested whether this novel compound is useful in the PTZ chemoconvulsant model and may treat generalized epilepsy. We tested two hypotheses: (1) the efficacy of GS967 depends on whether it is administered to zebrafish acutely with PTZ or pretreated with GS967 before PTZ exposure; and (2) the efficacy of GS967 can be demonstrated using various assays, including behavior, electroencephalogram (EEG), and calcium imaging (GCaMP). Pretreatment versus acute application of GS967 showed that GS967 pretreatment had a preventative effect against seizure induction and reduced seizures in acute treatments. We found that there was not a significant difference between the pretreatment groups and acute treatment groups' ability to reduce PTZ induced seizure activity in the behavioral experiments. We next tested acute treatment of the GS967 in the EEG and GCaMP assays using the observation window between 15 min post exposure and 30 min post exposure to see if the results matched the results correlated with the behavioral assays. Consistent and reproducible results in EEG, and GCaMP assays correlated with the behavioral experiments, strengthening and validating the findings using the GS967 AED reported here. This model system is being developed for its potential translational ability as an effective and efficient method to screen future novel AEDs, which could be useful for developing precision medicine and to guide clinicians in treatment choices for patients with refractory epilepsy.

Title: Mechanisms of neurological protection and death related with transcranial magnetic stimulation using kindled rats.

Authors: *W. MORENO ROMAN[1], P. RODRIGUEZ[2], L. F. HERNANDEZ, Jr.[2], M. RUBIO-OSORNIO[2], C. RUBIO[2];
[1]Inst. Nacional De Neurologia Y Neurocirugia MVZ, Mexico city, Mexico; [2]Inst. de Neurologia y Neurocirugia MVZ, Mexico city, Mexico

Abstract: Epilepsy is an extensively studied neurological disorder, research has been made from animal models to human experimentation, as a result there are several medications and some surgical treatments aim to control this disorder, despite this 30% of patients are hard to control. Transcranial magnetic stimulation (TMS) has been used as an anti-epileptic treatment and neuro-protective barrier, even though this is used as a treatment there is no cellular, molecular or physiological evidence to sustain this. The way we are evaluating cell death is with BCL-2, BAX, citocrom-c and caspase 3 and 8, all of this markers will tell us the pathway of cells death or protection. We are using 25 male Wistar rats, equally divided in five groups, the experimental and sham groups will get an electrode implant by a stereotaxic surgery at the amygdala, the implant will be use for the electrical stimuli using the Kindling model in the experimental group, once the subjects present the conduct associated to Racine 5 they will be randomly included to the TMS or kindling group, TMS group was stimulated before the electrical stimulus, each rat had its own time for the TMS which depended on the time of the last seizure, every EEG was analyzed in both groups, measuring amygdala and cortex response, after ten sessions in Racine 5 the rat will be decapitated immediately after the seizure, the brain will be extracted, dividing it in half, the right hemisphere will be fixated with paraffin for immunohistochemistry, the other half will be dissected for the bulbus olfactorius, motor cerebral cortex, hippocampus, amygdala and cerebellum. So far we have analyzed the EEG and the recordings for both experimental groups, the recording were also examined by a third party to compere the results, showing a difference between groups in a conduct stand of view, the time of seizures decreased as well in the TMS group. Based on the information above our preliminary results shows that there is a behavioral difference during the seizure, with the TMS group having less manifestations, and lower seizure time, with this results only we can say that TMS has an effect in epilepsy, the mechanisms in which the effect is made is still unclear. On the one hand, it can be from the neuro protection created, thus, limiting the recruitment of fibers and structures produced by the recruitment provoked by epilepsy. On the other hand, cell death can also be the cause of this behavioral changes, having fewer neurons to work within the structures affected will also reduce the time.

Title: Aceturate Diminazene Improves Cardiac parametrs and Remodeling in The Pilocarpine Model of Epilepsy

Authors: P. P. P. BRAGA, K. GOME, B. PACHECO, P. GHAZALE, C. QUINTINO, E. MENDES, M. BIANCARDI, F. ALCANTARA, A. P. PANSANI, C. H. CASTRO, ***D. COLUGNATI**;
Univ. Federal De Goiás, Goiânia, Brazil

Abstract: Sudden unexpected death in epilepsy (SUDEP) is a main cause of death in people with epilepsy, one of the factors underlying SUDEP is cardiovascular disorders. Thus, we aimed to analyze the effects of the diminazene aceturate (Dize), a potential activator of angiotensin-converting enzyme 2 (ACE2), on the cardiovascular function of rats with epilepsy. For epilepsy induction, we used the pilocarpine model in male Wistar rats. Four groups were formed: (1) CTL (non-epileptic rats treated with 1 ml/kg/day, 0.9% saline, s.c.); (2) EPI (epileptic rats treated with 1 ml/kg/day, 0.9% saline solution, s.c.); (3) DIZE (epileptic rats treated with diminazene aceturate 5 mg/ml/kg/day, s.c.); and (4) DIZE + A-779 (epileptic rats treated with diminazene aceturate 5 mg/ml/kg/day and the antagonist of Mas receptor - A779 120 µg/ml/kg/day, s.c.). Rats were video monitoring (24h/day) to confirm the first spontaneous seizures and only rats with spontaneous seizures of the chronic stage of epilepsy model. Treatment started 1 day after epileptic induction and lasted 60 days. Then cardiovascular function was measured *in vivo*: resting heart rate (HR) in conscious animals, blood pressure (BP), and left ventricular (LV) pressure in anesthetized animals. Also, morphological analyzes of the left ventricle were performed. The treatments do not alter the seizure frequency. Rats of the EPI (384.8 ± 6.4 bpm) group had a significantly higher resting HR than the animals from CTL (343.5 ± 9.3 bpm) and DIZE (345.9 ± 9.8 bpm) groups. In addition, combined treatment with diminazene and A-779 (DIZE+A779: 357.8 ± 14.4 bpm) attenuated the effects of Dize on HR. No significant changes were observed in both systolic and diastolic BP and either in the mean arterial pressure. LV systolic pressure was significantly higher only in rats of the EPI (140.4 ± 14.0 mmHg) group when compared to the CTL (115.3 ± 9.1 mmHg) and DIZE (120.6 ± 7.2 mmHg) and DIZE+A779 (122.6 ± 10.5 mmHg) groups. Cardiomyocyte hypertrophy and higher collagen deposition were observed in the hearts of the EPI (13.37 ± 0.10 µm and 15.54 ± 0.65 %, respectively) group when compared to CTL (13.00 ± 0.09 µm and 10.19 ± 0.67%) and DIZE (12.57 ± 0.07 µm and 10.44 ± 0.67%) groups. On the other hand, DIZE+A779 restored hypertrophy (14.96 ± 0.11 µm) and collagen deposition (18.52 ± 1.71 %) at even higher levels than those found in the EPI group. Taken together, we concluded that treatment with Dize restores cardiac function and remodeling induced by epilepsy, probably activating ACE2.

Title: Differential role of phyto-, synthetic- and endocannabinoids in Absence Epilepsy

Authors: *G. DI GIOVANNI[1,3], M. RADIC[1], T. MORAIS[3,1], F. DELICATA[2], V. CRUNELLI[3];

Abstract: The use of medical/recreational marijuana and its legal market size are on the rise worldwide. Medical Marijuana has potential benefits for different diseases, but the lack of biomedical research and its popularity based on anecdotal evidence poses a risk to society.For instance, medical use of cannabis and derived cannabinoids show promising results in severe paediatric epilepsies. However, cannabinoids acting on the endogenous cannabinoid system can aggravate different types of seizures.Here we have clarified how the cannabinoids affect absence seizure, the most common childhood epilepsy. The failure of first and second monotherapy with anti-absence drugs in 25% of children with absence seizures and the high rate of comorbidity, including attention-deficit-hyperactivity-disorders and learning/memory impairment (which persist in seizure-free children), demand novel therapeutic approaches and the cannabinoid system may be a promising target.Using cutting-edge in vivo and in vitro electrophysiological techniques, we have investigated the effect of drugs that increase the concentration of endogenous cannabinoids in absence seizures GAERS model by blocking key catabolic enzymes. Moreover, we have characterized the effect of exogenous cannabinoids in this absence seizure model. Our preliminary data indicate a complex role of exogenous versus endocannabinoids in controlling absence seizures.Since endocannabinoid modulators with an excellent safety record in humans are already available, our data may identify new targets that in the medium-term lead to a novel treatment for absence and their comorbidity.

Title: Electrophysiological Properties of Human Stem Cell-derived Neurons in Long-term Cell Culture: a Model for Antiseizure Drug Discovery?

Authors: *H. SALMANZADEH[1], R. F. HALLIWELL[2];
[1]Thomas J. Long Sch. of Pharm., Univ. of the pacific, Stockton, CA; [2]Thomas J. Long Sch. of Pharm., Univ. of the Pacific, Stockton, CA

Abstract: The identification and isolation of human stem cells from embryonic, adult and induced pluripotent stem cells (iPSCs) has revolutionized the availability of human neurons for disease modeling and drug discovery [1]. Studies in our lab address the neuropharmacological properties of receptors and ion channels expressed in neurons derived from human stem cell lines [2]. In the current study, we

utilized phase-contrast microscopy, immunocytochemistry and a multi-electrode array (MEA) system to determine the formation of neural networks in TERA2.cl.SP12 stem cell-derived neurons maintained in cell culture for up to 1 year.
The proportion of human stem cells differentiating to a neural phenotype, as indicated by β-III tubulin and MAP2 immunocytochemistry, increased over the first 3 months from approximately 5% at day 10 to ≥35% at day 80 *in vitro*. Using the MEA to record from populations of stem cell-derived neurons, we observed spontaneous spike-like activity from week 2 *in vitro* and burst firing from single cells at week 14. The spontaneously occurring spikes were inhibited by the ion channel modulators, tetrodotoxin (10nM), retigabine (1-10μM) and nifedipine (10μM), consistent with the generation of action potentials in these cells. The development of synchronous action potential firing across multiple neurons only developed by week 9 indicating the formation of neural networks. Utilizing multiple receptor antagonists and allosteric receptor modulators our pharmacological experiments showed that neurotransmission in the maturing neural networks was mediated *via* glutamate and $GABA_A$ receptors, the major excitatory and inhibitory systems in the mammalian brain, respectively.
To investigate the potential of our model for epilepsy studies, epileptiform activity was induced by 4-aminopyridine (100μM), a well-established convulsant agent in *vivo* and *vitro*. Pharmacological experiments showed the antiepileptic drugs topiramate, ethosuximide and carbamazepine significantly reduced seizure-like activity, supporting the potential of this model for drug discovery. To further test this hypothesis, we investigated the effects of the NSAID mefenamic acid on neural activity, because it also modulates $GABA_A$ receptors suggesting it might act as an anticonvulsant [3]. Mefenamic acid (100μM) reduced spike rate, number of neuronal and network bursts and epileptiform activity induced by 4-aminopyridine (100μM), suggesting an antiseizure role for this old drug. In conclusion, our data support the value of human stem cells and their neural derivatives in drug discovery.

Title: Evaluating effects of reversing distinct facets of immunosuppression in experimental GBM

Authors: *K. AYASOUFI[1], *Z. TRITZ[1], C. PFALLER[3], *L. GULBICKI[1], C. E. FAIN[2], R. KHADKA[1], F. JIN[1], M. J. HANSEN[1], A. J. JOHNSON[1];

Abstract: Glioblastoma is associated with severe and multifaceted immunosuppression affecting all immune organs. Immunosuppression in GBM is a critical barrier to the success of immunotherapies and patient survival. We demonstrated that immunosuppression in the GL261-model of experimental GBM presents with significant thymic and spleen atrophy, MHCII downregulation, presence of potent immunosuppressive factors in serum, and sequestration of T-cells in the bone marrow. Parabiosis studies determined that soluble factors with molecular weights larger than 100 kDa mediate immunosuppression by inhibiting T-cell proliferation, thymic involution, and loss of peripheral T-cells. In contrast, bone marrow T-cell sequestration was not mediated through soluble factors. While the immunosuppression in GBM is severe, a causative link between each facet of immunosuppression and overall survival is lacking. We used an immunotherapeutic strategy to block T-cell sequestration into the bone marrow and evaluated the extent survival was impacted in experimental GBM. We evaluated the extent a novel and off-the-shelf combination immunotherapy that uses extended 1/2-life IL-2 and anti-PD-1 reverses bone marrow T-cell sequestration. Sham treatment or anti-PD1 monotherapy did not alter T-cell sequestration in the bone marrow and animals had no enhanced survival. Extended 1/2-life IL-2 monotherapy and combination strategy both prevented T-cell sequestration into the bone marrow. However, only combined therapy, which also prevented MHC class II downregulation, improved survival. In addition, we determined that when splenocytes were exposed to serum isolated from glioma-bearing mice, MHCII levels were down regulated. Current studies in our lab are underway to determine the identity of the immunosuppressive factors in serum. In short, bone marrow T-cell sequestration alone does not correspond with overall survival in experimental glioma. Importantly, a concerted effort to reverse MHC class II downregulation and define inhibitory circulating factors may have the highest impact in immunotherapeutic efficacy and improving patient survival.

Title: Rhesus Monkey Model of Hypertension: 2-Kidney 1-Clip Induction of Renovascular Hypertension

Authors: *K. M. NIST[1], N. ARINZE[4], M. MEDALLA[2], D. L. ROSENE[5], R. D. WAINFORD[3], T. L. MOORE[6];

Abstract: AIM: The prevalence of hypertension (HT) increases with age and is the leading risk factor for cerebrovascular disease and cognitive decline. Both HT and aging are associated with increased neuroinflammation. While studies in rodent models of HT have shown evidence of HT related increases in neuroinflammation, the combined effect of HT and aging on neuroinflammation remains unclear with no data for the primate brain. To address this gap in knowledge, we developed a model of renovascular HT in the aging rhesus monkey to explore the concomitant effects on the brain in an animal similar to human brain.
METHODS: In this pilot study, three middle aged rhesus monkeys (2 females- AM363K, AM364K and 1 male- SM065K) underwent a well-established surgical procedure that involved placing an obstructing clip on the renal artery to 1 kidney (2-kidney 1-clip (2K1C) procedure), resulting in a significant reduction of blood flow to one kidney thereby inducing renovascular HT. Following surgery, blood pressure (BP) was measured biweekly using electronic oscillometry and blood was collected at various time points for analysis. BP measurements and blood values were compared to those from a male spontaneously HT monkey (AM379) in which BP was measured monthly over 5 months and clinical chemistry and complete blood counts were obtained via femoral artery puncture at euthanasia.
RESULTS: Over the course of a year, BP in 2K1C monkeys ranged from 116-235 mmHg systolic and with a mean increase of ~23 mmHg from baseline. AM379 had spontaneously occurring elevations in blood pressure indicative of severe hypertension (ranging from 163-184). Total Cholesterol, Potassium, Sodium, and Chloride were above normal limits in the 2K1C and the spontaneous HT monkey while total protein was lower than normal limits.
CONCLUSIONS: Monkeys who underwent 2K1C procedure became hypertensive and showed similar changes in blood chemistries to that of a monkey with spontaneously HT. Brain tissue from prefrontal cortex, an area known to be susceptible to HT and aging, is being analyzed with immunohistochemical methods in comparison with and normotensive age-matched controls. Markers being assessed include microglial reactivity (using antibodies against Iba1 and LN3) and cerebrovascular stiffness (using antibodies against collagen IV). Based on rodent studies, we hypothesize that immunohistochemical analysis of markers of neuroinflammation and vascular stiffening will be elevated in the HT monkeys compared to age-matched controls. These results will provide a basis for future studies of the effects of HT on markers of oxidative stress (8OHG and 4HNE), myelin damage, and how they may underly cognitive decline.

Ultrasound, Tongji Hospital, Tongji Med. College, Wuhan City, Hubei Province, China, Wuhan, China

Abstract: Aging-related cognitive decline is an emerging health crisis; however, no established unifying mechanism has been identified for the cognitive impairments seen in an aging population. A vascular hypothesis of cognitive decline has been proposed but is difficult to test given the contradictory radiologic needs of high-fidelity microvascular imaging resolution and a broad and deep brain imaging field of view. Super-resolution ultrasound localization microscopy (ULM) offers a potential solution by exploiting circulating microbubbles to achieve a vascular resolution approaching the capillary scale without sacrificing imaging depth. In this report, we apply ULM imaging to a mouse model of aging and quantify differences in cerebral vascularity, blood velocity, and vessel tortuosity across several brain regions. We found significant decreases in blood velocity, and significant increases in vascular tortuosity, across all brain regions in the aged cohort, and significant decreases in blood volume in the cerebral cortex. These data provide the first-ever measurements of subcortical microvascular dynamics *in vivo* and reveal that aging has a major impact on these measurements.

Cavanilles, Univ. of Valencia, Valencia, Spain

Abstract: Hydrocephalus is a neurologic disturbance produced by the abnormal production, circulation, and absorption of cerebrospinal fluid (CSF), which expands the ventricular system. The aqueduct of Sylvius is the narrowest portion of the entire ventricular system that communicates the third ventricle with the fourth one. The occlusion of this structure or severe stenosis is considered as a predisposing factor for hydrocephalus development. Late-onset idiopathic aqueductal stenosis induces normal pressure hydrocephalus (NPH) in adults. To date, no animal model replicating chronic NPH is available to study the pathophysiological changes observed in these subjects. Herein, we characterize an experimental model that induces chronic hydrocephalus in the adult mouse brain by producing a pre-aqueductual semiobstruction into the atrium of the aqueduct of Sylvius. This model generates a long-term ventricular enlargement with normal intracranial pressure and moderate glial reactivity. Importantly, this mouse model allows the reversibility of the ventricular enlargement after the removal of the obstructive film from the brain. This animal model may be useful to study the long-term cerebral alterations that occur during NPH or after its surgical resolution.

Title: Cytokines play a pivotal role in modulating the risk of both periodontitis and Alzheimer's disease

Authors: *R. P.-H. WANG[1], W.-K. LEUNG[2], T. GOTO[4], J. Y.-S. HO[5], R. C. CHANG[1,3];
[1]Lab. of Neurodegenerative Diseases, Sch. of Biomed. Sciences, LKS Fac. of Med., [2]Fac. of Dent., [3]State Key Lab. of Brain and Cognitive Sci., Univ. of Hong Kong, Hong Kong, China; [4]Div. of Oral Anat. and Histology, Grad. Sch. of Med. and Dent. Sci., Kagoshima Univ., Kagoshima, Japan; [5]Sch. of Nursing, The Hong Kong Polytechnic Univ., Hong Kong, China

Abstract: Periodontitis is a common health problem in the elderly, which can induce chronic systemic inflammation. We have been studying how systemic inflammation affects the brain immune responses, which can then affect progression of AD. We aimed to define the roles of cytokines in the pathogenesis of periodontitis and AD. By employing Micro-CT (micro-computed tomography) scan, our data revealed that in comparison to young mice, aged mice displayed significantly increased periodontal bone loss. The increased periodontal bone loss observed in aged mice was also accompanied by elevated levels of

inflammatory cytokines in the gums and the brain. The age-dependent increase in periodontal bone loss and elevated levels of cytokines in the gums and the brain of WT mice led us to further question whether cytokines play a key role in modulating the risk of periodontitis and AD. To address the question, female WT mice were injected with heat-killed *Porphyromonas gingivalis* bacteria into their buccal mucosa three times per week every other week for a total of 5 weeks to induce periodontitis. It was found that mice injected with heat-killed bacteria displayed worsened long-term memory functions. Bacterial-induced periodontitis also significantly increased periodontal bone loss and inflammatory cytokine levels in the gums of WT mice. In addition, bacterial-induced periodontitis led to significant elevated levels of inflammatory cytokines in the liver as well as different brain regions. Immunostaining and western blot analysis revealed significant increased levels of phospho-tau in WT mice injected with heat-killed bacteria. To further demonstrate the importance of inflammatory cytokines in modulating the risk of periodontitis and AD, another group of female WT mice were injected with IL-1β and TNF-α into their buccal mucosa three times per week every other week for a total of 5 weeks. It was found that mice injected with cytokines displayed hyperactivity and worsened short-term memory functions. Injections of IL-1β and TNF-α also induced periodontal bone loss in mice, which was accompanied by elevated levels of inflammatory cytokines in the liver as well as different brain regions. Taken together, our current study revealed that increased cytokine innate immune response in the gums led to periodontal bone loss and modulated the cognitive functions of mice. This research demonstrated that cytokines play a crucial role in the process of aging as well as the pathogenesis of periodontitis and AD.

Abstract: Aging, which acts as the major risk factor for Alzheimer's disease (AD) and other neurodegenerative diseases, results in deleterious changes in the brain. Emerging data has demonstrated that exposure to youthful-blood factors counteracts age-related decline in brain function. Specifically, the blood-borne, youth-associated factor tissue inhibitor of metalloproteinases-2 (TIMP2) was shown to revitalize aged mouse hippocampus and to be necessary for human plasma-induced synaptic plasticity and memory improvements in aged mice. Moreover, local depletion of TIMP2 impairs hippocampal long-

term potentiation (LTP), arguing for an unexplored critical role in hippocampal function. However, its mechanism of action in the hippocampus under normal conditions remains unclear. To begin to examine how TIMP2 regulates hippocampus-dependent function, we deleted TIMP2 and evaluated performance of the resulting mice in novel location recognition, contextual fear-conditioning, and Barnes maze tasks. We observed striking memory deficits in TIMP2 mutant mice and in a manner that is unrelated to perturbations in motor function. To examine molecular processes within the brain that are disrupted by TIMP2 deletion, we examined networks of transcriptomic changes within hippocampus, as assessed by RNAseq. We find changes in networks related to synapse organization, memory, and neurogenesis. To link these transcriptomic changes to changes in the hippocampal cellular microenvironment, we examined adult hippocampal neurogenesis, neuroinflammation, and other markers of plasticity. We find cellular changes that are consistent with the cognitive deficits we observed with TIMP2 deletion. We find that levels of TIMP2's canonical target, MMP2, are perturbed in hippocampi from TIMP2 mutant mice, suggesting that TIMP2 may alter function through regulation of the extracellular matrix. Ongoing work is focused towards further isolating the molecular events tying TIMP2 to hippocampal function. Together, our data define novel putative mechanisms through which TIMP2 regulates hippocampus-dependent function under normal conditions, potentially informing novel targets for aging and AD-associated therapies.

Abstract: Aging is associated with abnormalities in circulating glucose, altered secretion of glucocorticoids, and synaptic changes within the hippocampus, a brain region involved in cognition and regulation of homeostasis. These disturbances are particularly evident in Alzheimer's disease (AD), supporting a theory wherein age-related deficits in neural glucose metabolism underlie bioenergetic disruptions that contribute to memory loss and dyshomeostasis in AD. With the goal of elucidating the precise features of brain aging that could feasibly mediate this relationship, we evaluated differences in peripheral glucose regulation and central expression of glucose metabolizing enzymes in young adult (6 months) and aged (24 months) male F344×Brown Norway F1 hybrid rats. First, we observed blood glucose levels were significantly elevated in aged rats, but insensitive to modulation by glucocorticoids released when challenged with an acute stressor. Further, age-related differences in glucose modulation occurred in the absence of significant differences in liver glycogen content, measured after overnight fast. Second, level of phosphofructokinase-1 (PFK-1), which is the rate limiting enzyme of glycolysis, was marginally greater in aged hippocampal synapses whereas level of glyceraldehyde-3-phosphate dehydrogenase (GAPDH), another glycolytic enzyme, tended to decrease with age. Third, age-related changes to metabolic signatures in hippocampal synapses may be specific to glycolysis as we observed no difference in protein levels of representative enzyme subunits that comprise the mitochondrial electron transport chain, which are required for oxidative phosphorylation. Our initial findings exhibit how normally aging rats are a translationally useful model to examine the antecedents and consequences of glucose dysregulation. During aging, differences in peripheral glucose metabolism coincide with changes to glycolytic enzymes in hippocampal synapses without affecting mitochondrial abundance. Ongoing experimentation will examine the degree to which age-related alterations in peripheral and central glucose metabolism relate to memory function and whether variations in expression or trafficking of neural glucose transporters contribute to the metabolic insufficiency of aging synapses.

Title: Ketogenic diet improves memory and mitochondrial function in hippocampus of aging female rats

Authors: *T. J. COX[1], E. GORMAN-SANDLER[1], D. J. HOROVITZ[1], K. VELAZQUEZ[2], R. T. ENOS[2], F. HOLLIS[1], J. A. MCQUAIL[1];

Abstract: Metabolic irregularities of the aging brain are linked to severity of cognitive symptoms in the age-associated neurological disorder Alzheimer's disease (AD). Age- and disease-related defects in cerebral glucose utilization are proposed to limit metabolically demanding neural processes, such as synaptic neurotransmission, that are essential for normal memory function. Under circumstances of limited glucose, neurons can effectively metabolize fat-derived ketone bodies to replenish cellular energy needs. Unlike glucose, ketone bodies can cross cell membranes and directly fuel oxidative phosphorylation by mitochondria to produce ATP. This leads to the hypothesis that feeding a "ketogenic" diet, which elevates ketone bodies whilst attenuating blood glucose, could rescue memory in aging through a mechanism that involves improved function of synaptic mitochondria in the hippocampus. To test this hypothesis, we fed young adult (6 months) and aged (24 months) F344 × Brown Norway F1 hybrid rats a ketogenic (KETO) diet, enriched with medium-chain triglycerides, and evaluated behavioral and metabolic changes relative to identically aged rats fed a calorie-matched control diet that provided most energy in the form of carbohydrates. Weekly blood metabolite testing determined that all KETO-fed rats, regardless of age, entered ketosis within 1-2 weeks and maintained similar levels throughout the duration of the study. In the 6th week of diet, cognition was tested in the spatial reference memory-version of the Morris water maze. Consistent with prior work, aging impaired spatial learning and accuracy of spatial search was lower in females compared to males. KETO diet improved cognition in young and aged females relative to age-matched females consuming control diet; KETO produced no effect in males of any age. In the 8th week of diet, mitochondrial function in isolated hippocampal synaptic terminals was evaluated using substrate stimulated respirometry. In line with our behavioral results, we observed that respiration and spare capacity of mitochondria from aged females was lower than aged males maintained on a control diet and this effect was reversed in aged females who consumed the KETO diet. KETO diet had no effect on male hippocampal mitochondrial respiration at any age. These findings support our hypothesis that a ketogenic diet can improve memory by augmenting mitochondrial function in aging synapses, but also demonstrate that enhancing effects on brain and memory are most pronounced in females. Collectively, KETO may be a viable strategy to protect neural health, especially in aging women.

Title: Excitatory and inhibitory synapses in dorsal CA3 distinguish cognitive reserve from decline in normal aging

Authors: *D. J. HOROVITZ, L. A. ASKINS, G. M. REGNIER, J. A. MCQUAIL;
Pharmacology, Physiology, and Neurosci., Univ. of South Carolina, Columbia, SC

Abstract: Aging is characterized by declining memory and escalating risk for Alzheimer's disease (AD). Anomalous patterns of hippocampal activity manifest in prodromal AD, wherein a shift in the excitatory-inhibitory (E/I) dynamic signals the transition from normal brain aging to neurological disease. E/I imbalance is most evident within the dentate gyrus (DG)-CA3 network and is proposed to underlie age-related deficits in spatial learning that are ascribed to the dorsal, but not the ventral, hippocampus. Collectively, these observations indicate that a neuroanatomically precise characterization of changes to excitatory and inhibitory hippocampal synapses could elucidate the circuit basis of memory changes that confer age-associated risk for AD. Consequently, we quantified changes to VGluT1, a marker of glutamatergic synapses, and VGAT, a marker of GABAergic synapses, in hippocampal sections from young 6-months old F344×Brown-Norway F1 rats relative to strain-matched 24-months old rats that were rated as spatial-learning unimpaired (24M-U) or impaired (24M-I) based on performance in the Morris water maze. We identified significantly higher VGAT in the dorsal CA3 and CA1 of 24M-U rats compared to 24M-I rats. We also observed a significant decline of VGluT1 levels in the dorsal CA3 of 24M-I rats compared to 6M rats. Using a follow-up approach that leverages the full range of individual differences in spatial learning, correlational analyses applied across the entire spectrum of aged performance revealed significant relationships between spatial learning decrements and lower level of VGAT in multiple synaptic layers of the dorsal CA3 and CA1, including the strata radiatum (SR) and lacunosum moleculare (SLM). VGluT1 levels, however, were only correlated with SLM of the dorsal CA3. Further, we did not detect evidence for significant changes to E/I balance ventral hippocampal subregions or adjacent neural structures including the entorhinal and perirhinal cortices or the basolateral amygdala. These new findings are consistent with our hypothesis that E/I disruption centered on dorsal DG-CA3 network is of special relevance to age-related memory loss. More specifically, distributed augmentation of inhibitory synapses is associated with preserved spatial memory in aging whereas comparatively targeted deterioration of glutamatergic terminals synapsing upon apical dendrites of CA3 pyramidal neurons is indicative of memory loss. Overall, these data identify potential, complementary mechanisms that contribute to different rates of cognitive changes over the lifespan.

Title: Periventricular alterations and neuroinflammation in juvenile pigs with hydrocephalus

Authors: *M. GARCIA-BONILLA[1], L. CASTANEYRA-RUIZ[1], S. ZWICK[1], M. TALCOTT[2], D. MORALES[2], A. ISAACS[3], D. LIMBRICK JR.[2], P. MCALLISTER[2];

Abstract: Background Ventriculomegaly, white matter injury, inflammation, edema, and gliosis are the common neuropathologies in hydrocephalus in humans and experimental models. Our group has developed a large animal model of acquired hydrocephalus in juvenile pigs to evaluate the current treatments. We hypothesized that hydrocephalus is associated with subventricular and periventricular alterations and neuroinflammation that could mimic the neuropathology described in humans.
Methods Hydrocephalus was induced by percutaneous intracisternal kaolin injections in 35-day old pigs (n=7). Age-matched sham controls received saline injections (n=6). At 30-days post-induction, MRI, immunohistochemistry, flow cytometry, and cerebrospinal fluid (CSF) protein analyses were performed.
ResultsVentriculomegaly was especially pronounced in the body of the lateral ventricle (mean 2237 ± SD 1590 mm^3) compared with controls (2251 ± 86.8 mm^3), where ependymal disruption occurred. In this area, the periventricular white matter showed a 44% increase in cell death ($p<0.05$) and a 67% reduction of oligodendrocytes ($p<0.01$). In the subventricular zone (SVZ), the number of proliferative cells and oligodendrocyte progenitors decreased by 75% and 57% respectively ($p<0.01$). The SVZ size reduced when the ventricular volume increased ($R^2=0.6065$, $p<0.03$). Neuroinflammation occurred in the hydrocephalic pigs with an increase of astrocytes and microglia in the periventricular white matter ($p<0.02$), and high levels of inflammatory interleukins IL-6 and IL-8 in the CSF ($p<0.01$). Reactive microglia were prevalent showing reduced filament volume and length, and the number of branches ($p<0.03$).
Conclusion Acquired hydrocephalus produced changes in the periventricular white matter, reduced cell proliferation in the SVZ, and neuroinflammation. These findings mimic those found in human hydrocephalus, demonstrating that the pig model can be a useful tool for preclinical studies of the pathophysiology of hydrocephalus.

Title: Repurposing BT-11 for Treatment of Alzheimer's Disease

Authors: *E. BIRNBAUM[1,4], L. XIE[2], C. HENCHCLIFFE[6,5], P. SERRANO[3], P. ROCKWELL[1], M. FIGUEIREDO-PEREIRA[1];

Abstract: Alzheimer's disease (AD) is a devastating neurodegenerative disease with annual costs of over $300 billion. AD is characterized by the accumulation of amyloid plaques and tau neurofibrillary tangles, as well as chronic neuroinflammation, loss of neuronal connections, and neuronal cell death. Therapeutic strategies aimed at treating two of these key hallmarks of AD, i.e. amyloid plaques and tau tangles, have so far been unsuccessful at halting or reversing disease progression. Research points towards the pathology of neuroinflammation as an important target for treatment of AD. BT-11 is an orally active lanthionine synthetase C-like 2 (LANCL2) binding compound that has potential to treat AD based on clinical trials in Irritable Bowel Disease (IBD), demonstrating its immunomodulatory properties. This BT-11 benefit is relevant to AD, as AD is characterized by an imbalance in pro-inflammatory and anti-inflammatory signaling, allowing inflammation to go unchecked. Based on its ability to modulate inflammation through targeting LANCL2, and on in silico studies, BT-11 is a drug that could be repurposed to treat AD. Our studies utilized a transgenic rat model (TgF344- AD) that is unique as it exhibits hippocampal-dependent spatial learning and memory deficits, as well as hippocampal AD pathology in a progressive age-dependent manner that mimics the pathology exhibited by AD patients. BT-11 was administered orally to a cohort of WT and Tg-AD rats for 6 months, beginning at 5 months of age (pre-pathology) to 11 months of age (full AD-pathology). Age-matched, non-treated WT and Tg-AD rats were included as controls. At 11 months of age, spatial learning and memory were evaluated with an active place avoidance task that is hippocampal-dependent. At 11 months of age, untreated male Tg rats showed significant spatial learning and memory deficits compared to male WT rats. BT-11 treatment mitigated these deficits and showed learning improvements in Tg rats as compared to untreated Tg rats. Our results support that BT-11 is a potential drug candidate for AD treatment.

Abstract: Systemic immune dysfunction can catalise onset of Alzheimer's disease. Obesity, one of the strongest risk factors for AD, causes profound metabolic and immune perturbations. Here we hypothesized that changes in circulating metabolites associated with obesity might impair the ability of the immune system to cope with disease. To approach this, we used AD-prone 5xFAD mice, and wild-type controls, fed with high-fat diet (HFD), or control diet (CD). Using the novel object recognition assay, we found that the HFD impaired cognition specifically in 5xFAD mice. The worse cognitive performance was associated with increased neuronal loss and astrogliosis compared to CD-fed 5xFAD mice. Using a combination of flow cytometry and mass cytometry (CyTOF), we found that the HFD induced immune perturbations specifically in 5xFAD mice. In particular, we found increased frequencies of immune suppressive regulatory T cells and CD4+ effector memory T cells expressing markers of exhaustion. Next, we sought to characterize the metabolites that might be associated with the observed cognitive and immune changes. To this end, we performed non-targeted metabolomics of the blood and identified N-acetylneuraminic acid, or NANA, as the metabolite that was most strongly correlated with the obese-AD comorbid state. On a single-cell transcriptomic level, we found that the diet and AD pathology independently affected the hippocampal cell fate, thus suggesting a compound effect on brain cell vulnerability of both conditions. Interestingly, single-cell analysis of the visceral adipose tissue revealed increased proportions of macrophages expressing the gene Neu1 in the obese state. Neu1 codes for an enzyme that generates NANA. Therefore, increased NEU1 enzymatic activity in the adipose in obese condition might be one of the sources of increased NANA in the circulation. To mechanistically connect NANA to immune dysfunction, we injected NANA in regularly-fed WT mice, and found that NANA recapitulated the same immune perturbations observed in obese 5xFAD mice. Finally, using human T cell cultures, we found that NANA impaired T-cell proliferation and altered several transcriptional programmes associated with T-cell differentiation. To sum up, our results are in line with the notion that AD not only is a brain disease, but also an immune disease, and that the brain and immune aspects of the pathology are connected. In particular, we identified NANA as an obesity-induced modifying factor of AD through immune-exhausting effects. Finally, our findings imply that restoring T-cell function and targeting NANA might be applicable approaches to fight AD.

Abstract: Aims:Microglia are strongly implicated in the development and progression of Alzheimer’s disease (AD). To further understand how microglia impact AD pathology, we crossed 5xfAD mice with ‘FIRE’ mice, a novel model that genetically lacks microglia. Compared to other genetic or pharmacological methods, this new approach allows one to understand how a consistent absence of microglia impacts disease progression. The resulting empty microglia niche also enables the robust repopulation of microglia from genetically modified donors. Methods:‘FIRE’ mice harboring a deletion in the fms-intronic regulatory element of CSF1R and lack microglia were backcrossed with 5xfAD mice. Immunohistochemical and biochemical analysis was used to determine the impact of microglial absence on disease pathology. In addition, transplantation of wild-type donor microglia was performed to determine the impact of microglial replacement on these endpoints. Results:Pharmacological depletion of microglial has not been reported to effect AD mouse mortality. In contrast, we found that FIREKO-5xFAD mice that genetically lack microglia, exhibit a significantly shortened lifespan, with few mice reaching 6 months of age. Interestingly, this increased mortality is accompanied by a significant reduction in parenchymal beta-amyloid plaques intensity, but a dramatic increase in cerebral amyloid angiopathy (CAA) and other signs of blood brain barrier (BBB) pathology and disruption. Remarkably, transplantation of Wild Type donor microglia rescues many, but not all, of these changes. Conclusion:The FIREKO-5xFAD model provides a novel platform to determine how microglia influence the relationship

between plaque formation and blood vessel pathology and the impact of varying microglial donor cells on these outcomes.

Title: Asthma induced by house dust mite exacerbates Alzheimer’s-associated changes in App^{NL-G-F} mice

Authors: *B. SAHU, A. M. FLODEN, S. NOOKALA, C. K. COMBS;
Univ. of North Dakota, Grand Forks, ND

Abstract: Alzheimer's disease (AD) is a progressive age-related neurodegenerative disorder affecting approximately 35 million individuals worldwide. AD is a leading cause of death in the USA, with an estimated 5.8 million affected. There are several well-established genetic and environmental factors hypothesized to contribute to AD pathophysiology. Besides aging, various comorbid conditions also increase the risk of AD, including obesity, diabetes, air pollution, and asthma. Epidemiological studies have reported a 2.17-fold higher risk of dementia in asthmatic patients >45 years old and 1.27-fold in asthmatic patients ≥20 years old. However, the molecular mechanism(s) underlying this asthma-associated AD exacerbation is not known. This study was designed to explore the effects of house dust mite-induced asthma on AD-related brain changes using the App^{NL-G-F} transgenic mouse model of disease. Male and female C57BL/6 wild type and App^{NL-G-F} mice (8-9 months old) were exposed to either saline vehicle or house dust mite at a dose of 833μg/kg every alternate day for 16 weeks. Mice were sacrificed to collect bronchoalveolar lavage fluid (BALF), blood, and brains at the end of the experiment. BALF was analyzed for immune cell markers, cytokine levels, and overall protein content. Immunohistochemistry for Aβ was performed on fixed brain sections. Aβ ELISAs and cytokine arrays were performed on frozen hippocampal and cortical lysates and serum. As expected, asthma increased BALF inflammatory cells, several inflammatory and Th_2 cytokines, and pulmonary vascular permeability compared to the vehicle controls. Interestingly, asthmatic App^{NL-G-F} mouse hippocampi had a higher Aβ plaque load. Additionally, the cytokines TNF-α, IL-1β, IL-6, IFN-γ, and IL-5 were elevated in the cortices of dust mite exposed mice compared to vehicle controls, both in wild type and App^{NL-G-F} mice. Serum cytokines such as TNF-α, IFN-γ, IL-5, and IL-13 were also elevated in dust mite exposed wild type and

App^{NL-G-F} mice. Furthermore, soluble Aβ 1-42 was increased significantly in the serum of dust mite exposed *App*$^{NL-G-F}$ mice. Overall, our data suggest that chronic house dust mite exposure exacerbates AD pathophysiology potentially by increasing Aβ levels and inflammatory mediators systemically and in the brain. Understanding a mechanistic relationship linking AD and asthma progression may provide novel therapeutic interventions for both chronic diseases.

Title: Brain translocator protein 18kDa (TSPO) levels are associated with sex-dependent cognitive function deficits in the 5XFAD animal model of Alzheimer's disease

Authors: *J. L. MCGLOTHAN DZIEDZIC, D. A. MARTINEZ-PEREZ, D. ALBORES-GARCIA, D. R. BROOKS, T. R. GUILARTE;
Envrn. Hlth. Sci., Robert Stempel Col. of Publ. Hlth. & Social Work Florida Intl. Univ., Miami, FL

Abstract: Alzheimer’s disease (AD) is an irreversible neurodegenerative condition leading to dementia affecting the performance of daily tasks. Neuroinflammation is thought to play an important role in AD pathogenesis. Here, we used the 5XFAD transgenic mouse model of AD that expresses five of the human familial mutations and recapitulates features of the human disease including cognitive function deficits and amyloid pathology. Cognitive function was assessed in male and female wildtype (WT) and 5XFAD mice at 7 months (7M) of age using the Barnes Maze. We observed no significant differences in cognitive function between WT and 5XFAD male mice ($F_{1,15}$=1.646, p=0.219), but a highly significant impairment in 5XFAD female mice relative to WT ($F_{1,15}$=18.170, p=0.001) consistent with the gender differences observed in humans. TSPO is a validated neuroimaging biomarker of neuroinflammation that is widely used to study animal models of human neurological disease and neurodegenerative disorders including AD. To assess the level of neuroinflammation in the brain of 7M male and female WT and 5XFAD mice, we performed quantitative autoradiography using the TSPO-specific radioligand [^{3}H]-DPA-713. Brain regions analyzed included the cerebral cortex, striatum, septal nuclei, amygdala, hippocampus, thalamus, and hypothalamus at two different levels of the brain. That is, at +0.48 mm (level 1) and -3.3 mm (level 2) from Bregma based on the Paxinos and Watson mouse brain atlas. Two-way ANOVA of TSPO autoradiography in male mice indicates significant increases in TSPO levels by genotype [$F_{1,70}$=11.9, p=0.001] and brain region [$F_{7,70}$=3.87, p=0.0013] with no genotype x region interaction [$F_{7,70}$, p=0.59]. In female mice, we also found highly significant differences in TSPO levels by genotype [$F_{1,61}$=59.2, p<0.0001], brain region [$F_{7,61}$=5.4, p<0.0001] with no significant genotype x brain regions interaction [$F_{7,61}$=1.26, p=0.285]. The increases in [^{3}H]-DPA-713 specific binding to TSPO ranged from 0-52.8% in male 5XFAD mice and 31.4-134.9% increases in female 5XFAD compared to sex-specific WT mice. The results indicate that brain TSPO levels are inversely associated with cognitive performance in female 5XFAD mice at 7M. The findings in 7M male 5XFAD mice indicate that brain TSPO levels are

significantly increased prior to deficits in cognitive function. These results suggest that brain TSPO levels may be an early biomarker of declining cognitive performance in the 5XFAD mouse model of AD. Future studies will examine the association of brain TSPO levels with cognitive function, amyloid load, and the glial sources of the TSPO response using a life-course approach.

Title: Sex Differences in Metabolic and Hypothalamic Disturbances in the 3xTg-AD Mouse Model of Alzheimer’s Disease Across the Lifespan

Authors: *L. S. ROBISON[1], O. J. GANNON[2], A. SALINERO[2], D. A. RICCIO[2], R. D. KELLY[2], C. ABI-GHANEM[2], K. L. ZULOAGA[2];

Abstract: Alzheimer’s disease (AD) is often associated with cognitive decline and impaired function of hippocampal and cortical areas; however, several other domains and corresponding brain regions are affected. One such brain region is the hypothalamus, shown to atrophy and develop amyloid and tau pathology in AD patients. The hypothalamus controls several functions necessary for survival, including energy and glucose homeostasis. Changes in appetite and body weight are common in AD, often seen prior to the onset of cognitive symptoms. Therefore, altered metabolic processes may serve as a biomarker for AD and/or a target for treatment, considering they are likely both a result of and contributor to disease progression. Previously, we reported sex differences in metabolic disturbances in ~7-month-old 3xTg-AD mice, accompanied by systemic and hypothalamic inflammation. In the current study, we investigated metabolic outcomes and hypothalamic inflammation in 3xTg-AD males and females at 3, 6, 9, and 12 months of age to determine when these sex-specific metabolic phenotypes emerge. In agreement with our previous study, AD males displayed reduced weight gain and adiposity, as well as reduced blood glucose levels following a glucose challenge, compared to females by 6 months of age. Additionally, we note increased expression of inflammatory markers (Iba1, GFAP, TNF-a, and IL-1B) in the hypothalamus of AD males at 6-9 months. These findings provide additional evidence for sex-dependent effects of AD pathology on altered metabolism, which may be linked to hypothalamic inflammation.

Abstract: Memory enhancing effect of phosphodiesterase 2 inhibitor Bay 60-7550: involvement of cAMP/cGMP-dependent antioxidant stress and neuronal remodeling
Shichao Gao[1], Xiongwei Zhu[2], James M. O'Donnell[1], Ying Xu[1] 1. Department of Pharmaceutical Sciences, School of Pharmacy & Pharmaceutical Sciences, University at Buffalo, The State University of New York, Buffalo, NY 142142. 2. Department of Pathology, Case Western Reserve University, Cleveland, Ohio 44106
Phosphodiesterase 2 (PDE2) mainly catalyzes the hydrolysis of the second messengers cyclic AMP (cAMP) and cyclic GMP (cGMP), which play crucial roles in learning and memory processes. Previous studies suggested that inhibition of PDE2 by Bay 60-7550 ameliorates memory loss upon exposure to oxidative stress. However, whether PDE2 inhibition ameliorates memory deficits associated with Alzheimer's disease by enhancing antioxidant function and neuronal remodeling, are largely unexplored. This study investigated how Bay 60-7550 rescues the dysregulated cAMP/cGMP-related oxidative stress in Aβ oligomers (AβO)-treated neuronal cells and regulates memory behavior in Alzheimer's disease mouse model. The results suggested that exposure of SH-SY5Y cells to AβO resulted in time- and concentration dependent increases in PDE2 expression, which are parallel to increased oxidative parameter malondialdehyde (MDA) level and cellular apoptosis. However, this AβO-induced oxidative stress was blocked by pretreatment with protein kinase A or G inhibitor H89 or KT5823, suggesting the involvement of cAMP/cGMP-dependent signaling. The subsequent *in vivo* study suggested that microinjection of AβO into prefrontal cortex of mice increased MDA level; while Bay 60-7550 treatment reversed this effect and increased antioxidant and antiapoptotic factors' levels. Bay 60-7550 also rescued AβO-induced neuronal atrophy and working memory performance in the eight-arm maze and novel object recognition tests, which were also prevented by either H89 or KT5823. These findings suggest that inhibition of PDE2 contributes to antioxidant defense and neuronal remodeling in AD mouse model, indicating that PDE2 may be a potential target for the treatment of AD dementias.

Title: Simultaneous RNA and protein imaging using a spatial omics platform reveals cellular composition changes in Alzheimer's Disease mouse models

Authors: N. KOTOVA, R. YIN, I. OH, T. AWAD, ***M. OTERO-GARCIA**;
Rebus Biosystems, Santa Clara, CA

Abstract: Cell-type composition and expression of immune response genes are two key variables in neurodegeneration mouse model studies, but using Single-cell RNA sequencing to measure them sacrifices important anatomical and morphological information. Here we present a methodology which allows accurate gene expression quantification without compromising spatial resolution. Using Rebus' automated high-throughput spatial omics platform, we quantified the expression of 30 target genes at the single-cell level, in addition to two proteins of interest, in the hippocampus of two disease models plus a wild-type control mouse. We were able to define the major neuronal and glial cell types, anatomical structures, and quantify expression changes in disease-related genes. We measured changes in the relative abundances of the defined cell types and their spatial relationships between disease conditions. We also explored the relationship between these pathological gene-expression changes and the presence of proteins of interest. These results demonstrate the ability of the Rebus Esper spatial omics platform to yield high-throughput spatial omics data with single cell resolution. The combination of large imaging area, high-plex RNA quantification, and protein imaging offers a unique and powerful tool to explore complex tissues with an unprecedented level of detail.

Title: Il-1bas a key cytokine to regulate infiltration of monocytes/macrophages in the brain in systemic inflammation

Authors: *R. C. C. CHANG[1,2], X. K. CHEN[1], A. C. H. MA[3];
[1]Lab. of Neurodegenerative Diseases, LKS Fac. of Medicine, Univ. of Hong Kong, Hong Kong, China;

[2]State Key Lab. of Brain and Cognitive Sci., Univ. of Hong Kong, Hong Kong, China; [3]Dept. of Hlth. Technol. and Informatics, Hong Kong Polytechnic Univ., Hong Kong, China

Abstract: Our previous studies have shown that laparotomy of the intestine in laboratory mice stimulates cytokine production and activation of microglia in the brain. However, it is unclear whether activation of systemic monocytes/macrophages can migrate into the brain. Since it is easy to prepare gene knockout and mutation in zebrafish, we extend our study to zebrafish by using tail amputation as a model of traumatic injury. Tg(coro1a:DsRed) transgenic zebrafish was used to monitor microglia and macrophages. Tg(mpx:mCherry) was used for monitoring neutrophils, Tg(mepg1:GFP) was used for monitoring macrophages. We have used TALEN method to make knockout or mutation of IL-1β in zebrafish. Quantitative PCR and immunohistochemical staining were used for examination. Acridine orange and TUNEL were employed for labeling apoptotic cells. Tail amputation was performed at day 3 of embryos under anesthetization with tricaine. Tail amputation recruited accumulation of monocytes/macrophages into the wound site in zebrafish tail. Surprisingly, an increased number of macrophages and microglia were also found in the brain, which was tissue-specific as no other organs showed a similar phenomenon. The expression of mRNA for different cytokines was examined in the brain. Among these, IL-1β was significantly increased. Therefore, we prepared IL-1β knockout and mutated zebrafish. After amputation, the number of macrophages in the brain did not show any significant increase. To further understand why monocytes/macrophages migrate into the brain after peripheral wound injury, we found an increased number of apoptotic cells in the brain after wound injury. IL-1β had a key role in regulating the migration of monocytes/macrophages. Our study demonstrated that zebrafish is a good animal model to investigate how peripheral wound injury triggers neuroimmune responses. IL-1β is a key player to regulate the migration of monocytes/macrophages into the brain.

Abstract: Neurodegenerative diseases strongly correlate with the incidence of sleep apnea in humans. However, whether the neurodegeneration leads to sleep apnea or vice versa is not yet clear. To address this, we utilized a genetic mouse model of Alzheimer’s disease (AD; hemizygous 5xFAD) and exposed

them to chronic intermittent hypoxia (CIH), a hallmark of sleep apnea. This model mimics daily, untreated sleep apnea throughout a lifetime, beginning before disease symptom onset, to identify the impact of CIH on neurodegenerative decline. Male and female WT and 5xFAD mice received CIH (90s alternating 6.5%/21% O_2) or normoxia (90s alternating 21%/21% O_2) for 12 hrs/day during their sleep cycle from age 4 months to 10 months. Prior to, and every two months during CIH exposure, prefrontal cortex- and hippocampal-dependent behavioral testing was performed to assess disease-related decline. Preliminary behavioral data in both male and female 8-month-old animals demonstrated decline in cognitive function of control (normoxia) 5xFAD animals. Interestingly, CIH WT animals exhibited cognitive dysfunction at this time point, and the 5xFAD animals had exacerbated decline in conjunction with CIH. After final behavioral testing, brains were harvested for immunohistochemistry analysis and immunomagnetic microglial isolation. Imaging analysis demonstrated sexually dimorphic alterations in amyloid-beta plaque quantity and intensity. Studies are underway to analyze microglial immune responses, inflammatory and intercellular communication gene expression by RNA-sequencing. Together, these data suggest that CIH, prior to AD cognitive symptom onset, may exacerbate neurodegenerative disease that correlates with altered microglial function, in a manner that differs by sex. These observations have implications for individuals with sleep apnea and AD progression.

Title: Dynamic stimulus representation by somatosensory cortical circuits during sensory discrimination learning

Authors: *T. BAWA[1], R. CHÉREAU[1], S. PAGÈS[1,2], A. HOLTMAAT[1];
[1]Dept. of Basic Neurosciences, Univ. de Genève, Geneva, Switzerland; [2]Wyss Ctr. for Bio and Neuroengineering, Geneva, Switzerland

Abstract: Cortical networks are constantly remodelled to retrieve and encode new information. During sensory learning, the cerebral sensory cortices integrate sensory information that is fed forward from the thalamus with feedback information coming from higher-order cortical or thalamic areas. Previously, our lab and others have shown that in this process, pyramidal neurons (PN) in the mouse primary somatosensory cortex (S1) can adapt their response selectivity for sensory stimuli depending on the associated reward contingencies. Changes in such responses are thought to be the result of plasticity that ultimately promotes synapses activated by stimulus-driven feedforward signals. Other studies in our lab have revealed that feedback signals from the higher-order posteromedial (POm) thalamic nucleus of the somatosensory system mediate long-term potentiation of PNs in S1. Disinhibition through the activation

of vasoactive intestinal peptide-expressing (VIP) interneurons (IN) was identified as an important circuit mechanism for this form of plasticity. We sought to investigate whether the dynamic perceptual feature selectivity of PNs during learning is associated with changes in the stimulus-evoked responses of thalamocortical projections from POm or local VIP INs during sensory discrimination learning. We hypothesise that both POm and VIP INs, exhibit a transient change in their responses during sensory learning, which would forecast alterations in PN selectivity and the animal's discrimination performance. We use *in vivo* calcium imaging to longitudinally monitor the responses of individual layer 1 (L1) POm axonal boutons, and L1 and L2/3 VIP INs during reward-based and whisker-mediated texture discrimination learning. We observe that both POm axons and VIP INs are active during texture discrimination and both display an increase in texture selectivity as the animal learns. As observed with PNs, feature selectivity of POm projections and VIP INs is highly dynamic during the learning process. POm projections show distinctive responses for combinations of stimulus features and reward contingencies, while the selectivity of VIP INs tends to reflect more the stimulus contingencies. We are currently investigating whether the POm projections and VIP INs exhibit specific responses during the transition between the naïve and expert phases of learning. Altogether, our study suggests that the POm and VIP INs in S1 convey sensory discrimination information to L2/3 PNs, implying that they play an important role during sensory perception and learning.

Title: Morphological analysis of driver inputs from layer 5 corticothalamic axons in higher order posterior medial nucleus of thalamus.

Authors: *V. SAMPATHKUMAR[1], A. J. MILLER[2], S. SHERMAN[3], N. B. KASTHURI[2];
[2]Neurobio., [1]Univ. of Chicago, Chicago, IL; [3]Dept Neurobiol, Univ. Chicago, Chicago, IL

Abstract: Driving afferents to the thalamus, such as that from layer 5 of cortex, are generally subserved by inputs with large terminals forming onto more proximal dendritic locations. We combined large volume serial electron microscopy (EM) in Rbp4-cre transgenic mice to label differentially layer 5 axons and terminals from the somatosensory (S1) and motor (M1) cortices. With such an approach, we recently demonstrated that layer 5 inputs to neurons of the posterior medial (POm) nucleus of the thalamus indeed

commonly produce such synaptic inputs, but the population of such afferent terminals include some that are smaller and/or that terminate more distally on dendrites. We asked whether the variability in such terminal morphology was seen with input from individual layer 5 axons or whether such axons individually produced less variable terminal morphology. That is, does the variability in terminal morphology seen in layer 5 inputs exist within single axons or is it a feature of variability among axons? To address this, we reconstructed 34 layer 5 corticothalamic axons from S1 and 17 axons from M1 in POm in two mice. We found no evidence of distinct populations of axons with regard to terminal morphology and instead commonly found that individual axons from both M1 and S1 mostly formed large terminals that contact proximal dendrites but also produce a minority of smaller terminals that form more peripherally onto dendrites. Furthermore, despite the relatively low frequency of synapses along axons, we found commonly that individual S1 axons will synapse multiple times with the same postsynaptic POm neuron. That is, of 11 S1 axons found to innervate five different POm neurons, seven of these axons made multiple synapses onto the same cell. Only one of the five POm neurons did not receive multiple synapses from the same axon. Future studies will ask similar questions about the arborization patterns of POm neurons axons in secondary somatosensory cortex. These experiments suggest that the variability in the morphology of driver inputs from layer 5 is not due to subpopulations of afferents with variable morphology.

Title: A transthalamic pathway via the posterior medial nucleus is necessary for whisker discrimination

Authors: *C. MO, C. MCKINNON, S. M. SHERMAN;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: In sensory systems, pathways from primary cortex to secondary cortex can arrive directly (cortico-cortical) or indirectly through higher order thalamus (cortico-thalamo-cortical). The function of the transthalamic route is unknown, despite its ubiquity and driver-type glutamatergic synapses. In the somatosensory system in the mouse, we optogenetically inactivated the transthalamic pathway at its cortico-thalamic terminals and found that this projection is essential to drive specific cells in secondary cortex and for performance in whisker-based texture discrimination. To label layer 5 cortico-thalamic terminals, AAV8-CAG-FLEX-JAWS-KGC-tdTomato-ER2 was injected into primary somatosensory cortex (S1) of 9-11 week old Rbp4-Cre x Thy1-GCAMP6S mice. Two weeks later, a 4mm diameter glass window was installed over left S1 and secondary somatosensory cortex (S2). An optic fiber was also

implanted 3.2mm deep at 8° vertical into the posterior medial nucleus (POm) of the thalamus. Jaws-tdTomato expression was visualized through the window as confined to S1 barrels, which were located by intrinsic signal optical imaging. Mice were trained in a head-fixed, delayed go/no-go task to discriminate between texture panels presented to the right whisker field. A panel with a coarse grating (P60) on a foil background was the go stimulus, and a panel with foil alone was the no-go stimulus. A 1sec delay separated the end of the texture presentation period and the response period, signaled by an 8kHz tone. Once mice reached >70% correct for 2 days, 4 other gratings of variable coarseness were added to test psychometric performance. A 633nm laser inactivated cortico-thalamic Jaws-expressing terminals in POm. We found effects depending on the period of task processing. Inhibition during the texture period severely impaired discrimination performance, and, inhibition during the delay period increased the threshold of discriminability (n=5 mice). We also imaged GCAMP6S activity in layer 2/3 of either S1 or S2 during performance and found that S2 cells could discriminate texture trials better than S1 cells and laser inhibition suppressed texture-responsive S2 cells more than S1 cells. TdTomato-expressing mice (n=2) and Jaws-expressing mice with a fiber implanted away from POm (n=2) did not show any effects of laser activation. Our results suggest that the layer 5 S1 - POm - S2 transthalamic pathway propagates complex sensory information such as texture features.

Title: Demyelination impairs layer 5 corticothalamic feedback in the somatosensory system

Authors: *N. JAMANN[1,2], J. S. MONTIJN[1], S. DRIESSENS[1], J. A. HEIMEL[1], M. H. P. KOLE[2,1]; [1]Netherlands Inst. for Neurosci., Royal Netherlands Acad. of Arts and Sci., Amsterdam, Netherlands; [2]Cell Biology, Neurobio. and Biophysics, Dept. of Biology, Fac. of Sci., Univ. of Utrecht, Utrecht, Netherlands

Abstract: Myelination is essential for temporally precise and rapid action potential (AP) propagation. There is emerging evidence that myelin sheath properties differ widely across brain regions and can be altered activity-dependently to fine tune and adjust temporal delays. In the somatosensory whisker system, the information transfer via projections from layer 5 (L5) pyramidal neurons to the posteromedial nucleus of the thalamus (PoM) plays a powerful role in providing feedback information to thalamic neurons, who act as coincidence detectors for synchronized activity. Here, we studied the role of L5-to-PoM myelination in precise timing of corticothalamic feedback in vitro and in vivo. Using a retrograde AAV targeting approach in combination with a L5-specific Cre-driver mouse line (Rbp4-Cre) and immunofluorescent stainings against nodal compartments (Caspr, Ankyrin G), we investigated morphological parameters of nodes of Ranvier (noR) and internodes along the axonal projections within

the cortex, corpus callosum, striatum and thalamus. After 6 weeks of cuprizone-induced demyelination, we observed a diverse pattern of disassembly of nodal compartments. NoR either lacked one or both paranodes, most prominently in the cortex (~20% of the noR). In the white matter regions, paranode lengths were significantly increased, indicating impaired node clustering. To test how these changes in axon architecture associate with information transmission we used optogenetic stimulation of L5-to-PoM axons in acute brain slices in combination with whole-cell patch-clamp recordings of PoM neurons. The results showed a reduced conduction velocity in demyelinated L5-to-PoM axons (1 m/s vs 0.2 m/s, $P < 0.05$, $n = 8$) and a significant and frequency-dependent impairment of synaptic transmission (at 20 Hz, 30% reduction, $P < 0.01$). Furthermore, to understand how information transfer is affected in vivo we employed extracellular recordings with Neuropixels probes to record at high-density and simultaneously both whisker- and optically-evoked activity in S1 and PoM. Preliminary data suggests that demyelination increases the delay to spike triggering in PoM, as well as the jitter and failure rates. In vivo patch-clamp recordings will be utilized to identify whether L5-to-PoM projections are affected at the supra- and subthreshold levels. Taken together, demyelination disrupts the proper function of corticothalamic loops, which are key to sensory processing. Our findings demonstrate the crucial role of myelination for precisely timing the information transfer between neurons in distant brain-regions.

Title: Synchrony dependent corticothalamic gating of thalamocortical sensory encoding

Authors: *E. DIMWAMWA, A. PALA, G. B. STANLEY;
Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Amid the more canonically studied feedforward neuronal pathways that enable us to perceive the world through our senses, there are numerous feedback processes. Corticothalamic feedback neurons from layer 6 of the cortex (L6CT) is one such process that provides extensive inputs back to the thalamus. Despite corticothalamic projections outnumbering thalamocortical (TC) projections 10:1 (Deschênes, P. et al., 1998), the function of L6CT neurons remains elusive. L6CT neurons are well-positioned to play an important role in TC sensory signaling and our objective is to elucidate this role. Using the vibrissal

system of awake, NTSR1-cre mice selectively expressing ChR2 in L6CT neurons, we conduct simultaneous extracellular recordings of populations of individual neurons in the primary somatosensory cortex (S1) and Ventral Posteromedial nucleus (VPm) of thalamus. While optically driving the spiking activity of ChR2-expressing L6CT neurons, we investigate how L6CT neurons modulate thalamic and cortical neuronal activity. We find that firing rates of VPm neurons can be enhanced or suppressed depending on the synchrony of the L6CT inputs. More specifically, while a constant optical input decreases VPm firing rates relative to baseline, a noisy optical input to increase L6CT synchrony (while accounting for firing rate) in turn enhances VPm firing rates. In addition to providing monosynaptic excitation via direct projections to VPm, L6CT neurons also provide disynaptic inhibition via projections to the inhibitory Thalamic Reticular Nucleus (TRN). Interestingly, preliminary recordings in TRN show comparable, enhanced firing rates under both conditions. Taken together, we hypothesize a synchrony dependent L6CT excitatory window of integration (WOI) as the underlying mechanism gating net enhancement/suppression of VPm. This is akin to the well-characterized TC WOI in the feedforward pathway, and thus may emerge as a fundamental principle underlying sensory processing throughout the sensory hierarchy.This WOI can have important implications for the representation of sensory stimuli, which we explore. In preliminary results, we find that asynchronous L6CT input shifts both the pre-stimulus and sensory evoked response of both thalamic and cortical neurons to brief, punctate whisker deflections. These shifts increase the theoretical detectability of sensory stimuli; ongoing work will establish whether synchronous L6CT inputs further shift detectability of stimuli. Success of this work will illuminate a relevant context for the study of L6CT as well as provide a functional link between L6CT and sensory encoding.

Title: The timescale of adaptive dynamics in the thalamocortical circuit

Authors: *Y. LIEW[1], N. C. WRIGHT[1], Y. ZHANG[2], G. B. STANLEY[1];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Hlth. Sci. Ctr., Peking Univ., Beijing, China

Abstract: Sensory processing requires efficient transmission of sensory information across multiple brain regions, and flexible neural representation is often required to capture changes in the environment across a range of timescales, from seconds to minutes. When the brain is presented with persistent stimuli, neurons adapt their spiking responses accordingly to match the statistics of their inputs. Although sensory adaptation has been shown to be a vital mechanism for sensory encoding beyond just the loss of

sensitivity in response to persistent stimulation, the neural basis of sensory adaptation across timescales remains underexplored. While nearly all studies of adaptation focus on a single, relatively short timescale of seconds, here we ask how the effects of persistent stimulation depend on the duration of exposure, spanning multiple timescales. Specifically, we take advantage of the well-known anatomical and functional organization of the rodent whisker pathway to perform in vivo anesthetized, large-scale recordings from the ventroposteromedial nucleus of the thalamus (VPm) and layer 4 of primary somatosensory cortex (S1) to understand the effect of prolonged exposure to persistent stimuli on thalamic neurons and their downstream cortical targets. We presented punctate whisker deflection trains to individual whiskers and quantified the adaptive effects on VPm and S1 as a function of stimulus duration. Our preliminary results demonstrate that the degree of neuronal adaptation in both the thalamus and cortex increases with stimulus duration, and importantly, neurons adapt well beyond a single, short timescale that is typically described in the literature. In general, adaptation of response amplitudes and latencies of VPm and S1 neurons increased with time. Compared to VPm, adaptation was on average more variable across neurons in S1, likely due to the complex integration of feedforward thalamic and intracortical synaptic inputs to cortical neurons. Preliminary results also show that recovery from adaptation depended on the duration of the adapting stimulus. Finally, the synchronization of thalamic spiking adapted with persistent sensory stimulation, though the relationship with stimulus duration is complex and warrants further investigation. Although to what extent prolonged adaptation can cause a switch from reversible neuronal change to a permanent one remains unclear, here we found preliminary evidence that suggests distinct adaptive circuit motifs can emerge across multiple timescales.

Title: Higher-order thalamic nucleus contributes to sensory perception during active sensing in mice

Authors: *J. QI, C. YE, A. R. INACIO, S. LEE;
Natl. Institue of Mental Hlth., Bethesda, MD

Abstract: The higher-order thalamic nucleus in rodent somatosensory, the posteromedial thalamic nucleus (POm), is a critical network hub integrating sensory-motor processing. While POm has dense cortical and subcortical projections, POm neurons weakly respond to sensory stimulation, and the role POm plays in sensory perception during active sensation remains unclear. Here, we investigated the role of a higher-order thalamic nucleus in perceptual decision during active sensation in the vibrissa-related somatosensory system. We first develop a whisker-dependent, self-initiated, two-alternative forced-choice (2AFC) sensory perception task in freely moving mice to probe the circuit mechanisms of POm in context-dependent sensory processing. We demonstrate that chemogenetic suppression of POm activity

significantly impairs the behavioral performance in the whisker-dependent sensory discrimination task, leading to a progressively extensive impairment as the difficulty of the task increased. By combining optogenetic manipulation of the projections from the sensory cortex, motor cortex, or the brain stem to POm, we find that the corticothalamic projection from the layer 5 neurons in the primary somatosensory cortex is critical the contribution of POm to sensory perception. Our results suggest that 1) the POm thalamic nucleus significantly contributes to sensory perception during active sensing, and 2) the role of POm in sensory perception is mainly inherited from the primary somatosensory cortex but not from motor cortical projections or brainstem ascending pathway.

Title: Effects of arousal and movement on secondary somatosensory and visual thalamus

Authors: *G. H. PETTY[1], A. K. KINNISCHTZKE[1], Y. HONG[2], R. M. BRUNO[1];
[1]Neurosci., Columbia Univ., New York, NY; [2]Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: All neocortical sensory areas have an associated primary and secondary thalamic nucleus. While the primary nuclei encode sensory information for transmission to cortex, the nature of information encoded in secondary nuclei is poorly understood. We recorded juxtasomally from neurons in secondary somatosensory (POm) and visual (LP) thalamic nuclei of awake head-fixed mice with simultaneous whisker tracking and pupilometry. POm activity correlated with whether or not a mouse was whisking, but not precise whisking kinematics. This coarse movement modulation persisted after unilateral paralysis of the whisker pad and thus was not due to sensory reafference. POm continued to track whisking even during optogenetic silencing of primary somatosensory and motor cortex and after lesion of superior colliculus, indicating that motor efference copy cannot explain the correlation between movement and POm activity. Whisking and pupil dilation were strongly correlated, raising the possibility that POm may track arousal rather than movement. LP, being part of the visual system, is not expected to encode whisker movement. We discovered, however, that LP and POm track whisking equally well, suggesting a global effect of arousal on both nuclei. We conclude that secondary thalamus is a monitor of behavioral state, rather than movement, and may exist to alter cortical activity accordingly.

Title: Layer 6 corticothalamic neurons in the barrel cortex are not a homogenous population: distinct functional subtypes revealed through targeted recordings in awake behaving mice

Authors: S. DASH[1], D. M. AUTIO[1], *S. R. CRANDALL[2];
[1]Dept. of Physiol., [2]Michigan State Univ., East Lansing, MI

Abstract: Layer 6 corticothalamic (L6 CT) neurons are in a strategic position to control thalamocortical transmission and sensory responses in the cortex, yet we understand very little about their function during behavior. Apart from studying their anatomical, physiological and synaptic properties, most recent efforts have focused on the activity-dependent influences CT cells can exert on thalamic and cortical neurons through causal optogenetic manipulations. However, very few studies have attempted to study them during ethological relevant behaviors. In an attempt to address this gap, we performed targeted juxtacellular recordings from optogenetically identified CT neurons in vibrissa primary somatosensory cortex (vS1) of awake, head-fixed mice free to rest quietly or self-initiate bout of whisking and locomotion. We found a rich diversity of response profiles exhibited by L6 CT cells. Broadly, their spiking patterns were either modulated by whisking behavior (~33%) or not (~66%). Whisking-related CT neurons exhibited both increases as well as decreases in firing rates. We also encountered CT cells with preceding (putatively motor-related) modulations in firing rate before whisking onset. Overall, whisking better explained these changes in firing rates than overall changes in arousal. The CT cells that showed no whisking-related activity had low spontaneous firing rates (<0.5 Hz), with many all but silent. Remarkably, this relatively silent CT population generated precisely timed spikes during pupil constriction, corresponding to a transition from low to high delta cortical network state. Thus, our results demonstrate that L6 CT neurons in rodent vS1 show diverse activation patterns, perhaps subserving distinct functional roles related to precisely timed responses during complex behaviors and transitions between discrete waking states.

Title: Thalamic control of the cortical excitatory-inhibitory ratio and implications for cortical sensory representations

Authors: N. C. WRIGHT, P. Y. BORDEN, A. BORSA, G. B. STANLEY;
Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Inhibition has long been known to play a key role in the early sensory pathway, by balancing synaptic excitation to gate the sensory-evoked output of relay neurons. For example, parvalbumin-positive (PV) interneurons in cortical layer 4 (L4) provide dampening inhibition that shapes both the rate and timing of L4 firing evoked by synaptic excitation. This excitation-inhibition (E-I) balance is often considered to be a static property of anatomy, but recent work has demonstrated rapid changes in the L4 E-I ratio across states of wakefulness (Yu et al. 2016; Stringer et al. 2016). While this may involve a range of mechanisms that shape the E-I ratio across cortical sensory areas, layers, and timescales, one intriguing possibility is that the L4 E-I ratio is rapidly and focally altered via differential drive of excitatory and inhibitory neurons by primary sensory thalamus (Yu et al. 2016). This has profound implications for the shaping of L4 sensory representations via changes in feedforward inhibition and large-scale cortical activity, or "state" (Isaacson and Scanziani 2011; Stringer et al. 2016), but these predictions have yet to be directly tested. To determine the ability of thalamus to alter the L4 E-I ratio and thereby shape cortical sensory representations, we recorded spiking activity in primary somatosensory (S1) cortex and the upstream ventral posteromedial (VPm) thalamic nucleus in the vibrissa pathway of the awake, head-fixed mouse, while optogenetically manipulating baseline VPm rates and presenting precise whisker stimulation. We estimated the E-I ratio using the firing rates of cortical regular-spiking (RS, putative excitatory) and fast-spiking (FS, putative inhibitory) interneurons. We found that spontaneous, sensory-driven, and light-driven elevation of baseline VPm rates differentially elevates FS rates and alters spectral properties of the cortical local field potential (a descriptor of cortical state). A model network reproduces this decrease in the E-I ratio via differential thalamocortical connectivity to excitatory and inhibitory neurons. Further, such shifts in the baseline E-I ratio impact representations of simple stimuli, as RS responses to punctate whisker deflections are smaller when pre-stimulus FS rates are relatively elevated. Taken together, these results suggest that primary sensory thalamus can indeed shape cortical sensory representations in part by rapidly modulating the E-I ratio. Next, we plan to explore the implications for representations of more temporally rich sensory stimuli.

Title: Comparison of statistical learning signals between macaque inferotemporal and prefrontal cortex

Authors: *H. ESMAILPOUR[1,2], R. VOGELS[1,2];
[1]KU Leuven, Leuven, Belgium; [2]Leuven Brain Inst., Leuven, Belgium

Abstract: Many species are sensitive to temporal regularities in their environment. Such extraction of statistical regularities is referred to as "statistical learning". Studies in macaque inferotemporal (IT) showed stronger spiking activity to images that violated a learned image sequence ("deviants"; e.g. Meyer and Olson, 2011; Kaposvari et al., 2016; Schwiedrzik and Freiwald, 2017). However, it is unknown whether this enhancement originates within IT. One candidate origin is ventrolateral prefrontal cortex (VLPFC), connected with IT, and which may detect the difference between predicted and observed stimuli. We assessed whether VLPFC shows a different response to deviant versus predicted images and compared the time course of the deviant response between VLPFC and IT. We performed multi-site linear array recordings of spikes and local field potentials (LFPs) in IT and VLPFC simultaneously after exposing the 2 female rhesus monkeys for weeks to 5 triplets of images of animals for which within-triplet (S1-S2-S3) image order was fixed. Triplets were shown during passive fixation without interstimulus interval and stimulus duration of 500 milliseconds followed by a reward. During recordings, 16% of the second stimuli (S2) of the triplets were deviants, i.e. originated from another triplet. As IT, VLPFC showed enhanced LFP power to the deviant image for gamma frequencies, while beta frequency power was suppressed. The multi-unit activity (MUA) of each individual monkey in both IT and VLPFC demonstrated the enhancement to the deviant images. These effects were present for the LFP power and MUA for both the second (S2; =deviant) and third image (S3) of a triplet, indicating coding of only adjacent stimulus dependencies not only in IT (Meyer and Olson, 2014; Kaposvari et al., 2016), but also in VLPFC. The deviant response occurred approximately 33 milliseconds earlier in IT than VLPFC in both monkeys. Furthermore, cross-temporal decoding analysis (linear SVM) using the high gamma power showed no evidence of predictive stimulus coding in IT during the presentation of S1 and S2. These data suggest that at least the early part of the deviant response in IT does not originate from a prediction error signal in VLPFC.

Title: A gravitational reference frame for stable vision across head tilt

Authors: A. EMONDS[1], R. SRINATH[2], K. NIELSEN[1], ***C. CONNOR**[1];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Univ. of Pittsburgh, Pittsburg, PA

Abstract: We obtain visual information in a retinal reference frame, which is frequently tilted laterally, with the head, up to 45° or more during normal physical activity or at rest. Yet head tilts in this range (which are compensated only ~20% by ocular counterrotation) have little effect on visual function or the perceived orientation of the world. Here, we report that the brain transforms visual information into a gravitational reference frame, which would remain stable across head tilts. We measured neural tuning for object orientation in the final stage of ventral pathway object vision, in inferotemporal cortex (IT) of macaque monkeys, during combined body/head tilts of +/-25°. Test objects were high-response abstract 3D shapes (discovered through an initial search process) rendered photo-realistically with Blender, on a blank background in a dark room. Object tilt was sampled across a range of 200° centered on the original orientation of the high-response stimulus. Responses to this range of object tilts were sampled in 2 conditions, in which the monkey was tilted either 25° clockwise or 25° counterclockwise, around a sagittal axis bisecting the line between the two pupils and running through the fixation point on the screen. The video eye-tracking system rotated with the monkey and confirmed that there was no change in eye position during fixation after rotation. Object coding in a retinal reference frame predicts that the closest correspondence between responses in the two monkey tilt conditions would exist for object tilts shifted by 50°. Object coding in a gravitational reference frame predicts closest correspondence between objects at the same object tilt, regardless of monkey tilt. Many IT neurons showed strong correspondence in the gravitational reference frame (low mean squared error between response rates for identical object tilts) and low correspondence in the retinal reference frame (high mean squared error between response rates for object tilts shifted by 50°). The converse pattern was rare. We also modeled responses for each neuron as a weighted mixture of the two reference frames, and again the gravitational reference frame was dominant. Thus, IT neurons provide clear and easily extracted information about object shape in the gravitational reference frame, which could support stable perception of object structure, balance, and potential energy during real world vision with variable head tilt.

Title: Submillimeter fMRI reveals an extensive and fine-grained scene-processing network in monkeys

Authors: *X. LI[1,2], Q. ZHU[3,1], W. VANDUFFEL[1,2,4,5];
[1]Dept. of Neurosciences, KU Leuven Med. Sch., Lab. for Neuro- and Psychophysiology, KU Leuven, Leuven, Belgium; [2]Leuven Brain Institute, KU Leuven, Leuven, Belgium; [3]Cognitive Neuroimaging Unit, CEA DRF/JOLIOT/NEUROSPIN, INSERM, CEA, Univ. Paris-Saclay, Gif-sur-Yvette Cedex, France; [4]Athinoula A. Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA; [5]Dept. of Radiology, Dept. of Radiology, Harvard Med. Sch., Boston, MA

Abstract: Humans and monkeys are endowed with a dedicated cortical network for processing visual scene information, which is critical for navigation and object retrieval (Epstein & Baker, 2019). Given the intrinsic high dimensionality of complex scenes and large within-category variability, one may expect the contribution of many processing modules representing scenes, at least compared to faces and bodies. Currently available data, however, refute this hypothesis. For example, in macaques, about 6-7 occipito-temporal face-selective patches are consistently found, versus only 3-4 consistent scene-selective patches (Kornblith et al., 2013; Nasr et al., 2011; Verhoef et al., 2015). Hypothetically, smaller sized scene-processing modules may be difficult to identify with conventional-resolution fMRI. To overcome this limitation, we scanned monkeys viewing scenes and control stimuli with submillimeter resolution (0.22 mm3 voxels) contrast-agent enhanced fMRI, using implanted phased array receive coils (Janssens et al., 2012; Li et al., 2019). We performed two experiments using entirely different stimuli, aimed to control several high- and low-level features. For example, we included images of scenes familiar and unfamiliar to the monkeys, which appeared to be a surprisingly important determinant of scene-selective activations. Moreover, spatial frequency distributions were made indistinguishable between a mosaic face condition versus scenes. Also, we presented fractured scenes to control for local scene features, such as long lines and indoor textures. Our results revealed a robust, fine-grained, yet three-fold more extensive scene-processing network than previously documented. The core scene-selective network consists of eleven cortical patches distributed over occipito-temporal, parietal, and frontal cortex. Five additional non-core scene-selective patches show similar selectivity relative to all non-scene controls, but only for familiar spaces. Furthermore, the core scene selective patches form not only a functionally connected, but also a functionally relevant network, largely segregated from face and body networks. Functional scene responses correlated dominantly with functional connectivity fingerprints derived from the scene network than from patches from face and body systems. In general, our results invite to revisit the mesoscale functional architecture of all category-selective networks in human and non-human primates.

Title: Things-fmri/meg: a densely sampled-multimodal neuroimaging dataset of brain responses to a broad range of natural object images

Authors: *O. CONTIER[1], M. N. HEBART[1,2], A. H. DICKTER[2], L. TEICHMANN[2], A. KIDDER[2], A. CORRIVEAU[2], C. ZHENG[3], M. VAZIRI-PASHKAM[2], C. I. BAKER[2];

Abstract: A detailed understanding of object representations in brain and behavior strongly benefits from large-scale neuroimaging datasets for training and testing computational models. Most existing datasets focus on maximizing the number of presented stimuli. For the purpose of studying object representations however, another important dimension is object space coverage, i.e. extensive and representative sampling of objects. Furthermore, most previous large-scale efforts focus on spatial responses, leaving details about temporal response profiles largely unaccounted for. Towards the aim of object space coverage, we recently developed THINGS, a database of more than 26,000 images of 1,854 object concepts sampled from the American English language (Hebart et al., 2019). Here, we present THINGS-fMRI and THINGS-MEG, two large-scale neuroimaging datasets using functional magnetic resonance imaging (fMRI) and magnetoencephalography (MEG). These datasets are part of the THINGS-initiative, a multidisciplinary effort to study object recognition in several modalities by working on a shared set of objects. The two datasets comprise 7 participants (fMRI: n = 3, MEG: n = 4). Each participant viewed images from the THINGS database (fMRI: 8,740 images of 720 concepts, MEG: 22,448 images of 1,854 concepts) over the course of 12 sessions while performing an oddball detection task. Participants wore custom head casts in order to reduce head motion. We recently demonstrated the general quality, reliability, and validity of these two datasets, as indicated by head motion parameters, noise ceilings, split half reliability and a replication of the effect of object animacy. Building upon these efforts, we are presenting several extensions to the THINGS-fMRI/MEG dataset. First, we further validated the MEG data by showing that object concept and object image identity can be decoded from MEG recordings. Next, we developed a denoising strategy for the fMRI data based on semi-automated classification of independent components. Finally, we extracted single trial response estimates for the fMRI data which drastically decreases computational cost for subsequent analyses (compared to time-series data) and enables more data driven analysis approaches. Thereby, we hope to further increase the value of the data to the research community and facilitate its use. By covering a broad, representative, and multimodal sample of neural object representations, we hope that these datasets may be of use for visual neuroscience and computational vision research alike and will provide a basis for the extensive evaluation of object recognition in the human brain.

Title: The occipital place area responds to visual information about walking, not crawling

Authors: *C. M. JONES[1], J. BYLAND[1], D. D. DILKS[2];
[2]Dept. of Psychology, [1]Emory Univ., Atlanta, GA

Abstract: The occipital place area (OPA) - a cortical region supporting "visually-guided navigation" (i.e., finding our way through the immediately visible environment) in adulthood - has recently been found to be late developing, not fully developed until around 8 years old. But how is this prolonged development possible given that we move through our local environment long before 8 years old, beginning with crawling followed by "toddler" and "preschool" walking? One possibility is that OPA represents only the visual information from an "adult-like" walking perspective, and not from the other perspectives encountered during early development. To directly test this hypothesis, using fMRI in 15 human adults, we measured the responses in OPA to videos depicting the actual first-person visual experience of navigating the immediate environment - from either a "walking" or "crawling" perspective, as well as two baseline perspectives (i.e., an aerial "flying" perspective and a "scrambled" version of the walking videos). Consistent with our hypothesis, we found that OPA responded significantly more to the walking videos compared to the crawling, flying, and scrambled ones. Critically, we also found that OPA responded similarly to the crawling, flying, and scrambled videos, indicating that OPA does not respond to crawling information any more than either a perspective by which humans do not navigate ("flying") or a non-navigable perspective all together ("scrambled"). This pattern of results was unique to OPA, and was not found in other scene-selective regions, motion-selective cortex, or primary visual cortex - ruling out any general attentional, motion, or low-level visual information accounts. Collectively, these results 1) reveal that OPA is "tuned" to visual information about adult-like walking, not crawling, consistent with its prolonged development hypothesis, and 2) raise the intriguing question of whether crawling (and early walking even) is a mode of visually-guided navigation at all, or is processed by a different neural system all together.

Title: Understanding the development of attention and temporal binding

Authors: *J. KLEIN[1], A. COOK[1], H. ALLEN[2], J. CLIBBENS[1], V. AMANATIDOU[1], E. MAVRITSAKI[1];

[1]Birmingham City Univ., Birmingham, United Kingdom; [2]Univ. of Nottingham, Nottingham, United Kingdom

Abstract: To achieve the task at hand the brain relies on attention to select and process the most relevant information. Here, we compare how attention and perception interact to produce goal-oriented behaviour in children compared to adults. A total of 77 children (mean age 9.7 years) and 78 adults (mean age 20.72 years) were tested on four visual search conditions each with two display sizes (4 and 8), where the target item was always a blue letter "H." The first two baseline conditions were standard single-feature and conjunction searches (Treisman et al., 1980). Distractors were blue letter "A"s and a mixture of blue letter "A"s and green letter "H"s, respectively. The third condition was a standard preview search, where one distractor set (green letter "H"s) was displayed for 750 msec before the second set and target item appeared alongside. The standard preview search task has been found to generate a 'preview benefit,' where search slopes can become as efficient as a standard single-feature search (Watson et al., 1997). The final condition was a preview gap search. In this last condition, the first distractor set (green letter "H"s) was displayed for 750 msec, followed by a white, 250 msec 'gap' display. After the gap, the first set of distractors reappeared in their original positions alongside the second blue "A" distractors and blue "H" target item. The preview gap search has been shown to completely abolish the preview benefit in adults (Watson et al., 1997). A recent computational modelling study has shown this effect is due to the disruption of temporal binding by common onset in adults (Mavritsaki et al., 2016). Here, for the first time, children are tested in this condition. Children and adults showed typical performances in the single feature and conjunction conditions, where single-feature search slopes were significantly faster compared to conjunction search. Slopes in the standard preview search were significantly faster compared to conjunction search for both groups. In the preview gap condition, the preview benefit was abolished, with search slopes significantly slower than those in single-feature search. However, children's search slopes in the preview gap condition were significantly faster than slopes in the conjunction condition. These findings indicate that children have not yet developed the ability to use the common onset as a cue to temporally bind items. Further research should be undertaken to gain a better understanding of when temporal binding develops, and the mechanisms that underlie this process.

Title: Visualization of extra-classical receptive fields that affect visual representation in mouse V1

Authors: *H. ISHIDA[1], K. OHKI[1,2,3];
[1]Dept. of Physiology, Grad. Sch. of Med., The Univ. of Tokyo, Tokyo, Japan; [2]Intl. Res. Ctr. for Neurointelligence (WPI-IRCN), Tokyo, Japan; [3]Inst. for AI and Beyond, Tokyo, Japan

Abstract: Visual stimuli which exceed the receptive field (RF) modulate the responses of neurons throughout the visual processing pathways. This surround suppression/facilitation was first reported by using simple artificial stimuli like bars or drifting gratings, and when using natural images as stimuli, the responses of neurons are also modulated to be sparse. Surround suppression becomes the maximum when stimuli presented at the RF and its surround are similar, and it is thought to contribute to sparse and efficient coding by removing spatially redundant visual information. This suppressive surround was not extended uniformly but localized to limited areas of the surround. However, to fully understand the role of surround modulation on neural representations, it is necessary to determine the exact features of natural images that make neural responses sparse. We presented natural images clipped by the two different-size (40 and 90 degrees) circles to lightly anesthetized and sedated adult transgenic (Thy1-GCaMP6s) mice and recorded the visual responses of L2/3 neurons in the primary visual cortex with two-photon calcium imaging. We found that the natural stimuli presented outside the population RFs led to increase in lifetime/population sparseness. Next, we trained convolutional neural networks (CNNs) to predict neural population responses using natural images as input. CNNs could explain neural responses better than linear models, and using these trained neural networks, we visualized images that maximized each output unit of the trained CNNs. The visualized images had the gabor-like structures in most cases. These estimated RFs well predicted preferred orientation calculated from responses to conventional drifting grating stimuli. When the long bars were presented to the network, the trained models showed surround suppression. We identified extra-classical receptive fields structures by visualizing the stimulus features outside the classical RF which minimized the targeted unit responses while keeping stimulus features presented to the classical RF the same. We identified the visual features which make sparser responses in terms of lifetime sparseness. We found the same features also increased population sparseness. These surround structures were robust across training and visualizing initializations and confined to specific positions of the surround, which is consistent with the result of the asymmetric surround of the previous study (Walker et al., 1999). These methods and results can lead to a comprehensive understanding of the relationship between RF and surround structures

Title: Transition between perceptual spaces of low-level features and objects

Authors: *S. A. WARAICH[1], J. D. VICTOR[2];
[1]Weill Cornell Grad. Sch. of Med. Sci., New York, NY; [2]Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Elementary features (e.g., color or texture) lie on a continuous scale, while semantic representations (e.g., objects) are often categorical. The transformation of visual signals from elementary features into semantic content may therefore require a qualitative change in the way that information is represented. To probe this process, we developed and implemented a psychophysical paradigm to characterize the geometry of visual representations at several stages of this transformation. In parallel experiments, stimuli were drawn from five domains: (D1) the names of 37 familiar animals (from WordNet), (D2) images of these animals, (D3) pixelated but easily recognizable images of the animals, (D4) texturized images in which the animals were harder to recognize, and (D5) fully scrambled textures. In each experiment, subjects viewed displays consisting of one central reference stimulus and 8 surrounding stimuli. They were asked to rank the surrounding stimuli in order of similarity to the central reference. This rank-order design yielded 5994 unique choice probabilities, and included trials to check for context-dependence, i.e., whether judgments of "Is A (the reference stimulus) more similar to B or to C?" depended on the surrounding stimuli. We found that choice probabilities were consistent across subjects (2M, 6F) and contexts (n=3 for (D1), n=2 for (D2), n=4 for (D3), n=6 for (D4), n=5 for (D5)). To characterize the geometry of the representations of these five domains, we used a variant of multidimensional scaling (MDS). Representations of each domain were modeled by Euclidean spaces, in which points denoted stimuli, and relative distances, along with internal noise, explained choice probabilities. In all domains, five dimensions accounted for the choice probabilities to a large extent, but not completely. Visualizing MDS results showed that the organization of points varied across domains: in the low-level feature spaces (D4 and D5) points were relatively evenly distributed, but in the semantic space (D1) they occupied the periphery of the space. Hierarchical clustering revealed another difference between the domains. Trees obtained from the more semantic domains (D1 and D2) were more balanced than those obtained from the low-level feature domains, and the number of branches from the root of the tree to the individual leaves (objects) was lower in the semantic domains. These findings suggest that points in semantic space are more clustered. Overall, our results demonstrate subtle but systematic differences in the perceptual geometries of semantic and low-level features.

Title: Columnar processing of border ownership in primate visual cortex

Authors: *T. FRANKEN, J. REYNOLDS;
The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: To understand a visual scene, the brain needs to segregate figures from background by assigning borders to foreground objects. Prior studies with single electrodes have discovered neurons in visual cortical areas V2 and V4 that are selective for border ownership (border ownership selectivity, BOS), even if the features that define the object location occur outside of the classical receptive field (cRF; Zhou et al., 2000). It is unknown how BOS is established: a prominent role has been suggested for feedforward inputs (Sakai and Nishimura, 2006), or for horizontal connections and cortical feedback (von der Heydt, 2015; Zhaoping, 2005). Because these pathways have a distinct laminar profile, studying the laminar organization and timing of BOS may give important clues regarding its origin.
Here we investigated the laminar organization of BOS by using 32-channel laminar probes to record from well-isolated units and multiunits in V4 in two behaving male rhesus macaques. By replacing the dura with a transparent membrane we were able to position the probes orthogonally relative to the cortical surface. We presented isoluminant squares on a uniform background to evaluate BOS. We positioned the squares such that only one border overlapped with the cRF. BOS was thus defined by stimulus features outside of the cRF. We used current source density analysis of stimulus-evoked local field potentials to identify the input layer as the current sink with the shortest latency, and locate the units recorded from to superficial, input or deep layers.
We find that border ownership modulation occurs significantly earlier in deep layers than in input and superficial layers. In contrast, spikes evoked by small stimuli centered on the cRF arrive significantly earlier in the input layer than in the superficial and deep layers. BOS units recorded from the same penetration typically share the same preferred side of border ownership, also across layers, suggesting that BOS is organized in columns similar as preferred orientation. When comparing orientation tuning and BOS, we find that BOS can occur for different edge orientations, often far away from the preferred orientation.
Our data argue against the hypothesis that BOS in V4 is simply inherited from upstream visual areas along the feedforward pathway. Instead they are consistent with a model in which deep layer neurons first integrate asymmetric contextual information from a spatially contiguous, often wide area in visual space. Columnar clusters of shared border ownership preference suggest that this afferent contextual information is organized in functionally asymmetric clusters.

Title: Using a novel, stimuli-driven approach to uncover a robust image feature that drives human cortical scene selectivity

Authors: *A. CHENG, D. D. DILKS;
Psychology, Emory Univ., ATLANTA, GA

Abstract: Human neuroimaging studies have revealed a dedicated cortical system for visual scene, or place, processing. But what are the stimulus features that characterize visual inputs as a scene, and thereby engage cortical scene processing? While a recent study suggests that concavity is one such feature, it cannot be the only feature that does so. For example, the parahippocampal place area (PPA) and the occipital place area (OPA) respond similarly to both the inside of a building (displaying concavity) and its facade (displaying convexity). So, what are the other stimulus features that characterize visual inputs as a scene, and, perhaps more importantly, given scene images are so variable, how are we even going to identify these other features? Here, we use a novel, stimuli-driven approach to identify another scene-defining stimulus feature. Specifically, we first averaged over thousands of naturalistic images (Study 1), and found that scene images - but not object images - contain a "vertical luminance gradient" (VLG), with the top half of a scene image brighter than the bottom half. Thus, we hypothesized that VLG is a stimulus feature that selectively engages cortical scene processing. In Study 2, using fMRI data from BOLD5000, we then examined the response function of the scene-selective cortical regions, and asked whether VLG systemically increases as neural responses in the scene-selective cortical regions increase. Consistent with our prediction, we found a significant, positive correlation between VLG and the neural responses in the scene-selective cortical regions, but not in an object-selective region or in early visual cortex. To rule out the effects of other potential confounding stimulus features in naturalistic images, in Study 3, we generated tightly controlled VLG stimuli and directly tested the role of VLG in driving cortical scene processing. We found that PPA and OPA responded significantly more to images of VLG over the same, exact images in which VLG was disrupted via image inversion; moreover, no such effect was found in either an object-selective region or in early visual cortex. Taken together, these results reveal that VLG is a visual feature that selectively engages cortical scene processing, and highlight the potential of combining data-driven and hypothesis-driven methods to better understand human cortical processing.

Title: Information content and routing of visuomotor signals in the cortex

Authors: *A. SPEED, B. HAIDER;
Biomed. Engin., Georgia Tech. & Emory Univ., Atlanta, GA

Abstract: Flexible sensorimotor transformations are a hallmark of complex cognitive behaviors. It remains unclear how sensory signals are routed to motor areas of the cortex in the absence of direct connections. In particular, it remains debated if sensory and motor activity relevant for task performance exist locally in relevant cortical areas, or show distributed activation throughout the cortex. By directly and simultaneously measuring neural activity in sensory and premotor areas during a flexible sensorimotor transformation, we can begin to identify principles governing both the information content and the routing of signals relevant for sensorimotor behaviors. We developed a novel behavioral task where head-fixed mice report detection of different visual stimuli with different actions. Mice licked left to report stimuli detected in the central (binocular) visual field, and licked right when detecting stimuli in the right (monocular) visual field. Stimuli were presented in blocks of 15-35 trials in the same location before switching. Behavioral performance varied psychometrically with contrast at each stimulus location (N = 4 mice). We performed acute recordings with Neuropixels probes in primary visual cortex (V1) and anterolateral motor cortex (ALM), and estimated the information content about specific task variables in each area. Peristimulus time histograms from both areas showed clear effects of stimulus location and trial outcome, both as a function of visual stimulus detection (hit vs miss) and non-sensory motor action (false alarm vs correct reject). V1 signals peaked at short-latency (150 ± 53 ms) relative to the reaction time (630 ± 100 ms) and contained significant information about stimulus contrast (9.1 ± 6.3% variance explained), but almost no information about reaction time. Strikingly, in ALM, we also observed information about stimulus contrast (8.1 ± 2.0%) at short-latency (200 ± 16 ms), but with significantly more information about reaction time (15.5± 4.6%) at longer latency (390 ± 27 ms), as expected. To assess the routing of visual information to ALM, we leveraged simultaneous recordings from V1 and ALM. We found a significant delay between V1 and ALM activity on single trials where stimuli were successfully detected in the receptive field of the V1 neurons, with V1 leading ALM by 210 ± 114 ms. We found no such temporal relationship on miss trials where the stimulus appeared in the same position and contrast, or on trials where the stimulus was presented outside of the receptive field. We are currently investigating if visual and motor information is communicated to and maintained in ALM via distinct subpopulations of neurons.

Title: Paradoxical effects of stGtACR2 inactivation of mouse superior colliculus

Authors: *K. Z. SOCHA[1], .. INTERNATIONAL BRAIN LABORATORY[2,1], K. D. HARRIS[1,1], M. CARANDINI[1,1];
[1]Univ. Col. London, London, United Kingdom; [2]The Intl. Brain Lab., London, United Kingdom

Abstract: [Introduction] Mouse superior colliculus (SC) plays a key role in selecting actions guided by sensory cues (e.g. Huda et al. 2020, Duan et al. 2021, Essig et al. 2021). SC neurons exhibit strongly lateralized activity, responding after contralateral visual cues and before contraversive movements (Steinmetz et al. 2019). A longstanding hypothesis is that SC helps select actions thanks to competitive mechanisms that operate within and across hemispheres. We thus hypothesized that inactivating SC unilaterally would suppress contraversive choices and increase activity in the contralateral SC. [Methods] To test this hypothesis, we inactivated the left SC while recording with a Neuropixels probe in the right hemisphere, in mice that performed a visual discrimination task. We trained head-fixed mice to turn a steering wheel to indicate whether a stimulus appears on the left or right (Burgess et al. 2017, IBL et al. 2021), and we expressed the inhibitory soma-targeting opsin stGtACR2 (Mahn et al. 2018) in deep and intermediate SC layers. The opsin was activated by a laser for 1 s at or before stimulus onset (30% of all trials), through an optic fiber in left SC. In control experiments, we inserted an additional fiber in the right SC. [Results] Unexpectedly, unilateral optogenetic manipulation promoted contralateral choices (n=3 mice), instead of suppressing them. Moreover, it markedly reduced the reaction times, possibly suggesting a different behavioral strategy. Neuropixels recordings revealed that during SC inactivation, units located close to optic fiber in SC were mainly suppressed, but units located in the ipsilateral visual cortex increased spiking. Moreover, units in the opposite hemisphere exhibited a variety of response patterns. [Conclusions] These preliminary results confirm that mouse SC is involved in decision-making and triggers motor actions. However, the effects are opposite to what we expected. They resemble the effects of inactivating projections from anterior cingulate cortex to SC (Huda et al. 2020). Perhaps suppressing SC increases activity in cortex and elsewhere. To test this hypothesis we need further experiments, using different opsins and probing activity in multiple areas.

Title: The representation of visual feedback during courtship in Drosophila males

Authors: *N. RANGARAJAN, A. J. CALHOUN, B. R. COWLEY, M. MURTHY;
Princeton Univ., Princeton, NJ

Abstract: Social interactions rely on processing sensory feedback cues from social partners to sculpt ongoing behavior. Here, we investigate how male flies represent visual feedback cues from females as they chase and sing to them during courtship. The *Drosophila* visual pathway contains a large population of visual projection neurons called lobula columnar cells (LCs) that project from the optic lobe to distinct glomeruli in the central brain (Wu et al. eLife, 2016). The LCs are thought to serve as a set of feature detectors for specific behaviors, but how the population functions during natural social behaviors has not been investigated. In fact, male courtship behavior is so far thought to rely primarily on only one LC subset called LC10 (Ribeiro et al. Cell, 2018 and Sten et al. Nature, 2021). To study the LC population, we first used two-photon calcium imaging to record from five different LC subtypes in head-fixed, walking male flies. We presented a wide range of visual stimuli, from simple moving and rotating objects, to more complex fly-like stimuli that mimic the natural motion of the female. We find that all recorded LCs respond to female motion cues, and are additionally modulated by the male's locomotor state. We then built a deep neural network model to recapitulate the sensorimotor transformations that occur within the male nervous system, from processing female visual feedback cues to changes in locomotion and song patterning. We explicitly modeled the LC population within the neural network model by fitting it with neural silencing data and displayed the same stimuli to the model as the real flies. We then validated the model by assessing whether the model predictions matched the neural responses. These data support the idea that males use an LC population code during courtship to track and sing to females.

Title: Visual circuit for collision avoidance in walking Drosophila

Authors: *R. TANAKA[1], D. A. CLARK[2,1,3,4];
[1]Interdepartmental Neurosci. Program, [2]Dept. of Molecular, Cell. and Developmental Biol., [3]Dept. of Physics, [4]Dept. of Neurosci., Yale Univ., New Haven, CT

Abstract: Visual motion provides animals with rich cues about the spatial relationships between them and their environment, including whether they may be on a collision course with objects in the environment. As an object moves relative to the observer, the size and position of its retinal image change as dictated by geometry. While it has been well studied both at behavioral and neural levels how animals ranging from mammals to insects use apparent size increments (i. e., visual looming) to avoid collision with objects like predators, it has remained relatively unclear whether and how animals use positional cues to detect future collisions. In the present study, we demonstrate that, in walking *Drosophila*, a visual projection neuron type called LPLC1 is necessary and sufficient for slowing caused by small objects moving in the back-to-front direction on their retina. Since back-to-front visual motion predicts that the object is about to cross in front of the observer posing the risk of collision, the slowing behavior likely reflects a strategy for collision avoidance. Using two-photon calcium imaging, we then show that LPLC1 vigorously responds to short objects moving in the back-to-front direction as well as to expanding discs, mirroring our behavioral findings. Combining analyses of a connectomic dataset and optogenetics, we show that LPLC1 implements its response specificity by selectively pooling inputs from both elementary motion detectors and object detectors. In addition, we find spatial bias in the direction selectivity of LPLC1 achieved through glutamatergic inhibition, a potential adaptation to the geometry of collisions. Lastly, we identify a central pathway that conveys LPLC1's signals for the collision avoidance behavior. Overall, our results exemplify how outputs of elementary visual feature detectors can be combined to guide behavior that exploits a universal geometrical constraint of the visual world.

Title: Parallel processing of optic flow signals in central self-motion estimation networks

Authors: *M. ERGINKAYA[1], M. BROTAS[1], K. STECK[2], A. NERN[3], D. BOCK[4], M. B. REISER[3], M. E. CHIAPPE[1];

Abstract: Sensory experience critically depends on our own movement: the brain must incorporate information about self-movement to guide behavior, or discount self-generated sensory signals to detect external events in the world. How do sensory circuits process self-generated signals in different ways to meet specific demands?
In insects, the pattern of visual motion generated by self-movement, or optic flow, contributes to an

internal estimate of self-motion and is thought to actively control the walking course. Lobula Plate Tangential Cells (LPTCs) of the fly optic system respond to specific patterns of optic flow. LPTCs also receive extra-retinal signals related to head/body movements during locomotion, which suppress or enhance their activity depending on the task. Thus, the LPTC network is suitable to investigate task-dependent processing of self-generated sensory signals for behavioral control. Although some pathways that connect LPTCs to head rotations have been identified, the full extent of the central circuitry that enable optic flow signals to control behavior remains largely unidentified.
Using a complete adult *Drosophila* brain electron microscopy data, we identified synaptic partners of two classes of LPTCs, the Horizontal (HS) and Vertical System (VS) cells. We found that HS and VS cells receive synaptic inputs at their axon terminals located at a premotor center. Interestingly, neurons that receive the strongest convergent input from HS and VS cells are three distinctive classes of GABAergic interneurons that, in turn, provide the majority of synaptic inputs back onto HS and VS cells at their axons, likely modulating LPTC activity. By mapping the inputs and outputs of these key interneurons, we found two major subnetworks that contact distinct populations of central and descending neurons. Functional imaging revealed that these key interneurons are sensitive to specific optic flow patterns that are either induced by forward or turning movements. The same population of cells also respond in darkness, when the fly is either walking forward or turning, respectively.
The combination of the circuit architecture and functional responses suggest that one of the subnetworks can be used to detect voluntary turns and discount the resultant optic flow, whereas the other monitors the angular deviations and elicits turns to maintain a straight course. Altogether, our results reveal two central networks that process complex patterns of optic flow field into translational and rotational directions, which in combination with extra-retinal signals, modulate the activity of visual neurons according to the ongoing task of an animal moving through space.

Title: Diversity and organisation of projection neurons in the optic tectum of the larval zebrafish.

Authors: *R. WILLIAMS, M. GRUBB, M. MEYER;
King's Col. London Sch. of Med. and Dent., London, United Kingdom

Abstract: Background & aims: The optic tectum and its mammalian homologue, the superior colliculus, transform topographically organized visual information from the retina into goal-directed movement in body-centered space.

How the tectum transforms activity in retinotectal coordinates into commands that guide appropriate behavioural responses is not well understood. To address this, we are using the larval zebrafish to determine the identity and organization of cell types that connect the tectum to efferent areas of the brain. **Methods:** At 6 days post-fertilization (dpf) larval zebrafish are small and translucent and so fluorescently labelled neurons can be visualized in their entirety in the intact, living brain. Tectal projection neurons were sparsely labelled by embryonic injection with FoxP2:Gal4/UAS:LYN-tdT. High resolution, 3-dimensional confocal images of 38 labelled neurons were acquired at 6dpf and registered to an anatomical atlas of the zebrafish brain. All non-overlapping, sparsely labelled cells that had a soma within the optic tectum and at least one neurite projecting out of the tectum were imaged and traced. Interneurons, defined as any cells without a neurite projecting out of the tectum, were excluded from analysis. Whole-brain functional activity was recorded using a 2-photon microscope in fish expressing nuclear localised GCaMP6s. **Results:** Preliminary analysis of a novel library of tectal projection neurons suggests their projections are diverse, organised by both dendritic arborisation and soma position along the anterior-posterior axis. The data show that diversity of tectal targets increases along the anterior-posterior axis of the tectum. Functional imaging reveals correlated areas of activity in response to a prey stimulus. **Conclusion:** Topographic visual information from the retina is transformed differentially in the tectum based on both the location and morphology of the tectal projection neurons receiving it. Functional imaging gives insight into how these physical connections underlie correlated activity in the zebrafish brain.

Title: Adaptable internal representations drive cerebellum-mediated predictive control of an innate behavior

Authors: *S. NARAYANAN, A. VARMA, V. THIRUMALAI;
Natl. Ctr. For Biol. Sci., Bangalore, India

Abstract: The brain uses internal models to estimate future states of the environment based on current inputs and to predict consequences of planned actions. Neural mechanisms that underlie the acquisition and use of these predictive models are poorly understood. Using a novel behavioral paradigm coupled with two-photon calcium imaging, we show clear evidence for predictive processing in the larval

zebrafish cerebellum. We find that when presented with repetitive optic flow stimuli, larval zebrafish acquire supra-second internal representations of stimulus timing and modulate their optomotor response. Evidence for such predictive representations appears within two trials, lasts over minute timescales even after optic flow is stopped and readily adapts to changes in the pattern. Results from calcium imaging indicate that the cerebellum through an error feedback loop with sensory areas of the brain plays a central role in acquiring these timing representations. An algorithmic model constrained by our experimental findings acquires timing representations as observed in the fish cerebellum and explains the predictive component of the behavioral response, thereby providing a mechanistic description from sensory input to motor output of how the brain adaptively internalizes rules of the world.

Title: Identifying key structural connections from functional response data

Authors: *T. BISWAS[1], L. T. LI[2], J. E. FITZGERALD[3];
[1]Janelia research campus, HHMI, Ashburn, VA; [2]Yale Univ., New Haven, CT; [3]Howard Hughes Med. Inst., Ashburn, VA

Abstract: Being able to identify key patterns of neural network connectivity that are specifically required to generate functional response patterns is a challenging and aspirational goal in neuroscience. The difficulty, in part, is because we are typically only able to probe a network with a limited number of stimulus conditions, and there exists huge degeneracies in the ways we can connect the neurons to reproduce the observed responses. Here we present a new geometric ensemble modeling approach to this problem. Inspired by whole-brain imaging approaches, we assume that we have access to a finite number of steady state response patterns of all the relevant neurons in a given network, and we then ask if we can identify key excitatory or inhibitory connections that must exist to generate the responses. We assume that the network can be modeled by a recurrent neural network of rectified linear units that receive feedforward inputs. We first analyze a few toy models to illustrate the conceptual content of the theory. We then apply our theory to predict biological connectivity required to generate binocular responses of zebrafish pretectal neurons to various optomotor stimuli, which were previously recorded using whole-brain imaging. We finally present preliminary results trying to leverage the comprehensive connectomic data that now exists in fruit flies to test our theory on the ring attractor network in the fly central complex.

Title: Task-dependent representations of population activity in the superior colliculus during sensorimotor transformation

Authors: *E. C. AYAR[1], M. R. HEUSSER[1], N. J. GANDHI[2];
[2]Dept. of Bioengineering, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: For visually guided eye movements known as saccades, neurons in the superior colliculus in the midbrain emit a volley of action potentials to register a visual (sensory) stimulus. They also discharge another high frequency burst of spikes to move the line of sight. Deficits in sensory and/or motor processes are implicated in a number of neurological disorders, so our research is focused on how the context of behavioral tasks impacts patterns of SC population activity during sensorimotor transformation. Specifically, we investigated the representations of sensory- and motor-related activity produced by populations of SC neurons during three paradigms: the gap, visually-guided delayed, and memory-guided delayed saccade tasks. The gap and delayed (visually- and memory-guided) saccade tasks differ in instructing the time to initiate the eye movement, permitting different temporal evolutions of the sensorimotor transformation. The visually-guided and memory-guided delayed tasks differ in whether or not the target is present when the macaque must make an eye movement to it. Dimensionality reduction methods were used to summarize the activity of simultaneously recorded neurons to determine if the population responses in both tasks exhibit similar visual and motor patterns despite differences in event timing and cognitive context. Our analyses suggest that the visual patterns explored during the delayed and gap tasks largely overlap while patterns of motor activity display differences. This also holds true when strictly comparing between the visually-guided and memory-guided delayed saccade tasks. Yet, there is more separability in patterns of motor activity between the visually-guided delayed and gap task than between the visually-guided and memory-guided delayed task. The results imply that downstream structures may differentiate signal processing between behavioral tasks. For instance, these signals ascend through the thalamus to the frontal cortex, which could potentially discern the different cognitive demands of the delayed and gap tasks. Thus, the context of a behavior matters when considering how sensorimotor transformation occurs. The same signals also descend to the saccade generator region in the brain stem. The observation that the motor subspaces associated with the three tasks are not identical, albeit partially overlapping, indicates that the actual motor subspace may be larger than that characterized from an individual paradigm.

Title: Low-dimensional representations of population activity in the primate superior colliculus during a sensorimotor task

Authors: *M. R. HEUSSER[1,2], U. K. JAGADISAN[1,2], N. J. GANDHI[1,2];
[1]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA

Abstract: The superior colliculus (SC) is a midbrain structure that processes information contained in our visual field and converts it into an appropriate motor command. Neurons in its intermediate layers produce a burst of spikes both when a visual stimulus is presented in their response fields and when an eye movement to that stimulus is initiated. In the intervening time period, these neurons also emit spikes, although the reason for this elevated activity is still unknown. We therefore sought to better understand this "delay period" activity at a population level, aiming to categorize their instantaneous visual- or motor-like representations. To this end, we simultaneously recorded the spiking activity of a small population of neurons using a multichannel laminar microelectrode while two rhesus macaques (*Macaca mulatta)* performed a delayed saccade task. This task temporally dissociates the stimulus presentation from the eye movement, making it a paradigm well-suited for examining population activity patterns throughout the sensorimotor transformation process. We characterized the activity pattern across the population offline during small sliding time bins through a dimensionality reduction algorithm (Gaussian Process Factor Analysis, GPFA). The latent subspaces formed by population activity during the time of the visual burst and the saccade were categorized as the visual and motor subspaces, respectively. The high separability of these subspaces was confirmed via linear discriminant analysis classification. We then quantified latent activity throughout individual trials as more visual-like or more motor-like using a "Visuomotor Proximity Index" (VMPI, based on metric in Dekleva et al., 2018). When plotting the VMPI versus time in the delay period, we did not see a smooth transition from visual- to motor-like. Surprisingly, however, when the VMPI was aligned on the onset time of a detected microsaccade, a consistent trend did emerge—population activity patterns shifted toward the visual subspace approximately 100ms after microsaccade onset and slowly relaxed back to the pre-microsaccade VMPI value. This lends evidence to the potential purpose of microsaccades in refreshing the visual stimulus on the retina. Despite the apparent lack of connection between delay period activity and sensorimotor processing, we found through methods similar to Afshar et al., 2011 that the pattern of population activity at the time of the movement cue was correlated to the animal's reaction time on that trial. Therefore, we conclude that SC delay period activity acts akin to a holding pattern, but one that is still correlated to the metrics of the eventual behavior.

Title: Bayesian visuomotor-reflex modulation by remote state instabilities

Authors: *H. GOMI[1], N. ABEKAWA[2], K. DOYA[3];
[1]NTT Communication Sci. Labs, Kanagawa, Japan; [2]NTT Communication Sci. Labs., Kanagawa, Japan; [3]Okinawa Inst. of Sci. and Technol., Onna, Okinawa, Japan

Abstract: Hand reaching movement is quickly adjusted if surrounding visual motion is suddenly applied during reaching (named manual following response, MFR). Two alternative accounts have been proposed to explain this behavior: one is that an illusory self-motion drives this adjustment, the other is that an illusory target shift induced by surrounding visual motion drives this adjustment. The latter was supported by perception studies of motion induced position shift (MIPS), but the counter evidence was recently shown by the behavioral study (Ueda et al. 2019 Sci Rep). To examine these two accounts from the computational viewpoint, we have tested models of estimating self-motion and of estimating external-motion as to whether they can explain experimental observations of the response modulation caused by contexts of postural and visual instabilities. If we assume that the MFR is driven by an illusory self-motion estimated from prior probability of self-motion and likelihood of self-motion given observation of visual motion, Bayesian optimal model predicts that contexts of the unstable posture and the unstable visual field respectively increase and decreases the MFR. On the other hand, if we assume that the MFR is driven by an illusory target shift induced by visual motion, Bayesian optimal model predicts the contextual modulations of MFR oppositely. In the experiment, participants (n=16) were asked to stand on the stable or unstable (moving) platform in the context phase (5 s) with watching the screen on which grating pattern was filled. The grating pattern was stable on the screen in the static visual session while it was randomly moved in the unstable visual session. After the context period, they were asked to make reaching movement toward a target flashed on the screen. During reaching in randomly selected trials, grating pattern started to move rightward or leftward to induce the reflexive manual response in the direction of visual motion. When comparing the MFR amplitudes for four contexts (stable/unstable postural x stable/unstable visual), we found that the MFR increased following the context of unstable posture, and decreased following the context of unstable visual pattern. Further, variance of likelihood, estimated from the mean and variance of posterior probability, in the Bayesian optimal model, increased following the unstable visual context, compared with the stable visual context. These observations support the self-motion account, and suggests that the implicit visuomotor control mechanism modulates reflexive adjustment during reaching by accessing body state prior (postural instability) reflecting environmental context.

Title: Initial corticospinal responsiveness following visual target presentation during reaching reflects target direction rather than reach direction.

Authors: *R. DIVAKAR[1], G. E. LOEB[2], B. D. CORNEIL[3], G. WALLIS[1], T. J. CARROLL[1];
[1]Sch. of Human Movement and Nutr. Sci., The Univ. of Queensland, Brisbane, Australia; [2]Biomed Engin., USC, Los Angeles, CA; [3]Dept Physio & Pharmacol, Western Univ., London, ON, Canada

Abstract: During visually guided reaching, proximal limb muscles can be activated within 80 ms of target appearance. Such "express" muscle responses are invariably tuned towards the direction of the visual target regardless of the reach direction, which prompts the hypothesis that they are driven by a subcortical tecto-reticulo-spinal pathway. Here we measured motor evoked potentials (MEPs) evoked by transcranial magnetic stimulation (TMS) to probe the modulation of corticospinal excitability within 100ms after target presentation. Twenty participants were instructed to reach either towards (pro-reach) or away from (anti-reach) visual targets displayed randomly to right or left of the right hand. Electromyographic activity was recorded from the right Pectoralis Major (PEC), Posterior Deltoid (PD) and First Dorsal Interosseous (FDI). TMS was delivered over the left motor cortex 60, 70, 80, 90 or 100 ms after target presentation to induce MEPs in PEC. When the visual target and motor goal were congruent in the pro-reach condition, MEPs were enhanced when PEC was agonist and inhibited when PEC was antagonist, from 70ms onwards. In the anti-reach condition, corticospinal excitability at 70 and 80 ms initially reflected visual target location, but excitability reversed by 100 ms to reflect the reach direction. The PD muscle, which is antagonist to the PEC muscle in this task, showed a mirror opposite trend to the PEC results. By contrast, MEPs in a functionally irrelevant muscle, the FDI in the hand, were unchanged by target or reach direction, suggesting that the corticospinal excitability effects in proximal muscles are task-related. The observation that corticospinal excitability of proximal muscles invariably reflects the visual target rather than the reach direction at 70-80 ms after target presentation suggests that MEPs are modulated by processing associated with express muscle responses. The observation that corticospinal excitability reflects reach direction by 100 ms, irrespective of the physical location of the target, shows that motor output circuits are biased by "cognitive" rule-based processing surprisingly early. The early target and subsequent reach encoding in TMS evoked MEPs could arise at various levels in the neuraxis, including biasing of the: 1) motor cortex output neurons by incoming visual and reach signals through direct cortico-cortical or indirect tecto-cortical pathways; 2) spinal neurons by descending signals from the superior colliculus via the reticular formation followed by signals from cortical areas. Ongoing work will address whether these early target-directed changes in MEP size occur within the motor cortex or the spinal cord.

Title: Effector-specific spatial codes in dorsolateral prefrontal cortex during a head-unrestrained reach task.

Authors: V. NACHER, P. ABEDI-KHOOZANI, V. BHARMAURIA, H. ARORA, X. YAN, S. SUN, H. WANG, D. CRAWFORD;
Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Dorsolateral prefrontal cortex (DLPFC) is associated with executive control and response selection, but the extent to which it is involved in effector-specific transformations is unclear. We addressed this question by recording single neurons from dorsolateral prefrontal cortex (DLPFC) while two trained monkeys performed a head-unrestrained reaching paradigm that allowed freely coordinated motion of gaze, head reaching in depth. Animals touched one of three central LEDs at waist level while maintaining gaze on a central fixation dot and were rewarded if they touched a target appearing at one of 15 locations in a 40° x 20° (visual angle) array. Preliminary analysis of 239 neurons in one monkey showed an assortment of target/stimulus, gaze, pre-reach and reach-timed responses in DLPFC. Most neurons could be described as falling into three main groups. ‘Early” neurons increased firing rate during the target presentation and gaze onset. “Early-late” neurons responded in a sustained way from target presentation until reach. Finally, “Late” neurons increased firing rate during the pre-reach and peak when the monkey reaches. We first tested for gaze, head and hand gain fields during the different neuronal responses and found that 47 % of the responses were gain modulated by initial hand position. A fraction (12 %) of the neurons showed gain fields for initial gaze position, and for both initial gaze and hand position (7 %). A small fraction of neurons showed gain fields for initial head position (3 %), and for both initial hand and head position (2 %). After removing the gain field effects, we fitted the residual data against various spatial models, and found that the visual response best encoded the target relative to the space (Ts), whereas responses at gaze and hand onset showed a tendency towards coding hand displacement (dA). In addition, some (20 %) neurons showed a preference for coding final head position or displacement. A more complete analysis will describe the complete coding and distribution of gaze, head and reach signals in this region.

Title: Population receptive fields in human visual cortex during active vision

Authors: *A. FRACASSO, K. MORAVKOVA, J. H. FABIUS;
Univ. of Glasgow, Glasgow, United Kingdom

Abstract: To adequately localize sensory events, the brain must have an accurate representation of the receptor topography. In the visual system this is achieved with an organization that preserves the retinotopic topography of photoreceptors. However, because receptors can move with respect to other parts of the body, the mere topography of receptors is not sufficient for localization of external objects. In the case of vision, eye movements change the orientation of the entire retina with respect to the head and body. A computational solution to this problem is a modulation of response gain based on receptor orientation (e.g. based on eye position). In theory, gain fields allow for the transition from a purely retinotopic to an eye position invariant representation of visual space. Evidence for gain fields in the visual system comes primarily from neurophysiological studies with non-human primates. Still, it is not clear how and to what extent the gain field mechanism is implemented in the human visual hierarchy. Here, we measure high resolution functional MRI data while participants actively made guided eye movements. In our analysis, we first estimated population receptive fields (pRF) using data from a standard moving-bar paradigm. Next, we assessed to what extent these pRF estimates can account for the data from the eye movement paradigm. Finally, we estimate population gain fields on top of pRFs, testing whether eye-position based gain modulation increases the explained variance of the predicted contrast-based pRF response. Moreover, we assess how reliably eye-position can be decoded from different areas along the visual hierarchy. These results shed new light on how receptor position modulates sensory processing in the human brain, and our methods provide a new way of access to the computational code behind that modulation, accessing the large-scale organization of gain-field properties in human neocortex.

Title: Memory delay activity in visual cortex depends on movement preparation

Authors: *D. JONIKAITIS[1,2], T. MOORE[1,2];
[1]Stanford Univ. Sch. of Med., Stanford, CA; [2]Howard Hughes Med. Inst., Stanford, CA

Abstract: Visuospatial working memory and gaze control are two behavioral functions that are known to be heavily interdependent and appear to involve interrelated neural circuits. Past neurophysiological studies have shown that neurons in many areas within primate visual cortex exhibit activity associated with spatial working memory. Specifically, the activity of neurons during the memory (delay) period depends on the location of the remembered stimulus. However, the extent to which that activity reflects working memory, or instead reflects the preparation of a behavioral response, remains unresolved. To address this question, we trained rhesus monkeys on a pair of tasks that dissociated spatial working memory from the behavioral response and measured neuronal responses in area V4. In one of the tasks (Look task), monkeys memorized a cue location, and after a delay period (1 - 1.5 seconds), were rewarded for making an eye movement to targets appearing at the cued location. In the other task (Avoid task), monkeys were instead rewarded for making an eye movement to a target appearing at a novel

location. Although the behavioral responses differed between the two tasks, looking at or avoiding the cued location, neither could be solved without memorizing that location. However, only in the Look task could monkeys prepare the behavioral response. We measured neuronal activity in area V4 of two monkeys using 16 - 32 channel, linear array electrodes (Plexon, Inc.) which were inserted largely perpendicular to the cortical surface. We compared neuronal activity during the memory delay period between the Look and Avoid tasks. During the Look task, V4 neurons exhibited elevated activity during the memory delay period when the remembered location corresponded to the visual RF. This modulation was individually significant in the V4 activity measured in both monkeys. In contrast, we observed no elevated activity at the remembered location during the Avoid task, a pattern that was consistent in data from both monkeys. These results indicate that the delay period activity in this visual area depends critically on the preparation of the behavioral response, in this case, eye movement preparation.

Title: Visual deprivation-induced plasticity of higher order visual area inputs to the primary visual cortex

Authors: *S. PARKINS[1], X. CHEN[1], Y. JAOUI[2], H.-K. LEE[2,3,4,1];
[1]Cell Mol. Developmental Biol. and Biophysics (CMDB) Program, [2]Dept. of Neurosci., [3]Mind/Brain Inst., [4]Kavli Neurosci. Discovery Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Processing of sensory experience, which is essential for navigating and interacting with the world, relies heavily on feedback inputs from the higher-order cortical areas. This is further emphasized in the visual system where the connectivity between the higher-order visual areas and the primary visual cortex (V1) provides context to the information we see and allows us to pay attention to important aspects of the visual stimuli. It is well documented that V1 undergoes plastic changes in response to altered visual experience. For instance, in response to visual deprivation, V1 adapts by changing the strength of its connections in a layer specific manner. More specifically, we previously reported that after visual deprivation, lateral intracortical connections in V1 layer 2/3 increase in strength without changes in feedforward connections from layer 4. These changes were readily observed in adult mice, which suggests that visual deprivation is an effective means to produce plasticity in the adult brain. Feedback projections from higher-order cortical areas as well as other sensory cortical areas provide long-range intracortical inputs to V1 layer 2/3 neurons. Here we address the role of these long-range intracortical excitatory inputs in mediating visual deprivation-induced plasticity of V1. To do this, we first functionally identified different higher order visual areas (HVAs) surrounding V1 using the intrinsic signal imaging method developed by the Callaway's group. Using the anatomical landmarks, we then

performed stereotaxic injections to specific HVA to express channelrhodopsin-2. To assess the strength of these feedback inputs into V1, we recorded LED evoked Sr^{2+}-desynchronized miniature excitatory postsynaptic currents (mEPSCs) in V1 layer 2/3 neurons. Concurrently, we recorded mEPSCs in HVAs to determine whether the inputs to these regions also undergo experience-dependent plasticity as a result of visual deprivation. Our results will shed light on the cross-modal recruitment of V1 as well as the adaption of HVAs upon loss of vision.

Title: Optogenetic dissection of fronto-temporal neuronal circuits for audio-visual integration in primates

Authors: *B. AGAYBY[1], Y. KIKUCHI[1], R. S. MUERS[2], J. S. NACEF[1], M. C. SCHMID[3], C. I. PETKOV[1];
[1]Biosci. Institute, Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Inst. off Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom; [3]Dept. of Neurosciences and Movement Sciences, Univ. of Fribourg, Fribourg, Switzerland

Abstract: Although there can be multisensory interactions at nearly every stage of sensory processing, certain regions in the temporal and prefrontal cortex are often implicated in audio-visual integration. For instance, the upper bank of the Superior Temporal Sulcus (STS) and Ventro-Lateral Prefrontal Cortex (VLPFC, e.g., areas 44/45) have audio-visual bimodal neurons and clusters, interspersed within those that are primarily auditory or visual. Although there is evidence for monosynaptic input from auditory belt areas to VLPFC[1,2], it is not clear how this projection contributes to VLPFC function, including audiovisual integration. To address this, we tested whether optogenetic perturbation of auditory belt areas would influence VLPFC responses to voices, faces or both. We injected the optogenetic viral construct AAV9-CaMKII-ChR2-eYFP at multiple sites and depths (total volume = 36µl) in the anterior part of the auditory belt. Following expression, we confirmed strong spiking responses in auditory belt neurons in response to optogenetic stimulation modulated at 5Hz and 40Hz, using integrated optical fibres within Plexon S probes. Near the injected locations, there was an increase in multiunit activity (MUA) across the cortical layers in response to blue light (473nm) with the peak activity concentrated around the fibre location. Then, we investigated the effect of optogenetic stimulation of auditory belt neurons with or without simultaneous sensory stimulation with voices, faces or both on VLPFC area 44 neuronal and LFP responses across the cortical layers. Frontal Current Source Densities (CSDs) were markedly different to the sensory stimulation conditions and appeared to be modulated during auditory cortex optogenetic stimulation, in particular affecting deeper layer sinks/sources in the CSD. Work is underway in a second animal and we are also studying auditory optogenetic effects on STS neurons. Our preliminary results

demonstrate the feasibility of using macaque optogenetics to manipulate neuronal circuit activity during audio-visual integration, which aims to shed light on the role of rapid monosynaptic auditory input into fronto-temporal regions involved in sensory integration. 1. Title: The fundamental network of gaze-stabilization - Ancient origins of subcortical visuovestibular integration

Authors: *T. WIBBLE[1], T. PANSELL[1], S. GRILLNER[2], J. PÉREZ-FERNÁNDEZ[3];
[1]Dept. of Clin. Neurosci., Karolinska Institutet, Solna, Sweden; [2]Dept. of Neurosci., Karolinska Inst., Solna, Sweden; [3]CINBIO, Univ. de Vigo, Vigo, Spain

Abstract: Eye movements originally evolved as a mean to allow gaze-stability during locomotion and other movements. The two principal mechanisms are the vestibulo-ocular reflex (VOR), which produces compensatory eye movements in the opposite direction of the head mediated by vestibular inputs, and the optokinetic reflex (OKR), that sees both eyes follow a continuous visual motion. In addition, some vertebrate species show a locomotion-related stabilization through reafferents or corollary discharges. Despite the importance of gaze-stabilization, our understanding of basic circuitry remains incomplete. The aim here is to investigate the visuo-vestibular control of gaze-stabilization using the lamprey representing the oldest group of vertebrates. To this end, we have designed an eye-brain-labyrinth preparation. By using a moving platform synchronized with two monitors, we could elicit visual and vestibular stimulations of varying intensities, while recording from extraocular muscles and vestibular nuclei. We show that lampreys possess a clear OKR, which added to the motor response when combined with the VOR during slower stimuli. At higher velocities, the VOR dominated. Lesion experiments and tracer injections allowed a characterization of the gaze-stabilizing network. Lesions of pretectum

abolished the OKR, whereas a tectal inactivation instead enhanced the visual contribution. Behavioural tests using video eye-tracking on intact lampreys rotated in three dimensions showed that the lamprey VOR features clear nystagmus. Experiments on a semi-intact preparation during locomotion resulted in clear, albeit weak, compensatory eye movements. The fact that the lamprey possesses both OKR and nystagmus, show that the building blocks for all subsequent eye movements were present already at the start of vertebrate evolution, implemented in the OKR, VOR and locomotion-supported gaze-stabilization. We also show that basic gaze-stabilization relies solely on subcortical structures, supporting the notion that pretectum acts as a first level integrator of visual motion and that neither cortex nor cerebellum is needed for the OKR to integrate with the VOR. Tectal downregulation of visual responses is likely due to its role in producing goal-oriented gaze-shifts. In conclusion, this study suggests that the basic circuitry underlying gaze-stabilization existed already at the point when lampreys diverged from the evolutionary lineage leading to mammals some 500 million years ago.

Title: Cross-modal plasticity of the higher order auditory thalamus

Authors: *G. EWALL[1], A. LIN[2], P. O. KANOLD[3], H.-K. LEE[4];
[1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Mind/Brain Institute, Johns Hopkins Univ., Baltimore, MD; [3]Biomed. Engin., Johns Hopkins Sch. of Med., Baltimore, MD; [4]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: The phenomenon of cross-modal plasticity, or the process by which deprivation of one sensory modality induces alterations in processing of the spared modality, demonstrates that sensory processing in the brain is not siloed by modality is and more integrative than initially thought. We previously reported such cross-modal interactions by demonstrating visual deprivation-induced plasticity in the primary auditory cortex (A1) of adult mice. In particular, visual deprivation altered the A1 circuit to promote feedforward processing of auditory information, which may mediate heightened auditory function reported in blind individuals. Although the synaptic and circuit level alterations within A1 have been characterized, the mechanisms by which visual deprivation influences A1 is unknown. In addition, it is unknown whether cross-modal plasticity is a cortical phenomenon or manifests even in subcortical auditory circuits. To answer these questions, we examined the dorsal medial geniculate nucleus (MGd), a higher order auditory thalamic region known to receive inputs from multisensory areas and project broadly to auditory cortex. To test whether inputs to MGd undergo cross-modal plasticity, we performed whole-cell patch clamp recordings from MGd neurons in acute brain slices of adult mice deprived of vision by dark-exposure. We found a dramatic decrease in the strength of excitatory synaptic transmission

to MGd neurons with no change in the strength of inhibitory synaptic transmission following seven days of dark exposure. These results demonstrate that higher order thalamus exhibits cross-modal plasticity in adulthood and suggests a paraleminiscal route for multisensory influence on unimodal circuitry.

Title: Appreciating the diversity: morphology and electrophysiology-based cell type classifications in the mouse insular cortex reveals projection-target and location-specific specializations

Authors: *B. C. JONGBLOETS[1,2], I. K. GINGERICH[2], Y. CHEN[2], T. J. LAMEYER[2], M. A. MUNIAK[2], T. MAO[2];
[1]Cell biology, Neurobio. and Biophysics; Biol. Department;Faculty of Science;Utrecht Univ., Utrecht, Netherlands; [2]Vollum Institute; Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: The insular cortex is an important multi-sensory integration site, and is pivotal for cognitive functions, motivational and homeostatic state processing, and interoceptive awareness. The insula relays these processed state signals to specific cortical, thalamic, and amygdalar subregions. Recent studies have identified that the activities of subpopulations of insular neurons correlate with specific behaviors, indicating that insular circuits are composed of different neuronal subtypes. Yet, a comprehensive understanding of the excitatory neuronal types in the insular cortex is currently lacking. Neuronal type classifications based on other cortical areas do not necessarily apply to the insula due to its unique cytoarchitectural structure, including subdivisions into granular (GI), dysgranular (DI), and agranular (AI) insula depending on the existence of the cortical layer 4.
In this study, we performed whole-cell patch-clamp recordings of the pyramidal neurons in the AI and DI of adult mice using acute brain slice preparations. Electric measurements of passive and active properties, including membrane resistance, action potential waveform, and spike behavior were obtained under current-clamp using biocytin-filled pipettes. Dendritic morphologies of the recorded neurons were revealed using *post-hoc* biocytin staining. Cell type classification analysis was performed based on a dataset of over 850 reconstructed dendritic morphologies and 300 electrical profiles. The anatomical locations of the cells were tracked. In addition, cortical, thalamic, and amygdalar projection targets of

over 230 recorded pyramidal neurons were identified using retrograde anatomical tracers. We identified up to 22 morphological, 12 electrical, and 18 cross-modality cell types. Interestingly, several cell types are located at specific insular subregions and project to distinct brain regions, indicating that local specializations of the neuronal circuits are in place to accommodate multi-modal information processing. Comparative analyses with previously published datasets indicate that functionally different cortical regions have specialized neuronal cell types that may constitute different local connectivity properties.

Title: Deviance detection to multisensory mismatch in posterior parietal cortex of mice

Authors: *A. B. VAN DERVEER[1], C. G. GALLIMORE[1], J. P. HAMM[1,2];
[1]Georgia State Univ., Atanta, GA; [2]Ctr. for Neuroinflam. and Cardiometabolic Dis., Georgia State Univ., Atlanta, GA

Abstract: In a predictive coding framework, the brain is believed to generate predictive models which affect information processing at each stage in a hierarchically organized cortical network. Incoming sensory information is compared against these models, suppressing neural responses to expected stimuli and augmenting responses to unexpected stimuli. This modulation is evident in primary sensory cortices during a basic unisensory oddball paradigm; neural activity is reduced to repetitive stimuli (stimulus specific adaptation; SSA) and augmented to deviant stimuli (deviance detection; DD). It is unknown whether this occurs similarly in higher-order regions of cortex, such as posterior parietal cortex (PPC), a critical region for multisensory (MS) integration. Past work has shown that mouse PPC exhibits strong SSA, yet little DD to unisensory (US) stimuli. Here we test the hypothesis that PPC exhibits DD selectively to complex MS stimuli. We measured neuronal activity in PPC with two-photon calcium imaging in awake mice. All stimuli across paradigms were presented for 0.5s and had a 0.5-0.6s interstimulus interval. For the US visual "oddball" paradigm, we presented eight full square-wave gratings drifting in a random order (many standards control), then an oddball sequence with one redundant grating (88% "standards") and one deviant grating (12% "oddballs"). For the US auditory "oddball" paradigm, we presented mice with eight auditory frequencies in a random order, then an oddball sequence with one redundant tone (88% "standards") and one deviant tone (12% "oddballs"). Responses to the same stimulus were compared between oddball and many standards contexts to assess US DD (n=10, male and female). For the MS paradigm, visual (45º [Va] and 135º [Vb]) and auditory

stimuli (2.0kHz [Aa] and 4.0kHz [Ab]) were paired and presented semi-simultaneously (<10ms delay). Mice were trained with sequences of consistent AaVa and AbVb combinations, then presented MS "oddball" sequences, consisting of 87.5% trained pairs and 12.5% deviant pairs (AbVa (6.25%) ; AaVb (6.25%)). Responses to control and deviant MS pairs stimuli were compared (n=6, male and female) to assess MS DD. After averaging over all neurons, robust MS DD ($t(120)=4.29$, $p<.0001$), but not US DD (auditory: $t(318)=0.87$, $p=.385$; visual: $t(311)=0.56$, $p=.575$), was observed at the population level. These results suggest that while simple US prediction errors do not propagate through the cortical hierarchy to PPC, prediction errors to novel MS combinations generate genuine DD in PPC. This provides new evidence for the predictive coding framework.

Title: Associative modulation in sensory cortices by second order fear conditioning

Authors: G. TASAKA[1], Y. IDE[2], M. TSUKADA[2], *T. AIHARA[2];
[1]Grad. Sch. of Engin., Tamagawa Univ., Machida-Shi, Japan; [2]Tamagawa Univ., Tokyo, Japan

Abstract: The sensory cortex was defined by responses to physical stimuli of specific modalities from the external world. Recently, it has been reported that the human and mammalian cerebral cortex induces associative additional responses to stimuli other than the main specific modality. In our previous study, we measured the plastic changes produced by fear conditioning combining pure tone and electrical foot shock (US) in the auditory and somatosensory cortices of guinea pigs, using optical recording with voltage-sensitive dyes. The results showed that auditory information could be retrieved by only electric shocks to the foot. This indicates that the somatosensory and auditory cortices are activated by a single sensory information in an associative manner. In this study, to investigate the expression of associative responses in the visual, auditory, and somatosensory cortices, cellular responses after first-order or second-order fear conditioning using foot shock, tone, and light, were measured using optical imaging. The results showed that (1) associative responses to sensory conditioning with tone and light was not seen in heart rate change as behavioral phenomena but was seen as changes in responses at the neuronal level. (2) Pre-fear conditioning (light and foot shock preceding tone and light) decreased (extinction) the associative response to foot shocks in the primary visual cortex compared with the response after the first-order fear conditioning with light and foot shock. In contrast, Post-fear conditioning (light and foot shock following tone and light) resulted in an increase (facilitation) in the associative responses.These results suggest that various bottom-up information is integrated into cortically induced associative responses, which are repeatedly or alternately traced by plastic changes in cortical network including facilitation and

extinction. Such an information-coupling process of cortical responses may play an important role in the dynamically linking of memory in the brain.

Title: Novel Flexible Multielectrode Arrays Record Multiple Single Motor Units and Reveal Organization of Behaviors Across Time Scales

Abstract: Recent advances in motor control research are leading to new insights about the structural organization of spinal sensorimotor circuits as well as functional dynamics of cortical and subcortical networks. Understanding how these systems produce complex motor behaviors also requires recordings from their output: coordinated activation of motor units that produce forces and drive movement. We have developed a novel approach to designing and fabricating flexible multielectrode arrays to record populations of single motor units and bulk electromyograms (EMG) during motor behaviors. Our fabrication process allows us to adapt a range of parameters including array shape/size, electrode size and spacing, and electrode surface treatment. By adjusting these parameters during our rapid design iterations, we are able to optimize the signal quality and array design for a variety of anatomical targets across species and muscle groups. In addition, our arrays are designed and developed through an integrated effort of neuroscientists and electrical engineers that facilitates straightforward implantation and use. Our flexible arrays provide a significant advantage over traditional EMG methods because we can record multiple single motor units or bulk EMG with high SNR and stability for acute experiments as well as chronic studies. In songbirds, for example, data collected with our electrode arrays show that breathing is organized by neural and behavioral timescales ranging from milliseconds to minutes and hours.

Title: High-resolution EMG recordings during skilled behavior in mice

Authors: *K. A. THOMAS[1], M. J. WILLIAMS[1], A. L. JACOB[1], B. CHUNG[1], M. ZIA[2], M. BAKIR[2], S. J. SOBER[1];
[1]Biol., Emory Univ., Atlanta, GA; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Understanding how the nervous system controls skilled movements has been limited by our lack of tools for recording muscle activity at high resolution. To overcome this, we have developed flexible electrode arrays for use in multiple species and muscle groups. Here, we present details of the design and usage of arrays specialized for recording from the muscles of the mouse forelimb. Forelimb-specific electrode arrays consist of multiple "threads," each bearing an array of electrode contacts, allowing us to record from multiple muscles simultaneously. The arrays presented here have been optimized for ease of surgical implantation, reducing procedure time and improving signal-to-noise ratio (SNR). These innovations also lessen tissue damage, and improve surgical outcomes. We also tested various methods for grounding the arrays and optimized this feature based on the SNR of single motor units. Low-impedance PEDOT-coated gold contacts allow each contact to record single motor unit impulses. Furthermore, these single units can be resolved with high SNR weeks after the original implantation, allowing for chronic studies. We are currently optimizing the parameters of electrode size, spacing, and number to maximize the number of individual motor units that can be simultaneously recorded from forelimb muscles. In preliminary experiments, we have implanted threads both superficially and intramuscularly in the triceps and trapezius. During free behavior, different channels recorded different sets of motor units, as assessed by the firing pattern and the shape and amplitude of spike waveforms. In ongoing studies we are using these arrays to investigate motor unit activity patterns during bimanual coordination and locomotion and to quantify how activity patterns change during sensorimotor learning. Furthermore, we plan to expand our current range of array designs to target the musculature of the distal forelimb and to improve long-term signal resolution and ease of surgical implantation.

Title: A low-latency behavioral feedback system for training, analyzing, and perturbing skilled forelimb rotation in rats

Authors: *M. RIGOTTI-THOMPSON[1], S. O'CONNELL[1], A. N. CORSTEN[1], F. ZHU[2], Y. H. ALI[1], K. LI[1], S. J. SOBER[3], C. PANDARINATH[1,4];
[1]Wallace H. Coulter Dept. of Biomed. Engin., Emory Univ. and Georgia Inst. of Technol., Atlanta, GA; [2]Neurosci. Grad. Program, [3]Dept. of Biol., [4]Dept. of Neurosurg., Emory Univ., Atlanta, GA

Abstract: Among motor control tasks, skilled forelimb rotation is of particular interest due to its dependence on cortical input and involvement in naturalistic goal-oriented behavior (such as foraging and feeding). An unexplored aspect of this behavior which could provide insight on the closed-loop control mechanisms in the motor system is how subjects respond to perturbations during movement. To study the above, the rat model stands out as an appealing option due to its low-cost and potential for automated training, which enables scalability for large sample sizes. However, there is currently no highly configurable rat behavioral training system available for recording forelimb angular kinematics in response to torque perturbations, especially not one with low-latency (millisecond-timescale) feedback. In this work, we present a highly configurable behavioral feedback system that uses a rotary knob manipulandum for analyzing and sculpting skilled forelimb rotation behavior in freely moving rats. The system includes a variety of features which distinguish it from current alternatives in the literature. For example, it provides customizable torque feedback during motion, while simultaneously recording the kinematics, torques, and Cartesian forces applied by the subject. Using this system, we have trained several female Long-Evans rats to perform forelimb supination under varying torque conditions. The system's low-latency capabilities allows us to sculpt their behavior to execute knob supination to over 75 degrees, and to study how the timing of their behavior varies when torque perturbations are introduced at different stages of the task. Thus, our system provides an effective tool for probing rat motor control while collecting a range of behavioral variables. When paired with electrophysiological data such as neural recordings and electromyography (EMG), this setup will allow us to deconstruct motor command signals that drive forelimb rotation and investigate closed-loop control in a motor cortex-driven behavior.

Title: Generation of human-like reaching movements using the attractor dynamics approach

Authors: S. BLEX[1], T. SZIBURIS[1,2], **M. D. SCHMIDT**[1,2], I. RANO[3], T. GLASMACHERS[2], *I. IOSSIFIDIS[1];
[1]Ruhr West Univ. of Applied Sci., Muelheim An Der Ruhr, Germany; [2]Inst. for Neuroinformatics, Ruhr Univ. Bochum, Bochum, Germany; [3]Biorobotics, Univ. of Southern Denmark, Odense, Denmark

Abstract: Our research aims for a systematic understanding of the generation of human arm movements. The activation of a population of directionally tuned motor cortical neurons determines the direction of motion, which was particularly confirmed for reaching tasks (Georgopoulos et al., 1986). Motion parameters are continuously updated during movement when direction is changed. Such insights can be interpreted as the combination of a nominal trajectory with real-time optimal feedback control (Osu et al., 2015).
In accordance with these findings, direction-coded movement generation has been proposed for robotics: Based on behavioural attractor dynamics, motion is modelled by means of differential equations with behavioural variables in target approaching angles and velocity characteristics as dynamical system attractors (Rano and Iossifidis, 2013). Usually, a spherical representation of these variables and their time derivatives is employed in modelling.
The present work incorporates attractor dynamics to model natural human arm reaching behaviour by applying methods of parameter fitting in dynamical systems. The corresponding movement trajectories can be decomposed into a transport and a lift/descend component (Grimme et al., 2012). Assuming simple reaching tasks to consist of initiation, travel, and approach phase, the travel phase is defined as the time between the extrema of the lift/descend component. Based on human subject data from reaching experiments, we show that the hand trajectory in terms of position and velocity course can be successfully modelled for the travel phase.
The results of curve fitting by minimizing the mean square error can be remarkably improved when utilizing an ellipsoid-based representation of the attractor dynamics behavioural variables. Hereby, approaching of the angle-based attractor is conducted by means of an ellipsoidal coordinate transformation instead of the usually applied spherical one. Furthermore, we analyze and compare the fitted parameters for different tasks of individual subjects. Evaluation of human-likeness reveals that the generated movements exhibit typical human properties and that the applied model is well suited to describe the observations.
As a next step, we will evaluate different measures to quantify the variance of experimentally obtained trajectories. Further work will target at adapting varying movement tasks in order to explain and imitate natural biological behaviour as well as deviations in it. By that, we aim to obtain knowledge for pathological analysis, in particular the modelling and early detection of specific movement disorders by focussing on the hand trajectory.

Title: From motion to muscle

Authors: *M. D. SCHMIDT[1,2], T. GLASMACHERS[2], I. IOSSIFIDIS[1];
[1]Computer Sci., Ruhr West Univ. of Applied Sci., Muelheim An Der Ruhr, Germany; [2]Inst. for Neural Computation, Bochum, Germany

Abstract: Muscle activity plays an important role in understanding human motion execution and detecting neuromuscular diseases as well as being used to control prosthetic devices. The availability of experimental data is always a restricting factor, especially when large data sets are needed to train machine learning algorithms. Therefore, models which generate artificial muscle signals are currently under research. Most approaches are based on analytical models using muscle and signal characteristics to reveal the composition of muscle activity. We present the artificial muscle activity generator (AMAG) as a new approach to artificially generate muscle signals for the upper limb based on deep neural networks with the support of motion-related parameters. The EMG data were recorded from eight upper limb muscles (*deltoid anterior, lateral and posterior, biceps short head, triceps brachii lateral head, pronator teres, flexor carpi ulnaris, and extensor carpi radialis longus*) with the *Delsys Trigno System*. The motion data were obtained using the *Xsens Motion Capture System* with its sensors placed on each arm segment and the upper body. Each subject was asked to execute over 30 simple and complex motions with 19 repetitions in a single session. A total of 10 healthy subjects (3 female, 7 male in the age of 25 +4 years) participated in the experiment.We investigate different motion data as input of the deep learning algorithm and their impact on the artificial muscle signal. In particular, we compare using angular information of the associated body segments, with inputting the changes in muscle length computed using *OpenSim*. The latter corresponds to the neural signal sent from the brain to the muscle, whereas the angular information is the result of change in the muscle length and is needed for movement planning.Several different neural network architectures are considered starting from a basic feedforward neural network (FNN) to more advanced long short-term memory (LSTM) utilizing the time dependency of muscle activity. Besides these recurrent models, we tested a convolutional neural network (CNN) and generative adversarial networks (GAN).The LSTM and CNN show promising results with a mean absolute difference of 1.06% (SD=1.91) and 1.10% (SD=2.19) respectively to the original EMG data set for untrained motion-related data with the former needing much more computation time. The AMAG helps to gain insight into motion processing by varying the input data for example by considering motion data of different movements and comparing the resulting artificially generated muscle signals.

Title: Quantifying errors in the estimation of human motoneuron excitability through the use of hybrid motor unit spike trains

Authors: *C. K. THOMPSON[1], M. H. SURYAPALAM[1], F. NEGRO[2];
[1]Temple Univ., Philadelphia, PA; [2]Univ. degli Studi di Brescia, Dept. of Clin. and Exptl. Sci., Brescia, Italy

Abstract: Spinal motoneurons possess active channels which serve to alter their intrinsic excitability. Remarkably, the discharge of spinal motoneurons can be assessed in humans by recording and decomposing the discharge of the group of muscle fibers that individual motoneuron innervate. From these spike times, analyses can be performed to estimate the intrinsic excitability of spinal motoneurons (e.g. delta-f). In the past decade there have been substantial improvements in our ability to decompose human motor units. However, issues remain regarding the accuracy of these approaches. Here, we assessed the impact of motor unit decomposition errors and motor unit yield on the assessment of human motoneuron excitability. An average of 19 motor units were gathered from 10 participants during performance of linear time varying contractions. Each spike from all signals was corrected for accuracy. Using these highly accurate spike time data, we created millions of hybrid spike trains by imposing six forms of errors on these signals. From these hybrid signals, we found that errors in specific locations of the signals cause specific changes to delta-f values. For example, removing spikes at the onset of discharge and adding spikes randomly throughout the spike train caused delta-f values to increase, whereas removing spikes at the end of the contraction or randomly throughout the contraction caused delta-f values to decrease. Interestingly, small shifts in spike times had a negligible effect on any parameter calculated. Such data are consistent across multiple muscles. This work suggests that errors located at the onset and offset of motor unit discharge are critical to accurate assessments of motoneuron excitability. However, outside of these edges, the precise timing of any given spike is relatively insignificant for accurate estimates of human spinal motoneuron excitability. These results provide new insights into the impact of decomposition errors on our interpretation of these data and will guide future efforts for further automation of this cleaning. Further work will be focused on using these hybrid signals to provide an index of confidence in the original signal.

Res. of Common Dieases, The Chinese Univ. of Hong Kong and Kunming Inst. of Zoology of The Chinese Acad. of Sci., Hong Kong, China

Abstract: The non-negative matrix factorization (NMF), widely used in motor neuroscience for the identification of muscle synergies from electromyographic data (EMG), extracts non-negative synergies and is unable to identify potential negative components in synergies underpinned by inhibitory spinal interneurons. To overcome this constraint, we propose to utilize the rectified latent variable model (RLVM) to extract muscle synergies. RLVM uses an autoencoder neural network for parameter initialization. The weight matrix of its neural network could be negative while the latent variables must remain non-negative. If the input to the model is EMG, the weight matrix and latent variables are the muscle synergies and the temporal activation coefficients, respectively. Here, we compare the performances of NMF and RLVM in the identification of muscle synergies in simulated and experimental datasets. Our simulated datasets included one consisting of only non-negative values and another with both positive and negative values. On average, RLVM performed better in identifying the muscle-synergy subspace, but NMF outputs had a higher correlation with ground truth even when the simulated data were corrupted with signal-dependent or Gaussian noise. Finally, we applied RLVM to a previously published experimental dataset comprising EMG from upper-limb muscles and spike recordings of spinal premotor interneurons during voluntary grasping of two monkeys. The RLVM and NMF synergies were highly similar, but a few small negative muscle components were observed in the RLVM synergies. The muscles with negative components identified by RLVM were close to 0 in their corresponding synergies identified by NMF. Also, the negative components of the RLVM synergies agreed with the muscle connectivity of the premotor interneurons with inhibitory muscle fields, as identified by spike-triggered averaging of EMG. Our results demonstrate the usefulness of RLVM in extracting potential inhibitory muscle-synergy components from EMG.

Abstract: To study the neural strategies that underlie behavior, it is often necessary to estimate how muscles are activated across a variety of behavioral conditions. However, estimating the latent command signal that underlies muscle activation - often termed “neural drive” - is challenging due to the complexity of recorded electromyographic (EMG) signals. For example, differences in the timing of action potentials generated from separate motor units surrounding an EMG electrode may result in partial overlap of the recorded waveforms and cancellation of EMG signal on the channel. Common practices often estimate neural drive independently for each muscle channel (e.g., low-pass filtering), and require manual tuning of model hyperparameters (e.g., filter cut-off frequency) to capture estimates of neural drive that preserve behavioral-relevant features. Here, we adapted AutoLFADS, a large-scale, unsupervised deep learning approach, to estimate neural drive from multi-muscle EMG signals. As muscles are typically activated in coordination over time, we hypothesized that accurately modeling the spatial and temporal regularities that underlie multi-muscle activation using recurrent neural network (RNN) models like AutoLFADS can produce better estimates of neural drive for a given muscle. We tested AutoLFADS using two model systems: (1) rat hindlimb during locomotion and (2) monkey forearm during an isometric wrist task. When applied to the rat data, the model produced single-trial estimates of neural drive that improved decoding of joint kinematics over standard approaches to EMG processing like smoothing and Bayesian filtering. We found that AutoLFADS functions adaptively to adjust its frequency response characteristics according to the time course of different phases of behavior, removing the need to define a single fixed cut-off frequency for the entire behavior. Similarly, when applied to the monkey data, AutoLFADS enabled more accurate prediction of measured forces, including unexpected high-frequency oscillations that were obscured by traditional EMG processing. The AutoLFADS-inferred estimates of neural drive were also closely correlated with simultaneously-recorded motor cortical activity, suggesting that signatures of descending cortical commands are preserved when modeling dynamics governing muscles. Ultimately, this method leverages both dynamical systems modeling and artificial neural networks to provide precise estimates of neural drive for multiple muscles that can be used for further studies of multi-muscle coordination and their control by upstream brain areas.

Title: Investigation of evaluating method for neuromuscular function from the decomposed motor unit using delsys neuromap system

Authors: *H. FUNAKOSHI[1], Y. USAMI[3], M. YOSHIDA[1], T. ITO[1], T. MASUDA[4], T. KOKUBUN[2]; [2]Physical Therapy, [1]Grad. school of Saitama Prefectural Univ., Saitama, Japan; [3]Grad. school of Saitama Prefectural Univ., Saitama, Japan; [4]Fukushima Univ., Fukushima, Japan

Abstract: Motor unit action potential (MUAP) brings us important information about the neuromuscular function than compound action potential. In previous studies, the needle EMG or High-density surface EMG (HD-sEMG) are used for MUAP analysis. These studies reported that the change of inter-pulse interval (IPI), firing rate (FR), muscle fiber conduction velocity (MFCV) occurs according to fatigue. However, because the arrays of Delsys wireless 4 channel surface EMG (4ch-sEMG) are fewer than HD-sEMG, it's not clear whether 4ch-sEMG can evaluate neuro muscle function from MUAP. 4ch-sEMG has the possibility that enables us to evaluate muscle fatigue more easily and in detail. The purpose of this study is to investigate the evaluating methods from the MUAPs estimated by 4ch-sEMG and NeuroMap system. The subject was a healthy young man, and a 4ch-sEMG was put on dominant biceps brachii. The task was repeating isometric contraction holding a 3.5kg dumbbell with the elbow bent 90 degrees for 30 seconds 15 times. The intervals between repeated trials were 10 seconds. Then, we investigated the fluctuation of IPI, FR, MFCV referencing correlation coefficients. MFCV was calculated as the ratio between the electrode separation and the conduction delay between decomposed template MUAP of 2 of 4 channels lined vertically. The standard deviation and average of IPI were not changed according to repeated contraction. In FR, only peak FR of the total MU average showed a slight correlation ($r = 0.519$). Additionally, the mean and peak FR of the first 5 MUs recruited showed a negative correlation($r = -0.58$, -0.74) with the last 5 MUs. The first trial of MFCV was 3.89m/sec, the Final trial was 1.99m/sec, and it showed a slight negative correlation ($r = -0.68$). These results indicate adaptation to reduce fatigue as much as possible. Considering that the fast type of muscle fiber is fatigable, the slow type should be dominant for continuing tasks efficiently. We thought that correlation of peak FR could indicate increase activity of small MU because basically, big MU is low frequency. Additionally, negative correlation in the first and last 5MUs also indicates adaptation to fatigue because in constant torque MU combination fluctuated for each trial. In other words, the big MU is ready for the next contraction during small MU works and vice versa. Regarding MFCV, this result shows a similar result to a previous study about MFCV of fatigable biceps brachii. However, it is not clear whether this correlation of MFCV indicates fatigue or adaptation, Because the load is low. Further study is needed to elucidate if the results of 4ch-sEMG matchs HD-sEMG and, defference of neuromuscular function between low and high load.

Abstract: Motor units are the fundamental unit of motor control. Motor unit synchronization can be calculated to identify common synaptic inputs in neural circuitry during muscle coordination. This study compared common inputs to lower limb muscles across tasks requiring different muscle coordination patterns. Multichannel surface electromyogram (EMG) signals were recorded on the right and left tibiales anterior (dorsiflexors) and medial gastrocnemii (plantarflexors) muscles, while able-bodied human subjects conducted dynamic tasks involving either dorsiflexion (squats), plantarflexion (heel-raises), or both motions (anterior-posterior postural sway). After decomposing EMG into motor unit firings, we conducted coherence analyses of composite motor unit firing event trains in the beta (13-30 Hz) and low-gamma (30-60 Hz) frequency bands. Our results indicated similar levels of common input occurring between tasks involving activation of either dorsi/plantar-flexors or both antagonistic muscle pairs. Additionally, motor units within the same muscle consistently received the highest levels of common inputs, while decreased levels of common input occurred between bilateral homologous and antagonistic muscle pairs, respectively. The outcomes could help understand mechanisms of lower limb neuromuscular coordination and may provide a benchmark for individuals with neuromuscular conditions.

Title: Spatial coding of conspecific electrosensory signals by a heterogeneous pyramidal cell population

Authors: *O. E. MILAM[1], G. MARSAT[2];
[1]Dept. of Biol., [2]Dept. of Biol, Dept. of Neuroscience, Rockefeller Neurosci. Inst., West Virginia Univ., Morgantown, WV

Abstract: A ubiquitous feature of neural systems is to encode spatial information to help localize the source of sensory signals of ethological importance. Spatial processing varies across systems and many studies revealed sophisticated mechanisms in place to support the localization process but we are still unravelling the subtleties of how spatial and temporal information is processed. The electrosense of weakly electric ghost knifefish serves as an excellent model system for quantifying the neural coding efficiency of sensory signals. Behavioral studies on conspecific interaction suggest that the sensory system is extremely sensitive and supports the detection and localization of conspecifics tens of centimeters away. The localization of spatially localized objects in this system has been previously investigated but the signal of conspecific is spatially diffuse and the mechanisms that support their accurate localization are unknown. Here, we investigate the spatial representation of conspecific signals in the hindbrain to determine how the spatiotemporal properties of the heterogenous population of pyramidal cells affect the neural coding of conspecific signals in different spatial contexts. We hypothesize that specific subset of cells provide more accurate spatial information about conspecifics. We use extracellular electrophysiological techniques to record from pyramidal cells across multiple maps in the electrosensory lateral line lobe (ELL). We stimulated the fish with an artificial signal that replicates both the spatial and temporal structure of conspecific signals. The stimulus was emitted from various locations around the fish and consisted of a sinusoidal “beat” amplitude modulation experienced during social encounters. We recorded from cells with various receptive field positions covering the whole body and analyzed the spike train with spike-train distance metrics and neural network classifiers to determine how accurately the location of the stimulus is encoded. We found that some pyramidal cells encode the spatial information accurately while others contribute little to spatial coding of these signals. Our results help us understand how the heterogeneity of a population of cells allow the efficient processing of signals.

Title: Identifying stereotyped movement patterns during social interactions in weakly electric fish

Authors: *K. L. RAMACHANDRA[1], G. MARSAT[2];
[1]Dept. of Biol., [2]Dept. of Biology, Dept. of Neuroscience, Rockefeller Neurosci. Inst., West Virginia Univ., Morgantown, WV

Abstract: Sensory systems are typically adapted to encode behaviorally signals efficiently and so quantifying the characteristics of relevant sensory signals is key to understand the sensory task that must be performed by the nervous system. Localizing the source of a signal is crucial to guiding the behavior of the animal successfully. Studies on spatial processing have revealed intricate mechanisms allowing the animal to be extremely accurate in their motor output despite the localization cues being weak or small. The electrosensory system of gymnotid fish has the hallmark of such extreme sensitivity including, for example, when a fish localizes a conspecific to interact socially. Here we aim to better understand spatial processing in these fish by characterizing the signals they experience during social interaction and that allows them to navigate relative to one-another. To reach this goal we recorded fish interacting in infrared lighting to build a database of the swimming kinematic of fish interacting in a wide range of situations. To elicit a range of scenarios and obtain a wide range of swimming behaviors, we varied the social and environmental context. Complex behaviors such as social interactions are typically composed of stereotype bouts of movements. Ethograms can be used to identify these stereotyped patterns and their sequence; modern computational tools permit a more rigorous quantitative approach to identifying stereotyped behaviors and their sequence. We established an algorithm to identify stereotyped patterns of movements during a variety of social interactions. Knowing the relative position and movement of the two individuals while interacting allowed us to define the behaviorally relevant spatio-temporal structure of the electrosensory input mediating the behavior. We expect this information to be crucial in future studies of spatial processing in these fish aimed at revealing neural mechanisms enhancing localization accuracy.

Title: Reverse engineering Drosophila thermotaxis

Authors: *J. SIMÕES, J. LEVY, P. ZHAO, W. KATH, A. PARA, M. GALLIO;
Northwestern Univ., Evanston, IL

Abstract: Simple innate behavior is often described as hard-wired and largely inflexible. Here, we study the avoidance of unfavorable hot temperature in the fruit fly *Drosophila melanogaster*, a fundamental behavior and an ideal system to probe the extent to which simple innate behavior may be largely hard-wired. First, we produce the first high-resolution characterization of heat avoidance and thermotaxis in adult *Drosophila*. Our first goal is to define the basic functional organization of thesensory system that

guides these innate behaviors in adult fruit flies. Our next objective is to compare fly heat avoidance with the behavior of an *in silico* vehicle model (a "Braitenberg vehicle"), explicitly probing the notion that the fly's innate avoidance of hot temperature can be understood as a combination of hard-wired responses. Our results demonstrate that hot receptor neurons of the antenna and its molecular heat sensor, Gr28B.d, are essential for flies both to navigate shallow temperature gradients ("thermotaxis"), as well as to produce escape turns away from heat when the flies encounter steep thermal boundaries. High-resolution fly tracking combined with a 3D simulation of the thermal environment shows that, in steep thermal gradients, the direction of escape turns is determined by minute temperature differences between the antennae (0.1°-1 °C). In parallel, live calcium imagingconfirms that such small stimuli reliably activate both peripheral thermosensory neurons andcentral circuits. Based on our measurements, we evolve a fly/vehicle model with two symmetrical sensors and motors (a "Braitenberg vehicle") which closely approximates basic fly thermotaxis in steep thermal gradients. Critical differences between real flies and the hard-wired vehicle reveal that fly heat avoidance involves decision-making, relies on rapid learning, and is robust to new conditions, features generally associated with more complex behavior.

Title: Modeling the spatial dynamic of sensory image and receptors activation during social interaction in weakly electric fish.

Authors: *G. MARSAT[1], K. L. RAMACHANDRA[2], O. E. MILAM[2];
[1]Dept. of Biology, Dept. of Neuroscience, Rockefeller Neurosci. Inst., [2]Dept. of Biol., West Virginia Univ., Morgantown, WV

Abstract: Extracting spatial information from sensory signals can be computationally intensive when the signal activates most of the receptors and differences in activation must be compared to extract localization cues. Efficiency in this process relies in part on the spatio-temporal response properties of the receptors being adapted to the characteristics of behaviorally relevant signals. Heterogeneity in neural responses has been shown to be an important determinant of coding efficiency by populations of neurons but most of the work on this topic has focused on coding of the temporal aspects of the signal. Here, we investigate the effect of neural heterogeneity on the coding of spatial information by a population of neurons. We used the electrosensory system of gymnotid fish as a model system because we understand in detail how temporal information is encoded in sensory neurons. However, little is known regarding how spatial information about conspecific signals is encoded. When two fish interact socially, they are exposed to each other's constant electric organ discharged which enables them to localize other

individuals. These signals are spatially diffuse and often weak so localization relies on comparing minute differences across the array of receptors. We hypothesize that efficient localization relies on the heterogeneity of receptors' properties being adjusted to the properties of behaviorally relevant signals. By modeling 2 aspects of the sensory process. We first use a model of the electric fields generated by interacting fish to quantify the strength of the signal at each receptor location during social interactions. Second, we simulate a population of electroreceptors (tuberous p-units) with leaky-integrate-and-fire models calibrated to replicate the known response properties of these cells. The stimuli applied to these model neurons are based on the signal strength calculated from the electric field model. By changing the degree of heterogeneity present in the population we show that the accuracy of spatial coding is influenced by the degree of heterogeneity present in the population. Our study thus extends the generality of the role of heterogeneity in shaping coding accuracy to include spatial coding.

Title: Roles of neural signals descending from and ascending to the brain in the cricket escape behavior

Authors: *H. OGAWA[1], N. SATO[2], H. SHIDARA[1,3];
[1]Dept. of Biol. Sciences, Fac. of Sci., [2]Grad. Sch. of Life Sci., Hokkaido Univ., Sapporo, Japan; [3]Dept. of Biochemistry, Grad. Sch. of Med., Mie Univ., Tsu, Japan

Abstract: To survive a predator's attack, prey animals including insects must exhibit escape responses that are appropriately regulated in terms of their moving speed, distance, and direction. Insect locomotion is considered to be controlled by an interaction between the brain, which is involved in behavioral decision-making, and the thoracic ganglia (TG), which are primary motor centers. However, it remains unknown which descending and ascending signals from/to the brain are involved in the regulation of insects' escape behavior. In other words, it is still unclear what aspects in the escape locomotion of insects depend on the neural communication between the brain and TG. We addressed the distinct roles of the brain and TG in the wind-elicited escape behavior of crickets, which is mediated by abdominal mechanosensory organs called 'cerci'. We unilaterally cut the ventral nerve cord (VNC) at different locations, between the brain and TG, or between the TG and terminal abdominal ganglion (TAG), which is a primary sensory center of the airflow sensing system, to assess the effects of partial ablation of these intersegmental communications on escape responses. The half lesion of ascending signals to the brain greatly reduced the jumping response rather than running, indicating that sensory information processing in the brain is essential for the choice of escape responses. The half lesion of descending signals from the brain to the TG impaired locomotor performance and directional control of the escape responses,

suggesting that locomotion in the escape behavior largely depends on the descending signals from the brain. Finally, by an extracellular recording from the cervical VNC, we found the differences in the temporal profile of the descending spiking activities prior to the escape running or jumping. Our results demonstrated that the brain sends the descending signals encoding the behavioral choice and locomotor regulation to the TG, while the TG seems to have other specific roles, such as in the preparation of escape movement.

Title: Evaluating variability of phonotaxis and selective processing of its underlying neural elements in an insect model

Authors: *B. NAVIA, J. AN, J. RIM, G. ATKINS;
Andrews Univ., Berrien Springs, MI

Abstract: The phonotactic behavior of female cricket *Acheta domesticus* as observed in the lab, has been shown to vary among individuals. In response to computer-generated auditory stimuli, some females are finely tuned and attracted to calls with syllable periods which match those of the natural calls of the males (for *A. domesticus* 50 - 70 ms). Other females respond phonotactically to calls with a wider range of syllable periods (30 - 90 ms) including or not the most attractive range. Therefore, lacking the ability to discriminate between attractive and unattractive calls. Factors that contribute to this variability include age, temperature and levels of JHIII. We show the presence of neurochemicals such as histamine to influence phonotaxis. Prothoracic nanoinjection of histamine, resulted in females responding phonotactically to calls with a wider range of syllable periods, compared to the same females' preferences before injections and therefore acting as a neuromodulator. Additionally, when females are exposed to males, but not allowed to mate, their ability to discriminate attractive calls is reduced. This implies factors other than mating, alter the females' phonotactic behavior in a way that parallels the results reported for injection of histamine as well as lower levels of JHIII as seen in older females. The effect of said factors in identified underlying neural elements such as the auditory neuron L3/AN2, continues to be evaluated. The response of the L3/AN2 in females with the ability to discriminate attractive calls also varies in ways that parallel the phonotactic variability mentioned above. Evaluation of L3/AN2's response, provides insight to a proposed mechanism, involved in call recognition and phonotaxis. Implications of results of the study and proposed mechanism are discussed.

Title: Mechanosensory antennal inputs modulate cercal-mediated escape behavior in crickets

Authors: *O. N. IFERE[1], H. SHIDARA[2,3], N. SATO[1], H. OGAWA[2];
[1]Grad. Sch. of Life Sci., [2]Dept. of Biol. Sciences, Fac. of Sci., Hokkaido Univ., Sapporo, Japan; [3]Dept. of Biochemistry, Grad. Sch. of Med., Mie Univ., Tsu, Japan

Abstract: Animals avoid obstacles along their path successfully by acquiring and integrating information of surrounding objects such as shape and location using multiple sensory organs. Crickets detect air currents in nearfield by their abdominal mechanosensory organ, cerci, respond to it as a sensory cue of predator's approach, and exhibit escape movement in opposite direction to the stimulus. Antennae are another crucial mechanosensory organ of insects to detect surrounding objects. Crickets, which are nocturnal insects, rely mostly on tactile information of surrounding objects sensed by antennae to guide their locomotion in the environment. However, it remains unclear if crickets modulate their escape behavior mediated by the cercal system depending on the spatial information of surroundings acquired by the antennal system. Using an open looped treadmill system, we examined wind-elicited escape behavior in darkness when an object such as rod and wall were placed at different locations to be detected by the antenna. Our results indicated that crickets modulated the movement direction in the escape behavior depending on object shape, distance, and orientation. Crickets usually move forward in response to the air puff from behind. When a wall was placed on the side of crickets close to their antenna, the escape movement was biased to the object-free side. Whereas the lateral movement elicited by the air-puff from the side was biased backwards by that wall. These results imply that the crickets modulate their movements to avoid collision with obstacles on the escape path. These modulations of the movement direction were observed for the near wall positioned anteriorly but not posteriorly, suggesting that the crickets modulated their behavior adapting to the object location. We also tested the effects of the wall positioned in front of cricket on the escape behavior. The forward movement triggered by the airflow from behind was suppressed and curved bilaterally by the front center wall accessible to both antennae. In contrast, the one-sided frontal plate to be accessed by only one antenna biased the movement to the plate-free side. The escape trajectory was also biased by the one-sided wall even though the antenna on the wall side was unilaterally ablated, suggesting that a single antenna is sufficient to detect location of front objects. Probably, edge detection even by a single antenna would be more crucial for object localization than bilateral comparison of antennal inputs indicating 'presence or absence' of objects. We concluded that crickets modulated their escape behavior depending on spatial information of surrounding objects by using antennal inputs.

Title: Cricket changes their wind-elicited escape behavior depending on locomotion states

Authors: *K. KIUCHI[1], H. SHIDARA[2,3], Y. IWATANI[4], H. OGAWA[2];
[1]Grad. school of Life Sci., [2]Dept. of Biol. Sciences, Fac. of Sci., Hokkaido Univ., Sapporo, Japan; [3]Dept. of Biochemistry, Grad. school of Med., Mie Univ., Tsu, Japan; [4]4.Department of Sci. and Technology, Grad. Sch. of Sci. and Technol., Hirosaki Univ., Hirosaki, Japan

Abstract: Animals change their behavior depending on situation and context such as environmental and internal factors and their interaction. Since the adaptive behavioral changes are important in their survival strategy, many neuroscience studies address the issue about influence of internal and external factors on behavioral changes so far. Locomotion state of animals is one of the internal factors that have the greatest impacts on sensory perception and stimulus-triggered behavior. However, due to technical difficulty to apply high reproducible stimuli to moving animals repeatedly, the behavior changes depending on locomotion state have been investigated only on semi-restraint animals. To tackle this issue, we investigated wind-elicited escape behavior in the freely moving crickets, which exhibit jumping and running in response to airflow. We adopted the servosphere treadmill system with a markerless visual tracking technique, which allow us to keep small animals such as insects in the same position and orientation without restraint (Iwatani et. al., 2019). A short airflow was applied to spontaneously-walking crickets from a specific direction out of eight, and the airflow-elicited escape behavior was recorded with high-speed video camera. In most trials, when the walking crickets was stimulated, they quickly pause their movement and then started escape behavior. We compared the escape behavior between the moving and standing still crickets in various locomotion parameters, including response probability, jumping selection ratio, reaction time, velocity, distance, and directional accuracy of the movement. The probability of escape movement for moving crickets was higher than that for standing still ones. In addition, nearly 100% of moving cricket showed the pause response to even the slowest stimulus while less than 10% of crickets standing still showed the escape response. These results indicated that the threshold for pausing in moving crickets was much lower than that for escaping in standing still ones. There was no difference in the selection ratio of jumping between moving and standing still crickets. The locomotion state also affected other parameters. The moving crickets exhibited running escape with delayed reaction time, lower velocity, shorter distance. In addition, its movement direction was less accurately controlled than those in standing still crickets. Taken together, it is suggested that the high sensitivity to the airflow stimulus in moving crickets likely compensates poor performance in their escape response.

Title: Heterogeneity of vigilance states across cortical areas described by a low-dimensional manifold

Authors: *J. WANG[1], R. KWAPICH[2], S. CHAUVETTE[3], I. V. TIMOFEEV[4], T. A. ENGEL[2];
[1]Cold Spring Harbor Lab. Sch. of Biol. Sci., Cold Spring Harbor, NY; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [3]CRIUSMQ, Quebec, QC, Canada; [4]CRIUSMQ, Univ. Laval, Quebec, QC, Canada

Abstract: Brain states across sleep and wakefulness are conventionally divided into wake, Slow-Wave Sleep (SWS) and Rapid-Eye Movement (REM) sleep, which differ by a variety of psychological, physiological, and neurophysiological signatures. These states are usually classified by application of hand-crafted criteria to spectral power of Local Field Potential (LFP) or electroencephalogram (EEG) in specific frequency bands combined with differences in muscle tone measured with electromyography (EMG). Recent evidence indicates that the classical wake, SWS and REM are insufficient to capture the complexity of vigilance state dynamics on the brain-wide scale, which exhibit microstates and co-existence of heterogeneous electrophysiological signatures across different cortical areas. To account for the complexity and heterogeneity of vigilance states across the cortex, we developed an approach to uncover a low-dimensional manifold on which these states may be represented. To discover this manifold, we apply an unsupervised dimensionality reduction based on Variational Autoencoders (VAEs) to EMG and multi-site LFP activity recorded continuously from 14 different cortical areas in mice during the natural variation of sleep and wake cycles. First, we apply our model to activity on each of the 14 channels separately. For single channels, the inferred manifold reveals three clusters corresponding to the basic states of wake, SWS, and REM, as well as uncovers differences between cortical areas in the prevalence and characteristics of these states. Next, we apply our model to simultaneous activity on 14 electrodes to uncover the relationships between these cortical areas, such as when the entire brain is in one state, or split between multiple states. Our model discovers a continuous manifold that reveals the co-existence of states across cortical areas which occurs in the transitional region connecting the uniform cortex-wide states. Lastly, we fit the low-dimensional latent representations obtained from all cortical areas with a Hidden Markov Model (HMM) to segment and characterize the dynamics governing vigilance states. Our model provides a framework for understanding the propagation of heterogeneous states across the cortex, as well as for studying how these states are affected by factors such as sensory experience or disease. In conclusion, our work elucidates the regional co-existence of wake and sleep states as a common feature of laboratory mice brain activity.

Title: Cortical wide-field imaging reveals the dominant role of hippocampal Gamma-events in orchestrating modular activation

Authors: *R. PEDROSA, F. STELLA, F. P. BATTAGLIA;
Donders Inst. for Brain, Cognition and Behavior, Radboud Univ., Nijmegen, Netherlands

Abstract: Recent advancements in anatomical and functional imaging techniques have led to a profound reappraisal of the principles of cortical mapping, emphasizing whole-brain networks organization around few functional and connectivity gradients. Yet, how spontaneous activity propagates, its relationship with sub-cortical regions like the hippocampus and its involvement in memory processes, remain largely unknown. Here, we investigate the fine-grained spatiotemporal dynamics of spontaneous activity in the entire dorsal cortex together with its time-resolved interaction with the hippocampus. For this, we analyzed two different datasets: (1) mice under urethane anesthesia with simultaneous recordings of wide-field voltage sensitive dye transients (VSD), cortical ECoG, and hippocampal CA1 LFP. And, (2) transgenic mice expressing voltage sensitive indicator (VSI) during natural sleep with simultaneous recordings of wide-field voltage imaging and high density silicon probe in the hippocampus. When measuring transients from the VSD, ECoG and VSI signal, we find event size distribution to be well approximated by a power law-like distribution, with condition-dependent parameters. Nevertheless, separately analyzing groups of transients of different magnitude reveals a major modulation in the transient activity structure. In fact, while small transients consist of a limited number of co-activation modes involving a sub-set of cortical networks (related to the Default Mode Network), larger transients extend to a substantial portion of the cortical surface and can be clustered depending on where they originate: one family is preceded by Retrosplenial cortex (RS) activation, the other is instead triggered by Somatosensory Cortex. Such classification also allows to identify hippocampal gamma oscillations as the principal signature of cortico-hippocampal interactions: hippocampal gamma power is proportional to the size of the cortical transients and shows a preferential association with RS-led transients. Accordingly, we also find a significant causal interaction pointing from RS activation to hippocampal gamma amplitude. On the contrary, ripple events appear to have a much looser association with cortical activity evolution. Taken together, our results provide a concrete description of the complex hierarchical structure shaping activity propagation between cortical areas and within the cortico-hippocampal loop, and points to RS and hippocampal gamma oscillations as the main organizational elements of the network.

Abstract: ACh regulates differential role of sleep stages in sleep dependent memory consolidation
Michael Satchell[1], Alexis Simmons[2], Sara Aton[3], Michal Zochowski[4]
1.**Department of Physics, University of Michigan, Ann Arbor, MI 48109**2.**Department of Physics, Baylor University, Waco, TX 76706**3.**Department of Molecular Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI 48109**4.**Department of Physics and Biophysics Program, University of Michigan, Ann Arbor MI 48109**
Across vertebrate species, behavioral states transition consistently from wake to non-rapid eye movement (NREM) sleep to REM. The functional significance of this state ordering (with NREM preceding REM during sleep cycles) is unknown. Critically, NREM and REM sleep states are associated with dramatically different physiological features – including characteristic differences in neuronal firing patterns and rates, network oscillations, neuromodulation, and even gene expression. We have built a reduced computational model of interacting excitatory and inhibitory networks to probe how state-specific changes in ACh alter network dynamics and consequently engram consolidation via synaptic, spike timing dependent plasticity (STDP). We show that the sequential, bidirectional changes in ACh neuromodulation during NREM and REM sleep may play a vital role in consolidation, particularly when more than one memory trace is being stored simultaneously in a neural network. In the low-ACh (NREM-like) state, synapses from neurons activated by learning (i.e., engram neurons) to other neurons in the network are primarily strengthened through spike timing-dependent plasticity. In the subsequent high-ACh (REM-like) state, recruitment of GABAergic neurotransmission in the network suppresses activity among neurons not actively recruited into expanded memory traces by engram neurons during prior NREM. In scenarios where two separate memory traces (i.e., two groups of engram neurons) are introduced to the network, this sequence of changes to ACh signaling is vital to the generation of two completely segregated, but expanded, memory traces.

Title: Creating an Entirely Automatic Sleep Scoring Algorithm Using EEG and EMG power

Authors: *K. M. KEUS[1], K. K. M. WRIGHT[1], J. HOLLOWAY[1], V. MATHUR[2], Y. CABRERA[1], G. R. POE[3];
[1]UCLA, Los Angeles, CA; [2]UCLA, Los Angles, CA; [3]Dept. of Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: Sleep scoring is a process by which states of sleep are characterized for later analysis. This process is traditionally accomplished manually by an "expert scorer" using the frequency makeup of either electroencephalography (EEG) or local field potential (LFP) recordings in the mammalian brain. In 2018, Bagur et al. discovered that an automatic sleep scoring algorithm could be constructed using LFP-derived gamma (50-70 Hz) power in the olfactory bulb (OB) and the ratio between theta (5-10 Hz) and delta (2-5 Hz) power in the hippocampus in mice. Gamma power was used to delineate sleep and wake states, and theta/delta power ratio to delineate NREM/REM, bypassing the need for manual scoring. In this study, we replicated these results in rats rather than mice and using EEG rather than LFP; furthermore, we improved on the existing method by recording from the frontal cortex (LfEEG) and the parietal cortex (LpEEG) rather than the OB and the hippocampus, respectively, resulting in easier surgical implantation without sacrificing efficacy. A scoring method based on electromyography (EMG) power was also constructed to demarcate wake from sleep. This method was then used as a check on gamma power-derived sleep classification, where output from the LfEEG thresholding was run through EMG scoring to remove erroneously classified stages of wake. We used a thresholding method to assign sleep states based on the distribution shape of power values of the gamma range, theta/delta ratio, and EMG range (30-245 Hz, excluding points around 60 Hz to reduce noise). To build this program, we used novel in-house MATLAB code in combination with pre-existing MATLAB sleep scoring and power analysis code (Brooks et al., 2009). We then compared our state classification output to manual scoring of the same recordings. Preliminary average percent agreement between wake/sleep distinction was 91.03% and average Cohen's Kappa was 0.8158. Average values calculated from a confusion matrix, including accuracy, precision, F1, and recall values, were 0.9131, 0.9257, 0.9741, and 0.8822, respectively. For EMG thresholding, average percent agreement was 89.99% and average Cohen’s Kappa was 0.7919. For NREM/REM distinction, average percent agreement was 94.50% and average Cohen’s Kappa was 0.8255. To date, we have successfully shown that gamma power from LfEEG and EMG power from the nuchal muscle in rats can be utilized to delineate wake and sleep, and theta/delta power from LpEEG can be used to delineate NREM and REM. Ultimately, we have created a simple program that can be used to score sleep entirely from electrical recordings, bypassing the need for training data and traditional manual scoring entirely.

Abstract: Classification of neurobiological signals has immense potential for various applications such as anomalous brain signal detection, individual identification, and BCI (brain-computer interface). Moreover, it can also benefit neurobiological studies on animal models by helping to classify brain states from recorded brain signals. However, the classification of neural signals has traditionally been a laborious task requiring manual labeling by experts. Recent studies have proposed ways to alleviate the necessity of large labeled datasets by applying self-supervised learning in tandem with transfer learning. Meanwhile, neural oscillations are known to be largely preserved across mammalian species. Therefore, this study tested the possibility of applying transfer learning to a human EEG pre-trained model in the task of classifying sleep stages within mouse neurobiological recordings. A previously reported transformer-based pre-trained model (BENDR), trained on a large human EEG dataset with contrastive predictive coding, was adapted and fine-tuned with mouse LFP signals from sleep experiments. This approach dramatically reduced the amount of required labeled data in the fine-tuning step while retaining competitive performance in the mouse sleep-stage scoring task. Furthermore, the transformer-based nature of the model allowed raw neural data to be used as the input while intuitively visualizing neural signatures attended by the network during classification. This study opens up the possibility of utilizing a general-purpose classifier, pre-trained with abundant unlabeled data acquired from the same or different species, in performing downstream classification of neural time series data, especially under circumstances of data scarcity.

Abstract: In the past decades, neuroscience excelled at accumulating a rich, heterogeneous landscape of datasets and methodologies. However, it is a challenge to effectively leverage the benefits of such diversity by combining the insights from across experiments, species, and measurement techniques. Integration of this heterogeneity requires rigorous analysis workflows that offer to distill consistent, reproducible, comparable, and reusable conclusions. Aligning data from various sources enables not only "big-data" analysis approaches, but also allows to produce a broader experimental basis for validating models and theories across the experimental and computational scales of description.
Here, we explore such an approach in the context of slow cortical waves (up to 5 Hz). Slow waves are persistently observed in sleep and anesthesia across various species and various measurement techniques [Alkire et al. (2008) Science 322.5903]. Furthermore, such activity is expressed by various models [Sanchez-Vives et al. (2017) Neuron 94.5; Pastorelli et al. (2019) Front Syst Neurosci 13:33]. First, we address the issue of providing a comparable quantitative description of the wave dynamics to compare such heterogeneous data on a conceptual level by designing a general and modular analysis pipeline approach that is adaptable to a variety of applications. Here, the key objective is to interface existing methods, standards, and tools in a flexible manner in order to serve the requirements of a wide range of datasets and research questions using a common set of analysis components. Moreover, by building on and co-developing other specialized open-source tools, we further emphasize the reusability and extendability of each of the pipeline components.
Based on this design, we present the Slow Wave Analysis Pipeline (SWAP) as a concrete, reusable implementation to perform broad, detailed, and rigorous comparisons of slow wave characteristics, such as velocities or directions. We apply SWAP to a range of openly available ECoG [De Bonis et al. (2019) Front Syst Neursci 13:70] and calcium imaging [Celotto et al. (2020) M&Ps 3.1:14] datasets and investigate the influences of experimental parameters such as the mice's genetic strain, the type and dosage of anesthetics, the measurement technique and the spatial resolution. We also demonstrate the pipeline's capabilities to benchmark specific methods within the analysis by exchanging them with another method and by analyzing the same pool of data.
Finally, we discuss how the premise of reusability and modularity helps to derive other analysis pipelines for similar research endeavors to amplify collaborative research.

Title: Diet and Parent-of-Origin Dependent Effects on Body Composition, Locomotor Activity, and AgRP Neuronal Activity are Sex Specific in PWK/PhJ x C57BL/6J F_1 Mice

Authors: A. C. KORGAN, S. L. A. MARTIN, Z. J. D. BRIDGES, K. M. S. O'CONNELL;
The Jackson Lab., BAR HARBOR, ME

Abstract: Interactions between genetics and environment (GxE) impact brain development, behavior, and risk for disease, such as obesity and type II diabetes. Additionally, food intake and body composition are regulated by parent-of-origin effects throughout development and into adulthood via differential allele-specific gene expression in various brain regions. The arcuate nucleus of the hypothalamus (ARH) is a hot-spot for allele-specific expression in these studies. A primary neuronal subtype in the ARH, agouti-related peptide (AgRP) neurons, are essential for driving food intake. These neurons play a key role in integrating peripheral and central signals to modulate food intake, body weight (fat mass), and locomotor (food seeking) behavior. Consistent with their role in energy balance, AgRP neuronal activity is tightly correlated with nutritional status. We have previously demonstrated that AgRP neuronal activity is sensitive to diet, thus diet-dependent plasticity may be a causal factor in obesity. Previous research has primarily used inbred mouse models and single parent-of-origin designs that lack genetic and epigenetic diversity, and do not capture the considerable influence that genetic factors play in controlling obesity and bodyweight. Therefore, we utilized an F_1 panel of mice that are resilient and susceptible to diet-induced obesity (DIO): DIO resilient wild-derived PWK/PhJ mice were bred with DIO susceptible C57BL/6J mice (expressing a NPY^{GFP} reporter) to generate both paternal PWK (PWKxB6) and paternal B6 (B6xPWK) mice. We found that fat-content, locomotor activity, feeding, and AgRP neuronal activity were influenced by parent-of-origin in a sex-specific manner. B6xPWK males had increased body fat, an effect attenuated by HFD feeding, and were less active in the elevated plus maze (EPM), compared to PWKxB6 males. Further, only PWKxB6 males were susceptible to diet-induced increases in AgRP neuronal activity, because chow fed B6xPWK males had an increased firing rate. HFD fed B6xPWK females had increased body fat, compared to B6xPWK chow and both chow and HFD PWKxB6 mice. Chow and HFD fed B6xPWK females were less active in the open field and EPM. B6xPWK females had decreased AgRP neuronal activity but we did not identify diet-induced changes in AgRP neuronal activity in female mice, which aligns with previous research. Ongoing work will explore parent-of-origin dependent changes in food preference, hypothalamic gene expression, and explore the impact of maternal care on offspring development. These studies will identify genetic traits linked to weight gain and obesity, providing insights into the diversity of the human response to DIO.

Title: Hypothalamic angiotensinergic AT1 receptor mRNA expression and angiotensin II responses in female SHR treated with estradiol

Authors: E. D. PEREIRA, Jr, L. M. OLIVEIRA, G. C. NUNES, P. P. C. SOUZA, L. A. DE LUCA, Jr, E. COLOMBARI, D. S. A. COLOMBARI, ***J. MENANI**, C. A. F. ANDRADE;
UNESP, Araraquara, Brazil

Abstract: Hypertension is one of the most prevalent non-communicable diseases in the world. The spontaneously hypertensive rat (SHR), an animal model of primary hypertension, ingests more NaCl than normotensive strains. Estrogens have significant influence on cardiovascular regulation and hydromineral balance. We have shown that estrogens reduce NaCl intake and palatability in female SHRs, but we do not know whether such an effect involves the brain renin-angiotensin system (RAS). Here we investigated: 1) the expression of hypothalamic RAS components, 2) central angiotensin II-induced pressor and drinking responses in female SHRs treated with estradiol. Adult ovariectomized (OVX) female SHRs with a guide cannula implanted in the lateral ventricle and a femoral artery catheter were used. Rats were treated with β estradiol (E2, 10 μg/kg of body weight - b.w.) or vehicle (VEH, sunflower oil, 0.1 ml) for 8 days. Angiotensin II (ANG II, 50 ng/1 μl) was administered intracerebroventricularly (icv). E2 treatment reduced icv ANG II-induced water intake (3.7 ± 0.5, vs. VEH: 6 ± 0.5 ml/100 g b.w.) and pressor response (22 ± 7, vs. VEH: 37 ± 4 mmHg). Quantitative real-time PCR analysis (qPCR) showed that the relative hypothalamic mRNA expression of angiotensinergic AT1 receptor (Agtr1a) was reduced in E2-treated OVX female SHRs (0.82 ± 0.16, vs. VEH: 1 ± 0.11). There was no effect on relative mRNA expression of hypothalamic Agtr2, ACE and ACE2. The results suggest that the reduction of hypothalamic Agtr1a mRNA expression might be a reason for the reduction in ANG II-induced pressor and dipsogenic responses in female SHRs treated with E2.

Title: Evaluation of the function of hindbrain ependymal cells in glucose sensing by analyzing the counterregulatory responses to glucoprivation in female rats with ependymal denudation.

Authors: *M. SATO[1], F. MAGATA[1], H. TSUKAMURA[2], F. MATSUDA[1];
[1]The Univ. of Tokyo, Tokyo, Japan; [2]Nagoya Univ., Nagoya, Japan

Abstract: The hindbrain has been suggested to play a pivotal role in maintaining reproductive function, gluconeogenesis, and feeding during malnutrition. Our previous studies showed that ependymal cells lining of the 4th ventricle (4V) express glucokinase and glucose transporter 2, which are important molecules for glucose sensing, and that ependymal cells are activated by hindbrain glucoprivation. These findings suggest that the 4V ependymal cells function as a glucose sensor. The present study aimed to determine whether the 4V ependymal cells mediate the counterregulatory responses against hindbrain glucoprivation. We generated rats, whose 4V ependymal cells were denuded, and analyzed the effect of hindbrain glucoprivation on their luteinizing hormone (LH) secretion, blood glucose level, and food intake. Estrogen-implanted ovariectomized female rats (n = 6-8 in each group) were used. Neuraminidase dissolved in UPW (100 mU), which reportedly causes ependymal denudation, or UPW was infused into the 4V of female rats for 10 min. Consecutively, 2-deoxy-D-glucose (2DG), a glucose utilization inhibitor, or xylose, as an isosmotic control, was infused into the 4V for 100 min (40 mg/kg body weight). For the analysis of the pulsatile luteinizing hormone (LH) secretion, blood samples were collected every 6 min for 3 h started from 1 h before the 4V neuraminidase infusion and blood glucose levels were also measured every 30 min from just before the 4V neuraminidase infusion. After the last blood sampling, food intake was measured for 3 h. Immediately after the food intake measurement, rats were transcardially perfused with 4% paraformaldehyde and the brain was obtained to make paraffin-embedded sections. Histological analysis of the brain sections with HE staining revealed that 4V ependymocytes were denuded in the rats treated with 4V neuraminidase administration. 4V 2DG infusion enhanced food intake in control rats but failed to increase the food intake of rats with ependymal denudation. On the other hand, rats with 4V 2DG infusion showed lower LH pulse amplitude and higher blood glucose levels in both control rats and rats with ependymal denudation. Taken together, the present study suggests that the 4V ependymal cells, at least in part, function as a key glucose sensor to mainly regulate feeding during malnutrition.

Abstract: Menopause is a condition associated with a greater perception of painful stimuli and an increase in adipose tissue. In addition weight gain is known to be related to changes in pain perception; however, its mechanism is unclear. Objective. The aims of this study were to analyze the behavioral responses of hypoestrogenic overweight Wistar rats to thermal stimuli and to analyze the glucose and uric acid levels in this population. Methods. Animals with hypoestrogenism induced by bilateral ovariectomy were used. Animals received a hypercaloric diet (30% sucrose) or normal water with standard laboratory food *ad libitum* for 4 weeks; thermal nociception and body weight were measured during this period. Four weeks after treatment, glucose and uric acid levels and abdominal fat weight were measured in both groups. Nociception was assessed using the "Plantar test". Results. Overweight ovariectomized Wistar rats showed significantly higher body weight and abdominal fat weight than the control group. A hyperalgesic response was observed in sucrose-fed animals. Thermal latency was also significantly decreased during the 4th week in these animals compared to that of the controls. There were no differences in glucose levels, but uric acid levels were altered between groups. Conclusions. Our data indicate that increased body weight, abdominal fat and increased uric acid levels are associated with the hyperalgesic responses observed in ovariectomized overweight female rats.

Title: Loss of ciliary adenylyl cyclase 3 in the ventromedial hypothalamus resulted in a sex-dependent obese phenotype

Authors: *G. DENG, K. SAITO, U. SINGH, Y. DENG, J. DICKEY, J. JIANG, H. CUI;
Univ. of Iowa, Iowa City, IA

Abstract: Obesity, a metabolic disorder characterized by an excessive accumulation of body fat, continues to be a major economic and health burden to the global populace, as it is the most significant risk factor for heart disease, diabetes, and hypertension. Genome-wide association studies have identified several genes involved in obesity development, including *ADCY3*, a gene encoding for the enzyme adenylyl cyclase 3 (AC3). AC3 is a critical mediator of the cyclic adenosine monophosphate (cAMP) signaling pathway and is enriched in the primary cilium, a solitary immotile organelle protruding from most mammalian cells, including neurons. The primary cilia act as the cellular antenna to sense and relay changes in the extracellular microenvironment and mounting evidence support a role for the primary cilia as a critical regulator of the energy homeostasis. Patients carrying loss-of-function *ADCY3* variants are obese and are at increased risk of developing type II diabetes mellitus (T2DM). Consistently, whole-body *Adcy3* knockout mice also develop obesity; however, the underlying mechanisms by which AC3 affects metabolic homeostasis remain unclear. Here, we examined the impact of AC3 loss within the ventromedial nucleus of hypothalamus (VMH), a brain region critical for coordinated control of energy and glucose homeostasis, on energy metabolism. We generated mice with VMH-specific *Adcy3* loss (Adcy3$^{SF\text{-}1KO}$ mice) by crossing SF-1^{Cre+} mice with Adcy3$^{F/F}$ mice and subjected them to metabolic phenotyping to assess energy balance and glucose homeostasis. We observed a sexually dimorphic effect on body weight under standard chow diet; male Adcy3$^{SF\text{-}1KO}$ mice displayed normal body weight gain comparable to control littermates, whereas female Adcy3$^{SF\text{-}1KO}$ mice gained a significant more weight compared to control littermates (Con 24.34g v KO 30.61g, $p < 0.0001$). Strikingly, however, both sexes of Adcy3$^{SF\text{-}1KO}$ mice exhibited improved glucose tolerance (AUC: M Con 17,826 v KO 15,165, $p = 0.02$; F Con 15,263 v KO 13,238, $p = 0.03$) without affecting fed and overnight fasting blood glucose levels. Taken together, these results underscore the importance of AC3-mediated ciliary cAMP signaling in VMH neurons for the regulation of energy balance and glucose homeostasis in a sex-dependent manner.

Title: Effects of chronic central leptin infusion on food intake of offspring of dams with mild hyperglycemia associated with snack intake

Authors: *G. P. OLIVEIRA[1,2], A. G. CRUZ[1,2], G. V. SILVA[2], L. P. RODRIGUES[2], M. G. MARTINS[1,2], B. WOODSIDE[3], A. C. I. KISS[1,2];

Abstract: There is evidence that offspring from diabetic dams show differences on energy balance and leptin levels. Besides maternal metabolism, it is known that maternal nutrition can also compromise those parameters in the offspring. However, the effects of their association on offspring food intake have not been explored yet. Therefore, the aim of this study was to evaluate the effects of chronic central leptin infusion on food intake of offspring of dams with mild hyperglycemia associated with snack intake. Sprague-Dawley rats were used. Female rats were mated and on pregnancy day (PD) 0 were randomly divided into 2 experimental groups: standard diet (n=28) or standard diet + snacks (n=27). Snacks compromised of potato chips and a red fruit-flavored sucrose syrup solution 1.5%). On pregnancy day 7, both experimental groups were then subdivided into normoglycemic dams and dams that were rendered hyperglycemic by streptozotocin administration (STZ, 35mg/kg, i.p.). Thus 4 experimental groups: Control (n=15), Control-Snack (n=14), STZ (n=13), and STZ-Snack (n=13). On PD 21, rats gave birth naturally and litters were culled to 4 males and 4 females. On postnatal day 75 (PND 75), 2 male and 2 female offspring from each litter were used and each received a different central treatment (saline or leptin). Thus, the offspring experimental groups were formed according to maternal metabolism (normoglycemic or hyperglycemic), maternal diet (standard chow or standard chow plus snacks), sex (male or female) and treatment (saline or leptin). On PND 82 animals underwent surgery for implantation of a cannula in the cerebral lateral ventricle (Alzet® model 2001) which released saline 0,9% or leptin (1 µg of leptin per day at a rate of 1 µl/hour for 7 consecutive days). Body weight and food intake were daily monitored for 7 days before and 7 days after surgery. On PND 89, rats were killed and cannula placement was evaluated. All experimental procedures were approved by the local ethics committee (Protocol 1134). Offspring of hyperglycemic dams were hyperphagic, presenting an increased food intake even before surgery. As expected, leptin treatment reduced food intake and body weight in all treated animals. Response to leptin was modified by sex and also by maternal snack intake, with offspring from dams fed with snacks showing an increased response to central leptin, regardless of maternal metabolism. In conclusion, maternal hyperglycemia changed offspring food intake pattern. Maternal snack intake increased offspring response to central leptin in a sex dependent manner. However, the association of both maternal factors did not lead to further effects for the offspring food intake.

Title: Elucidation of sex-specific hedonic and homeostatic disturbances caused by an obesogenic diet in Sprague Dawley (Rattus norvegicus) rats

Authors: *J. GAULIN, K. SALHANY, Jr., J. MELO, Z. DJABAKATIE, F. DEJU-CALIXTO, A. TOORIE;
Biol., Rhode Island Col., Providence, RI

Abstract: Chronic overconsumption of hyperpalatable, hypercaloric foods is a growing concern in modern society, despite increased awareness and mitigation efforts to reduce its prevalence. It is a significant contributing factor to metabolic syndrome, a cluster of symptoms that includes hypertension, hyperglycemia, abdominal obesity, and abnormal cholesterol levels. Unresolved metabolic syndrome can paradoxically result from or lead to insulin resistance and the development of type 2 diabetes, among other diseases. Dysregulation in both central (brain) and peripheral tissue (i.e., liver and adipose tissues) contributes to the development of metabolic syndrome. In this study, male and female subjects were fed a high-fat diet (HFD) or a standard control diet for 12 weeks. Findings revealed that males are prone to development of metabolic dyshomeostasis while females are resilient to the effects of chronic HFD exposure. While no differences in anhedonia were discerned, HFD males displayed behaviors suggestive of enhanced anxiety. We posit that glucoregulatory and anxiety-related effects are likely due to changes in stress hormone physiology in both central and peripheral tissues, in tandem with dysregulated hepatic glucose metabolism.

Abstract: Binge eating disorder, characterized by the overconsumption of food in a discrete time period, is the most common eating disorder in the United States and affects women more than men. Both the

neuropeptide, pituitary adenylate cyclase-activating polypeptide (PACAP), and the limbic brain region, the paraventricular nucleus of the thalamus (PVT), have been implicated in feeding behavior. We have recently identified high levels of the peptide isoform, PACAP-27 (more than PACAP-38), in cells of the PVT. To investigate possible mechanisms behind sex differences in the rate of binge eating disorder, we used limited home-cage access (2 hours/day, 4 days/week) to Milk Chocolate Ensure Plus® to induce binge-type eating in male and female mice. Control groups of male and female mice were given access to chow and water but not Ensure. Chow, water, and Ensure were measured before and after the two-hour "binge" period. Under this 6-week paradigm, and with chow available ad libitum, female compared to male mice demonstrated greater binge-type eating of Ensure, consuming more calories per body weight during the two-hour binge period. While these male and female mice did not differ in 24-hour caloric intake per body weight, female mice in the binge-type eating group consumed significantly more calories from sugar than male mice during this period, indicating that they are preferentially consuming this carbohydrate as a calorie source. In the control groups, male and female mice did not differ in their chow intake during the two-hour binge period. Using quantitative real-time PCR (qRT-PCR) to examine PVT PACAP mRNA in adult male and female mice with no history of binge eating, we found that females had higher gene expression of PVT PACAP than males. Similarly, in rats, females also had higher levels of PACAP mRNA, in both the anterior PVT and posterior PVT. Finally, using immunohistochemistry in rats, we found that females had higher PACAP peptide levels, of both PACAP-27 and PACAP-38, across the entire PVT. Our results indicate that females demonstrate greater binge-type eating and higher levels of PVT PACAP than males. Given the known associations of PACAP and the PVT with feeding, this suggests that PACAP in the PVT could drive binge eating behavior.

Abstract: Considering the obesity epidemic is largely attributed to an energy imbalance, it is crucial to understand the behavioral and biological mechanistic interactions between intake of energy dense food and level of physical activity. Previous research has shown sex dependent influences of physical activity on diet preferences, specifically differences in palatable high fat diet intake. We hypothesize that this sex difference involves principles of reward substitution. Female rats have been shown to demonstrate higher

levels for the self-administration of drugs of abuse, palatable food intake, and voluntary wheel running, when compared to males. Considering this sex difference across multiple rewarding events, the present study explored how palatable diet intake and physical activity may be influenced by reward substitution in male and female Wistar outbred rats. Following a 1-week acclimation to voluntary wheel running access (RUN) with ad libitum standard chow diet, rats were given access to both ab libitum high fat diet (60% fat) along with standard chow diet for the next 4-week testing period (Weeks 2-5). Food consumption, body weight, and running duration and distance were recorded daily. All groups were given 1 week in the RUN condition (week 2) followed by 1 week of a locked wheel condition (SED) (week 3), to determine diet preference change between the RUN and SED conditions. During weeks 4 and 5, one half of the males and females were placed back in the RUN condition, while the other half remained in the SED condition. At the end of week 5, striatal and hypothalamic brain regions and plasma were collected, and multiple gene and protein profiles were assessed. Results showed that there was a sex dependent effect of RUN treatment on decreasing palatable food intake in males, which was reversible by returning rats to SED conditions.

Title: Guiding the future by linking the past: Adolescent development of value-based generalization

Authors: *A. QUACH[1], D. SHOHAMY[2,3], G. WIMMER[4], A. GALVAN[5], B. CASEY[6], J. Y. DAVIDOW[1];

Abstract: Generalizing from past experience is important for guiding adaptive decision-making in new situations. Adolescence is a life-stage full of new experiences during which individuals face increasing opportunities for self-guided decision-making. Research has shown that adolescents can make adaptive value-guided decisions, however, protracted neural coordination of subcortical learning systems with cortical systems may constrain their ability to flexibly generalize value across related experiences to guide novel decision-making. To test this hypothesis, participants (N=111, ages 8-30) completed a motivated learning and generalization task with three stages. First, participants learned stimulus-stimulus associations in the absence of feedback, then a subset of stimuli from these pairs underwent probabilistic reward conditioning (i.e., learned stimulus-outcome associations), and finally, a critical decision-making test evaluated the extent to which value generalized across overlapping experiences. We found that stimulus-stimulus and stimulus-outcome learning did not vary by age, suggesting that all participants learned the contingencies similarly, and allowing us to ask about age-related differences in how these

associative relationships are used to guide novel decision-making. While participants of all ages were similarly able to make optimal choices based on previously conditioned options, in contrast, optimal choices requiring the integration of value across overlapping learning experiences increased with age. This pattern of results suggests protracted development of the ability to generalize value across related experiences. Ongoing examination of resting-state functional connectivity will relate these differences in value-based generalization to age-related changes in intrinsic neural networks. These findings will shed light on mechanisms underlying how adolescents make decisions as they navigate new experiences throughout development.

Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [4]Dept. of Social Psychology, The Univ. of Tokyo, Tokyo, Japan; [5]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Decision making behaviors, including the selection and purchase of products by consumers, can be explained by the "*decision utility*" in conventional economics. Meanwhile experiences that occur around the decision (*experienced utility*) also affect the actual decision making. In our previous research, we developed a new monetary task to measure the neural correlates of decision utility as well as 2 important aspects of the experienced utility i.e. *instant utility* and *remembered utility*. We identified the brain regions involved in each utility calculation and constructed a mathematical model by using this task. However, it is unclear how generalizable the findings from the abstract fractal images are to actual consumer purchasing behavior. Here we sought to investigate the neural mechanisms of purchasing behavior by using a modified version of the previous task. The experiment comprised 4 sessions, with each session comprising 3 parts: A Selection part and Evaluation part (repeated 10 times) and a Remember part (at the end of the session). In the Selection part, the participants were shown 2 lipsticks, the combination of which was selected at random without replacement from a total of 5 lipsticks. The participants were asked to select the lipstick which more preferred. In the Evaluation part, they saw a photo of their own face made-up virtually with the chosen lipstick, superimposed on a scene. The virtually made-up face was presented four times in total in the Evaluation part, superimposed on four

different scenes (e.g. party, mountain, or funeral). In the Remember part, the participants were asked to evaluate the remembered value of each lipstick. During this task, fMRI was used to investigate the neural responses. We found no statistically significant response at the decision to choose a lipstick during the Selection. During experiencing whether the lipstick suits them during the Evaluation part, right fusiform (rFG) was significantly activated. When they remember the value of the lipsticks, significant activation was shown in the Angular Gyrus (AG) and in part of the Midbrain. We suggest that during the Evaluation part, the processing of the face activates the rFG. Meanwhile, in the Remembering part, the significant activation in the AG and midbrain was consistent with our previous study and likely reflects memory retrieval and reward process, respectively. We speculate that remembering the simulated cosmetics experiences triggers reward processes, such that future choice of cosmetics can be based on this remembered utility. Although future studies are necessary, the neuronal process underlying purchasing behavior can support product development.

Title: Neural mechanisms underlying expectations of reward-based task performance

Authors: *J. LEE[1], V. S. CHIB[1,2];
[1]Biomed. Engin., Johns Hopkins Sch. of Med., Baltimore, MD; [2]Kennedy Krieger Inst., Baltimore, MD

Abstract: When performing a motor task, it is essential for us to generate expectations of the outcomes of our actions. Both our actions and external environmental factors contribute to the realization of our outcomes, and it is important for us to understand how these different factors give rise to our eventual expectations. There is a limited understanding of how the brain integrates information about motor performance and environmental factors when generating our expectations of performance. To dissociate these factors, we had subjects perform a skilled button-pressing task in which they controlled a cursor into a variable size target for reward. Participants were also presented with cues associated with probabilistic outcomes that were not contingent on performance. This meant that even if a participant successfully performed the task, there would be a chance of not receiving a reward. The probabilistic outcome was independent of the participants' performance. The difficulty of the game (target size) as well as the probabilistic outcome cue were presented to participants prior to starting a trial, and at separate time points. In addition to performing the skilled task for reward, subjects also made choices to either perform the tasks of varying difficulty, or accept potential probabilistic outcomes (i.e., monetary gamble) that was not associated with task performance. Using the choice data, we computed the preference of each subject

to perform the task over the probabilistic outcome. Participants' choices showed that they were accurate in assessing their performance during easy trials, but significantly over-estimated their performance for the difficult trials. We plan on doing further analysis of our imaging data to examine how BOLD activations in reward regions differentially encode task performance and probabilistic outcomes.

Title: Trends in instant utilities determine decision through remembered utility

Authors: *K. IIJIMA[1,2], K. MATSUMORI[1,3,4], Y. SAHEKI[5], K. HIRABAYASHI[5], K. TAGAI[5], K. MATSUMOTO[1];
[1]Tamagawa Univ. Brain Sci. Inst., Tokyo, Japan; [2]Dept. of Preventive Intervention for Psychiatric Disorders, Natl. Inst. of Mental Health, Natl. Inst., Shiseido Co., Ltd., Yokohama, Japan

Abstract: There has long been tension between two different usages of the term "utility". *Decision utility*, adopted in current economics and decision theory, refers to the weight of an outcome in a decision and is inferred from observed choice behavior. However, in classical utilitarianism, utility refers to pleasure and pain, and such *experienced utility* can be reported in real time (*instant utility*), or in retrospective evaluations of past episodes (*remembered utility*). To bridge these two core meanings of utility in the human brain, we developed a novel task for measuring neural correlates of decision, instant and remembered utility. By choosing between two fractal images, participants received a series of monetary rewards depending on the chosen image in 10 discrete steps repeated. Occasionally, participants were asked to report their current pleasantness (instant utility) or retrospective pleasantness (remembered utility) for the fractal image. We assigned six different patterns of reward series (descending (D), constant (C), and ascending (A) patterns of large rewards and those patterns of small rewards) to six fractal images, respectively. Participants gradually learned the value of fractals and showed rational choice behavior (large vs. small). Interestingly, even among the same reward category (large or small), they showed particular preference for reward series (i.e., D > C > A). The remembered utility for each reward series gradually dissociated from the others, reflecting the learning of value. Reported instant utility roughly reflected the trends of monetary reward series. However, the sums of instant utilities over the whole steps were dramatically dissociated from objective reward amounts. The instant utility of later steps seemed to be less affected by reward amounts. The sum of instant utilities over the whole steps also seems to reflect the preference for reward series in choice behavior. Moreover, a multiple regression analysis to instant utility indicated that presenting particular series itself affected instant utility regardless

of current amounts of monetary reward. Furthermore, we developed computational models to examine the dependency among utilities and reward. Model selection confirmed that instant utility, in addition to the objective reward, had a role in determining remembered and decision utility. The selected model suggests that trends in instant utility determine decision utility through remembered utility. As the next step, we will analyze the neural responses with the newly developed decision-making model to differentiate the three utilities in the brain.

Title: The intrinsic value of choice of free versus forced choice in human subjects

Authors: *J. MUNUERA[1], M. R. AGOST[2], V. CHAMBON[2], B. LAU[1];
[1]Paris Brain Inst., Paris, France; [2]Inst. Jean-Nicod, Ecole Normale Supérieure, Paris, France

Abstract: When deciding between opportunities leading to further choices and those that do not, humans and other animals frequently choose to choose, even when doing so does not immediately lead to reward. We sought to understand the mechanisms involved in choice preference by asking human subjects to perform a two-stage task separating decisions to choose from actions that lead directly to reward. In each trial, subjects made a 1st stage choice (meta-choice) between two options defining the 2nd stage: the opportunity to choose between two fractal targets (free condition) or performing an obligatory selection of another fractal target (forced condition). Rewards were delivered probabilistically for 2nd stage actions, and in different blocks we varied either overall expected value (keeping maximal reward probabilities equal between free and forced actions) or relative expected value (increasing the reward probability of forced actions). We found that subjects prefer free to forced actions when they yielded similar expected reward (65%). Increasing the expected value of forced actions progressively reduced preference for free actions (39% when p(reward|forced) = 0.95 and p(reward|free) = 0.75). However, we observed substantial inter-subject variability, with ~13% of subjects exhibiting near-exclusive preference for free actions. We fit temporal-difference reinforcement learning (TDRL) models to investigate inter-subject differences and test whether trial-by-trial data could be explained by distortion of rewards obtained from free actions (overvaluation) and/or the use of greedy targets in calculating reward prediction errors (Q-learning variants compared to SARSA). Model comparisons indicated that it was necessary to incorporate overvaluation of rewards obtained from free actions to account for choice-seeking behavior, and that

using greedy targets alone was insufficient to explain observed choice preference. Our results advance our understanding of one facet of "intrinsic motivation" related to why people value choice

Title: Exercise attenuates incubation of craving for food high in fat

Authors: *G. E. KIRKPATRICK[1], T. E. BROWN[3], P. M. DINGESS[2];
[1]Biomed. Sci., [2]Univ. of Wyoming, Laramie, WY; [3]Neurosci., Washington State Univ., Pullman, WA

Abstract: Exercise attenuates incubation of craving for food high in fat
Kirkpatrick GE[1,3], Dingess PM[2], Brown TE[1,2,3]
[1]Biomedical Program, University of Wyoming, Laramie, WY 82071[2]School of Pharmacy, University of Wyoming, Laramie, WY 82071[3] Neuroscience Program, Washington State University, Pullman WA 91163
We have previously shown that cue-induced craving for food high in fat increases over time (incubation of craving); however, whether this time dependent increase can be attenuated is unknown. To address this question, 60d male Sprague Dawley rats underwent self-administration training for a 60% high-fat (HF) pellet, which was associated with the presentation of a compound stimulus (light+tone) for 10 d. Rats were tested for lever responding in the absence of the HF pellet but in the presence of the cues one day after training. Rats did not undergo any subsequent operant training for 30d. During the 30d abstinence period, a subset of rats were exposed to high intensity interval exercise. Both groups were tested again on day 30, identically to the 1d test. Consistent with our previous work, we found that rats without exercise demonstrated significant incubation of craving (1d: 28.23±3.26; 30d: 58.62±7.31; data are mean ± SEM). However, rats exposed to exercise during the abstinence period did not show an incubation of craving effect at 30 d (1d: 26.67±3.41; 30d: 30.25±3.66). These results indicate that exercise could reduce increased craving during abstinence, which may reduce overeating and the development of obesity.

Title: Subthalamic nucleus modulation and dopaminergic treatment influence free choice preference on Parkinson's disease patients

Authors: *D. BENDETOWICZ[1,2], B. LAU[1], E. HAINQUE[1,2], C. KARACHI[1,3], J. MUNUERA[1]; [1]Sorbonne Université, Inst. du Cerveau - Paris Brain Inst. - ICM, Inserm, CNRS, Paris, France; [2]Neurol., [3]Neurosurg., AP-HP, Hôpital de la Pitié Salpêtrière, Paris, France

Abstract: Dopamine neuron activity is closely related to the reinforcement of newly experienced appetitive stimuli or rewards. According to the common currency theory, the dopaminergic system acts as a stimulus reinforcer regardless of the reward type which can be basic like food or reproduction or more complex (or cognitive), like getting advanced information or having the ability to choose between several options in uncertain situations. Cognitive rewards can be regarded as rewarding by increasing knowledge or influence of the agent on its environment. Animals and humans express a natural preference for situations when choices are available compared to the absence of choice. However, the neural mechanisms underlying such behavior are poorly understood. We hypothesize that cognitive rewards are encoded by the dopaminergic system. We tested cognitive rewards (choice preference) using a task on patients with Parkinson's disease as a model of dopamine depletion. We designed a two-step task where subjects had to select between two rewarding images, either by choosing themselves (choice trials) or forced by the computer (forced trials). Before testing, subjects were extensively trained on paired-images with imbalanced probability of reward, one being more rewarding than the other. Reward contingencies were equivalent between forced and choice conditions and the most rewarding image was always selected by the computer in the forced condition. By doing so, forced and choice conditions were economically equivalent in terms of maximizing the total amount of reward.
We tested 37 patients and compared their performance with (ON) and without (OFF) surgical or dopaminergic treatment. 13 patients were treated with Deep Brain Stimulation (DBS group) of the subthalamic nucleus (STN) and 24 patients were treated with levodopa medication only (MED group). Preliminary results show that DBS patients have a higher preference for choice when DBS was ON (Mean=76%) compared to OFF (Mean=46%). No difference was observed in MED patients, with a high preference for choice trials both ON (Mean=76%) and OFF treatment (Mean=74%). Notably, we observed a positive and negative association respectively between L-DOPA daily dose and duration of disease with preference for choice.
We observed that free choice opportunity is influenced by neuromodulation of the STN activity. In line with the idea that DBS of the STN enhances incentive stimulus selection, this result suggests that free choice acts as a cognitive reward. Furthermore, higher choice preference on MED patients could be related to long-term effects of chronic L-DOPA intake.

Title: The reward positivity is enhanced in individuals with alcohol use disorder

Authors: *G. SINGH[1], E. CAMPBELL[1], J. HOGEVEEN[1], E. CLAUS[2], K. WITKIEWITZ[1], J. CAVANAGH[1,2];
[1]Dept. of Psychology, Univ. of New Mexico, Albuquerque, NM; [2]Mind Res. Network, Albuquerque, NM

Abstract: The Reward Positivity (RewP) is a positive deflection in the EEG following reward receipt. Recent evidence suggests that the RewP is modulated by both reward probability as well as subjective rating of liking. Here we examined the sensitivity of the RewP to positive affective and alcohol images in individuals with alcohol use disorder (AUD). We recruited 49 participants (AUD =27, Control= 22). Participants completed both a standard 2-doors task with point feedback (green +1 or red -1) as well as a reinforcement learning task with picture feedback (puppy or alcohol images over a green or red screen). The AUD group had an enhanced RewP to point feedback in the 2-doors task ($F(1,48) = 21.78$, $p<0.001$), as well as a main effect of larger RewP to all valanced picture feedback ($F(1,48) = 29.2$, $p<0.005$), yet there was no difference between puppy or alcohol images ($F(1,48) =3.88$, $p=0.88$). Across all participants, there was a positive correlation between image "liking" ratings and RewP amplitudes ($\rho= 0.321$, $p=0.05$), replicating prior findings of an affective influence on the size of the RewP. These findings indicate that individuals with AUD have a larger RewP at baseline and suggests a domain-general enhancement of reward responsiveness in the AUD group while any modulation of this signal by alcohol-specific cues is in line with general "liking" related trends observed in control samples. Title: Disentangling the content of sensory prediction errors in the human midbrain

Authors: *J. D. HOWARD[1,2], D. S. EDMONDS[2], T. KAHNT[2];
[1]Psychology, Brandeis Univ., Waltham, MA; [2]Neurol., Northwestern Univ., Chicago, IL

Abstract: Prediction errors encoded in the dopaminergic midbrain represent a fundamental mechanism by which reward predictions are updated during learning. Recent studies in rats and humans have demonstrated that, in addition to signaling violations in value expectations, these responses also signal violations in the sensory properties of expected outcomes. Moreover, such sensory prediction errors have been shown to carry information about the specific identity of the reward that is delivered at the time of the outcome. However, whether this ensemble information reflects what was unexpectedly not received (i.e., the omitted reward) or what was unexpectedly received (i.e., the experienced reward) has not been tested. To answer this question, we designed a novel transreinforcer reversal learning task in which hungry human participants (N=30) intermittently experienced violations in three value-matched food odors while undergoing function magnetic resonance imaging (fMRI). Preliminary analysis of the fMRI data revealed that activity in the midbrain was significantly higher on error trials (i.e., when an unexpected odor was delivered) compared to non-error trials ($F_{2,58}$ = 6.92, p = 0.003), replicating previous studies showing that value-matched rewards evoked sensory prediction errors in this region. Critically, by incorporating 3 distinct food odor rewards in this experiment, we are able to create comparisons between conditions in which the expected odor reward is different but the received odor reward is identical, and conversely in which expected odor reward is identical but the received odor reward is different. By conducting pattern-based analysis of the fMRI activity ensembles evoked in these conditions, we aim to test whether information represented in sensory prediction error responses reflects omitted or received reward identity. Such findings would have implications for understanding how error signals originating in the dopaminergic midbrain support model-based learning of associative information.

Title: Obesity, binge-eating and food addiction: Mental health and cognitive risk factors

Authors: *J. JEONG, Y. JEON, K. BAEK;
Pusan Natl. Univ., Pusan, Korea, Republic of

Abstract: Obesity is a serious health issue, and compulsive eating problem such as binge-eating and food addiction has been implicated as potential causes. However, the comorbidity of obesity, binge-eating and food addiction is still not much clear, and the psychological and cognitive factors underlying these eating problems. Here we recruited 102 normal-weighted subjects and 115 obese subjects in the outpatient clinic

and local community to investigate the relationship between obesity, binge-eating and food addiction. We used the following clinical questionnaires: Binge Eating Scale (BES), Yale Food Addiction Scale 2.0 (YFAS), Eating Disorder Diagnostic Scale, General Food Craving Questionnaire-Trait (G-FCQ-T), Beck Depression Inventory (BDI), State/Trait Anxiety Inventory (STAI), Barratt Impulsiveness Scale-11 (BIS-11), The Behavioral Inhibition and Behavioral Approach Systems (BIS/BAS), and Emotion Regulation Questionnaire (ERQ). As shown in Fig. 1A, the prevalence of binge-eating was double in the obese population. However, clinical questionnaire scores were not affected by obesity itself ($p > 0.05$ in 3-way ANOVA on obesity, binge-eating and food addiction) except BIS/BAS. Thus, we collapsed these two body weight groups and divided into 3 groups for later analysis: Normal vs. Binge-eating only vs. Binge-eating + Food addiction as shown in Fig.1B~F. Interestingly, both binge-eating and food addiction increased not only food craving but also depression and anxiety measured with BDI, STAI and Impulsiveness (Normal < Binge-eating only < Binge-eating + Food addiction, all $p < 0.001$, Tukey's test). Reappraisal strategy in ERQ was much less observed in the binge-eating group compared to the normal population as shown in Fig.1F. The present study suggests that binge-eating disorder is not only affecting on body weight but also mental health (e.g. depression and anxiety). Food addiction often manifested as a more severe form of compulsive eating problem. In conclusion, cognitive risk factors for binge-eating/food addiction such as impulsiveness should be further investigated.

Fig 1. (A) The prevalence rate of binge-eating and food addiction in the normal weight and the obesity populations. (B) ~ (F) Comparison of questionnaire scores across 3 groups: Normal vs. Binge-eating only vs. Binge Eating + Food addiction (Here both normal weight and obesity populations are collapsed together).

Title: Nucleus accumbens and central amygdala D1-type and D2-type neurons promote reward motivation

Authors: *D. NGUYEN, K. C. BERRIDGE;
Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Both the nucleus accumbens (NAc) and the central nucleus of the amygdala (CeA) are striatal-type structures that contain two populations of medium spiny neurons (MSNs): one population expresses primarily D1-type (D1R) dopamine receptors, whereas the other expresses D2-type (D2R) dopamine receptors. Much evidence indicates that D1R and D2R are involved in reward and anti-reward processes, respectively; however, emerging evidence suggests that D2R neurons can also promote reward motivation depending on the situation and behavioral task. The potentially bi-valent properties of D2R neurons raises the question of whether the selectivity of neuron activation is important, given that D2R is also expressed on cholinergic interneurons and elsewhere in addition to MSNs in both NAc and CeA. To explore this question, the present study uses a novel line of transgenic rats that express Cre in neurons containing adenosine 2a receptors (A2aR), which are expressed solely on D2R MSNs in both the NAc and CeA. A2aR-Cre and D1R-Cre rats were tested for positive optogenetic self-stimulation in NAc and CeA in a place-based self-administration task (RTPP) and in active-response instrumental tasks (spout touch, lever press, nose poke). We found that in both regions, D1R neurons produced robust laser self-stimulation in both place-based and active-response tasks. By contrast, A2aR neurons produced self-stimulation only in the place-based and not in the active-response tasks. Furthermore, the degree of self-stimulation varied depending on the length of laser activation (1 sec vs 8 sec bins) as well as on the parameters used for laser activation (10-40 Hz frequencies and 1-10 mW intensities). Our results are consistent with strong D1R involvement in reward motivation. Our results also suggest that A2aR (D2R MSNs) can also contribute to lesser reward motivation, but only in situation-dependent ways, promoting reward when self-stimulation is administered passively but not when an active instrumental response is required to earn laser illuminations.

Title: Intra-nucleus accumbens insulin reduces food intake and motivation for food

Authors: *J. E. FINNELL[1], C. R. FERRARIO[1,2];
[1]Pharmacol., [2]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Insulin receptors are expressed throughout the brain, including within mesocorticolimbic circuits. For example, insulin from the periphery is rapidly distributed into the striatum, which has a high proportion of insulin binding (Havrankova et al., 1978). In humans and rodents, insulin alters neural function to decrease food intake, but mechanisms are unknown. Recent studies showed that insulin alters dopamine transmission within the NAc and VTA, and that insulin receptor activation enhances presynaptic glutamate release within the NAc. This region plays critical roles in food-seeking and feeding behaviors. Furthermore, diet-induced obesity reduces NA insulin receptor expression and the ability of insulin to enhance NAc glutamate transmission. However, how insulin within the NAc may influence food-seeking and feeding behavior is unclear. Therefore, here we determined how intra-NAc insulin affects cue-triggered food-seeking, food intake, and motivation to obtain food in adult male rats. Food intake, break point using a progressive ratio schedule, and Pavlovian conditioned approach were measured in healthy weight rats. Direct infusion of insulin into the NAc did not affect conditioned approach compared to vehicle infusion. However, home cage food intake immediately following this test was significantly reduced. Furthermore, intra-NAc insulin reduced break point compared to vehicle, and this effect was partially reversed by insulin receptor blockade. Additional studies examining effects of insulin on conditioned aversion are currently under way and will inform interpretation of key results. Results to date show that insulin within the NAc does not alter the incentive-motivational properties of a food cue, but instead reduces the motivation to consume food. This not only has implications for the regulation of food-seeking and eating, but may also be important in the dysregulation of feeding that accompanies obesity.

Title: Optogenetic identification of hedonic hotspots in orbitofrontal cortex, insula, ventral pallidum, and anterior cingulate cortex that control liking and wanting for sweet reward

Authors: *I. MORALES[1], M. AYOUB[1], J. OLNEY[1], K. C. BERRIDGE[2];
[1]Psychology, Univ. of Michigan Ann Arbor, Ann Arbor, MI; [2]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Reward consists of learning, 'liking', and 'wanting' components, but 'liking' remains the least understood. Hedonic function is causally amplified by brain hedonic hotspots in nucleus accumbens, ventral pallidum, orbitofrontal cortex (OFC), and insula when neurochemically stimulated during the taste reactivity test. This test categorizes affective reactions to positive 'liking' and aversive 'disgust' components. Here we present novel data showing that optogenetic manipulations to control neuronal activity in the hedonic hotspots of cortical OFC and insula, as well as in subcortical ventral pallidum doubles the number of hedonic 'liking' reactions elicited by the sweet taste of sucrose. Hedonic enhancement was anatomically restricted to the hedonic hotspots as the same manipulations inside the same brain structures but outside the hedonic hotspots fails to increase 'liking' and even may oppositely suppress hedonic 'liking' despite still generating robust increases in incentive motivation to food. Furthermore, we identify a novel hedonic hotspot in caudal anterior cingulate cortex (pACC) never previously described and find that ChR2 stimulation of neurons within this new pACC hotspot doubles hedonic 'liking' as well as incentive motivation or 'wanting' for sucrose. Subcortically, we also show that VP neurons bidirectionally control hedonic impact, as optogenetic inhibitions of the VP hotspot suppresses hedonic 'liking' reactions to sucrose and replaces them with aversive 'disgust'. VP control of 'wanting' and 'liking' was further explored by selectively targeting VP^{GABA} neurons within the VP hotspot, using transgenic GAD1 Cre rats, finding that GABA neurons particularly promote hedonic 'liking' reactions to sucrose. Overall, our findings suggest that hedonic hotspots in the brain are robust hedonic entities in brain corticolimbic sites, whether stimulated pharmacologically or optogenetically, that form a functional hedonic circuit to enhance 'liking'.

Title: The role of CRF neurons in cocaine pursuit and addiction

Authors: *K. EMERY[1], L. TITTLE[2], K. C. BERRIDGE[3];
[1]Univ. of Michigan Neurosci. Grad. Program, Ann Arbor, MI; [3]Psychology, [2]Univ. of Michigan, Ann Arbor, MI

Abstract: The role of CRF neurons in cocaine pursuit and addiction Katie Emery, Lucas Tittle, Kent Berridge
Neurons that express corticotropin releasing factor (CRF) are typically regarded by opponent-process and allostasis theories of addiction as an "anti-reward" mechanism of aversive states in drug withdrawal, which causes addictive relapse and drug consumption to alleviate the distress (George et al., 2012). However, our lab has shown that optogenetic stimulation of CRF neurons in either central amygdala (CeA) or nucleus accumbens (NAc) instead activates incentive motivation, with positive motivational valence (e.g., laser self-stimulation), to increase pursuit of laser-paired intravenous cocaine or sucrose rewards (Baumgartner et al. 2021; submitted). Conversely, optogenetic stimulation of CRF neurons in bed nucleus of the stria terminalis (BNST), while plausibly aversive, failed to increase pursuit of cocaine or sucrose. However, it is possible that drug experience with extended cocaine access, to induce greater dependence, might switch the role of CRF neurons to better fit the traditional opponent-process view of distress-induction to drive hedonic self-medication. For example, stress experience has been shown to flip the valence of NAc CRF-induced motivation from positive to negative (Lemos et al. 2012). To test this hypothesis, we gave *crh*-Cre rats experience with two weeks of a long-access schedule of cocaine self-administration (6 hrs per session) to induce DA-receptor downregulation and dependence. We then assess whether optogenetic activation of CRF neurons in CeA or BNST causes an aversive state that promotes cocaine consumption, as posited by allostasis theory. Alternatively, we test whether CRF neurons instead promote cocaine pursuit primarily via incentive motivation even after extended drug self-administration, as it does in relatively drug-naïve rats. In a separate line of studies, we assess whether CRF neurotransmitter itself specifically mediates motivation produced by optogenetic stimulation of CRF neurons, versus whether other co-released neurotransmitters are primarily responsible. To assess this, we intraventricularly deliver a CRF antagonist (D-Phe-CRF) together with optogenetic stimulation of CRF neurons prior to motivational tests.

Title: Afferent control of cholinergic interneurons in the nucleus accumbens medial shell

Authors: *C. BAIMEL, E. JANG, S. L. SCUDDER, P. G. ANASTASIADES, K. MANOOCHERI, A. G. CARTER;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Despite representing less than 1% of neurons in the nucleus accumbens (NAc), cholinergic interneurons (ChIs) exert dominant modulatory influence over the region and play a central role in guiding motivated behaviour. ChIs provide dense local innervation and are tonically active, but alter their activity patterns in response to salient stimuli and during reward learning. While the regulation of ChIs is well studied in the dorsal striatum, little is known about how they are engaged in the NAc. Multiple excitatory inputs project to the NAc, but how they target and regulate the activity of ChIs is largely unknown. We have identified the circuit and synaptic mechanisms through which long range inputs alter ChI firing in the NAc medial shell. We find that the paraventricular nucleus of the thalamus (PVT) and the ventral hippocampus (vHPC) are the main excitatory inputs to ChIs in the NAc medial shell. While the PVT activates ChIs, the vHPC strongly pauses firing, due to pronounced recruitment of feed-forward inhibition. In contrast to the dorsal striatum, this inhibition reflects strong connections from local parvalbumin interneurons onto ChIs. Our results highlight how different afferent streams operate through the local circuit to engage ChIs in the NAc medial shell, revealing fundamental differences in local connectivity.

Title: Pathway-selective silencing of ventral striatum neurons projecting to the ventral pallidum elevates motivational states under approach-avoidance conflict in nonhuman primates

Authors: *J. OH[1,2], S. AMEMORI[2], K.-I. INOUE[1], K. KIMURA[1], M. TAKADA[1], K. AMEMORI[2]; [1]Systems Neurosci. Section, Primate Res. Institute, Kyoto Univ., Inuyama, Japan; [2]Inst. for the Advanced Study of Human Biol. (ASHBi), Kyoto Univ., Kyoto, Japan

Abstract: Studies have suggested that both the ventral striatum (vStr) and the ventral pallidum (VP) are involved in regulating approach motivation in reward-seeking behaviors and avoidance motivation in challenging situations where animals are required to escape from aversive events. Because the vStr sends a massive projection to the VP, the vStr-VP pathway could play a causal role in regulating motivation depending on the approach or avoidance behavioral contexts. To address this issue, we trained a macaque

monkey to perform Approach-Avoidance (Ap-Av) conflict and Approach-Approach (Ap-Ap) tasks. Unlike the Ap-Ap task, where the monkey chose between two rewarding options, the Ap-Av conflict task required the monkey to decide whether to accept or reject offers composed of rewarding and aversive outcomes (an air-puff delivered to the face). By comparing the behaviors in these two tasks, we could investigate how an aversive context influences behaviors, including Ap-Av decision-making. During the performance of the tasks, we manipulated the vStr activity by using the DREADDs technique. We injected a viral vector carrying the gene of inhibitory hM4Di receptor (AAV2.1-CaMKII-hM4Di) bilaterally into the vStr. Then we locally infused DCZ (deschloro-clozapine), a novel ligand for DREADDs, into the VP to suppress synaptic input from the vStr. The selective suppression of activity of the vSTr-VP pathway exhibited notable effects in the Ap-Av conflict task. First, we observed a significant elevation of the monkey's motivation to perform the Ap-Av conflict task. The suppressed activity significantly reduced the frequency of omission errors (Kolmogorov-Smirnov test, $P<0.001$) and the reaction time of the target selection (two sampled t-test, $P<0.001$), as compared to the control sessions. Second, we found a significant elevation in arousal level, characterized by an evoked pupil dilation (t-test, $P<0.001$). Moreover, such manipulation induced a significant change in the Ap-Av decision-making, characterized by the increases in Ap choice for the rewarding offers (t-test, $P<0.05$) and in Av choice for the aversive offers (t-test, $P<0.01$). The change in the choice pattern could be interpreted as reduced fluctuations in the Ap-Av decision-making. Importantly, the silencing of the vSTr-VP pathway did not cause the increase in either the motivational state or the arousal level in the Ap-Ap task. The induced behavioral change is in favor of the hypothesis that the vStr-VP pathway regulates motivation, specifically in challenging situations with approach-avoidance conflict.

Title: Progressive recruitment of dorsolateral striatum dopamine signaling underlies cue-evoked movement invigoration

Authors: *L. ENGEL[1], A. WOLFF[1], S. SINHA[2], M. BLAKE[1], V. COLLINS[1], B. SAUNDERS[1]; [1]Univ. of Minnesota, Minneapolis, MN; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Environmental cues, through Pavlovian learning, become conditioned stimuli that guide animals toward the acquisition of rewards (for example, food) by invigorating and directing seeking behavior. We have previously shown that brief optogenetic excitation of dopamine neurons, in temporal association with visual sensory cues, can instantiate those cues as conditioned stimuli that evoke

conditioned movements. It remains unclear 1) how dopamine-neuron mediated, cue-evoked behavior is signaled by dopamine release downstream in striatal subregions and 2) how subregional signals evolve across stages of learning. Here, we made use of a genetically encoded dopamine biosensor (dLight) to monitor dopamine signaling simultaneously in multiple striatal regions with fiber photometry, while tracking detailed movement features, during optogenetic Pavlovian cue conditioning of VTA or SNc dopamine neurons. Our results demonstrate a serial, progressive pattern of cue-evoked dopamine signaling across ventral to dorsal striatal subregions that correlates with different features of cue-evoked behavior. Cues paired with optogenetic activation of VTA dopamine neurons evoked dopamine release in the nucleus accumbens core relatively early in training, when behavioral responses were slower and directed toward the cue. This pattern evolved as conditioning progressed. Late in training, cue-evoked signals emerged in the dorsolateral striatum, as movement patterns became more vigorous and not directed at the cue. Cues paired with optogenetic activation of SNc dopamine neurons did not reliably evoke dopamine release in the dorsolateral striatum, even though those cues spurred vigorous movements. Further, optogenetic inhibition of DLS dopamine terminals during the first 2 seconds of cue presentations late, but not early, in training decreased the probability of cue-evoked locomotion and increased the latency of movement initiation in VTA conditioned animals. Together our studies show dissociable, parallel functions for ventral and dorsal striatal dopamine signaling in guiding versus invigorating behaviors. Further, they suggest that large-scale plasticity across ventral-to-dorsal striatal dopamine networks emerges during Pavlovian learning to coordinate behavioral diversity.

Title: Neural basis of empathy for pain in mice

Authors: *S. J. POULSON[1,2], I. ARAIN[1], A. MANDATORI[1], A. NAIR[4], L. J. MARTIN[1,2,3];
[1]Dept. of Psychology, [2]Collaborative Program in Neurosci., [3]Cell & Systems Biol., Univ. of Toronto, Toronto, ON, Canada; [4]Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: Social animals, including humans and rodents, can detect signals from group members that indicate changes in the environment, such as threats or potential for injury. Signals from group members indicating potential for pain or injury likely range across modalities of perception, e.g. visual cues like paw licking, vocalizations, and olfactory cues. Interestingly, social context plays a large role in enhancing pain behavior. Research in mice has shown that familiar mice express more pain when together than when alone, and bystander mice develop sensitivity to painful stimuli after interacting with cagemates in pain.

Yet the neural mechanisms that drive the enhancement of pain due to social stimuli are unknown. Our aim was to develop a short paradigm where mice express overt cues of pain, then use modern tools to explore neural mechanisms underlying enhanced pain in the uninjured partner. We paired same-sex cagemate adult mice (C57Bl/6, 8-10 weeks, male or female) in a 14.6 cm x 14.6 cm cubicle and deemed one mouse the observer and the other mouse the demonstrator. After a 1-h habituation, pain (2.5% formalin, 20 µL, intraplantar to the left hind paw) or control (0.9% saline pH 7.2, 20 µL) was applied to the demonstrator mouse and returned to the cubicle with the uninjected observer mouse. We video-recorded 30-min of interaction between the observer and demonstrator and scored social interactions, location and movement in the cubicle, and anxiety behaviors. The demonstrator mouse was then removed from the cubicle. Next, enhanced behavioral responses in the observer mouse were measured following evoked stimuli on the hind paw including a chemical pain stimulus that does not normally evoke significant pain behaviors (0.5% formalin, 20 µL, intraplantar, 1-h) or increasing mechanical pressure (Ugo Basile, Dynamic Plantar Aesthesiometer). We found that mice that observed cagemates in pain expressed more pain behavior in the post-test than mice that observed saline controls. After the 1-h formalin post-test, we collected brain tissue of the observer mice and used immunohistochemistry to detect cells with increased expression of c-fos protein, a marker for neuronal cell activation, and compared number of activated neurons in brain regions of interest. We show exploratory behavioral pharmacology and whole tissue immunohistochemistry data between groups. Our findings promote continued investigation of the neurobiology underlying contextual pain modulation, including how others influence our pain experiences, building a greater understanding of the social-communicative elements of the biopsychosocial model of pain.

Title: Distinct oscillatory patterns of the basolateral amygdala-medial prefrontal cortex circuitry of winning and losing during the tube test

Authors: *Y. LEE[1], J. CHOI[2];
[1]Dept. of Animal Sci. & Biotech., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Brain Sci. Inst., KIST, Seoul, Korea, Republic of

Abstract: During conflict situations, neural activities of relatively dominant and submissive subjects are noticeably distinguishable. Since not only just information the two subjects accept but also how that information is processed differ, this will be outwardly expressed into various behaviors. In addition, how confidently the outcome is determined also affects neural activity of both subjects. The medial prefrontal

cortex (mPFC) plays an important role in determination of dominance. The mPFC is known to regulate social behaviors and decision-making, with numerous projections to subcortical regions. Among those regions, the basolateral amygdala (BLA) is stimulated by the mPFC during social cognition and emotion processing. Number of studies have shown different brain activity depending on the dominance of each individual, but dominance dependent neural activities have rarely identified, especially with real-time data. In this study, we would like to present neural dynamics in the mPFC-BLA circuit during the tube test, one of the robust behavioral experiments of measuring dominance states in laboratory rodents. The trial starts as two mice are located at the middle of the tube and ends when one mouse pushes out the opponent to the outside of the tube. With the position data extracted from video during the test, speed of each mouse is calculated. As we inspect the data with regard to the speed of the mice, the power of the 24~32 Hz beta oscillations in the mPFC and the BLA increased as the winner pushes the loser mouse more confidently, with faster proceeding speed. Moreover, fear- and stress-related BLA gamma oscillations (low gamma, 40~60 Hz, high gamma, 70~100 Hz) appeared stronger as the mouse is pushed back roughly. As the BLA is known to receive top-down modulation from the mPFC, mPFC-BLA connectivity will show difference depending on different situations and relative dominance of the mouse. Thus in this study, we would like to present dynamical directionality in the mPFC-BLA circuit during the tube test and build up a classifier that can predict the behavior of the mouse with the neural activity.

Title: The effect of estrogens in the paraventricular nucleus on rapid social recognition in male mice

Authors: *P. PALETTA, S. MCGUINNESS, E. CHOLERIS;
Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Both estrogens and oxytocin have previously been shown to be necessary in order for social recognition (SR) to occur, as knocking out the genes for the estrogen receptors, oxytocin (OT), or the OT receptor (OTR) resulted in impaired SR. Similarly, administrations of 17β-estradiol (E2), estrogen receptor agonists, or oxytocin facilitated SR. Since both estrogens and OT are needed it had been hypothesized that they may interact in some way to facilitate SR. A proposed model of this interaction suggested that estrogens binding to their receptors in the paraventricular nucleus of the hypothalamus (PVN), where the majority of OT is produced, would facilitate the production and release of OT. The OT would then bind to the OTR in the medial amygdala (MeA), a region important for OT mediated SR, so that olfactory information about encountered individuals can be used to recognize a familiar individual, since the MeA also receives direct projections from the olfactory bulbs. We have previously tested this model in female mice, to determine if it is accurate and if it occurs through estrogens' rapid mechanisms.

We first infused E2 into the PVN of ovariectomized mice and found that it rapidly facilitated SR. We next infused a subeffective dose of an OTR antagonist (OTRA), a dose that by itself cannot block SR, into the MeA and the most effective dose of E2 into the PVN, and found that the OTRA was able to block the rapid facilitating effect of E2 on SR. These results showed support for the interaction between estrogens and OT on SR, as well as this effect occurring through estrogens' rapid mechanisms. However, this has only been tested in females so far and the current experiment aims to replicate these tests in males. Castrated male mice receive E2 infused into the PVN and are tested in a SR paradigm. In this paradigm, two same-sex stimulus mice are presented to the experimental mouse for 2 five-minute sample phases. This is followed by a five-minute test phase, where 2 stimulus mice are presented again, however one is replaced with a novel mouse. Since, mice prefer novelty, if the novel stimulus mouse is investigated more, it suggests they recognize the familiar mouse. The paradigm takes place within 40 minutes to test the rapid mechanisms of estrogens and was designed to be "difficult" so that the vehicle group will not show SR, and therefore any facilitating effects of the treatment can be observed. If it is found that SR is facilitated, it would suggest that estrogens in the PVN of both males and females can rapidly facilitate SR. If, however, we find that E2 in the PVN does not facilitate SR, it will show a sex difference in how SR is mediated.

Title: Increase of the excitability of neurons projecting to medial prefrontal cortex in basolateral amygdala in social fear-conditioned mice

Authors: J. YEO[1], *S. LEE[2];
[1]Dept. of Brain and Cognitive Sci., Daegu Gyeongbuk Inst. of Sci. and Technol. (DGIST), Daegu, Korea, Republic of; [2]Korea Brain Res. Inst., Daegu, Korea, Republic of

Abstract: The basolateral amygdala (BLA) to the medial prefrontal cortex (mPFC) pathway plays a role in fear and social behaviors. However, the changes in this pathway upon social fear formation are not exclusively examined. We adopted a social fear conditioning paradigm and evoked a high level of social fear in mice without changing general anxiety and learning ability. We used a retrograde tracer to identify neurons projecting to the mPFC in BLA. The frequency of action potential evoked by intracellular current injection increased upon social fear conditioning. In addition, the resting membrane potentials and rheobase currents are changed in social fear-conditioned mice. These results indicate the increase in

excitability of neurons projecting to the mPFC in BLA upon social fear conditioning and suggest a reciprocal modulation of activity between the BLA and mPFC in social fear behavior.

Title: Androgens and estrogens in the Bed Nucleus of the Stria Terminalis of male mice rapidly modulate social recognition and aggression, possibly interacting with vasopressin

Authors: *D. ASPESI, Z. R. BRILL, G. GUILLAUME, E. CHOLERIS;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Social recognition (SR) allows to identify previously investigated conspecifics and to emit appropriate pro-social or -aggressive behaviours. Androgens are involved in both SR and aggression, with effects possibly mediated by estrogenic action, including those regulated by rapid mechanisms. Testosterone (T) can rapidly interact with other neuroendocrine systems such as vasopressin (AVP) to modulate SR and aggression. The AVP system includes highly sexually differentiated brain regions, such as the bed nucleus of the stria terminalis (BNST) and the lateral septum (LS), which show more AVP neurons and fibers in males than in females. The androgens/AVP interplay impacts social and aggressive behaviours, even if the mechanisms involved are currently poorly understood. To elucidate the rapid, non-genomic, effects of androgens and estrogens on SR and AVP in the BNST, adult castrated (CX) male mice were intracerebrally infused with one of 4 doses of T (0.25, 0.5, 0.75, 1µg of T in 0.5µl of DMSO/side), one of 3 doses of 17β-estradiol (E2; 25, 50, 100nM of E2 in 0.5µl of aCSF/alcohol) or one of 4 doses of dihydrotestosterone (DHT; 0.0625, 0.125, 0.25, 0.5µg of T in 0.5µl of DMSO/side). Mice were then exposed to a 'difficult' SR paradigm, in which CX mice showed an impairment, consisting of two 5-min sample phases with 2 familiar conspecifics, and one test phase with the choice between a familiar or a novel mouse. To evaluate the specificity of the effects on SR, other groups of CX mice were tested in a 'difficult' object recognition (OR) paradigm, in which gonadally intact animals showed an impairment, consisting of one 5-min sample phase with 2 different objects, and one test phase with a new and a familiar object. To assess aggression, mice were tested in a resident-intruder (RI) paradigm at either 35- or 120-min post-infusion to evaluate rapid and long-lasting effects. Results revealed that infusing T, E2, or DHT in the BNST facilitated SR, with CX mice spending more time investigating a novel over a familiar CX mouse, with an inverted U-shaped dose-response. An opposite effect was found in the OR test, in which T, E2, or DHT impaired OR with a U-shaped dose-response. In addition, none of the steroids elicited overt aggression towards the intruders, but they all increased the dominance score in CX mice at 35-min and 120-min. Immunohistochemical analysis revealed a transient increase of AVP fiber

density in the LS 35-, but not 120-min, after the infusion of T, suggesting a rapid interaction of T with AVP, probably affecting its trafficking. Elucidating the AVP-sex hormones interplay may lead to new therapeutic approaches for psychopathologies of social behavior with marked sex differences.

Title: Dopamine 1 receptor activity modulates social behavior and cortical influence on amygdala activity in an age-dependent manner.

Authors: N. C. FERRARA[1], W. MCMICHAEL[2], M. PADIVAL[1], J. A. ROSENKRANZ[1];
[1]Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [2]The Col. of Wooster, Wooster, OH

Abstract: Adolescence is characterized by transitions in social engagement and ongoing cortical maturation, which likely contribute to the age-dependent changes in the regulation of emotions. Engagement in social behavior and brain maturation influence each other and are critical for appropriate social responding later in life. The basolateral amygdala (BLA) is critical for social behavior and receives extensive inputs from the prefrontal cortex (PFC). During adolescence, PFC inputs to BLA increase in strength and more readily activate intra-BLA inhibitory circuits. Understanding the way in which PFC-BLA circuits are regulated to alter social behavior, particularly in an immature circuit, is essential for a clear understanding of neuropsychiatric disorders characterized by abnormal social behavior. One way in which PFC-BLA circuits are regulated is through dopamine 1 receptors (D1R), but much less is known about D1R regulation of social behavior and what this does in the still maturing PFC-BLA circuit. Here, we investigated the relationship between D1R modulation of PFC driven changes in BLA activity and social behavior in adults and adolescents. We found that D1R activation resulted in elevated zif268 expression, used as a proxy for cellular activity, as well as increased glutamate sensitivity in the BLA. D1R agonism reduced PFC-driven inhibition of BLA activity in adults but facilitated this process in adolescents, suggesting that while D1R agonism can increase BLA neuronal activity, it has a distinct impact on the maturing PFC-BLA circuit. Further, we found that D1R agonism had opposing effects on social interaction, where age-specific social behaviors were increased in adolescents but were modestly reduced in adults, but D1R agonism uniformly increased BLA activity in both adults and adolescents during social engagement. These results begin to provide insight to the changes in D1R modulation of cortico-amygdala circuitry from adolescence to adulthood that contribute to the refinement of social behaviors.

Title: Social effect of learning that food is inedible in Aplysia californica

Authors: Y. ZHANG[1], ***R. WILCOX**[1], J. P. GILL[1], A. J. SUSSWEIN[2], H. J. CHIEL[1];
[1]Case Western Reserve Univ., Cleveland, OH; [2]Bar-Ilan Univ., Ramat-Gan, Israel

Abstract: In previous studies, it has been shown that Aplysia can learn that food is inedible after repeated exposure to netted food. Aplysia retain this knowledge for 24 hours. Aplysia are social animals, and the presence of other animals affects their ability to learn (Schwarz, M., Blumberg, S., & Susswein, A. J., Behavioral Neuroscience, 1998). We have now shown a more advanced form of social signaling in which one animal's training affects another animal.We studied this question in 7 pairs of animals. The training procedure was performed with inedible food—dulse wrapped in plankton netting. This allowed animals to taste the seaweed without allowing ingestion. Animals were trained and tested in pairs, with one individual receiving training earlier than the other. To acclimate animals to the scent of food, 0.2 grams of inaccessible food was added to the water one hour prior to the first training session. During training, animals could not make physical contact due to a perforated barrier between them. Netted food was given to the first animal to induce it to feed, and the animal attempted to swallow the food until it ceased responding to the inedible food. The training time—the time between food first entering the mouth and the animal giving up on food—was recorded. One hour later, the training time for the second animal was then recorded in the same manner. We found that when two Aplysia were trained on netted food sequentially, the second animal consistently stopped responding to inedible food more quickly than the first animal. Of the 7 pairs of animals, 6 showed this reduction in response to inedible food. Furthermore, this study tested the animals for memory retention 24 hours after training, with the order of testing blinded. In animals that had been trained first, 5 out of 7 showed a reduced time to stop responding to inedible food, suggesting that they had retained memory of the training. Of the remaining two animals, one was not tested and the other did not show a reduction in testing time. In animals trained second, we found that 3 out of 7 showed a reduced time to stop responding after 24 hours. In this group, 2 animals did not show a reduction in testing time, whereas the remaining animal was not tested. These results suggest that memory retention is not affected in animals that were trained first, but may be reduced in the animals that were trained second. It is possible that this may be due to the reduced time they spent responding to inedible food on the first day. We will test the hypothesis that the interaction between the animals is due to pheromone release by the first animal as it learns that food is inedible.

Title: A machine-learning approach to choreographic analysis of pose and motifs in rhythmic movements of Snowball, the dancing cockatoo

Authors: T. HU[1], B. SANGHERA[1,2], *J. S. KANWAL[1];
[1]Georgetown Univ. Med. Ctr., Washington, DC; [2]Univ. of Miami, Coral Gables, FL

Abstract: Rhythms constitute a fundamental organizing feature of processes and activities in the natural world. Humans have a special ability to entrain rhythmic movements in the form of dancing to the beat and other acoustic patterns in music. Only a few nonhuman species have the capability of entraining their bodily movements and dancing to human-created music. Here, using a deep-learning neural network, DeepLabCut (DLC), we tracked movements of multiple body parts in a cockatoo, Snowball, that was previously shown to dance to the sound of music (Keehn et al., 2019). To test for a modular organization of movement patterns in response to music, we conducted pose analysis using normal-mixtures clustering and the recently developed Variational Animal Motion Embedding (VAME) software for multivariate time-series analysis. DLC tracked well (> 90% probability) 11 of the 14 hand-scored dance movements using markers placed on 8 key body parts (neck, foot, head, wingtip, etc.). Our machine-learning approach to dance movements yielded a discretization of continuous body movements into behavioral syllables or “dynamic poses” and the presence of several elementary modules or "motifs" hidden within the previously classified dance movements. The clustering algorithm yielded a best fit for 14 dynamic poses, some of which wholly or partially overlapped with the hand-scored dance movements, such as Down-Shake, Downward, Foot-Lift, etc. Other poses were distributed among 2 to 4 of the hand-scored dance movements. VAME analysis, specified for 11 motif clusters matching the qualitatively described 11 dance movements, revealed a mismatch between hand-scored and machine-learning assessment of movement modules. On average, each previously described dance pattern contained 3.72 motifs. “Foot-Lift” and “Head-Foot Sync” shared 3 of the 5 VAME-specified motifs present within each dance pattern. “Down-Shake” and “Downward”, however, had no overlap in motifs despite both dance movements appearing similar. A somewhat similar result was obtained for a second VAME-specified clustering of 22 motifs. For this, on average, each hand-scored dance movements contained 5.36 motifs. Both, the “Head-Foot Sync” and the “Foot-Lift Down-Swing”, dances involved the rhythmic movement of the head and foot. These two dance movements shared 4/5 VAME-specified motifs, suggesting that directionality of motion of a body part was over-ruled by synchronous patterns of movement of multiple body parts by a VAME-specified classifier. We speculate that movements entrained by a predictive music rhythm allow automated dopamine-mediated selection of action patterns that are intrinsically rewarding.

Title: Affect modeling of stereoencephalographic signals during naturalistic acoustic stimuli

Authors: *A. PATEL[1,2], G. CHAU[1], J. HUANG[1], S. BEN-HAIM[3], J. SHIH[4], T.-P. JUNG[2], V. GILJA[1]; [1]Electrical and Computer Engin., [2]Inst. for Neural Computation, [3]Neurolog. Surgery, [4]Neurosciences, UCSD, La Jolla, CA

Abstract: Human affect is a complex signal composed of changes in behavioral response, physiological response, and perceived experience. The mapping of these behavioral and physiological responses to reported experiences can vary greatly across individuals and be influenced by a multitude of factors at both short and long timescales. Existing decoders utilizing non-invasive electroencephalography (EEG) and heart-rate variability have demonstrated an ability to classify affect across a range of auditory and visual stimuli. These recordings capture heavily processed features and provide a glimpse at the underlying subcortical networks. Looking to better understand the underlying mechanisms driving affect, recent invasive stereoEEG studies have demonstrated discriminability among affect measures across long, unstructured recordings (Kirkby et. al., Cell 2018). Exploring the temporal sensitivity of affect modeling techniques in relevant subcortical structures, we apply similar techniques to selected sounds maximizing evoked responses in two primary axes of affect – valence and arousal – from the International Affective Digitized Sound (IADS) database (Bradley & Lang, 2007). The study was administered to four male subjects being treated for intractable epilepsy and implanted with stereoEEG probes in limbic regions including the amygdala, hippocampus, insula, and cingulate. The task involved presenting a series of 6 second auditory stimuli and subsequent survey (self-assessment manikin or simple engagement-oriented) pairs. As an initial strategy, physiological power bands of the neural data including alpha (8-13 Hz) and beta (13-30 Hz) corresponding to active stimuli presentation periods are decomposed into independent components. These features are used to construct statistical models and are evaluated against results from existing IADS-EEG studies (Bos, 2006) with comparable decoder performance (> 60%) in a subset of subjects. Examining neural responses across subjects, we attempt to identify coherence networks as outlined in Kirkby et. al. and apply dynamical systems modeling approaches to better understand the mapping from neural activity in limbic networks to perceived affect. Such a direct measurement and understanding of the neural circuits that give rise to affect could enable objective evaluation of affect and mood through machine learning based inference.

Title: Anatomical Mapping and Gene Expression Patterns of the Human Thalamus Midline Nuclei.

Authors: *A. MEDINA[1], R. CALZAVARA[1], W. E. BUNNEY[2], B. BUNNEY[3], R. M. MYERS[4], A. SCHATZBERG[5], J. D. BARCHAS[6], F. LEE[7], H. AKIL[1], S. J. WATSON, Jr[1];

Col., New York, NY

Abstract: The thalamus is generally considered as a relay center, a hub of sorts where information is collected and processed, then transmitted to specific areas of the cerebral cortex. In fact, the thalamic areas dedicated to sifting motor and sensory information constitute the majority of the structure's mass. However, small, specific subnuclei within the thalami appear to be involved in operations pertinent to the limbic system and connect to subcortical limbic structures. The most recognizable of them is the Paraventricular Nucleus (PVT). In humans, the PVT is a thin cellular cluster located along the edge of the third ventricle. Embryologically, this nucleus develops as part of the epithalamus, along with the pineal gland and the habenular nuclei. Therefore, it can be expected that its connectivity and function differ from the majority of thalamic structures. And yet, the human PVT is hardly distinguishable histologically from the neighboring nuclei. In this study, we aim to gain some insight into the functionality of the human PVT and the similarities or differences it may have with surrounding structures by comparing their gene expression patterns. Materials and Methods: Human brain blocks containing the thalamus were obtained from the Brain Donor Program at the University of California, Irvine by agreement with the Pritzker Neuropsychiatric Consortium. Five subjects with no history of psychiatric or neurological disease were used for this study. Variables that could alter gene expression patterns were controlled for, so all samples used had a tissue pH above 6.5 and agonal factor scores (AFS) of zero. The fresh-frozen blocks were sectioned at 10um and serial sections were processed for acetylcholinesterase stain, Kluver/Luxol Fast Blue stain, and different *in situ* hybridization probes including calcium-binding proteins, transcription factors, and neurotransmitter-related enzymes. Results: the combined use of histological stains and *in situ* hybridization allowed us to discern the distribution of midline thalamic nuclei while also providing insights into the possible functional relationships between them, i.e. areas that appear histologically

indistinguishable from one another show divergent gene expression patterns that hint at discreet functional differences.

Title: Determining frequency bands to observe amygdala for a neurofeedback task using MEG beamformers

Authors: *A. WANG, F. W. CARVER, J. STOUT, T. HOLROYD, A. NAMYST, J. Y. CHUNG, A. C. NUGENT;
NIH, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Neurofeedback is a process in which auditory and/or visual feedback is used to guide a participant to gradually alter the amount of activity produced in part of the brain. While highly researched in EEG and fMRI, there are relatively fewer studies employing neurofeedback in MEG (magnetoencephalography). In addition, most MEG neurofeedback studies involve data directly from channels, rather than utilizing source localization. Subcortical regions such as the amygdala are also considered more difficult to observe with MEG. Prior to executing a neurofeedback experiment designed to alter activity levels in the amygdala, we must determine what frequency bands to target. We used a CTF MEG System with 275 channels and collected data from twenty-two healthy controls. Subjects completed a Hariri Hammer task, an emotion matching task that produces strong amygdalar activation, and were instructed to match either emotional faces or shapes (control) in a blocked trial format. MEG adaptive beamforming was used to analyze the one second interval after presentation of the target faces and shapes in theta (4-7 Hz), alpha (7-13 Hz), beta (13-35 Hz), low gamma (35-65 Hz), and high gamma (65-115 Hz) frequency bands. Furthermore, a time frequency analysis was conducted to narrow down specific time windows within the one second interval where amygdala activity is most prominent. One sample statistic t-tests of the contrast between faces and shapes revealed that within the alpha frequency band from 0.2 to 1 seconds, there was significantly more activity present in response to faces vs. shapes in the left amygdala with a cluster peak effect size of 1.133 ($q < 0.005$, $p < 0.001$). In addition, within the beta frequency band from 0.2 to 1 seconds, the right amygdala showed significantly more activity to faces vs. shapes with a cluster peak effect size of 0.799 ($q < 0.005$, $p < 0.005$). However, in the theta, low gamma, and high gamma frequency bands, no significant differences between faces vs. shapes was found in the amygdala. Our findings provide evidence that both the alpha and beta frequency bands can be

considered candidates to target the amygdala in the future neurofeedback task and other experiments. Additionally, theta, low gamma, and high gamma frequency bands would not be optimal to use in the neurofeedback task. These exploratory results will be confirmed with future research that will be able to verify whether amygdalar activity can be observed within the alpha and beta frequency bands in the context of real-time neurofeedback. Nonetheless, successful observation of the amygdala using MEG adaptive beamforming suggests that real-time neurofeedback MEG studies are feasible.

Title: Overlapping and distinct neural mechanisms for emotion generation and reappraisal

Authors: *K. BO[1], T. KRAYNAK[2], M. SUN[1], P. J. GIANAROS[2], T. D. WAGER[1];
[1]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Dept. of Psychology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Reappraisal is an emotion regulation strategy that involves reinterpreting the meaning of a stimulus such that the resultant emotion is changed, and early studies suggested that reappraisal is represented in the prefrontal cortex (PFC). Emotion generation is thought by some theorists to be mediated by non-meaning related subcortical limbic areas. Recent electrophysiological data, however, suggests that reappraisal begins in the meaning construction period of emotion generation, suggesting the possibility of share (co-localized) neural representations. In this study, participants (n=182) viewed or reappraised aversive pictures from the International Affective Picture System (IAPS) while undergoing fMRI. On 'reappraise negative' trials, participants generated thoughts to reduce the negative feelings evoked by aversive images. On 'look negative' and 'look neutral' trials, participants viewed matched aversive or neutral images without reappraising. We computed Bayes Factors to evaluate relative evidence that brain regions encode or do not encode several psychological hypotheses -- (1) emotion generation and reappraisal share overlapping neural mechanisms, (2) reappraisal involves specific neural mechanisms that do not involve emotion generation, and (3) there might exist emotion generation regions that are not affected by reappraisal. Emotion generation was modeled by the contrast between 'look negative' vs. 'look neutral', while reappraisal was modeled by the contrast between 'reappraisal negative vs. look negative'. We found that emotion reappraisal and generation shared overlapping features across multiple regions, including anterior cingulate cortex (ACC), dorsolateral prefrontal cortex (DLPFC), supplementary motor area and inferior parietal lobe, featuring high Bayes factors for both contrasts. We also found distributed brain regions activated specific to reappraisal, including the temporal pole, ACC, and DLPFC. Finally, we found generation-specific regions including amygdala, primary visual cortex,

orbital frontal cortex, putamen, as well as the posterior portion of the DLPFC, and putamen. The present findings suggest that there are both shared and dissociable neural representations of emotion generation and reappraisal processes. The unique neural activity involved in reappraisal play roles in goal maintenance and cognitive control.

Title: Using ERP measures of attention during encoding to constrain tests of the emotional Context Maintenance and Retrieval model of free recall.

Authors: R. HELLERSTEDT[1], V. K. ZARUBIN[2], K. R. MICKLEY STEINMETZ[3], N. D. DAW[4], ***D. TALMI**[1];
[1]Psychology, Univ. of Cambridge, Cambridge, United Kingdom; [2]Northwestern Univ., Evanston, IL; [3]Psychology, Wofford Col., Spartanburg, SC; [4]PNI, Princeton, NJ

Abstract: Supported by vast behavioural and neural data, retrieved-context theory is the state-of-the-art in describing the rules which govern the chances that a present experience will come to mind later (Howard & Kahana, 2002). It determines the likelihood of recalling an experience through the similarity between its encoding and retrieval "contexts" - abstract constructs implemented in brain states. In addition to similarity between temporally-contiguous brain states, retrieved-context theory recognises that semantic and experiential similarity also influence which experience would come to mind. Our variant of retrieved-context theory, eCMR (emotional Context-Maintenance and Retrieval), focuses on the emotional sub-dimension of experiential similarity as a way of explaining emotional memory enhancement in terms of more general memory processes.
eCMR simulates increased attention towards emotional items during encoding with the parameter Φ_{emot}. In simulations, increased values of Φ_{emot} predict increases in emotionally-enhanced recall. The Late Positive Potential (LPP) is a widely used electrophysiological index of increased attention towards emotional stimuli. Increased LPP amplitudes provide sensitive, specific measure of the impact of emotion at the individual subject level (Schupp & Kirmse, 2021). Thus, if Φ_{emot} controls differential LPP amplitudes, then variations in emotion-enhanced LPP amplitudes during encoding will correlate with subsequent emotion-enhanced recall. LPP amplitude differences may then be used to constrain empirical tests of eCMR - a joint neurocognitive modelling approach.
To test this hypothesis, we reanalysed data from the mixed list condition in Zarubin et al., 2020. We replicated their observation of subsequent memory effects in LPP which were greater for negative than

neutral pictures. However, analysis of Bayesian Pearson correlations between LPP and memory enhancements (emotion vs. neutral) across participants provided moderate evidence favouring the null hypothesis. Similarly, although LPP amplitudes were consistent across experimental blocks, Bayesian one-sample *t*-tests showed that the average within-subject Spearman correlations between LPP and memory enhancements (emotion vs. neutral) across experiment blocks again moderately favoured the null hypothesis.
Taken together, our findings suggest the relationship between emotion-dependent increases in LPP amplitudes and free recall are not consistent at any level of analysis. This result suggests that the LPP component may not be useful for the purpose of model constraint.

Title: Distinct inter-subject synchronized responses to movie clip in emotion and language brain networks

Authors: Y. TIE[1,3], L. RIGOLO[1], A. J. GOLBY[2,3], ***E. LIEBENTHAL**[4,3];
[1]Neurosurg., [2]Neurosurg. & Radiology, Brigham & Women's Hosp., Boston, MA; [3]Harvard Med. Sch., Boston, MA; [4]Inst. for Technol. in Psychiatry, Mclean Hosp., Belmont, MA

Abstract: Background: Watching a movie dialogue closely mimics the receptive aspects of participating in a real-life conversation, and was shown to engage the distributed multimodal neural networks that support spoken language communication. We previously demonstrated the feasibility of using movie-fMRI for mapping the language network on an individual basis. Here, we tested whether a movie clip with an emotionally evocative narrative and social interactions would elicit highly synchronized responses across individuals, and could be used to reliably map emotion and language brain networks.
Methods: A 7-min clip from the movie "The Parent Trap" was shown to 22 right-handed healthy subjects (11 women, mean age 26.3 yrs, range 19-39 yrs, all English speakers) during an fMRI scanning session. The clip consisted of a sequence of scenes with spoken emotional dialogue and an evolving narrative interleaved with scenes of background music and no dialogue. Voxel-wise inter-subject correlation (ISC) was applied to reveal brain regions with similar responses across subjects. Independent component analysis (ICA) was applied to identify emotion and language components from the movie-fMRI, based on spatial correlation with functionally-defined canonical templates of the networks derived from Neurosynth. Emotion and language regions of interest (ROIs) were defined as the intersection of the ISC

map and the corresponding ICA map, and the mean time-course was extracted from each ROI in each subject.
Results: ISC indicated that movie watching induced synchronized responses in extensive brain areas, including auditory, visual, temporoparietal language, and fronto-limbic emotion, networks. ICA identified two emotion components comprising the bilateral amygdala and bilateral anterior insula, respectively, and one language component comprising left lateralized inferior and middle frontal, and middle temporal, cortices. There were strong positive correlations between the time courses of the left and right amygdala ($r=0.63\pm0.20$), and left and right insula ($r=0.59\pm0.12$), and weak correlations between the time courses of the amygdala and language ROIs ($r=0.27\pm0.24$), and the insula and language ROIs ($r=0.32\pm0.19$). The activation peaks in the language ROI corresponded to scenes with spoken dialogues, whereas the activation peaks in the emotion ROIs corresponded to emotional scenes with and without dialogue.
Conclusions: These findings suggest that different movie features induce spatiotemporally distinct responses in different functional networks, and that emotion and language networks can be mapped reliably from movie-fMRI using strictly data-driven approaches.

Abstract: Evidence from studies involving patients with Parkinson's disease, Huntington's disease and schizophrenia proposes a role for the neurotransmitter dopamine (DA) in emotion recognition. However, to date studies in which DA is pharmacologically manipulated in healthy volunteers have failed to provide behavioral evidence in support of this thesis. The lack of behavioral effects of dopaminergic manipulation on emotion recognition, as well as contradictory findings of effects of DA agents on blood oxygenation level dependent (BOLD) responses in areas crucial for emotion recognition, may be attributable to interindividual differences in susceptibility to pharmacological interventions. Whilst it has been well established in cognitive studies that responses to dopaminergic drugs can depend on individual baseline DA function, the emotion recognition literature so far has failed to statistically account for these possible interindividual differences. Using an approach that accounts for individual differences in baseline DA function, the present study tested whether the DA D2 receptor antagonist haloperidol

modulated emotion recognition from dynamic, whole-body motion cues.
We used a double-blind, placebo-controlled cross-over design to test effects of the D2 antagonist haloperidol on participants' emotion recognition from gait, using dynamic point-light-walker (PLW) stimuli. On two separate days, once after receiving 2.5mg Haloperidol and once after receiving placebo, 32 healthy participants (16 males; mean age = 26.36) first completed a visual working memory (WM) task (WM span has been shown to be a reliable indicator for striatal DA synthesis capacity and hence was used as a proxy for individual baseline DA function). Subsequently, participants viewed angry, happy and sad PLWs and rated how intensely they felt each emotion was expressed in each stimulus.
Using Bayesian mixed effects models, we observed that drug effects on emotion perception depended on WM span, such that under the drug, participants with low WM span gave increased emotion intensity ratings (ß = 0.47, CrI = [0.16, 0.78]), whereas high WM individuals gave decreased intensity ratings (ß = -0.47, CrI = [-0.78, -0.15]). Whilst the involvement of dopaminergic processes in facial emotion recognition has been previously established, this study is the first to show that DA modulates emotion recognition from whole-body motion. Furthermore, the present study confirms that dopaminergic drug effects on emotion recognition depend on individual baseline DA function and highlights the need to model interindividual differences in drug responsivity for future studies.

Title: Spike-field interactions in human subgenual cingulate related to emotional decision making

Authors: *N. A. ZALASKY[1], D. L. CLARK[1], L. H. KIM[1], M. S. NOOR[1], F. LUO[1], A. J. GRUBER[3], *Z. H. KISS[2];
[2]Dept Clin. Neurosci, [1]Univ. of Calgary, Calgary, AB, Canada; [3]Dept. of Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: The subgenual cingulate gyrus (SCG) sits at the intersection of important emotional processing and regulation circuits. Because of its connectivity, it is a deep brain stimulation (DBS) target for treatment resistant depression. Network oscillations in this area may influence cognitive emotional regulation through coherence in the beta frequency band (13-30 Hz). How network dynamics influence single neuron activity in this area has never been studied in humans but is critical in linking SCG contributions to depression. Thus, we sought to determine the relationship between beta oscillations and single neuron activity in the SCG. We hypothesized that spiking activity of single neurons would be

modulated by network dynamics via beta-band spike-field synchronization.
Microelectrode recordings collected during SCG-DBS surgeries were used to compare single neuron spiking activity (filtered at 100Hz-10kHz) to local field potential (LFP) beta band (13-30Hz) dynamics during an emotional faces Stroop task. Spike-phase interactions were quantified using several measures. Instantaneous phase was calculated from the filtered signal in relation to spike times, and **phase-locking distributions** were determined for each cell. Rayleigh's test for non-uniformity was used to quantify **phase preference**. To measure the magnitude of coupling between single cells and beta oscillations, relative phase-locking was also computed. These **modulation indices (MI)** estimate the strength of beta modulation compared to an unsynchronized control sample.
Twelve patients participated in this study, for which 33 recording sites in SCG were obtained with 41 distinct cells isolated (21 cells with sufficient spontaneous firing). 83% of SCG neurons demonstrated significant phase-locking during the task, compared to 43% during spontaneous firing. All phase-locked neurons showed a preferred phase between 180 and 360 degrees, falling within the troughs of the beta oscillation. Modulation indices ranged from -2 to +8, with a higher proportion of single SCG cells showing significant modulation (MI >3) by the beta band during the task (39%) compared to spontaneous activity (24%). No changes in the strength of modulation were observed.
Preliminary analysis suggests that single neurons in the SCG are, in part, modulated by synchronization in the beta band, being driven by dips in beta oscillatory activity. This study is the first to examine the relationship between network oscillations and single neuron activity within the human SCG. Further analysis will provide us with a novel understanding of the role of SCG in emotional processing, and could inform possible closed-loop DBS.

Title: Frontal theta/beta ratio predicts attentional bias to threat in individuals with high social anxiety

Authors: *N. KWON[1], J. KIM[1], K. KIM[2], S.-Y. KIM[1];
[1]Psychology, Duksung Women's Univ., Seoul, Korea, Republic of; [2]Computer Sci. and Engin., Hanyang Univ., Seoul, Korea, Republic of

Abstract: Previous studies have demonstrated abnormal attentional bias to socially threatening stimuli in individuals with social anxiety disorder (SAD). Recent studies reported the frontal alpha asymmetry (FAA) and the theta/beta ratio (TBR) are the most prominent EEG-based biomarkers in SAD. However, it is still undefined which of the two components (FFA and TBR) is a key factor to explain attentional bias

to threat in SAD. Thus, we aimed to examine attentional bias to threat in individuals with high social anxiety (HSA) both in behavioral and electrophysiological levels. Thirty-five neurotypical adults performed a continuous performance task to examine attentional bias patterns. In the task, participants were asked to detect a target ('T') while ignoring concurrently presenting face distractor (angry/neutral). Attentional bias patterns were defined as attentional capture and attentional holding effects. Anxiety levels of participants were also collected using State-Trait Anxiety Inventory (STAI), Social Phobia Scale (K-SPS), Social Interaction Anxiety Scale (K-SIAS), and Social Avoidance and Discomfort Scale (K-SADS). Finally, using resting state EEG, FAA and TBR were collected and analyzed. To identify EEG components related to high social anxiety, we divided our participants into two anxiety groups based on the three social anxiety scales (K-SPS, K-SIAS, K-SADS): High social anxiety (HSA; N=14) and Low social anxiety (LSA; N=21) groups. Results reveled that only the HSA group showed both attentional capture and holding effects to angry faces. In addition, only the HSA group showed significant positive correlation between attentional holding scores and social anxiety scores. Next, multiple regression analyses were performed to discover the neural biomarkers related to the attentional bias to threat in individuals with HSA. Results showed that both the FAA and TBR significantly explained the increased attention bias in HSA individuals who showed both attentional capture and holding effects. Importantly, increased TBR was revealed as a key component to explain the attentional bias; that is, the effects of TBR on attentional bias was significant after controlling for the effects of FAA. Notably, it has been suggested that higher TBR is related to inefficient emotional control, which may cause a vigilant response to threatening stimuli in individuals with HSA. In sum, our study demonstrated similar attentional bias patterns in non-diagnosed adults with HSA to those in people with SAD. Further, we found that increased TBR during rest can be an important electrophysiological biomarker related to excessive attentional bias to threat in people with HSA.

Title: Cerebellar seeded functional connectivity changes in anxious individuals undergoing attention bias modification training

Authors: *K. ELWELL[1], L. FANG[2], J. CARLSON[2];
[2]Psychological Sci., [1]Northern Michigan Univ., Marquette, MI

Abstract: A hallmark symptom of anxiety is attention bias to threatening stimuli, and an abundance of studies have indicated a significant relationship between attention bias and the maintenance of anxiety disorders—with similar neural mechanisms driving them. The majority of neuroimaging studies have fixated on the roles of the anterior cingulate cortex, the prefrontal cortex, and the amygdala as key regions

for neural correlates of attention bias. However, new and converging research provides empirical evidence that the cerebellum's functional connectivity and shared network structure with threat processing regions contribute to anxiety. Attention Bias Modification (ABM) is a newly-emerging promising treatment for anxiety disorders in which participants are unconsciously trained to divert their attention away from threatening stimuli, with the goal to reduce attention bias towards threat. Therefore, the aim of the current study was to assess the effect of six-weeks of ABM training on cerebellar-seeded resting state functional connectivity changes in individuals exhibiting high trait anxiety and an attention bias towards threat. Participants (N = 41) were between the ages of 18 and 38, right-handed, free of any neurological history, and were not undergoing any form of psychological therapy, or taking any psychotropic medications. Functional connectivity was extracted from a 10-minute resting-state functional magnetic resonance imaging session. Resting-state functional magnetic resonance imaging scans were collected immediately prior to, and immediately following the conclusion of the six week ABM training. The results showed a decrease in both attention bias, as well as a decrease in cerebellar-seeded resting state functional connectivity. Specifically, relative to the control group, the ABM training group showed a decrease between cerebellum seeds to regions such as the anterior cingulate cortex, lateral occipital cortex, posterior cingulate cortex, thalamus, hippocampus, salience network, and default mode network. Our findings suggests that neural changes in cerebellar-based functional connectivity may underlie the ABM-related changes—such as decreased attention bias. This also implies that the cerebellum may contribute to the etiology and maintenance of anxiety and attention bias.

Title: Impact of COVID 19 Pneumonia on the quality of life, mental health and autonomy of patients

Authors: *S. CHAKROUN[1,2], A. CHAKER[1,2], K. KCHAOU[1,2], S. MOKADDEM[1,2], S. BEN KHAMSSA[1,2];
[1]Pulmonary Function Tests, Abderrahmene MAMI Hosp., Ariana, Tunisia; [2]Physiol., Fac. of medicine . Tunis Manar Univ., Tunis, Tunisia

Abstract: Introduction Respiratory sequelae of COVID19 are now well identified but their impact on the quality of life, mental health and autonomy of patients is still unsufficiently studied.
Objective This prospective study was conducted to assess the quality of life, mental health, and independent living skills of COVID-19 pneumonia patients, 3 months after recovery .
Patients and methods This study included 154 patients who consulted the Respiratory Functional Explorations Department of the Abderrahmane MAMI Hospital in Ariana. Each patient undertook the Nottingham Health Profile (NHP) and SF-12 scales to assess quality of life, Hospital anxiety and depression (HAD) to assess mental health and the Lawton Instrumental Activities of Daily Living (IADL) Scale to estimate the level of autonomy in the instrumental activities of daily life

Results The sex ratio of our population was 1.3 with a mean age of 59.39 ± 11.76 years. On a scale of 100, the mean NHP different dimensions were distributed as follows: 34.34 for lack of energy, 19.87 for pain, 18.31 for sleep disturbance, 18.13 for exaggerated emotional reactions, 16.90 for mobility difficulties and 12.86 for social isolation. The average SF-12 score was 39% for the physical dimension and 50.73% for the mental dimension. The HAD scale confirmed anxiety in 23.4% and depression in 16.9% of patients. However, the average IADL score was 7.24 per 8, which is in favour of preserved autonomy in daily activities.

Conclusion

Our results revealed COVID-19 effects on the physical and mental health of patients and its negative impact on their quality of life contrasting with a preserved autonomy in daily life.

Title: Depression symptoms associated with brain function underlying attention bias in social anxiety disorder

Authors: *J. STOUT[1], S. GOLDBERG[1], S. JOSHI[1], J. ABELSON[1], I. LIBERZON[2], E. R. DUVAL[1]; [1]Univ. of Michigan, Ann Arbor, MI; [2]Texas A&M Med. Ctr., College Station, TX

Abstract: Social anxiety disorder (SAD) is often characterized by biased attention to threatening information, along with aberrant brain activation in regions associated with attentional control. People with SAD commonly experience comorbid depression symptoms; however, the brain activation underlying depression symptoms in people with SAD has not been well studied. This study aimed to investigate activation in brain regions associated with attentional control in people with SAD and a continuum of depressive symptoms measured on the Beck Depression Inventory (BDI-II). Participants include 29 right-handed adults ages 18-55. All participants have SAD, and depression symptoms ranging from minimal to severe. Participants completed a modified dot probe task during MRI scanning to assess attention bias and measure activation in brain regions involved in salience processing and attentional control. Participants indicated the direction of an arrow probe that randomly replaced a happy or threatening face. A trial is considered congruent when the arrow replaces the threatening face, and a trial is incongruent when the arrow replaces the happy face. We hypothesized that participants with SAD and more severe depressive symptoms will have increased activation in regions involved in attentional control and salience processing, including the right ventrolateral prefrontal cortex (vlPFC), dorsolateral prefrontal cortex (dlPFC), dorsal anterior cingulate cortex (dACC). Preliminary results indicate that higher depression symptoms were associated with greater activation in the dlPFC during all trials vs implicit

baseline (33, 9, 34, $p < .01$) and during incongruent vs congruent trials (-43, -0, -2, $p < .01$). Higher depression symptoms were also associated with less activation in the insula during all trials vs implicit baseline (-46, -1, 2, $p < .01$), and less activation in the dACC during incongruent vs congruent trials (18, 21, 26, $p < .01$). These results suggest that higher depression symptoms are associated with greater activation in regions involved in attention control (dlPFC) and less activation in regions involved in salience processing (insula, dACC). These findings suggest that people with SAD who have higher levels of depression demonstrate a compensatory response in attention control regions and a blunted response in salience processing regions.

Title: A Systematic Review on the Effects of Air Pollution on Anxiety and Depression

Authors: *D. H. DAHER[1], C. G. ZUNDEL[1], B. A. BORG[1], J. M. EVANSKI[1], P. RYAN[2], C. BROKAMP[2], J. R. STRAWN[2], H. A. MARUSAK[1];
[1]Wayne State Univ., Detroit, MI; [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Although the harmful effects of air pollution on human physical health (e.g., respiratory ailments) have been well established, the effects on mental health are less clear. Research shows that air pollutants can negatively impact the central nervous system, including inducing neuroinflammation and oxidative stress. Importantly, these mechanisms are also implicated in the pathophysiology of anxiety and depression, which are the most prevalent mental health disorders and affect 284 and 264 million individuals worldwide, respectively. Anxiety and depression are also associated with significant morbidity and disability. Given the public health significance of anxiety and depression, it is critical to understand the role of environmental factors, such as outdoor air pollution, in these disorders. Here, we performed a systematic review of the literature to examine the impact of outdoor air pollutants on anxiety and depression. The MEDLINE (PubMed) database for articles published before August 27th, 2020, and a total of 92articles was included in the review. Included articles focused on outdoor air pollutants (e.g.,PM2.5, PM10, and NO2) on anxiety and depressive symptoms or behaviors in humans or animal models. Sixty-eight percent (n = 62) of studies included humans, 22% included mice (n = 20),and 10% included rats (n = 9). PM2.5 was the most studied air pollutant and demonstrated consistent positive associations with anxiety (66%; n = 18 out of 27) and depression (75%; n =37 out of 49) across studies, particularly among adolescents and elderly populations. Although there were fewer studies, positive associations were also observed for PM10, O3, NO2, SO2, CO2,and PAH. This review demonstrates

consistent effects of outdoor air pollutants on anxiety and depression across studies. Evidence that outdoor air pollutants can increase the risk of mental health disorders, in addition to well-established effects on physical health, has implications for policy. Indeed, new legislation that sets restrictions on the sources of air pollution is needed to lower the environmental risk of mental health disorders, particularly in vulnerable populations(i.e., adolescents, elderly). As well as being a push for future studies that investigate the brain-behavioral mechanisms of the linkages between air pollution and mental health disorders. Given the rising prevalence of anxiety and depression over recent years, these data highlight the role of salient environmental factors — particularly air pollution — in influencing human health, which has implications for prevention and intervention.

Abstract: Anxiety and depression in Mongolia: translation, reliability, and structural validity of the hospital anxiety and depression scale in the Mongolian general population

Abstract Various psychological, biological, and social factors make people vulnerable to mental health issues. There has been no screening tool for the assessment of anxiety and depression available in Mongolia that is adequately validated for the use on mental health, and neuropsychiatric functions of the brain. Therefore, we aimed to translate and validate the hospital anxiety and depression scale (HADS) in the healthy general population in Mongolia. The HADS is reliable, valid, and practical for identifying the most common psychological disturbances, and a well-practiced scale. A test-retest study was carried out on 80 participants with an interval of 16.3±1.7 days between 2-time points. This observational comparative study for the validity of the self-reported measure was conducted between June and December 2020, 1094 participants were randomly selected, aged 13-75, mean age was 37.7±13.7, 60.9%

were females, and 63.9% were married. The HADS total score was 13.0±5.7, the HADS-Anxiety score was 6.8±3.6, and the HADS-Depression score was 6.0±3.1. The Intraclass correlation coefficient (ICC) values were 0.872, 0.837, and 0.801 for the HADS-T, the HADS-A, and the HADS-D, respectively. Indicating internal reliability, the Cronbach's alpha value was 0.776 for the HADS-T, 0.756 for the HADS-A, 0.582 for the HADS-D. External reliability was good in the whole scale, and both subscales using ICC. These findings suggest that the questionnaire can be considered a sufficiently homogenous measurement tool. The reliability of the both 2-factor and 3-factor structures of the HADS was confirmed using the confirmatory factor analysis with a satisfactory model fit on a separate sample. In conclusion, the Mongolian version of the HADS is a valid and reliable instrument to assess potential anxiety and depression cases in the Mongolian general population and can be used in various scientific practices.

Title: Intersection of psychiatric disorders, epilepsy, and emotional conflict resolution

Authors: *D. SOPER, A. C. PAULK;
Massachusetts Gen. Hosp., Boston, MA

Abstract: Patients with epilepsy suffer from a high prevalence of psychiatric comorbidities, particularly anxiety, indicating an essential intersection between seizure disorders and psychological state. Understanding the mechanism underlying this comorbidity could help develop therapies for both epilepsy and psychiatric disorders and help understand the intersecting neural underpinnings. Through analyzing the relationship between intracranial neural activity, task data, self-report questionnaires, and neuropsychological evaluations, we tested the hypothesis that more anxious patients with epilepsy would have an impaired ability to resolve emotional conflict. We also hypothesized that connectivity between brain regions typically involved in emotion regulation and anxiety would be different depending on anxiety levels. We ran an emotional conflict resolution task (ECR) and Multi-Source Interference Task (MSIT) with two groups: patients with intractable epilepsy undergoing clinically invasive electrode placement to determine seizure onset (n=24) and healthy controls (n=36). ECR and MSIT, variants of the classic Stroop task, measure conflict resolution through changes in reaction time and accuracy for sequential presentations of congruent and incongruent trials, though ECR contains an emotional

component while MSIT does not (as a control). All participants also filled out self-report psychological questionnaires and a subset underwent neuropsychiatric testing. We show here, for incongruent trials, that participants with epilepsy (EPs) are less accurate with higher variability in the ECR task than healthy controls (HCs) (EP mean=81.79% +/-0.035, HC mean=93.24% +/-0.008, $p<0.05$, Wilcoxon Rank-Sum), while no accuracy difference was present during MSIT. Similarly, participants with higher Beck Anxiety Index (BAI) scores also had poorer accuracy on ECR. No such relationship existed between BAI scores and MSIT accuracy. We also examined differences in network connectivity in patients with epilepsy with low and high scores using coherence measures. These preliminary results suggest a deficit in emotional conflict resolution which corresponds with measured anxiety levels for patients with intractable epilepsy.

Title: State anxiety differentiates value-driven and random exploration in an aversive multi-arm bandit experiment

Authors: *R. T. PHILIPS[1], K. FORAY[2], E. WEISS[1], C. GRILLON[1], M. ERNST[1];
[1]NIMH-NIH, Bethesda, MD; [2]Univ. of California Davis, Davis, CA

Abstract: Human decision making often involves exploration and exploitation, which may be impacted by anxiety. The goal of this study was to investigate the interaction between different exploration strategies (value-driven or random) and anxiety, using a computational model. 32 healthy volunteers (18 F, mean age 25) performed 2 versions of a 4-arm aversive (probabilistic shock) bandit task, in which participants were asked to choose the arm perceived to have the lowest probability of shock. In one version, the best strategy relied on purely value-driven exploration (choosing to explore only when there is a *perceived* better choice); whereas, in the other, it involved random exploration. Performance was analyzed using a reinforcement-learning model. The performance metrics included: 1) accuracies (defined as the proportion of choosing the lowest *true* shock probability option) and 2) persistent exploitation (defined as the proportion of repeatedly choosing the options with best *perceived* value). State-trait was measured using State-Trait Anxiety Inventory (STAI). While accuracies did not significantly differ between versions (paired t-test, $p = 0.1273$), persistent exploitation showed a significant difference between versions (paired t-test, $p = 0.0005$). Additionally, the persistent exploitation difference-score showed a strong negative correlation with the state STAI score ($R = -0.55$, $p = 0.0035$). Participants exhibited higher value-driven than random exploration, evidenced by higher persistent exploitation in the version favoring random exploration. Furthermore, individual differences in persistent exploitation between versions decrease as a function of state anxiety scores. In conclusion, state anxiety might influence exploratory behavior, suggesting an ambivalence between random and value-driven exploration

in higher state anxiety. These insights could help us understand the circuitry mediating explore/exploit decisions and aberrations in anxiety.

Title: Using TMS to uncover the role of the intraparietal sulcus in in anxiety expression and hypervigilance.

Authors: *N. L. BALDERSTON, M. TEFERI, W. MAKHOUL, D. OATHES, Y. SHELINE; Univ. of Pennsylvania, Philadelphia, PA

Abstract: Neuromodulation is a promising avenue for novel anxiety treatment. However, optimal targets for treatment are not known. Our recent neuroimaging work suggests that the intraparietal sulcus (IPS) demonstrates elevated excitability and functional connectivity during periods of elevated arousal. We have also shown decreases in arousal by targeting the IPS with online 1 Hz stimulation. In the current work, we present data from two studies. The first study uses fMRI to examine the role of the IPS in hyperexcitability during a visual short term memory (VSTM) task. During each trial subjects see a cue pointing either left or right. They then see a bilateral array of squares, and are instructed to attend only to the squares in the cued hemifield. After a short delay they then see a response prompt with an example square that is either a match or a mismatch. Trials were grouped into blocks of safety and unpredictable threat. The second study uses simultaneous TMS/fMRI targeted at the right IPS to examine the role of the IPS in anxiety expression during unpredictable threat. The NPU threat task consists of Neutral, Predictable, and Unpredictable periods. During the neutral periods, subjects are not at risk for shock. During the predictable periods, subjects are only at risk for receiving a shock when a cue is present. During the unpredictable periods, subjects are at risk throughout. In the VSTM task, we sampled IPS activity using a 5mm sphere centered on coordinates from our previous IPS connectivity paper. We found marginally greater right IPS activity during threat compared to safe periods. Although preliminary, these results suggest that threat may have a stronger effect on right IPS BOLD activity during the VSTM task. In the unpredictable threat task, we extracted BOLD from the contralateral IPS, a measure of activity downstream elicited by the TMS pulse. We found marginally greater TMS-evoked BOLD responses during the threat compared to the safe periods. Although data collection is ongoing, these results suggest an increased responsiveness to IPS stimulation during unpredictable threat. Anxiety is known to impact attention control and anxiety patients have trouble focusing attention in a variety of cognitive tasks, including working memory. Threat-related hypervigilance is a prominent symptom of clinical anxiety, cutting across diagnoses, and this hypervigilance may be mediated by hyperactive orienting processes

mediated by the IPS. These results, combined with our previous work, offer promise that modulation of IPS excitability may reduce arousal and restore attention control in anxiety patients.

Title: Pilot study demonstrates potential short-lived beneficial effects of the visuospatial interference task Tetris on subjective emotion

Authors: *V. RETTERHOLT, M. JERJOUS, A. JACOB, G. H. GOTTHARD;
Muhlenberg Col. Neurosci. Program, Allentown, PA

Abstract: Internationally, math anxiety is shown to affect many students (Luttenberger et al., 2018). However, little research has been done on methods of easing math-related anxiety This pilot study examined the effect of a visuospatial interference (VSI) task (Tetris) on subjective experience of mood in relation to math-related anxiety. When multiple cognitive tasks compete for working memory (WM) resources, there will be reduced information processing (Kessler et al., 2020). One way to induce this interference in information processing is by using a VSI task. The game Tetris was used in the current study because it has been shown to have an effect on the consolidation of traumatic memories and subjective recall of the traumatic event (Holmes, et al., 2010). Anecdotal evidence indicates that Tetris may produce calming effects on subjective emotion (Iyadurai et al., 2017). The current study extends the literature on VSI by examining the effects it has on subjective emotion.
Undergraduate students (n=24; 18-22 years old) participated in this pilot study (control: n=12; Tetris: n=12). Participants met with researchers via Zoom video calls to complete the study synchronously. In Session 1, participants were randomly assigned to a control or experimental group. They then completed a mood-assessment questionnaire, followed by a set of math problems. Upon completion of the math problems, participants in the control group answered true/false trivia questions (PubQuiz) for 10 minutes, and participants in the experimental group played Tetris for 10 minutes. Both groups then filled out the mood assessment a second time. During Session 2, which occurred one week later, participants completed the mood assessment one more time.
Mood assessments were analyzed at three time points: baseline, post-intervention, and one-week follow-up. While the n-sizes of this pilot study did not allow for significant differences to emerge, repeated measures ANOVA uncovered two findings that warrant further examination: (1) Tetris trended toward lower reports of “worry” post-intervention that increased one week later [$F(2,44)=2.15$, $p=.12$]; (2) Tetris maintained moderate levels of “relaxation” post-intervention that declined one week later [$F(2,44)=2.08$, $p=.14$]. These results may indicate that Tetris initially produces a calming effect that dissipates over the course of one week. Further examination with larger n-sizes will be necessary to further evaluate these data.

Title: Salience Network Topography in Pediatric Anxiety Disorders

Authors: E. CARLSON, ***B. TABER-THOMAS**;
SUNY Geneseo, Geneseo, NY

Abstract: Anxiety disorders are prevalent in people of all ages, often beginning in childhood or adolescence with 50% of diagnoses occurring by age 11 (Kessler et al., 2005). Due to the prevalence of pediatric anxiety disorders, early detection and intervention are advantageous for creating a positive prognosis for those who are affected. Here we examine salience network topography as a potential marker of anxiety, allowing for the implementation of earlier, personalized interventions. Taber-Thomas et al. (2016) found a topographical pattern of salience network connectivity related to anxiety risk in children. We further examined the robustness of this pattern using open source fMRI data in adults and children. In data from adults in the Brain Genomics Superstruct Project (n=1,000; Buckner et al., 2014) we found a normative pattern of salience network connectivity consistent with the pattern of children at low risk for anxiety (Fig. 1). In children with (n=8) and without (n=20) pediatric anxiety disorders, we hypothesized that, like shy children at risk for anxiety, children with an anxiety diagnosis will have less functional connectivity between the dorsal anterior cingulate cortex and the anterior insula compared to children without anxiety. Participants were children between ages 5.5 to 9.5 who had taken part in a previously published early childhood brain development and anxiety disorders study (Carpenter et al., 2015) for which open source data are available at OpenNeuro. Data were preprocessed and analyzed using AFNI. A psychophysiological interaction analysis was conducted using the right anterior insula as the seed region. Connectivity values were extracted for ROIs spanning ACC. Results show anxious children, like shy children at risk for anxiety, had significantly lower functional connectivity between the insula and dorsal anterior cingulate cortex than non-anxious children ($t(27) = 2.473$, $p = 0.02$). Consistent with the pattern found in children at risk for anxiety (Taber-Thomas et al., 2016), anxious children show altered salience network connectivity.

Title: The developmental effects of prenatal exposure to curcumin on anxiety- and depressive-like behavior in mice

Authors: *M. Y. ROBERTS[1], S. HANIF[1], A. VILLEGAS[1], N. S. BURGHARDT[1,2];
[1]Dept. of Psychology, Hunter Col., New York, NY; [2]Dept. of Psychology, The CUNY Grad. Ctr., New York, NY

Abstract: Curcumin, the primary active ingredient in the turmeric root, has been used for decades in Chinese and Indian traditional medicine. In the United States, it has recently become popular to take curcumin as a dietary supplement, because of its anti-inflammatory, tumor-suppressing, and antidepressant properties. These beneficial effects have been identified in adults taking curcumin, but it is not known if consumption during pregnancy is safe for offspring. We tested the effects of prenatal exposure to curcumin on the development of emotional behavior in mice. This involved giving female mice a rodent chow containing 1.5% curcumin or a control chow throughout pregnancy and replacing each chow with regular colony pellets shortly before birth. Offspring (n=18-22 males/group; n=17-29 females/group) remained on regular colony chow for the remainder of their development and were weighed weekly from 4-8 weeks of age. At approximately 9 weeks of age, behavioral testing began in the open field, novelty suppressed feeding test, and forced swim test. In addition, fear learning was tested with auditory fear conditioning. We found that prenatal exposure to curcumin significantly reduced bodyweight throughout development and promoted immobility in the forced swim test, effects that were more pronounced in females than males. In contrast, only males exposed to curcumin exhibited decreased exploration in the open field test and increased latency to feed in the novelty suppressed feeding test, indicating enhanced anxiety. Prenatal exposure to curcumin in males also led to an impairment in extinction learning, an effect that was not found in females. Our data indicate that exposure to curcumin *in utero* promotes the development of depression-like behavior in mice of both sexes, but increases anxiety-like behavior and affects learned fear in males only. Consumption of curcumin during pregnancy may therefore have detrimental effects on the development of neural circuits underlying emotional behavior in offspring.

Title: Exploring Sex Differences in Affective and Cognitive Symptoms in a Streptozotocin Model of Diabetes

Authors: *K. GILLEY, H. RODGERS, K. JENSEN, R. MCCREADY, P. SHARMA, E. G. VICHAYA; Baylor Univ., Waco, TX

Abstract: Diabetes is a common metabolic disorder associated with low grade systemic inflammation as well as an increased risk of developing affective and cognitive symptoms. Results indicate that symptom

risk is sex specific, suggesting sex-related divergent mechanisms. However, few preclinical studies have been conducted in female mice due, in part, to their greater resistance to diabetic induction. Therefore, we examined behavior in male and female mice following chemical induction of diabetes using streptozotocin (STZ). We hypothesized that male mice would have more severe hyperglycemia and cognitive deficits following STZ, while female mice would display higher depressive-like symptoms. We used a 2 (+/- STZ) x 2 (male vs female) factorial design (n = 4-6/group). Fasting blood glucose was measured by handheld glucometer. As expected, male mice exhibited more severe hyperglycemia (393.3 +/- 15.3 vs 318.0 +/- 38.49, $p<0.001$). We did not observe cognitive impairment in the spontaneous alternations Y-maze task in this cohort, but we did observe a main effect of STZ in the forced swim task (FST) ($p = 0.01$). We also observed a main effect of sex, such that male mice had higher immobility irrespective of STZ ($p = .001$). In a separate experiment, conducted in one year old mice using a 2 (+/- STZ) x 2 (male vs female) experimental design (n= 4 mice/group), we investigated the impact of STZ on willingness to work for rewards in a fixed ratio 5 task. There was a trend for mice to show a great reduction in number of rewards earned following STZ ($p < 0.1$), this effect was more robust in male mice. Our data indicate that despite lower levels of hyperglycemia in the STZ model, female mice are still vulnerable to developing affective symptoms with relatively equal severity to male mice, but may be more resilient to developing motivational deficits. Due to the sex-specific contrast in hyperglycemia severity, it will be necessary to consider severity when interpreting the data. Future research will confirm and extend these behavioral findings as well as examine potential mechanisms.

Title: Early prenatal exposure to homocysteic acid leads to alterations in behavior and gene expression that are consistent with bipolar disorder

Authors: *K. BOSIS, G. TAYLOR, A. LUNDERBERG, S. SIMKO, L. CHASE;
Hope Col., Holland, MI

Abstract: We have previously demonstrated that early post-natal exposure of rat pups to the NMDA receptor agonist, homocysteic acid (HCA) from P3-P21 leads to the development of mixed manic/depressive behaviors following puberty. The manic behaviors are effectively reversed by lithium treatment, and the depressive behaviors are reversed by acute ketamine treatment. Thus, HCA appears to induce a bipolar-like phenotype in rats. The goal of this study was to determine whether HCA exposure also induces gene expression changes that are consistent with a bipolar phenotype. Microarray analyses

were performed on tissue obtained from the prefrontal cortices saline- and HCA-treated rats at 3 weeks and 32-weeks of age. At 3 weeks, HCA rats exhibited 132 differentially expressed genes relative to control, many of which suggest there is a delay in oligodendrocyte development. Interestingly, several genes that have been identified as exhibiting reduced expression in bipolar disorder and schizophrenia, including MBP, PLP1, MAG, MOG, ERMN, and GSN. At 32-weeks, 316 differentially expressed genes were identified, including many genes which are associated with GABAergic interneuron function or regulate excitatory/inhibitory balance including SST, PVLB, GABRB2, GABRA6, KCNA1. We confirmed several of these alterations in gene expression using qPCR. Collectively, these results suggest that HCA treatment leads to changes in gene expression that mirror those previously identified in GWAS and microarray studies in post-mortem BD patients.

Title: Sapap4 deficiency leads to postsynaptic defects and abnormal behaviors relevant to hyperkinetic neuropsychiatric disorder in mice

Authors: *T. WANG, **Y. BAI**, X. ZHENG, X. LIU, S. XING, L. WANG, Y. XIE, H. WANG, *C. LI; Key Lab. of Brain Functional Genomics (STCSM & MOE), Sch. of Psychology and Cognitive Science, East China Normal Univ., Shanghai, China

Abstract: Postsynaptic proteins play critical roles in synaptic development, function, and plasticity. Dysfunction of postsynaptic proteins is strongly linked to neurodevelopmental and psychiatric disorders. SAP90/PSD95-associated protein 4 (SAPAP4; also known as DLGAP4) is a key component of the PSD95-SAPAP-SHANK excitatory postsynaptic scaffolding complex which plays important roles at synapses. In the brain, SAPAP4 is highly expressed in cerebral cortex, the CA1 and CA3 regions of hippocampus, thalamus, striatum, amygdala and Purkinje cells of the cerebellum and localized to excitatory synapses. Recent studies have found that the mRNA or the protein expression levels of SAPAP4 were changed in neurological and psychiatric disorders. A microarray analysis indicates that SAPAP4 mRNA is a FRMP (fragile X mental retardation protein) target, translationally repressed in fragile X syndrome cells, and activity-dependent dendritic SAPAP4 mRNA transport is regulated by FMRP and impaired in a fragile X syndrome mouse model. High-density SNP genome-wide linkage analyses in one of the largest known autism pedigrees have suggested SAPAP4 is a potential candidate gene for autism in the chromosomal 20q11.21–q13.12 region. Truncation of the CG-

rich SAPAP4 promoter region triggered by the chromosome translocation t(8;20)(p12;q11.23) was also shown to induce epigenetic modifications at SAPAP4, perturb its expression, and segregate with cerebellar ataxia. In addition, a recent study has identified and validated SAPAP4 as a novel target gene of miR-1908-5p, a bipolar disorder-associated microRNA. However, the physiological role of SAPAP4 at excitatory synapses remains poorly understood. In this study, to understand the function of SAPAP4 in the brain, we generated Sapap4 gene KO mice. The analysis of our mouse model reveals structural alterations of excitatory synapses and postsynaptic composition changes of postsynaptic density in the prefrontal cortex. These synaptic defects are accompanied by a cluster of abnormal behaviors including hyperactivity, impulsivity, reduced despair/depression-like behavior, hypersensitivity to low dose of amphetamine, memory deficits and decreased pre-pulse inhibition, that are reminiscent of mania. Furthermore, the hyperactivity of Sapap4 KO mice could be partially rescued by valproate, a mood stabilizer used for mania treatment in humans. Together, our findings provide evidence that SAPAP4 plays an important role at synapses and reinforce the view that dysfunction of the postsynaptic scaffolding protein SAPAP4 may contribute to the pathogenesis of hyperkinetic neuropsychiatric disorder.

Title: Stress induced emotional dysregulation in a mouse model of Tuberous Sclerosis Complex

Authors: *P. SHRESTHA[1], C.-Y. JUAN[2], M. M. OLIVEIRA[2], K. S. A. RUIZ[2], M. MAMCARZ[2], M. SINGH[2], R. TRIANA-DEL RIO[2], M. HOU[2], C. FARB[2], A. CHIME[2], N. PENA[3], A. FRASER[1], J. E. LEDOUX[2], E. KLANN[2];
[1]Neurobio. & Behavior, Stony Brook Univ., Stony Brook, NY; [2]Ctr. for Neural Sci., NYU, New York, NY; [3]Univ. of Arizona, Tucson, AZ

Abstract: Tuberous Sclerosis Complex (TSC) is a neurodevelopmental disorder caused by mutations in Tsc1 or Tsc2, the genes that encode the protein components of TSC complex. TSC is one of the leading monogenic causes of autism spectrum disorder, and is associated with several neuropsychiatric disorders, collectively referred to as TSC associated neuropsychiatric disorders (TAND). TSC protein complex acts as an intracellular signal integrator and puts a brake on anabolic signaling mediated by mammalian target of Rapamycin complex (mTORC1), this occurs through its inhibition of small GTP-ase Rheb, which is a direct activator of mTORC1. Aside from the canonical TSC-Rheb-mTORC1 pathway, TSC complex has

recently been identified as a regulator of integrated stress response via TSC-Rheb mediated activation of eIF2alpha kinase PERK. Here, we show that heterozygous deletion of Tsc2 in Oxytocin receptor expressing cells (OxtRCs) precipitates behavioral susceptibility to social isolation stress. The manifestation of this behavioral susceptibility to stress is sex-specific. Male heterozygous null mice, upon prolonged social isolation, exhibit anxiety in tests that involve exploration of the environmental context or novel objects, specifically the open field test and marble burying test. On the other hand, social isolation reveals social anxiety in the female heterozygous null mice. We did not detect any impairment in associative learning and memory in the mutant mice, or motor stereotypy, indicating that OxtRC-specific haploinsufficiency of Tsc2 leads to aggravation of distinct indices of anxiety while sparing other behavior modules. Systemic administration of PERK inhibitor, GSK2606414, rescued all indices of anxiety-like behavior in male and female mutant mice whereas systemic Rapamycin, an mTORC1 inhibitor, only rescued anxiety in the marble-burying test for male mutants. Further, cell type-specific knockdown of Rheb in prefrontal OxtRCs rescued arena-related exploratory anxiety in male mice as well as social anxiety in female mutant mice. Our data indicate that aberrant behavior responses to stress are primarily mediated by TSC-Rheb-PERK signaling axis in Oxytocin responsive cells in the medial prefrontal cortex, and provide insight into the molecular underpinnings for emotional dysregulation evident in TSC.

Title: Rescuing stress induced anxiety in a mouse model of tuberous sclerosis complex

Authors: *K. SAN AGUSTIN RUIZ[1], M. M. OLIVEIRA[1], M. MAMCARZ[1], C.-Y. JUAN[1], M. SINGH[1], A. CHIME[1], P. SHRESTHA[3], E. KLANN[2];
[1]Ctr. for Neural Sci., New York Univ., NY, NY; [2]Ctr. for Neural Sci., New York Univ., New York, NY; [3]Neurobio. and Behavior, Stonybrook Univ., New York, NY

Abstract: The mammalian target of rapamycin complex (mTORC1)pathway is implicated in integrating and responding to various cues including cellular stress and growth factors. Tuberous Sclerosis Complex (TSC) is involved in mediating the mTORC1 pathway by inhibiting Rheb, an mTORC1 activator. However, when a ligand binds to an oxytocin receptor, it leads to Akt activation which phosphorylates Tsc2, effectively releasing the block of TSC on to mTORC1, allowing for increased translation. Thus, given that oxytocin receptors mediate the mTORC1 pathway through TSC, we chose to look into the role of Tsc2 in Oxytocin receptor neurons and what happens when you delete Tsc2 in these cells. Given that there is sexual dimorphism in oxytocin receptor expression we postulated that there could be sex

differences in how TSC manifest when Tsc2 is selectively deleted in oxytocin receptor neurons. In order to answer this question, we carried out different behavioral protocols with male and female heterozygote Tsc2 mutant mice. We used social isolation stress because oxytocin is thought to play a role in anxiety related behavior and we wanted to induce a stress related phenotype. Amongst the behaviors carried out, we found that socially isolated mutant male mice display more anxiety-like behavior in the open field test as they spend less time in the center of the field and in the marble burying test as they bury less marbles. On the other hand, female mice displayed social anxiety such that socially isolated females showed no preference for the object or mouse in a three chamber social interaction test. We tried to rescue these behavioral phenotypes using a PERK inhibitor given that TSC also plays a role in the integrated stress response through the activation of eIf2alpha kinase PERK. We found that PERK inhibitor was able to rescue all behavioral phenotypes of anxiety-like behavior in male and female mutant mice.

Title: The impact of postpartum estrogen withdrawal following a hormone-simulated pseudopregnancy on anxiety and motivational behaviors in adult female mice

Authors: *R. C. SIMAMORA, B. L. ALONSO, L. T. COSTA, L. E. BEEN;
Dept. of Psychology, Haverford Col., Haverford, PA

Abstract: During pregnancy, estradiol levels increase 100 to 1000-fold higher than baseline levels. However, following birth and the expulsion of the placenta, estradiol levels plummet to below baseline levels and remain suppressed until ovulation resumes. Ongoing studies are investigating how this tremendous endocrine change generates a behavioral profile associated with peripartum mood and anxiety disorders. We used a hormone-simulated pseudopregnancy (HSP) in C57BL/6 adult female mice to model the impact of postpartum estrogen withdrawal on changes in behavior. In this model, ovariectomized mice receive daily injections that simulate estradiol and progesterone levels during early pregnancy, late pregnancy, and the postpartum period. Specifically, an estrogen-withdrawn group, which models the the drop in estradiol seen during the postpartum period, can be compared to an estrogen-sustained group, which continues to receive high levels of estradiol, and a control group, which receives vehicle injections throughout the simulated pregnancy and postpartum period. Previously, we have shown that estrogen withdrawal following HSP increases ΔFosB, a marker of plasticity, within the nucleus accumbens (NAc). Given that the NAc is associated with affect and motivation, we hypothesized that an estrogen-withdrawn state following HSP would also be correlated with behavioral deficits in anxiety and motivation. An open field test and elevated plus maze were used to quantify anxiety in the postpartum period in one cohort of

mice (n=32). In a separate cohort of mice (n=23), we performed a sucrose preference test and social motivation test. Estrogen withdrawal increased anxiety-like behavior in the elevated plus, as evidenced by more time spent in the closed arms than the open arms. Behavior in the open field did not vary with hormone condition. Behavioral data collection for the sucrose preference and social motivation tests is ongoing, but we hypothesize that the estrogen-withdrawn mice will display deficits in motivational behaviors through reduced sucrose preference and less interaction with the social stimulus. This would support the conclusion that estrogen withdrawal is implicated in postpartum reductions in motivation, which is a core feature of depression, and would complement our finding of increased ΔFosB in the NAc. Future research will look further into mechanisms of neural plasticity that may account for differences in motivation and mood.

Title: Sexually dimorphic effects of adolescent stress in an X-linked congenic strain showing passive coping and increased anxiety

Authors: *M. T. JI, N. PASHANKAR, K. J. PRZYBYL, E. E. REDEI;
Dept. of Psychiatry and Behavioral Sci., Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL

Abstract: Individual variations in stress vulnerability are connected to stress-coping behaviors and influenced by both genetics and the environment. The adolescent period is particularly vulnerable to stress; however, how genetic vulnerabilities can alter the long-term consequences of adolescent stress is not well known. This study aimed to investigate the effects of acute adolescent stress on adult behavior, using the F344.WKY-*Stresp3*/Eer (F.WX) inbred congenic strain. The F.WX shows passive coping and anxiety-like behaviors. During adolescence, male and female F.WX rats were exposed to a modified Forced Swim Test (FST), while controls were undisturbed. In adulthood, learning and memory were assessed by Contextual Fear Conditioning (CFC) and Novel Object Recognition (NOR), anxiety-like behavior through the performance in the Open Field Test (OFT), and finally, coping behavior was tested in the classic FST. It is hypothesized that F.WX animals with adolescent stress will show more passive coping and anxiety-like behaviors than F.WX animals without adolescent stress, and the behavioral differences could be associated with expression of genes within the QTL region. Furthermore, both adult males and females were hypothesized to be made equally vulnerable by stress during adolescence. The results did not confirm these hypotheses. Instead, this study found that the consequences of adolescent stress were sex-dependent in adulthood. In females, adolescent stress significantly increased inactivity in

the OFT (stress, $F[1,35]=5.54$, $p<0.05$) but decreased fear memory in the CFC (sex x stress, $F[1,43]=4.75$, $p<0.05$). It also significantly decreased the high innate passive coping of females in the FST as measured by immobility (sex, $F[1,34]=44.38$; $p<0.001$; sex x stress, $F[1,34]=5.39$, $p<0.05$). In contrast, stressed males appeared to be positively influenced by adolescent stress, having shown increased spatial recognitions in NOR and increased active coping in the FST (spatial recognition; sex x stress $F[1,28]=4.21$, $p<0.05$; coping, sex x stress, $F[1,36]=4.73$, $p<0.05$). Sequence variations between F344 and WKY genetically mapped within the QTL region were identified. The expression of three genes with sequence variations in their coding regions, along with glucocorticoid (*Nr3c1)* and mineralocorticoid (*Nr3c2)* receptor expressions of the adolescent stressed and non-stressed adult male and female F.WX animals were measured in multiple brain regions and showed association with behavioral measures. Thus, stress during adolescence can lead to resilience or vulnerability to distinct environmental challenges in males and females differently.

Title: A Game-Theoretic Computational Approach for Identifying the Neurobiological Basis of Multi-Person Social Interactions

Authors: *V. KURTZ DAVID[1], A. BRANDENBURGER[2], P. W. GLIMCHER[3,4];
[1]Grossman Sch. of Med., New York Univ., NY, NY; [2]Stern school of Business, [3]Grossman Sch. of Med., New York Univ., New York, NY; [4]Ctr. for Neural Sci., New York Univ., Ny, NY

Abstract: Objective and Rationale: Seminal work in social neuroscience identified the role of the temporo-parietal junction (TPj) in reasoning about the mental state, actions and goals of others, a process usually referred to as “mentalizing”. Nonetheless, the study of mentalizing behavior is still lacking a strictly computational approach, which could lay the foundation for a neuronal-mechanistic account of social interactions. Here, we present a novel framework to examine the cognitive basis of strategic social interactions. Our goal is to investigate how the brain decodes social interactions into subclasses of cognitive functions associated with different cortical modules. Leveraging modelling architectures from game theory, alongside experimental design concepts from computational psychology, we identify orthogonal cognitive modules that we hypothesize play a role in mentalizing.
Methods and results: The complexity level of any social interaction is effectively the product of the social-representation complexity itself, and the number of options or outcomes that must be represented independent of social factors. When complexity level increases sufficiently, subjects struggle to fully represent the social setting and hence tradeoff the representation of valuation and mentalizing demands according to subject-specific capabilities and/or preferences. We utilize the Ring Game (Kneeland, 2015) to directly measure the allocation strategies of human subjects managing varying demands across these domains. In the Ring Game, each subject’s payoff depends on her own choices and the choices of all

other players in the ring. The number of players in each ring on a given trial determines the mentalizing requirements on that trial, while the complexity of the choice structure on a given trial imposes domain-general valuation demands. By varying the number of players in each ring (to manipulate mentalizing demands), as well as the number of choice options and choice structure (to manipulate domain-general representation requirements) from trial to trial, we develop a full, subject-specific, psychometric characterization of behavior in an array of social interactions. We identify subject-specific capacity constraints, namely, the percentage of games she was able to reason about, and then point at each subject's position along the valuation-social tradeoff axes.
Conclusions: This framework suggests a novel approach for examining social interactions, and can be applied to neuroimaging, to study tradeoff mechanisms between reward and social cognition networks in the brain, as well as to the study of pathologies in disorders of social cognition.

Title: Action Consequence during Reward-Driven Decision-Making

Authors: M. DEPASS, G. CECCHINI, ***I. COS**;
Univ. de Barcelona, Barcelona, Spain

Abstract: Characterizing Action Consequence During Reward-driven Decision MakingAuthors*M. A. DePass, G. Cecchini, I. Cos; Faculty of Mathematics & Informatics, University ofBarcelona, Barcelona, ES**DisclosuresM. A. DePass:** None. **G. Cecchini:** None. **I. Cos:** None.**Abstract**Previous research reported neurobehavioral correlates of reward signals, reward prediction error,and even state-space representation throughout the learning process of stimulus-response anddecisional patterns. However, a detailed characterization how the consequences of makingspecific actions influences decisions between them, remains to be properly formalized (Palidis etal., 2020; An et al., 2019; Akam et al., 2021). To this end, we developed a novel decision-makingparadigm, to be performed by human participants. We explicitly parameterized consequencewhich we defined as the change a decision may exert on subsequent ones, which could assumeone of four levels (zero, low, medium, high). A Latin square design was used to reduce potentialorder effects. We then fit reinforcement learning models to the behavioral data. We found model-free models could fit the behavioral data in the absence of consequence; however, in the presenceof consequence, a model combining model-free & model-based learning best replicated ourbehavioral data. Moreover, we found the RL learning rates correlated to the magnitude of actionconsequence. For some participants (n=2), LFP and EEG were recorded during task executionfrom the anterior insular, hippocampal, and orbitofrontal brain regions. We found the magnitudeof action

consequence could be decoded from power spectral density, spectral magnitude, andfrom electrode pair-wise correlation in these brain regions (with the largest contribution comingfrom the anterior insula). Network-like representations of the functional connectivity underlyingeach consequence level were also calculated. Finally, we fit generalized linear models to the dataand determined that consequence and reward can, in fact, be disambiguated as they havedifferential influences on several neurobehavioral metrics. Our results support the notion thataction consequence, though seldom analyzed, is a key metric that should be investigated; and,though it is often related to reward, can be disambiguated from it.

Title: Inverse reinforcement learning to infer multiple intentions behind decision-making in a bandit task

Authors: *K. NAKANISHI[1], S. KOTANI[1], S. HIROSE[1], Y. YAMASHITA[2], K. KATAHIRA[3], S. SUZUKI[4], M. FUKUSHIMA[1];

Sch. of Informatics, Nagoya Univ., Nagoya, Japan; [4]Brain, Mind and Markets Laboratory, Dept. of Finance, The Univ. of Melbourne, Parkville, Australia

Abstract: Computational psychiatry has attempted to uncover individual characteristics of computations in decision-making (i.e., computational phenotypes) associated with psychiatric symptoms by computational modeling in order to overcome the imprecise nature of psychiatric nosology. In this study, we propose an inverse reinforcement learning (IRL) algorithm combined with a clustering method, aiming to provide novel insights on the computational phenotypes in decision-making tasks. IRL is a promising technique to infer intention behind decision-making from a reward/cost function under a Markov decision process (MDP) formalism. The proposed algorithm is based on a well-known probabilistic maximum entropy IRL technique, the guide cost learning (GCL). Our approach estimates a reward/cost function for each cluster representing a group of state-action trajectories associated with decision-making. Although our approach applies to a broad class of decision-making tasks, the current study focuses on a three-armed bandit task with time-varying reward probabilities. When people play the bandit task, they can act based on obtained information that is updated as the task progresses. To represent such a process and formulate an IRL problem, we introduce an information state. Specifically, we apply the volatile Kalman filter (VKF) to calculate the information state for each participant playing the task. The VKF is an extended Kalman filter algorithm for a volatile environment as in the bandit task. The proposed algorithm takes the information states and actions (i.e. selected arms) of multiple participants as the input of state-action trajectories. Then, it alternately performs clustering the trajectories and estimating the reward/cost functions until the cluster assignment becomes stable. Here, we take a non-parametric Bayesian approach for the clustering, using the Dirichlet process mixture model without

pre-specifying the number of clusters (i.e. the number of distinct reward/cost functions). We confirmed that the proposed algorithm groups the state-action trajectories of the multiple simulation agents (e.g. greedy agent) correctly into the clusters, each corresponding to the known intention. Finally, we apply the proposed method for the data obtained from human participants performing the bandit task. Thus, our approach suggests a new computational phenotype to evaluate information processing underlying decision-making in both psychiatric and normal populations.

Title: Using process models to disentangle stimulus-driven and controlled processes during value-based decision making

Authors: *H. RITZ, R. FRÖMER, A. SHENHAV;
Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: There is growing interest in neuroeconomics in how cognitive control over value based decision making allows people to flexibly change how they make choices. Grounded in motivated control research, a recent theory by Vassena, Deraeve, & Alexander (2020) proposed that people recruit cognitive control to invigorate responses when difficult decisions won't make a deadline. To support this proposal, the authors fit a drift diffusion model (DDM) to participants (n=22) making value-based decisions under a short response deadline (750ms). They show that participants had a lower response threshold for difficult decisions, and interpret this as an index of controlled invigoration. Here, we critically examine the theoretical and empirical support for this proposal. First, we reanalyzed data from this study, and found that previous evidence for value-based invigoration (threshold changes) was an artifact of model misspecification. Once accounting for features of these data that were overlooked in the original DDM implementation (e.g., influences of decision urgency and overall set value), we no longer find that thresholds decreased with decision difficulty. Second, we show that a well-characterized and biologically plausible model of value-based choice (the leaky competing accumulator) can parsimoniously account for the features of these and similar datasets, without requiring an additional vigor-based controller. Together, our results suggest that the controlled invigoration theory of decision-making currently lacks empirical

support, and that its proposed mechanism may in most instances be obviated by existing models of value-based choice that lack such a control mechanism. More generally, our work demonstrates potential sources of mimicry between parameters of decision models that may lead to misattributions of control to evidence accumulation processes that are instead primarily stimulus-driven.

Title: Information sampling for trust decisions in children with autism

Authors: W. LIU[1], N. SHAH[1], I. MA[2], *G. ROSENBLAU[1];
[1]George Washington Univ., Washington, DC; [2]Leiden Univ., Leiden, Netherlands

Abstract: In humans, a significant shift in trust and cooperation is expected to occur in pre-adolescence but the changes in underlying strategies remain unknown. It is also unknown whether typically developing (TD) children differ from children with Autism Spectrum Disorder (ASD) in their cooperation strategies.To address this question, we used an information sampling trust game. Participants were told that trustees played the trust game 25 times with other players. They were then given the opportunity to sequentially sample information about each trustee's reciprocation history before deciding to invest or not. Unknown to them, trustee's reciprocation probabilities were computer generated and varied between 0 and 1.Our preliminary sample includes 42 TD (9.8 ± 1.8y) and 12 ASD children (11.2 ± 2.1y). We found that both TD and ASD groups invested more frequently when trustees reciprocated more in the past. This effect is modulated by age (older children invest more) and group (TD invested more) when trustee is more trustworthy. We also tested whether children's decisions to continue sampling was affected by the uncertainty about the trustee's intention to reciprocate. We found that both TD and ASD children sampled more when information was less conclusive, i.e., when the trustees made a similar number of decisions to reciprocate and defect in the past. This information sampling strategy was modulated by age. In the TD group, a quadratic age effect indicated that the youngest and oldest participants differentiated most between high and low uncertainty trials. In ASD, we found a linear age effect. Older participants sampled more information with higher information uncertainty. We investigate age and group related shifts in information sampling strategies in TD group only, due to our current smaller sample of ASD group. To test whether our models are robust and can be differentiated, we conducted model recovery and all models were recovered 100% on their own simulated data. We found that the behavior of TD participants was best described by a full Bayesian information updating model. To confirm our results, we performed a 10-fold cross validation, and our model predictions can generalize beyond the model fitted data. Overall, we found children adapt information sampling and cooperation decisions to the reciprocation probability of their partners differently based on their age and social

cognition. A normative Bayesian model best described TD participants' strategy. In a next step, we will describe differences in sampling strategies of children with ASD and investigate whether strategies predict behavioral and neural signatures of sustained cooperation and autistic traits.

Title: An online game to assess evidence accumulation and rule learning in humans

Authors: *Q. DO[1], G. KANE[2], J. T. MCGUIRE[3], B. B. SCOTT[4];
[1]Boston Univ. Grad. Program For Neurosci., Boston, MA; [2]Dept. of Psychology, Princeton Univ., Princeton, NJ; [3]Dept. of Psychological & Brain Sci., [4]Psychological & Brain Sci., Boston Univ., Boston, MA

Abstract: Pulse-based accumulation of evidence tasks have been used in human and animal studies to evaluate working memory and perceptual decision making. Here we developed an online game that trained humans with feedback on a visual pulse-based evidence accumulation task. We evaluated the performance of human subjects on this task, and compared the performance of those trained with feedback alone versus those who were given explicit written instructions and feedback. Across both groups, human performance was well described by a model in which choices were determined by the difference in the number of flashes, previous reward location and a side bias. Error rates were consistent with a scalar variability model of perceptual noise accumulation. No significant difference between subjects trained with feedback versus those given both feedback and written instructions was observed and learning through feedback could be achieved in 10 trials. These results suggest that online games inspired by pulse-based accumulation tasks provide a valuable behavioral assessment platform to examine perceptual decision making and learning in humans. In addition, the feedback-based training pipeline developed for this game may be useful in evaluating perceptual decision making in human populations with difficulty following verbal instructions.

Title: The effect of memorability on food choice: do people prefer more memorable foods?

Authors: *X. LI, W. A. BAINBRIDGE, A. BAKKOUR;
Psychology, Univ. of Chicago, Chicago, IL

Abstract: Making adaptive decisions often relies on memory; the latter allows past experiences with choice options to guide actions. But not all memories are created equal. Some items are better encoded into memory than others; i.e. some choice options are more memorable. However, the effect of memorability on choice is unknown. We propose that more memorable food items are more likely to be chosen than less memorable foods of equal subjective value. To test this prediction, we first measured the memorability scores of 138 images of food. Participants (N = 199, 35% women, age ranges between 18-35) were presented with a series of images and asked to respond with a button press when the image on the screen was seen before (i.e., when the image is old). The memorability score for each image was calculated as Corrected Recognition, which was significantly consistent across people ($p < 0.014$). We then conducted a value-based food choice experiment; a different sample of 44 participants (30% women, M = 30.93, SD = 4.17) viewed the same 138 food images in random order, and were asked to rate how much they prefer to eat each item (a measure of subjective value). After the rating phase, participants chose between two food items based on their personal preferences. The pairs of items were generated based on ranking of the indicated subjective values across items for each individual. Mixed-effects regression models replicated previous findings and showed that participants' choices were associated with their stated subjective values for food (*Odds Ratio (OR)* = 3.32, *CI* = 2.81 - 3.92, $p < .001$) and that participants spent more time making choices between options that were similarly valued (β = -0.04, *CI* = -0.06 - 0.02, $p < .001$). Exploratory analyses revealed that more memorable items tended to be perceived as tastier (β = 0.083, p = 0.004), and tastier foods tended to be rated higher on subjective value (β = 0.65, $p < 0.001$). However, contrary to our prediction, there was no significant relationship between item memorability and choice behavior (p = 0.91). This result suggests that intrinsic item memorability of foods does not influence decisions about what to eat, and perhaps value-based decisions more generally. We proffer that, rather than a unique attribute that drives choice, memorability may constitute but one attribute among many used for the construction of subjective value of individual items during decision making.

Title: Virtual Human Foraging Behavior Follows Predictions for Heavy-Tailed Search

Authors: *K. N. MOORE, C. YI, M. F. DUNNE, C. E. STERN, J. T. MCGUIRE;
Boston Univ., Boston, MA

Abstract: Studies suggest humans and animals favor foraging strategies that allow them to broadly explore the global search environment in large "steps" punctuated by periods of concentrated local search ("heavy-tailed search"). Despite a variety of studies on human foraging, few studies have sought to replicate evidence for this search strategy, as opposed to random diffuse search, in a virtual open-field foraging task. To investigate the extent to which humans engage in heavy-tailed search strategies in a virtual environment, we studied human participants (ages 18-35, N=5, F=4) as they completed 2 sessions of a virtual coin foraging task. Participants were instructed to freely explore and to collect coins in the virtual field, which was surrounded by four walls. In each foraging bout, 100 coins were randomly dispersed, and 225 coins were predictably clustered in four Gaussian-distributed patches. Trajectory step lengths were extracted from 8 min foraging bouts (total N=100) by segmenting trajectories where turn angles exceeded 40 degrees. Maximum Likelihood Estimation was used to fit step-length distributions for participants' foraging bouts to probability density functions of common models in foraging literature including power law, lognormal, and exponential distributions. We analyzed frequency distributions for goodness-of-fit using Akaike Information Criterion (AIC). Frequency distributions of participants' search trajectories were best fit by the power law model for 8 out of 10 sessions. Participants' trajectories from individual foraging bouts were also best fit by power law models, fitting 54% of all foraging bout step length distributions (N=100), while the exponential model fit 41% of the foraging bouts, and the lognormal fit just 5% of the bouts. Analyses of the best fitting parameters of the power law model suggested that virtually all estimated power law exponents (μ=1.43, SD=0.12) fell within the predicted range for Lévy walks: $1 < \mu \leq 3$. These results indicate that virtual human foraging behavior, much like in the natural world, can be described as a heavy-tailed search process. The emergence of the power law model as the best fitting model for search trajectories and corresponding estimated model parameters suggest that power law distributions (e.g. Lévy walks) approximate foraging step lengths at a large scale. However, exponential (Brownian) movement patterns were also apparent in this data set. Additional analyses are necessary to better understand the conditions in which Lévy vs. Brownian motion predominates distributions of step lengths in a virtual environment.

Inst. & Dept of Psychology, Princeton Universiry, Princeton, NJ

Abstract: When in a new situation, we have to infer which set of rules to use. For example, when entering a new restaurant, we use contextual cues to infer whether it is a sit-down or a fast-food restaurant. Once this is determined, we can apply a set of previously learned rules to guide our behavior in each context. In humans and monkeys, inferring a behavior is believed to happen in the prefrontal cortex. To understand how one learns to infer which rule is in effect, we trained two monkeys to perform a category-response task with multiple latent rules. The monkeys were trained on three different rules; each requiring them to categorize the color or shape of a stimulus. Changes in the rule were not cued, forcing the animals to determine which rule was in effect on each block based on reward feedback alone. The animals performed the task well, quickly switching between rules. To understand the mechanisms supporting behavior, we compared several classes of models including incremental learning and Bayesian inference models. Both classes of models produce learning effects - i.e., experience-driven changes in behavior - but with different patterns and neural predictions. However, only a noisy version of the inference model captures the key qualitative features of the data, including differences in performance and learning following stimuli that either had congruent or incongruent responses across the rules. These results suggest monkeys can use inferential reasoning when determining how to behave in an uncertain world.

Title: Temporal Analysis of Learning Negative Values in Non-Human Primates

Authors: *H. STEALEY, Y. ZHAO, E. CONTRERAS-HERNANDEZ, SR, S. R. SANTACRUZ; Biomed. Engin., Univ. of Texas at Austin, Austin, TX

Abstract: Frequently, decision-making tasks are between two positive outcomes of which one is relatively more valuable. In tasks where negative outcomes are considered, often the “value” associated with it cannot be quantified with the task value system. However, recent work has demonstrated a behavioral task that allows negative outcomes to be quantified in terms of units of the positive outcomes, such as juice volumes (see Fiorillo, 2013). In this task, alternative juice volumes are presented to determine how much the subject is willing to sacrifice to avoid the negative outcome (bitter juice solution). Here, we expand on this work by developing a temporally precise reinforcement learning (RL) model, including parameters that account for total fluid intake, daily task learning, and changes in

aversiveness over shorter timescales (e.g. on the order of trials). First, we determined a concentration of denatonium benzoate (bitter agent) so that the subject was equally likely to choose the standard option (e.g. 180 µL bitter juice) over an alternative option (e.g. 110 µL juice only) to determine the relative difference or "negative value" of the denatonium (e.g. -70 µL). Then, our subject performed a decision-making task in which they were presented with one of five trials types every five trials in which each trial type was the standard juice only option (180 µL bitter juice) against one of the five alternative juice only options with relative differences of -210 µL, -140 µL, -70 µL, 0 µL, or +70 µL. Each trial type was denoted by a specific stimulus color, and colors were not changed between experimental days. With our RL model, we demonstrate the relative influences that aversiveness, relative value, time, and learning have on changes in choice behavior for each trial type. This is a powerful framework to determine neural correlates of choice behavior with negative outcomes.

Title: Distinct patterns of serial dependence of binary decision making in classification and categorization tasks

Authors: *H. LEE[1], S.-H. LEE[1], H.-J. LEE[1], K.-W. CHOE[2];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Psychology, Univ. of Chicago, Chicago, IL

Abstract: Distinct patterns of serial dependence of binary decision making in classification and categorization tasks
Classification and categorization have long been favored as task platforms for studying cognitive operations underlying perceptual decision-making. Despite their similarity on the surface, the two tasks fundamentally differ in statistical structure: classification requires sorting the items within a single population into two halves according to their relative quantities (e.g., "His pet seems big for a pet") whereas categorization requires selecting between two alternative populations from which given items are sampled based on their quantities (e.g., "It seems a dog rather than a cat by its size"). Thus, according to the Bayesian decision-making theory, which posits that ideal observers combine their knowledge about the statistical structure of a given task with the present evidence to infer the world state of interest, ideal classifiers and categorizers should learn differently as they make a sequence of decisions. Specifically, the former classifier always updates the single population distribution for each instance (e.g., the average size of pet animals increases whenever seeing a pet of an above-average size) whereas the latter categorizer selectively updates only one of the two population distributions to which a given instance belongs (e.g.,

only the average size of dogs, but not that of cats, increases after seeing a dog of an above-average size). Consequentially, it is implied that Bayesian observers' choices show distinct patterns of serial dependence on previous stimuli and choices depending on whether they perform a classification or categorization task: (i) classifiers either alternate or repeat choices depending on memory noise whereas categorizers repeat choices; (ii) classifiers' and categorizers' choices are both repelled against previous stimuli, but repulsion being more pronounced in the former. We subjected these implications to empirical tests by regressing human observers' binary choices onto previous choices and stimuli, respectively in classification and categorization tasks. The observed regression coefficients were highly consistent with the model implications on serial dependence. Our findings suggest that humans indeed deploy distinct cognitive algorithms when classifying and categorizing, as implicated by the distinct statistical structures of the two tasks.

Title: Tdcs restores natural decision-making performance in simulated network with excitatory-inhibitory balance

Authors: *P. ADKISSON[1], S. XU[3], G. FRIDMAN[1], C. R. STEINHARDT[2];
[1]Otolaryngology, [2]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [3]Otolaryngology, Johns Hopkins, Baltimore, MD

Abstract: Transcranial DC stimulation (tDCS) has been shown to affect decision-making tasks, despite open questions regarding its mechanism of action. Recent evidence suggests that the behavioral effects of tDCS may be largely explained by stimulation-induced changes in the effective excitatory-inhibitory (E-I) balance of the targeted brain region. In this study, we developed a computational model to more closely emulate the natural cortical physiology subjected to tDCS. We extended a standard attractor model to one with two excitatory cortical populations connected via an inhibitory intercortical population, where each cortical population had a mixture of excitatory and inhibitory neurons. The E-I balance of each cortical population was varied in steps of 0.2 between 0-0.8 (portion of inhibitory neurons), while the intercortical population remained entirely inhibitory. The extended model was used to replicate the Javadi et al. (2015) visual two alternative forced choice task decision-making study, where left versus right choice indicated a gradient from a tall to long rectangle. The model took object "tall-ness" saliency as direct excitatory input to cortical populations, and tDCS was introduced an ionic current input to cortical neurons. We found that increasing the proportion of inhibitory neurons increases network decision time. Physiologically relevant

decision-making times (0.2-1 sec) were observed only when E-I balance was less than 0.4. Cortical populations with E-I balance of 0.6 (emulating pathological E-I imbalance) resulted in a 5-fold increase in decision time. When tDCS was introduced to the network with an E-I balance of 0.6, it reduced the decision time by 1.5 times (N=50 trials), suggesting that tDCS can reverse the network-level effects of E-I imbalance. At E-I balance of 0.4 and lower, tDCS had reduced effects that nevertheless matched those observed experimentally. These findings suggest tDCS may act as a target treatment that can reverse network-level pathologies deriving from E-I imbalance. They also provide concrete testable hypotheses about how tDCS affects both healthy and those suffering from neural disorders.

Title: Choice-tuned inhibition supports decision-making though competition in recurrent neural networks.

Authors: J. P. ROACH[1], A. K. CHURCHLAND[1], T. A. ENGEL[2];
[1]Neurobio., Univ. of California Los Angeles, Los Angeles, CA; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: In decision-making circuits, the firing rates of choice-tuned neurons are modulated by an upcoming choice. Neural circuit are an indispensable tool for understanding how choice-tuning accounts for decision-making computations. These models have primarily considered excitatory choice-tuning and have highlighted the importance of highly structured connections between choice-tuned excitatory populations. However, these models treat inhibitory neurons as an untuned and nonselective pool within these circuits. There is growing evidence for inhibitory choice and stimulus tuning in cortical areas important for perceptual decision-making. Here we aim to expand the explanatory power of decision-making circuit models by considering cases where inhibitory neurons are choice-tuned. We trained recurrent neural networks (RNNs), consisting of excitatory and inhibitory neurons, to perform a decision-making task. The task required the network to compare two inputs to the excitatory populations and report which is higher by increasing one of two outputs. We found that RNNs had similar fractions of choice-tuned excitatory and inhibitory neurons. Networks displayed a consistent circuit structure where excitatory-to-excitatory (EE) and excitatory-to-inhibitory (EI) connections tended to link similarly tuned neurons and inhibitory-to-excitatory (IE) connections tended to link oppositely tuned neurons. This result reveals a common motif where decisions are driven by recurrent excitation and competitive inhibition. To evaluate the importance of this common motif on the decision-making function of the circuit we shuffled the outputs of the top 10% of choice-tuned neurons. Shuffling EE connections lead to a large decrease in

performance, while shuffling EI and IE connections lead to a more moderate decrease in performance. In each case the performance reduction resulted from an increased rate of trials without a choice. When shuffling the outputs of neurons that were active, but were in the bottom 10% of choice-tuned neurons a significantly smaller performance reduction was observed. These results indicate that RNNs find a common solution to a decision-making task driven by selective recurrent excitation within choice-tuned populations and supported by competitive inhibition from choice-tuned inhibitory neurons. Inhibitory choice-tuning emerges naturally in the training process, even though these neurons receive no direct stimulus information, suggesting that dedicated pools of inhibition for each choice-tuned subpopulation could be a requirement for decision-making circuits.

Title: A meta-reinforcement learning network exhibits model-based behavior via an augmented state representation in the two-step decision making task

Authors: *J.-A. LI, M. G. MATTAR;
UCSD, San Diego, CA

Abstract: Striatum and prefrontal cortex (PFC) both play critical roles in reward-driven reinforcement learning (RL). In the striatum, phasic dopamine driving synaptic plasticity represents prediction errors of model-free temporal-difference RL algorithms. In comparison, the neuronal dynamics in PFC is thought to implement flexible model-based RL algorithms. The meta-RL framework offers a promising perspective to reconcile the roles of striatum and PFC on decision making (Wang et al., 2018). In this framework, striatal model-free prediction errors are used to adjust the synaptic weights of the PFC network to implement a model-based algorithm through neural dynamics. However, it is not clear which model-based algorithm emerges from the learning process of meta-RL networks. To address this question, we trained a recurrent neural network (LSTM units with Advantage Actor-Critic architecture) on the two-step task (Daw et al., 2011). In this task, each trial consists of two stages: in the first stage, the agent selects one of two actions (A1 or A2), which probabilistically leads to one of two second-stage states, S1 or S2. Each second-stage state leads to a different probability of a unit reward, with the most valuable state switching stochastically. Our networks achieve near-optimal performance in this task. Projecting the neural dynamics onto the top three principal components of the hidden-layer state space, we found that the neural activity lies on four approximately parallel lines (edges) of a cube spanned by three roughly orthogonal axes: a second-stage state axis (S1 or S2), a reward axis (reward of 0 or 1), and an action axis encoding action probability favoring A1 or A2. To elucidate the mechanism determining these lines, we fit cognitive models to the networks' behavior (following Akam et al., 2015), including model-free Q(0), model-free Q(1), model-based (MB), reward-as-cue, and latent-state (LS) models. The MB and LS models provided the best fits. Surprisingly, the trial-by-trial choice probability in the LS model, but not in

the MB model, was consistent with the action probability on each line. Together, these results suggest that our meta-RL networks use an augmented state representation to exhibit apparent model-based behavior in the two-step task.

Title: Neural mechanisms of optimism bias in learning

Authors: *F. TALEB[1,2], S. FARASHAHI[3], A. SOLTANI[4];
[1]Sch. of Electrical and Computer Engineering, Col. of Engin., Univ. of Tehran, Tehran, Iran, Islamic Republic of; [2]Robotics, Perception and Learning, Sch. of Electrical Engin. and Computer Sci., KTH Royal Inst. of Technol., Stockholm, Sweden; [3]Ctr. for Computat. Neuroscience, Flatiron Inst., New York, NY; [4]Psychological & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: There is growing behavioral evidence that reward learning is adjusted according to different aspects of the reward environment. Such adjustments in learning are often measured by estimating the so-called learning rates via fitting choice behavior with different reinforcement learning (RL) models. Although the estimated learning rates vary between tasks and experimental conditions, there is recent evidence that their values exhibit certain regularities. For example, it has been shown that the learning rate for updating the reward value of the chosen option is larger for rewarded than unrewarded outcomes, a phenomenon referred to as optimism bias. Although a few normative accounts (mainly based on reward optimization) for such asymmetry in learning rates have been proposed, the underlying neural mechanisms are still unknown. To address this, we re-examined behavioral data during three related learning tasks but with different levels of complexity and across three species: (1) probabilistic reversal learning in mice in which two choice options provided reward with different probabilities that reversed between blocks of trials; (2) probabilistic reversal learning with additional reward magnitude in monkeys where in addition to reversals in reward probabilities, different reward magnitudes were presented on the two options in each trial; (3) multi-dimensional probabilistic reversal learning (MdPRL) in humans in which choice options had two features predicting reward probabilities that underwent reversals. Moreover, we tested the ability of two different mechanisms for explaining the observed adjustments in learning: reward-dependent metaplasticity (RDMP) and mixture of experts (MoE). By fitting choice behavior using standard RL models but with either two learning rates (α_+ and α_- for rewarded and unrewarded outcomes) or four learning rates (α_{b+}, α_{b-}, α_{w+}, α_{w-} for rewarded and unrewarded outcomes on the better and worse options) we found evidence for optimism bias ($\alpha_+ > \alpha_-$) in all three tasks. Importantly, we found that this asymmetry was accompanied by opposing patterns of the learning rates for the better and worse options: $\alpha_{b+} > \alpha_{b-}$ and $\alpha_{w-} > \alpha_{w+}$. These results were compatible with simulations based on the

RDMP model that adjusts learning according to regularities of the reward environment. Moreover, simulations of choice behavior during the three tasks using the MoE model revealed consistent results but based on very different mechanisms: i.e., larger weighting of experts with $\alpha_+ > \alpha_-$ on choice behavior. Together, our results suggest that very different mechanisms could account for the observed optimism bias in learning.

Title: Evolving Memory: From Simple Foraging Associations to Cognitive Map Construction

Authors: *E. D. GRIBKOVA[1,2], R. GILLETTE[1,3];
[1]Neurosci. Program, [2]Coordinated Sci. Lab., [3]Dept. of Mol. and Integrative Physiol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Cognitive mapping builds internal representations of the world and is essential to episodic memory and mental imagery. Here we show how circuitry of basic foraging decision can be straightforwardly expanded for affective valuation and cognitive map construction in the agent-based foraging simulation, ASIMOV, reproducing likely evolution.
Behavioral choice in foraging is governed by reward learning and motivation, which interact to assign subjective value to sensory stimuli. These qualities characterize foraging generalists that hunt in variable environments, and are precursors to more complex memory systems. ASIMOV's core decision network is based on neuronal circuitry of cost-benefit decision in the predatory sea-slug *Pleurobranchaea californica*. ASIMOV's virtual forager affectively integrates sensation, motivation (hunger), and learning to make cost-benefit decisions for approach or avoidance of prey, providing reward and nutrition upon consumption. Olfaction is used for both odorant discrimination and spatial navigation.
We developed a Feature Association Matrix (FAM) with reward learning and hippocampus-like sequence learning to map and establish relations. It does the basic tasks as most models of hippocampal function, but with much less computational demand. For sets of inputs or features, like sensation and reward, the FAM memorizes presented sequences by changing associative strengths between pairs of inputs. Expected reward values are assigned to each association, allowing replay of memorized sequences. Memorized sequences may be unlearned if no longer presented or rewarded, and if there are other presentations of competing sequences.
We show how sequence memorization is achieved by chaining pair-wise associations made through simple higher-order conditioning mechanisms. Spatial learning for distant landmarks in terms of direction and distance is enabled by a simple path integration system. Addition of the FAM's spatial and episodic

memory to ASIMOV's forager shows how the neuronal circuitry of foraging decision can serve as the framework for cognitive mapping in evolution.

Title: Planning in monkeys during an abstract strategy board game

Authors: *M.-Y. PARK[1], B. V. OPHEUSDEN[2], H. LIANG[1], M. OEMISCH[1], K. OSBORNE[1], W. MA[3], D. LEE[1];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Princeton Univ., Princeton, NJ; [3]New York Univ., New York, NY

Abstract: Making sequential decisions in dynamic social settings requires agents to search, evaluate, and optimize alternative strategies according to the current state and desired outcomes. To investigate the dynamics of learning and sequential decisions and the underlying neural mechanisms, we trained two monkeys to perform a simplified form of Go-Moku, namely Four-in-a-Row (different from Connect Four). The monkeys used a joystick to place their pieces on a 4-by-9 board, one at a time, taking turns with a computer opponent. A player could win by placing four pieces in a row horizontally, vertically, or diagonally. The game outcome could be a win, loss, or tie for the animal, which was rewarded only for wins.
We trained both monkeys to gradually become familiar with the rules of the game, by using stages of increasing difficulty. In the beginning, the monkeys were given two or three pieces that were already connected, and learned to complete a pattern of 3 or 4 in a row by choosing one of several cued locations in the board. Both animals learned to choose the locations to complete the desired patterns even if the distance of the choice from the existing pieces was not the closest compared to the other choices. Throughout training, both animals also tended to complete the 4-in-a-row patterns horizontally more frequently than vertically or diagonally.
Good performance in the Four-in-a-Row game requires a player to prevent the opponent from winning by predicting the future states of the game resulting from the opponent's choices. We found that the proportion of winning in which the animal actively blocked the opponent's winning move steadily increased from 26% to 41% during training. These results demonstrate that an abstract board game can provide a useful platform to investigate the neural mechanisms of sequential decision making.

Title: Sex modulates the role of noradrenergic signaling in the exploration-exploitation tradeoff

Authors: *C. S. CHEN[1], E. KNEP[1], D. MUELLER[1], B. A. EBITZ[3], N. M. GRISSOM[2];
[2]Dept. of Psychology, [1]Univ. of Minnesota, Minneapolis, MN; [3]Neurosciences, Univ. de Montréal, Montreal, QC, Canada

Abstract: In an uncertain world, we balance two goals: exploiting rewarding options when they are available, and exploring potential better alternatives. Individuals approach this problem with divergent explore-exploit strategies, but we know little about the neural bases of this interindividual variability. One major axis of interindividual variability in executive function and decision-making is sex. Sex significamtly modulates the locus coeruleus-norepinephrine (LC-NE) system, which has long been thought to underpin exploration and learning. However, it remains unclear how the balance between exploration and exploitation differs across sexes, and whether noradrenergic signaling contributes to these sex differences. Here, we systemically administered propranolol (5mg/kg), a non-selective β-adrenergic receptor antagonist, and isoproterenol (0.3 mg/kg), a non-selective β-adrenergic receptor agonist, in male and female mice in a restless two-arm bandit task, using a within-subject design. In this restless bandit task, mice chose from two options that were associated with certain reward probabilities, which changed independently and stochastically over trials. Thus, animals could only infer values through sampling and integrating reward and choice history. We found that propranolol administration (NE antagonist) resulted in "stickier" choice behaviors, reflected in increased win-stay behaviors and decreased lose-shift behaviors compared to controls. The modulatory effects of propranolol on choices were stronger in males than females. On the other hand, there was no significant difference in win-stay behaviors between control and isoproterenol (NE agonist) group. A Hidden Markov model (HMM) was fitted to infer latent state of exploration and exploitation. The result suggested that propranolol decreased the probability of exploration in both males and females, with a stronger modulatory effect on males than females. Fitting reinforcement learning models revealed that blocking noradrenergic beta receptors with propranolol reduced the level of decision noise without affecting learning rate. Together, these results suggest that a novel, sex-modulated role for LC-NE system in differentially regulating exploration via regulating behavioral stickiness, rather than the rate of learning, across sexes.

Title: Shifts in learning strategies underlie rodent behavior during dynamic foraging

Authors: *N. M. LE[1], M. YILDIRIM[2], H. SUGIHARA[2], Y. WANG[1], M. SUR[1];
[1]Brain and Cognitive Sci., [2]Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: In uncertain foraging environments, a critical problem agents face is how to adapt their learning in accordance with the uncertainty of the environment and knowledge of the hidden structure of the world. In this context, previous studies distinguished between two modes of learning: model-free learning updates action values while balancing between exploration and exploitation, while inference-based behavior leverages knowledge of world's dynamics to infer the current state of the world. However, it is unclear how these behavioral strategies can be cleanly distinguished based on behavioral data and how animals transition between these modes during training. Here, we tackled these questions by examining rodent behavior in a dynamic foraging task. We trained head-fixed mice to select between two choices, left and right wheel turns. Only one direction was rewarded in each trial, and the target direction changed in blocks of 15-25 trials. To determine whether rodent behavior was better described by the model-free or inference-based strategies during learning, we simulated choice sequences of model-free and inference-based agents to gain insights into their behavioral signatures. Our model-free agent implements a Q-learning algorithm, while the inference-based agent performs Bayesian inference assuming a 2-state model of the world. We identified four criteria to characterize the behavior of these agents and used them to fit rodent behavioral data: the slope and offset of their switching decisions, the degree of exploration, and the relationship between switching and the performance in the previous block. Across all animals, we observed a consistent decrease in the times to switch the wheel turn direction, and a decrease in the degree of exploration with training. By performing a model comparison using log-likelihoods, these observations were better explained by a transition from model-free to inference-based mode of learning, as opposed to an increase in learning rate in a model-free agent. A 3-state Hidden-Markov model was fitted to the rodent behavioral data, revealing transitions between left-exploit, right-exploit and exploratory states. The duration of exploratory states decreased with training, consistent with the transition to the inference-based strategy. These analyses and characterizations form the basis of understanding shifts in behavioral strategies during dynamic foraging. Together with widefield calcium imaging across the whole cortex during the task, they will be important for identifying unique neural signatures of global brain states that are associated with distinct modes of learning.

Title: Separable neurocognitive changes underlie the development of communicative reasoning in adolescence

Authors: *C. WANG, M. CONG, Q. MI, G. YU, Y. SU, L. ZHU;
Peking Univ., Beijing City, China

Abstract: Humans possess a remarkable ability to read between the lines. Prior research suggests that decoding what is meant from what is said involves intertwining cognitive operations, such as inhibiting the literal interpretation of a communicative signal, and recovering the speaker's most probable intention based on context. Despite recent progress in understanding the neural bases of communicative reasoning, little is known about when and how humans acquire this ability, and whether basic cognitive functions such as executive control and social reasoning would interact with one another in support of its development. Combining computational modeling, cross-sectional and longitudinal fMRI data, we examined the neurobehavioral changes in communicative reasoning during the transition in and out of adolescence—a period critical for the development of both cognitive and social functioning.
A total of 316 subjects (ages 8-24, fMRI N = 141, behavior N = 175) participated in the experiment, among which 53 fMRI subjects were scanned twice, spanning 1.7-year. The ability of communicative reasoning was assessed using the combination of a well-established referential communication game, previously used to elucidate the neurocomputations underlying communicative reasoning in adults.
The accuracy of communicative reasoning continuously increases with age in both cross-sectional and longitudinal data. According to results from the cross-sectional fMRI data, such age-related performance changes are related to (i) increased involvement of reasoning about speaker's choices when interpreting speakers' messages, subserved by the changes in the engagement of ventromedial prefrontal cortex across age, and (ii) decreased egocentric processing of communicative contexts, subserved by the changes in sensory cortical activity. Importantly, longitudinal data further suggest that the contributions of the two processes are differentially modulated by changes in the activation of the frontoparietal network (FPN) during communicative interpretation.
These results suggest a prolonged development of communicative reasoning over the entire period of adolescence. It likely involves a delicate balance between the egocentric processing of sensory information and the reasoning about social partners, which is likely linked with the development of FPN functioning, previously implicated in executive control in adolescence. These results suggest a potential mechanism by which the maturation of communicative reasoning is shaped by separable, yet interacting neurocognitive processes.

Title: Neural correlates of responsibility for inequality

Authors: *J. SCHULTZ;
Univ. of Bonn, Bonn, Germany

Abstract: People dislike inequality. More specifically, people are averse to unequal outcome distributions, and experience negative social emotions when subjected to unequal outcomes. Being responsible for negative social outcomes also leads to negative social emotions, such as guilt (Berndsen et al., 2004; Zeelenberg & Breugelmans, 2008). Together with inequity aversion (Bolton & Ockenfels, 2000; Charness & Rabin, 2002; Fehr & Schmidt, 1999), guilt aversion is considered one of the major factors influencing social decision-making (Fehr & Schmidt, 2006). Better understanding the neural mechanisms involved in experiencing such social emotions may allow to better understand human social behaviour and its variations. Here, we aimed to study the neural mechanisms involved in experiencing responsibility for inequal outcomes using a risky social choice task about monetary rewards. In a series of trials performed during functional magnetic resonance imaging, participants or a partner repeatedly chose between a lottery or a safe option. The outcome of each decision affected both participant and partner. If the lottery was chosen, unequal outcomes (either advantageous or disadvantageous for the participant) ensued in 50% of cases. Outcomes were revealed after each choice, and participants reported their momentary happiness every second trial. Linear mixed models revealed that both advantageous and disadvantageous inequality reduced participants' happiness [$t(458) = -8.02$, $p << 0.001$; $t(465) = -15.64$, $p << 0.001$, respectively]. Crucially, participants' happiness was lower after advantageous inequality resulting from their own rather than their partner's decisions [$t(457) = -3.1488$, $p < 0.002$]. Analysis of fMRI data revealed clusters of voxels in dorsomedial prefrontal cortex (dmPFC), precuneus, bilateral temporo-parietal junction, insula and inferior frontal gyrus with significantly higher BOLD signal when participants experienced unequal compared to equal outcomes. Among those regions, a cluster in dmPFC (peak MNI coordinates = 4, 48, 44; $Z = 4.49$) showed higher activity during the occurrence of unequal than equal outcomes when these outcomes resulted from decisions of the participant rather than the partner (interaction). All reported neuroimaging results survive thresholding at $p = 0.05$ corrected for multiple comparisons (FWE) at the voxel or cluster level. Our results thus suggest that the dmPFC is a part of the neural mechanisms engaged when experiencing unequal outcomes for which one is responsible.

Title: Shifting Expectations: Criterion shift association of Electroencephalography, in a recognition memory security patrol paradigm.

Authors: *C. G. BOARDMAN[1], E. A. LAYHER[1], M. B. MILLER[1], J. M. VETTEL[2];
[1]Univ. of California Santa Barbara Neurosci., Santa Barbara, CA; [2]CCDC Army Reserch Labratory, Adelphi, MD

Abstract: Depending on the situation, it may be prudent to switch between a liberal and a conservative criterion. For instance, security personnel should maintain a liberal criterion when questioning individuals at a security checkpoint. However, when use of physical force on suspected individuals is anticipated, a conservative criterion should be used to minimize the risk of harming a potentially innocent person. Here we use EEG to explore the temporal and oscillatory dynamics associated with maintaining a conservative versus liberal criterion during a recognition security patrol task. We predicted that maintaining a conservative versus liberal criterion would be associated with a large positive event-related potential (ERP) peak around 300ms after stimulus onset (P3) and the more loosely defined late positive potential (LPP). Previously our work had indicated that the tendency to shift varies greatly between individuals, some shift easily while others do not shift at all. However individual tendency to shift is highly stable. We predicted that EEG oscillation power over time would be correlated with individual tendency to shift between liberal and conservative criterion placement.
In a screening task, we identified 31 EEG participants (aged 17-28, 7 male) who sufficiently shifted their criterion when instructed to focus on avoiding targeting innocent people in the conservative condition and to focus on avoiding missing suspicious people in the liberal condition. We found that maintaining a conservative versus liberal criterion is associated with a modest increase in frontal power ($F=10.54$, $p<0.003$, $r^2=0.20$) in the P3 range (600-850ms post stimulus), coinciding with large positive peaks in conservative>liberal contrast waveforms. Additionally, we created correlations between ERSP power (1-30 Hz) and individual tendency to shift. We averaged ERSP power over 193ms intervals, adjusted correlation p values using the Benjimaini and Hochberg method (fdr=0.05), and averaged over 9 brain regions (left, midline, and right, frontal, central, and posterior). We found high alpha and beta power was negatively correlated with individual tendency to shift across for hits and correct rejections, but not for misses or false alarms. This effect appeared in all brain regions when maintaining a liberal criterion, with the largest liberal correct rejection correlations around 13-21 Hz in the right prefrontal cortex (mean r=-0.59, mean adjusted p=0.006), from 300-3,000ms post stimulus. Overall, our results show maintaining a conservative criterion is associated with P3 and individual criterion shifting affects may be observed in oscillatory dynamics.

Title: The resolution of stimulus- and action-based choices is mediated by different dynamics of brain oscillations.

Authors: *E. PIERRIEAU, J.-F. LEPAGE, P.-M. BERNIER;
Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: It has been shown that conflict processing in the context of instructed choices is associated with increased midfrontal theta, possibly driven by a microcircuit including the supplementary motor area and the midcingulate cortex, and involved in conflict detection and signaling through synchronization with task-relevant regions. Here we test whether similar modulations are also observed when conflict arises from action costs. 31 participants (15 females) performed an action selection task by reaching with their right arm toward one of two visual targets. In instructed choice trials, participants had to reach the target indicated by a central arrow, surrounded by peripheral arrows which directions could be congruent or not, thus manipulating the level of conflict (flanker task). In free choice trials, the presented stimulus was non-directional and participants could reach the target they preferred. Target positions were manipulated so that one target was biomechanically preferable or both targets were similarly preferable, thus inducing low and high conflict, respectively. Results showed that in spite of similar sensory input and motor output, brain oscillations were differently modulated by the context of choice. In instructed choices, conflict was associated with higher midfrontal theta power and lower contralateral sensorimotor beta power, a finding consistent with results from previous studies. However, these results were not observed in free choices, as conflict was rather associated with lower parieto-occipital beta power. Overall, these results indicate that the resolution of stimulus and action-based conflicts involves distinct circuitries, suggesting that this process is not centralized in the brain but instead differs depending on the level of abstraction of decisional variables.

Title: Functional connectivity of human risk decisions: Cognitive control and systematic deviation from risk neutrality

Authors: T. ASAMIZUYA[1], H. TAKESUE[2], S. OTA[3], *J. KATO[4];
[1]The Univ. of Tokyo, Tokyo, Japan; [2]Tokyo Metropolitan Univ., Tokyo, Japan; [3]Meiji Univ., Tokyo, Japan; [4]Grad. Sch. of Law and Politics, Tokyo, Japan

Abstract: <META NAME="author" CONTENT="加藤 淳子">Functional connectivity of human risk decisions: Cognitive control and systematic deviation from risk neutrality
Takeshi Asamizuya, Hirofumi Takesue, Shozo Ota, and Junko Kato
Human rational decision making is often considered based on objective evaluation of probabilities and outcomes. Prospect theory challenges this presumption and illuminates the systematic deviation of human decisions, i.e., risk aversions and risk seeking, respectively, when outcomes are framed as gain and loss. The psychological principles have attracted much attention of cognitive scientists, but the underlying brain mechanism is still unknown. This fMRI study estimated the value functions of risk decisions when subjects drew the lotteries both in the gain and loss framings and examined the functional connectivity across activated regions. Activation was found when making risk decisions in the BA 10, BA 32, the bilateral, ventral anterior insula, and the precuneus. When decisions were made along with prospect theory, i.e., risk aversion to gain outcomes and risk seeking of loss outcomes, the functional connectivity was strengthened from BA32 to BA10. The result implies that systematical deviation from risk neutral choices result from the connectivity of the regions implicated with cognitive control. Moreover, stronger connectivity from BA10 to BA32 was specific to risk seeking in expectation of losses, but the bilateral connectivity between the right anterior insula and BA32 was strengthened only by risk aversion expecting gains. Connectivity between the precuneus and the left anterior insula was just the opposite, i.e., strengthened from the precuneus in risk aversion for gains but from the left anterior insula in risk seeking to avoid losses. Overall, our functional connectivity analyses imply that the systematic deviation from risk neutrality result from the working of cognitive control. Social cognition might play a role in risk aversion in gain framing, but metacognition, that is, high executive control, in risk seeking in loss framing.

Title: The value of politics: Neurobiological representations of political valuation

Authors: *B. B. LU, P. W. GLIMCHER;
Ctr. Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY

Abstract: Unlike value-based decisions, it is unclear if political decisions are made using a principled evaluation of alternatives. Social scientists have long considered political preferences to be a privileged class of decision-making, much like religious beliefs, that defy logical thought processes. It is thus tempting to assume that political preferences are represented in the brain by a unique set of neural processes or structures. Broadly-based studies of valuation, however, have revealed that nearly all valuations that guide decision-making are represented in the medial prefrontal cortex and striatum. These areas are known to accurately represent individual-specific subjective values for monetary rewards, lotteries, consumer goods, aesthetic judgements, charitable contributions, and social interactions. In this

study we asked whether a construct as complex as a political preference uses the same neural machinery that seems to represent all previously studied subjective valuations using a "common neural currency". Building on prior work our lab, we scanned forty participants with political preferences that span the American political spectrum using a novel psychophysical task that orthogonalizes partisanship and political information. Functional MRI scans were completed while subjects made preference ratings on real proposed laws that have appeared before US Congress. They first reported their preferences based solely on a synopsis of the law, and about 30m later reevaluated those preferences (all while in the scanner) after learning about the actual percent of members of Congress in each party who voted in favor of the law. Subjects thus stated their preferences for each law before and after receiving information about the true partisan support for each law. The laws' true congressional support were, by design, completely uncorrelated with the participants' estimates of that support.
We observed that participants' political preferences shifted dramatically when the true partisan support was revealed. These data allow us to identify the neural representation of political valuation both before and after partisan information was revealed. Preliminary results suggest that political valuation is represented in the common subjective value network.

Title: Talk informatively: shared dmPFC coding of informativity in listener and speaker

Authors: *Q. MI, L. ZHU;
Peking Univ., Beijing, China

Abstract: Objective Human communicates informatively. Recent development in computational linguistics has proposed that--similar to value-based decisions--a speaker selects an expression to deliver certain intention based on the amount of information contained in the expressions, and a listener interprets the received expression as a rational decision made by the speaker. Although these theories highlight the central role of informativeness in communication in a manner analogous to value in goal-directed behavior, no direct evidence is available that the brain indeed evaluates informativeness of expressions in conservational contexts. Here, by combing fMRI, computational linguistics, and game theory, we investigate whether and how expression informativeness, as quantified by Shannon information, is represented in patterns of neural activity in listeners, and whether listeners and speakers have similar or distinct underlying patterns in coding communicative informativeness. **Methods** Employing a well-established communicative game previously used to investigate neurocomputations of intentional

communication, we conducted two independent fMRI experiments (N1=34, N2=26). The first is to establish the informativeness representations in listeners, and the second is to replicate the listeners results and then to evaluate the degree to which the identified patterns could be generalized across contexts and to speakers. **Results** Multivariate analyses show that expression informativeness, derived on a trial-by-trial basis, is robustly represented in patterns of neural activity in the listener's dorsal medial prefrontal cortex (dmPFC). Interestingly, further analyses suggest that the listener and speaker dmPFC use a common neural coding to represent the same amount of expression informativeness across different communicative contexts. **Conclusion** These results support a model of intentional communication whereby the effective interpretation and production of communicative signals arises from evaluating expression informativeness, providing a neurocognitive basis for rational communication accounts.

Title: Convergent evidence indicates that activity in distinct neural circuits predicts risk seeking versus avoidant choices

Authors: *L. MORTAZAVI[1], C. C. WU[1], B. D. KNUTSON[2];
[1]Stanford Univ., Stanford, CA; [2]Dept Psychology, Stanford Univ. Dept. of Psychology, Stanford, CA

Abstract: Functional Magnetic Resonance Imaging (FMRI) evidence has implicated cortical and subcortical circuits in risky choice, but whether activity in one or more circuits predict risky choice remains unclear. We convergently analyzed original data using a temporally staged risky gambling task to identify neural activity that predicted risk seeking versus averse choice (Leong et al., 2018), and then applied a classifier derived from that data to predict risky choice in a different risky gamble dataset (Tom et al., 2007). For original data, healthy participants (n=20) were scanned using FMRI as they chose between risky gambles for actual money or a no-risk/no-outcome option. Risky options were equated for expected value and variance but varied with respect to skewness (i.e., positive skew: 25% +$5.25, 75% -$1.25; symmetric: 50-50% +/-$3.05; negative skew: 75% +$1.25, 25% -$5.25). Based on the Affect-Integration-Motivation framework, activity immediately prior to choice was extracted from targeted Volumes Of Interest (VOIs) in the Nucleus Accumbens (NAcc), Anterior Insula (AIns), and Medial PreFrontal Cortex (MPFC) and submitted to models that predicted risky choice on a trial-to-trial basis. As predicted, NAcc and MPFC activity predicted risk-seeking choices but AIns activity instead predicted risk-averse choices. A whole-brain linear model as well as a model-free classifier (i.e., Support Vector Machine with Recursive Feature Elimination) confirmed that activity in these regions (but not sensorimotor regions) predicted risky choice. To test the features' generalizability, the classifier was applied to a distinct risky choice dataset (i.e., the Mixed Gambles Task of Tom et al (2007)). Despite

differences in task, sample, and scanner, activity from the same regions predicted risky choice with comparable effect sizes. Thus, neural features that predict risk-seeking choices are distinguishable from those that predict risk-averse choices, and each may be associated with different types of anticipatory affect. Together, these findings also further identify and refine a “risk matrix” of reliable, valid, and generalizable neural features that predict risky choice.

Title: Neural Representation of Expectations on Somatic Pain, Vicarious Pain, and Cognitive Effort

Authors: *H. JUNG[1], L. SLIPSKI[1], M. AMINI[1], M. HEILICHER[2], B. J. HUNT[1], E. I. MURPHY[1], X. HAN[1], P. A. KRAGEL[3], M. A. LINDQUIST[4], T. D. WAGER[1];
[1]Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Univ. of Colorado Boulder, University of Colorado Boulder, CO; [3]Dept. of Psychology, Emory Univ., Atlanta, GA; [4]Dept. of Biostatistics, Johns Hopkins Univ., Baltimore, MD

Abstract: Expectations can shape the way we perceive the world. For example, word of mouth on a difficult math exam may shape one's test performance. However, studies to date have examined expectations in separate domains, i.e. cognitive and affective, which does not allow for comparing or contrasting neural representations of expectation across different domains. These neural representations may be strikingly different ("domain-specific"), or they may indicate the existence of a common representation that acts upon different experiences ("domain-general"). We used fMRI to compare the neural representation of expectations and their influence on stimulus perception across domains: via thermal pain, vicariously observed pain and cognitive mental rotation tasks. On each trial, participants were presented with perceived social cues (high/low) and then asked to rate their expectations to a subsequent stimulus intensity (pain/vicarious/cognitive); afterwards, they would experience the stimulus and subsequently rate their experience. We preregistered an analysis plan for a target sample of 120 participants; here, we present preliminary results from 18 participants. We compared the 1) non-modulated stimulus experience phase and 2) cue-modulated stimulus experience phase across three tasks, within-participants. The non-modulated pattern of activation in response to the stimuli, averaged across seven networks (Buckner et al., 2008), was different across task domains. In addition, the patterns of cue-modulated activations were also found to be significantly different across task domains, suggesting that cue-modulated expectation effects are domain-specific. From this, we plan to conduct a mediation analysis using the univariate/multivariate x domain-specific/domain-general parametric modulation maps, per our pre-registered plan. By identifying the neural mediators that link expectation cues and experience,

these findings will advance our understanding of the neural representation of expectations and modulated experiences.

Title: Overlapping functional networks in the mouse brain

Authors: *H. VAFAII[1], F. MANDINO[3], D. O'CONNOR[4], X. PAPADEMETRIS[3], T. CONSTABLE[3], E. M. R. LAKE[3], L. PESSOA[2];
[1]Physics, [2]Psychology, Univ. of Maryland, College Park, MD; [3]Radiology & Biomed. Imaging, [4]Biomed. Engin., Yale Univ., New Haven, CT

Abstract: Large-scale functional connectivity analysis has revealed a highly modular community structure. A common strategy in studying these networks is using disjoint community detection algorithms that assign a binary membership value to each region. Recent findings suggest this may not be the most effective approach, as some regions (e.g., hubs) likely participate in multiple networks. Here, we studied overlapping community organization in a functional MRI dataset of N=10 mice scanned under light anesthesia using a mixed-membership Bayesian model. This model allows each brain region to belong to all communities simultaneously with varying membership values — a measure of a region's "belonging" strength to communities. The results showed that the majority of regions resided on dense overlaps between communities, and only a minority of regions exhibited sharp memberships to a single network. To test the reliability of our approach, we collapsed the membership distribution of each node to its maximum value and obtained disjoint communities as a special case. Doing so allowed us to recover the network structure observed by other researchers that used standard disjoint algorithms. Thus, our approach finds reproducible results that provide information lost by using standard alternatives. Next, we identified the most prominent networks, including a Default Mode Network (DMN), a latero-cortical network, and a visual network. Our analysis suggests that the mouse DMN involves three different subnetworks: 1) a cortical component that contains anatomical hubs such as Retrosplenial and Anterior Cingulate areas; 2) a midline subnetwork that partially intersects with somatosensory and motor areas; and 3) a network containing bridges between cortex and subcortical areas including Agranular Insula, Ectorhinal, and Perirhinal areas. Furthermore, we used Shannon entropy to quantify the membership diversity of regions. Combining the entropy measure with the measure of degree centrality revealed three major brain region types: i) low degree, high entropy: hubs in the DMN joined by long-range anatomical

pathways; ii) high degree, high entropy: mostly belonging to the midline subnetwork of DMN; and iii) high degree, low entropy: exclusively from sensory networks with dense, local connectivity. Such characterization illustrates the type of information that is gained by using the proposed approach, and which is lost by standard non-overlapping methods. Taken together, our results demonstrate the utility of overlapping community detection in quantifying the membership diversity of brain regions and understanding the rich patterns of functional interactions in the brain.

Title: Investigating the neural and behavioral basis of Dynamic Functional Connectivity

Authors: *D. THIBODEAUX[1], S. SHAHSAVARANI[3], C. J. NWOKEABIA[1], W. XU[1], F. LODGHER[1], D. A. HANDWERKER[4], J. GONZALEZ CASTILLO[5], P. BANDETTINI[6], E. M. HILLMAN[2]; [2]Biomed. Inst. of Mental Hlth., Bethesda, MD; [5]SFIM/LBC/NIMH/NIH, Bethesda, MD; [6]Section on Functional Imaging Methods, NIMH-NIH, Bethesda, MD

Abstract: Resting state functional magnetic resonance imaging (rs-fMRI) has revealed brain-wide correlation patterns throughout the human brain, interpreted as functional connectivity. Dynamic Functional Connectivity (dFC) expanded on this technique via sliding window correlation analysis, revealing moment-to-moment changes in functional connectivity across an imaging session. However, the meaning of these transitions in terms of neural activity and behavior are not well understood.
In this work, we utilized dFC analytical techniques in conjunction with Wide Field Optical Mapping (WFOM) in the awake, behaving and anesthetized mouse. We hypothesized that the neural activity observed with WFOM would exhibit similar transitions between functional connectivity states as reported by fMRI dFC studies. We also explored whether changes in functional connectivity would correspond to changes in behavioral state, during both awake and anesthetized conditions.
Simultaneous neural and hemodynamic activity was collected using WFOM from 5 freely behaving head-fixed Thy1-jRGECO1a mice. Behavioral metrics such as movement, whisking and pupillometry were also acquired simultaneously. Raw neuroimaging data was dimensionally reduced to 92 representative time courses across the dorsal surface of the cortex for each subject utilizing a semi-supervised clustering technique. A 10 second sliding window was then used to calculate moment-to-moment dFC maps across each session. These dynamic correlation maps were k-means clustered into 7 dynamic states, which could

then be used to calculate the most representative state for any given epoch.
dFC analysis revealed a diverse set of brain states, with some states exhibiting a notable desynchrony between visual and frontal motor regions. Behavioral metrics during state transitions revealed consistent, unique trends within dynamic state changes. States with low, desynchronous correlations had little to no movement and exhibited pupil constriction. Alternatively, other states exhibited elevated behavioral metrics with differing temporal trends, indicating that some dynamic states represent specific behavioral sequences, such as movement onset. During anesthesia-induced immobility, dFC analysis revealed systematic changes in brain state metrics that closely matched awake states during voluntary immobility, a property that was quickly reversed after recovery. These results suggest that dFC analysis is capturing stereotyped spontaneous neural fluctuations and that movement has an immediate and widespread impact on neuronal Functional Connectivity.

Title: Bridges or Mirages Connector Hubs and Inter-Subject Variation in Connectivity Profiles

Authors: *D. M. SMITH[1], A. DWORETSKY[1], B. KRAUS[1], E. M. GORDON[2], C. GRATTON[1]; [1]Psychology, Northwestern Univ., Evanston, IL; [2]Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Connector hubs (hubs) are regions with connections evenly distributed across functional brain networks, found most commonly in association cortex. Because of these characteristics, hubs are hypothesized to play a critical role in network structure and in contributing to higher-level cognitive control functions. However, the hub literature is primarily based on group average functional connectivity and recent work has demonstrated that association regions of the brain can also show substantial inter-individual variation. This raises the question of whether putative hubs are mirages, only appearing hub-like due to their correspondence with locations of pronounced individual differences in connectivity profiles. To answer this question, we compared the locations of typical (group-level) hubs and regions of idiosyncratic functional connectivity ("network variants") in both the Midnight Scan Club and Human Connectome Project datasets. Group hubs defined based on participation coefficient (a measure of how evenly distributed a node's connections are between networks) did not overlap strongly with network variants. In contrast, group hubs defined based on community density (a measure of the number of networks present within a certain radius) were shown to overlap substantially with network variant locations. Additionally, in single subjects, typical hubs showed connectivity profiles with a good degree

of similarity to the group average. Our results demonstrate that group hubs are not simply driven by the presence of large inter-subject variations in connectivity profiles, suggesting that they may represent real elements of brain networks. In contrast, our findings suggest caution is warranted when defining hubs based on community density, which may be associated with inter-subject variation in the boundaries of functional brain networks.

Title: The functional relevance of flexible hub connectivity in cognitive control networks

Authors: *C. V. COCUZZA[1], R. D. MILL[2], M. W. COLE[1];
[1] Rutgers Univ. Ctr. for Mol. and Behavioral Neurosci., Newark, NJ; [2]Rutgers Univ. Ctr. for Mol. and Behavioral Neurosci., Newark, NJ

Abstract: Increasing evidence suggests that cognitive processes are shaped by brain network interactions, yet it remains unclear how task-driven changes in those interactions relate to changes in cognitive information processing. We sought to address this gap in the context of cognitive control, which is the flexible implementation of goal-directed cognition and behavior. In prior work we established that connectivity patterns in two large-scale cognitive control networks - the frontoparietal and cingulo-opercular networks - exhibit flexible hub mechanisms in support of cognitive control. We have observed that cognitive control network regions dynamically reweight their connectivity in a systematic, task-relevant manner, which prompts the question of how such reconfigurations instantiate cognitive control. To address this, we utilized a recently developed approach for mapping activity flow processes: the movement of task-evoked activity between neural populations. Importantly, these models are constrained by empirical connectivity estimates, which allows us to probe the functional relevance of task-based connectivity changes. To determine the network mechanisms underlying cognitive control, we used resting- and task-state fMRI data of N=41 healthy adult participants. During task fMRI participants engaged with a rapid instructed task learning (RITL) paradigm that demanded high levels of cognitive control via rapid switching amongst 64 permuted rule sets (all participants performed with above-chance accuracy: mean=76.84% correct, S.E.M.=1.99). The activity flow model exhibited high prediction accuracy of task-evoked activations across RITL states and cortical regions (r=0.82, p<0.01), which suggests that distributed processes specified by task-state functional connectivity changes have a dominant influence upon cognitive-control-related activity across the cortex. We found preliminary evidence that activity-flow-based prediction accuracy was higher for cognitive control network regions

exhibiting stronger flexible hub properties, suggesting a particularly important functional role for flexible hubs in the generation of task-evoked activations during cognitive control tasks. Together these results provide a mechanistic framework for understanding the functional role of task connectivity changes implemented via flexible hubs in the generation of cognitive control.

Title: Evaluating the reliability, validity, and utility of overlapping networks: implications for cognitive control

Authors: *S. COOKSON[1], M. D'ESPOSITO[2];
[1]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [2]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: The Dual Networks model posits that two whole-brain networks, the frontoparietal (FPN) and cinguloopercular (CON), subserve distinct aspects of cognitive control (Dosenbach et al, 2008). While this model has been a fruitful basis for ongoing study, it does not propose a defined mechanism for integration between the FPN and CON, nor does it capture the role of other potentially relevant networks. The model's incompleteness is in part due to a common assumption in network neuroscience - namely, the implicit assumption that regions are members of one primary network, i.e., that networks do not overlap. The methods borne out of this assumption lose crucial information not only about individual regions' connections to multiple networks but also the specific networks they bridge between. Here, we explore the between-sample reliability, relative validity, and practical utility for a method of assigning regions to multiple overlapping networks, using the Dual-Networks model as an example case for potential applications. This method, the "mixed membership algorithm", assigns regions a probability distribution across a predefined number of overlapping "communities" (Najafi et al, 2016). Using a 200-subject sample of 15-minute resting state data from the Human Connectome Project (van Essen et al, 2013), we conducted a series of topographic comparisons with the communities generated by this algorithm using a bootstrapped Dice coefficient analysis. To assess reliability, we split the data into two halves and compared the communities generated for each, showing good agreement between samples. To assess validity with the greater literature, we compared the communities from the full 200 subjects with nonoverlapping networks generated using established methods (Yeo et al, 2011), revealing a close 1:1 relationship between most of the networks and a single unique community. Finally, to demonstrate the utility of overlapping networks for cognitive applications, we assessed the community membership of the regions of the FPN and CON. These regions were revealed to be members of more than two communities

and that all of them were members of multiple communities, suggesting potential areas of overlap between the FPN, CON, and other networks that may support their integration.

Title: Executive task fMRI activations overlap and diverge in domain-general cortex following fine-grained resting-state architecture

Authors: *M. ASSEM[1], S. SHASHIDHARA[2], M. F. GLASSER[3], J. DUNCAN[4];
[1]MRC Cognition and Brain Sci. Unit, Univ. of Cambridge, Cambridge, United Kingdom; [2]Psychology department, Ashoka Univ., Sonipat, India; [3]Dept. of Neurosci. & Radiology, Washington Univ. Sch. of Med., Saint Louis, MO; [4]MRC Cognition and Brain Sci. Unit, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Domain-general or multiple-demand (MD) cortex refer to a set of frontal, parietal and occipito-temporal cortical patches that are co-activated by many different kinds of demanding cognitive tasks. Numerous studies of tasks targeting different components of executive functions show co-activations of MD cortex, but the limited spatial resolution of traditional imaging methods blurred the line between overlapping and segregated activations for the different components. Here we used state-of-the-art multimodal MRI techniques of the Human Connectome Project (HCP) to scan subjects performing three kinds of executive tasks: working memory, set shifting and inhibition; each with a hard and easy version. In line with a “common” executive function component, the hard>easy contrast showed robust overlaps in MD cortex at the single subject level. But in line with relatively specialized components, each task showed different and precise quantitative variations in MD activations. Peaks of activation for each task often lay at the borders between MD and more specialized regions, with different peaks for different executive demands.
Using an independent HCP resting-state dataset, we found that seed regions within MD cortex show differential connectivity patterns that closely predict each task’s precise topography. Most prominently, inhibition showed right lateralized activations at the borders between MD and cingulo-opercular networks (e.g. dorsal frontal border between p9-46v (MD) and 46). Set shifting showed left lateralized activations prominent in IFJp and the ventral border of p9-46v. Working memory showed overlaps between MD and dorsal attention networks (e.g. dorsal frontal i6-8 (MD) and 6a).
Collectively, these results show that the three executive tasks engage a common cortical MD network. The detailed pattern of activity, however, is modulated according to each task’s content. Using precise

imaging methods, the results suggest domain-specific networks closely interact with their neighbouring MD cortex to generate distinct executive functions.

Title: Human thalamic hubs shape task-evoked activity across multiple cognitive domains

Authors: E. SORENSON, ***K. HWANG**;
Univ. of Iowa, Iowa City, IA

Abstract: Evidence from resting-state functional connectivity studies suggests that the human thalamus is a network hub well suited for promoting integrative functions (Hwang et al. 2017; Greene et al. 2020). Such connectivity properties predict that a single thalamus hub integrates multiple cognitive functions, and thus a diverse range of cognitive and behavioral tasks should induce a common converging activation profile in thalamic hubs. The goal of our study is to evaluate this prediction. Our study used the Multi-Domain Task Battery dataset (MDTB; King et al. 2019) that included 24 participants, who performed 26 unique tasks across multiple domains. We then used PCA to identify thalamic evoked response patterns that are associated with task-general activities across multiple domains. The PCA summarized multi-task activity with 10 components, with the first three PCA components collectively explaining 78.8% of the variance. The first PCA component shows significant activation in the posterior thalamus while the

second component shows strong activation in the medial thalamus. Using the loadings from PCA, the second component was shown to have the least variance across tasks and likely represents a task-general activity pattern in the thalamus. The activation of the posterior and medial regions of the thalamus overlap with thalamic connector hubs previously identified using resting-state functional connectivity data. Furthermore, the calculated connector hub values, estimated using the task activation data and hierarchical clustering of task activation patterns, are similar to those calculated using resting-state functional connectivity data. To determine to what extent task-general thalamic activity influences task-evoked cortical activity, we performed thalamocortical activity-flow analysis (Cole et al., 2016) to compare observed cortical task-evoked responses with responses predicted by thalamocortical activity. We found that thalamic evoked response propagated through thalamocortical functional connectivity can significantly predict cortical evoked responses across different tasks (averaged r across tasks = 0.4149, std = 0.1884, $p<.001$). Our findings suggest that thalamic hubs support a wide range of cognitive tasks and shape cortical cognitive task activations. Specifically, task-general evoked responses in the medial thalamus can influence region-wide cortical evoked responses via the thalamic hub's extensive connectivity with cortical systems.

Title: Interactions among frontal-parietal and cingulo-opercular networks supporting cognitive control

Authors: *J. L. WOOD, D. E. NEE;
Dept. of Psychology, Florida State Univ., Tallahassee, FL

Abstract: Cognitive control involves directing one's actions based on current and future relevant demands. The frontoparietal control network (FPCN) has been shown to fractionate as a function of cognitive control demands such that rostral-most regions are selective for future-oriented planning or temporal control, mid-regions for adapting behavior according to contextual circumstances or contextual control, and caudal regions for linking stimulus to action or sensory-motor control. Furthermore, this somatomotor distal to somatomotor proximal control demand organization maps onto an abstraction gradient representing future to current behavioral demands, respectively. Concurrently, the cinguloopercular network (CON) is engaged during control tasks, yet the organization of the regions therein and their specific interactions with the FPCN remain unknown. This study analyzed fMRI data on two separate groups of young, healthy participants who completed a comprehensive control task designed to elicit the three proposed control demands: temporal control, contextual control, and sensory-motor control. Areas within the CON fractionated as a function of temporal and contextual control – the dorsal medial prefrontal cortex (dmPFC) mirrored the FPCN in a rostro-caudal manner, while the anterior Insula

(aI) showed a ventral-dorsal gradient. We next considered the brain-behavior relationships through each region's correlation with current and future behavior. CON temporal control regions were positively correlated with future trial reaction time while contextual control regions were positively correlated with current trial reaction time, a pattern mirroring the FPCN. To further distinguish the CON and FPCN interactions on behavior we employed a set of mediation analyses within- and between-networks. Results showed that the relationship between CON contextual regions and current trial reaction time was fully mediated by the FPCN contextual regions. Likewise, the relationship between CON temporal regions and future trial reaction time was fully mediated by FPCN temporal regions. Further dividing the CON regions showed a serial order of the dmPFC and the FPCN mediating the relationship between the aI upon relevant control behavior. Collectively, the data indicate separable aI to dmPFC to FPCN to behavior interactions for temporal and contextual control, respectively. These results show an important separation between the highly interconnected CON regions as well as the interactive relationship between the FPCN and CON during cognitive control.

Title: Noradrenergic modulation of brain network topology and energy landscape dynamics mediates conscious perception under perceptual ambiguity

Authors: *G. WAINSTEIN[1], K. A. EHGOETZ MARTENS[2], V. MEDEL[3], E. J. MÜLLER[4], B. MUNN[4], B. ANDERSON[2], E. STÖTTINGER[5], J. DANCKERT[2], J. M. SHINE[3];

Abstract: Previous studies investigating the perceptual updating and bistable perception have consistently implicated a distributed set of regions within the cerebral cortex. Indeed, its activity is consistent with the broader notion that cognitive capacities arise from the coordinated interactions amongst interconnected networks. Despite these clear links, less is known about the neurobiological basis of its modulation in shaping the large-scale network. On this matter, the Locus Coeruleus noradrenaline system is well-suited to mediate the large-scale brain state switches required to flexibly alter conscious perception. In previous work, it has been argued that phasic release of noradrenaline from the LC acts as a "network reset" signal, which effectively disrupts ongoing processing allowing animals to reconfigure their ongoing neural dynamics. Based on these concepts, we hypothesized that the resolution of perceptual ambiguity is intricately related to LC activity which act as a 'network reset' to reconfigure conscious awareness to resolve perceptual uncertainty. To test this hypothesis, we used a cognitive task

designed to augment perceptual ambiguity. The task consisted on a set of transforming images that transition from an initial object (e.g., a plane) into a second object (e.g., a shark; Figure 1A) and subjects were instructed to press a button to indicate the perceptual change. Crucially, conscious awareness of a change in stimuli to a second object is known to 'pop out'. To test our hypothesis, we analyzed both pupillometric data (Figure 2B) - a robust marker of LC activity- and fMRI data to track the putative impact of LC on brain network dynamics in light of graph theory analysis such as network-level integration (Figure 2C-D) and energy landscape changes. We confirmed our hypothesis that phasic bursts of LC activity increases network integration and perceptual changes are related to peaks in pupil diameter, which leads to the resolution of perceptual ambiguity.

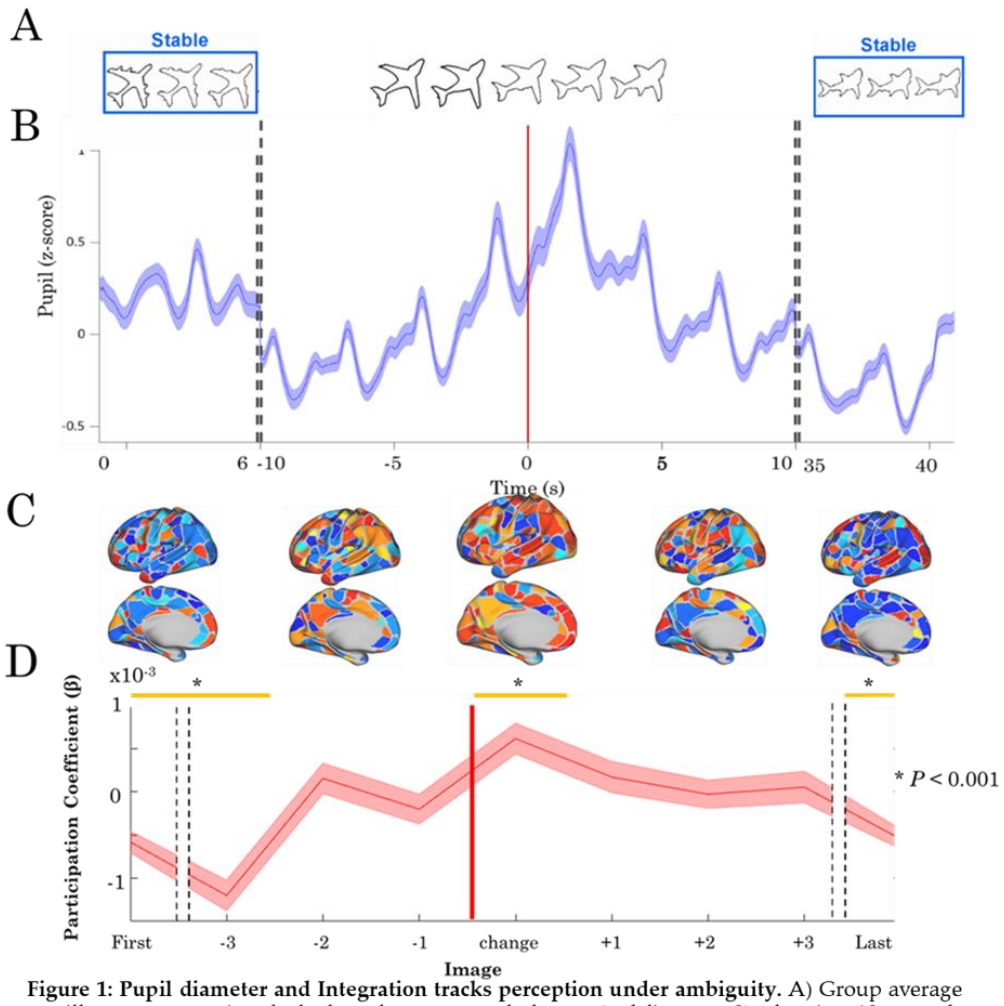

Figure 1: Pupil diameter and Integration tracks perception under ambiguity. A) Group average pupillary response time locked to the perceptual change (red line, t = 0), showing 10 seconds around that point. The first and last 6 seconds are shown in the left (right) section of the plot (dotted line). B) Brain cortical map representation of the evoked participation coefficient (i.e., βPC). Color represent the loading of the PC with red being positive and blue negative. C Average βPC for each regressor across all subjects and regions. Orange bars shows the significant regressors ($\beta \neq 0$, $p_{FDR} < 0.001$). Red vertical line represents the perceptual change.

Abstract: Non-invasive brain stimulation (NIBS) technologies such as transcranial direct current/alternating-current stimulation (TCDS/TCAS) and transcranial magnetic stimulation (TMS), have quickly outpaced advances in techniques for neuronavigation. Recent evidence suggests that the effectiveness of TMS for clinical depression treatment not only depends on the spatial accuracy of the area to be stimulated, but also on the patient's unique brain connectivity. Current methodologies for targeted brain stimulation rely on measuring a fixed distance from the motor cortex, based on the EEG 10-20 positioning system, or real-time, neuronavigation based on stereotactic image-guided positioning based upon the patient's neuroanatomy. However, recent evidence suggests that the spatial correspondence of functional topography is highly variable across participants, which could be a source of the variability in NIBS intervention outcomes. Using precision functional brain mapping methods from resting-state fMRI data in 6,106 9-10 year olds from the Adolescent Cognitive Brain Development (ABCD) study, we created a new open-source, method-flexible set of probabilistic network atlases: the Masonic Institute for the Developing Brain (MIDB) Precision Atlas.
Using a MIDB probabilistic map of the frontoparietal network, we demonstrate that a seed placed within a region of high network probability (0.75) within the dorsolateral prefrontal cortex (DLPFC) showed consistent anticorrelation with the subgenual cortex, (a connection targeted in NIBS treatment for clinical depression), both in the adults from Midnight Scan Club (n =10) and subset of ABCD subjects (n=10). However, when the seed was moved slightly outside of the region of high network consensus to a region

with high network heterogeneity (0.35 probability), the correlation with the subgenual cortex was inconsistent. These results provide one potential use case for the MIDB precision atlas and the associated probabilistic templates that provide a frame of reference for spatial location of a network of interest when conducting therapeutic brain stimulation.

Title: Diurnal fluctuations in testosterone tied to variation in intrinsic functional connectivity in a densely sampled male

Authors: *H. GROTZINGER[1], L. PRITSCHET[1], T. SANTANDER[1], E. G. JACOBS[1,2];
[1]Psychological and Brain Sci., [2]Neurosci. Res. Inst., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Sex hormones are powerful neuromodulators of learning and memory, influencing the brain at the level of microscopic intracellular events to macroscopic brain organization. A central feature of the mammalian endocrine system is that hormone secretion varies over time. Human neuroimaging studies that densely sample individuals over timescales of days, weeks, and months provide unique insight into the role our endocrine system plays in regulating the dynamic properties of the human brain. For example, we recently established estrogen's ability to drive widespread patterns of connectivity and enhance the global efficiency of large-scale brain networks in a densely-sampled female (Pritschet et al., 2020). In men, sex hormone production follows a sinusoidal pattern with a peak in testosterone between 6-7am and nadir between 7-8pm. To capture these diurnal changes in hormone production, a male participant (age 26) underwent brain imaging (T1, T2 hippocampal, and resting state fMRI scans) and venipuncture every

12-24h for 30 consecutive days, resulting in 40 sessions. This dense-sampling, deep-phenotyping approach offers a unique opportunity to probe the relationship between testosterone and functional brain networks with high spatiotemporal precision. Results confirmed diurnal fluctuations in testosterone, cortisol, and estradiol, with decreases of ~63%, ~92%, and ~89%, respectively. Standardized regression revealed predominantly positive associations between whole-brain patterns of coherence and total testosterone, cortisol, and estradiol concentrations. In particular, nodes in the Salience/Ventral Attention and Dorsal Attention networks displayed the strongest associations with all three hormone concentrations. Stratifying the data by morning and evening reveals fewer whole-brain patterns of coherence associated with testosterone concentrations in the evening, when testosterone concentrations are low, compared to morning sessions. Together, findings from this study enhance our understanding of testosterone, cortisol, and estradiol as rapid neuromodulatory hormones, and provides evidence that diurnal changes in steroid hormone production impacts whole-brain functional network architecture.

Abstract: Large-scale brain activity evolves dynamically over time across multiple time-scales. The structural connectome imposes a spatial network constraint since two structurally connected brain regions are more likely to coordinate their activity (*1*). It also imposes a temporal network constraint by virtue of time delays via signal transmission, which has modulatory effects on oscillatory signals (*2*). Specifically, the lengths of the structural bundles, their widths, myelination, and the topology of the structural connectome influence the timing of the interactions across the brain network. (*3*). We introduce a novel in vivo approach for directly measuring functional delays across the whole brain using magneto/electroencephalography and integrating them with the structural connectome derived from magnetic resonance imaging. We developed a map of the functional delays characterizing the connections across the human brain and a map of the corresponding functional velocities. This yields a topochronic map of the human brain dynamics. The functional delays are tightly regulated, showing, as expected, that larger structural bundles had faster velocities, with the delays varying much less than expected if they only depended upon distance (permutation test, $p<0.001$), both at the group and individual level. Then, we estimated the delays from magnetoencephalography (MEG) data in a cohort of multiple sclerosis

patients, who have damaged myelin sheaths, and demonstrated that patients showed greater delays across the whole network than a matched control group (KS test, $p<0.001$). Furthermore, within each patient, individual lesioned connections were slowed down more than unaffected ones (permutation test, $p<0.001$). Our technique provides a practical approach for estimating functional transmission delays in vivo at the single-subject and single-fiber level and, thus, opens the possibility for novel diagnostic and curative interventions as well as providing empirical, subject-specific constraints to tailor brain models.

Title: Global brain connectivity reliably predicts individual differences in intelligence

Authors: *E. D. ANDERSON, A. K. BARBEY;
Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Individual differences in human intelligence can be predicted from patterns of neurobiological connectivity spanning multiple brain networks. Much current theorizing into the neural basis of intelligence, however, has adopted a localizationist perspective, mapping human intelligence to a single specialized brain region or brain network. Current neuroscience evidence points to the importance of both specialized neurobiological systems and global network topology for predicting individual differences in intelligence, suggesting that purely localizationist theories of intelligence may fail to fully capture or

explain important sources of individual variation in cognitive ability. To what extent does neuroscience evidence support either global or localized neurobiological connectivity as a key source of individual differences? To further explore the systems-level neurobiology identified by state-of-the-art neuroscience theories of intelligence, we deployed a connectome-based predictive modeling framework to systematically investigate the predictive power of both localized and global functional connectivity patterns theorized in the literature to underpin intelligence. We administered a comprehensive battery of fluid and crystallized intelligence tasks to a large sample of healthy young adults (N=297), including figure series completion, LSAT analogical reasoning, Shipley-2 Vocabulary, and the Adult Decision-Making Competence Battery. Structural equation modeling was used to generate confirmatory factor loadings and produce individual estimates of general intelligence from this battery. Using reproducibly processed resting-state data, our connectome-based predictive modeling study found that intelligence was best predicted from global, whole-brain patterns of resting functional connectivity. In contrast, we observed low or non-existent performance for predictive models trained only on localized connectivity profiles. Critically, we found that weakly-connected edges known to support functional segregation and small-world organization are important neurobiological predictors of individual differences in intelligence, and that these edges were distributed across the entire connectome. Our results point to a need for neuroscience theories of intelligence that integrate specialized and necessary neurobiological substrates of intelligence within a larger information-processing architecture, suggesting important future directions for research into the neurobiological properties that underlie individual differences in cognitive ability.

Title: Two processing streams in response inhibition revealed by fMRI and time-resolved TMS

Authors: *T. OSADA[1], A. OGAWA[1], A. SUDA[1,2], K. NAKAJIMA[1,4], M. TANAKA[1], S. OKA[1], K. KAMAGATA[3], S. AOKI[3], Y. OSHIMA[4], S. TANAKA[4], N. HATTORI[2], S. KONISHI[1];

Abstract: Multiple cognitive processes are recruited to achieve adaptive behavior. However, it is poorly understood how such cognitive processes are implemented in temporal cascades of human cortical areas as processing streams to achieve behavior. In the present study, we used functional MRI (fMRI) and transcranial magnetic stimulation (TMS) to explore the multiple processing streams for response

inhibition. We first identified cortical areas critical for response inhibition in a stop-signal task with fMRI: the ventral posterior inferior frontal cortex (vpIFC), dorsal posterior inferior frontal cortex (dpIFC), presupplementary motor area (preSMA), and intraparietal sulcus area (IPS). To analyze the stream structure among the areas, network analyses with functional connectivity were performed: the vpIFC and preSMA belonged to the cinglo-opercular network whereas the dpIFC and IPS belonged to the fronto-parietal network. Next, single-pulse TMS (spTMS) was administered during performance of the stop-signal task by taking advantage of the high temporal resolution of spTMS. Each of the target areas was stimulated in half of the trials, and trials with and without stimulation were intermixed within runs. Prolonged stop-signal reaction time (SSRT), a behavioral index for response inhibition, was observed in spTMS to the vpIFC at the time window of -90 to -60 msec, with the end of the SSRT (i.e., stopping) for no-stimulation trials defied as zero (mean difference: 20.5 msec, $t(19) = 5.2$, $p = 4.9 \times 10^{-5}$, paired t-test). The dpIFC and preSMA showed a transient disruption effect at the subsequent time window of -60 to -30 msec (for the dpIFC, mean difference: 18.1 msec, $t(19) = 4.6$, $p = 2.1 \times 10^{-4}$, paired t-test; for the preSMA, mean difference: 17.2 msec, $t(19) = 4.6$, $p = 2.1 \times 10^{-4}$, paired t-test). The IPS showed a disruption effect at the time window of -30 to 0 msec (mean difference: 19.6 msec, $t(19) = 5.2$, $p = 4.7 \times 10^{-5}$, paired t-test). Finally, we tested whether or not the information flowed effectively from the vpIFC to the preSMA and from the vpIFC to the dpIFC during response inhibition. SpTMS following suppression of the vpIFC with repetitive TMS (rTMS) showed that prolonged SSRT was still observed by spTMS to the dpIFC, but not to the preSMA. A significant area (preSMA/dpIFC) × Pre/Post-rTMS interaction effect was observed in a two-way ANOVA of ΔSSRT ($F(1,19) = 11.9$, $p = 2.6 \times 10^{-3}$). These results indicate that the flow from the vpIFC to the preSMA was effective whereas the flow from the vpIFC to the dpIFC was not effective. Our study suggests two parallel processing streams for response inhibition (vpIFC-preSMA vs. dpIFC-IPS) where the vpIFC and dpIFC act as the origins, respectively.

Title: Effects of slow cortical potential neurofeedback on the contingent negative variation in children and adolescents with autism spectrum disorder

Authors: *K. PRILLINGER[1], S. T. RADEV[2], P. L. PLENER[1], L. KONICAR[1];
[1]Dept. of Child and Adolescent Psychiatry, Med. Univ. of Vienna, Vienna, Austria; [2]Inst. of Psychology, Univ. of Heidelberg, Heidelberg, Germany

Abstract: The contingent negative variation (CNV) is a well studied indicator of attention- and expectancy-related processes in the human brain. However, its role as a potential biomarker of successful clinical interventions in autism spectrum disorder (ASD) remains unclear.
With this randomized controlled trial, we investigated how the CNV changes following an intensive neurofeedback training. Twenty-one adolescents with ASD in the experimental group underwent 24 sessions of EEG-based slow cortical potential (SCP) training and were compared to twenty adolescents with ASD in the control group receiving treatment as usual. During SCP training, feedback was provided at the participants' monitor as an object that participants had to direct upwards in negativity trials and downwards in positivity trials (50 % negativity and positivity trials in sessions 1-12 and 80 % negativity and 20 % positivity trials in sessions 13-24). CNV waveforms were obtained from a continuous performance test (CPT), which all adolescents performed before and after the corresponding three-month long intervention period.
In order to utilize all available neural time series, trial-based area under the curve (AUC) values for all four EEG channels were entered into a hierarchical multivariate Bayesian model. The model achieved considerable uncertainty reduction and revealed markedly different pre-post changes in both groups: CNV amplitudes increased slightly in the control group but decreased markedly in the experimental group. The effects of the intensive SCP neurofeedback intervention on the CNV in children and adolescents with ASD are discussed regarding the potential use of the CNV as a biomarker for treatment outcome and the role of attention-related comorbidities in ASD.

Title: Executive functioning in college students with comorbid anxiety and depression symptoms

Authors: *L. E. THOMPSON[1], L. L. WEYANDT[1], C. T. SCHULZ[2], A. T. PIEPMEIER[3];
[1]Interdisciplinary Neurosci. Program, [2]Dept. of Psychology, Univ. of Rhode Island, Kingston, RI; [3]Dept. of Exercise Sci., Elon Univ., Elon, NC

Abstract: *Background:* Few studies have investigated how comorbidity, the presence of two or more distinct disorders in an individual, is related to executive functioning. Impairments in executive functioning in young adults are associated with poorer academic performance and psychological disorders, such as depression and anxiety. The present study had two main hypotheses: hypothesis A) those with symptoms characteristic of comorbid major depressive disorder and anxiety would self-report worse executive functioning and a lower grade point average (GPA) compared to those with symptoms of either depression or anxiety alone, and hypothesis B) those with singular or comorbid symptoms would report worse executive functioning and a lower GPA than those without symptoms of anxiety and/or

depression. *Method:* A sample of 77 undergraduate college students completed self-report measures of anxiety symptoms, depression symptoms, executive functioning, and GPA. A multivariate analysis of variance (MANOVA) was conducted to test hypotheses A and B. *Results:* MANOVA results revealed significant differences in self-reported executive functioning according to level of symptomatology (F = 23.87, $p < .001$). While self-reported GPA decreased across groups, this trend was not statistically significant (F = 1.91, p = .156). *Limitations:* Limitations of the current study include a small sample size, additional comorbidities present in the sample, and lack of treatment information. *Conclusions:* Self-reported executive functioning was significantly different between symptomatology groups, with comorbid disorder symptoms resulting in worse executive functioning compared to singular disorder symptoms or no symptoms. There was no significant difference in GPA between groups based on symptomatology.

Title: Test anxiety is associated with a decreased error-related negativity in tasks requiring top-down and bottom-up attention

Authors: *H. MATKINS, E. A. BOURASSA;
Dept. of Biol. Sci., Mississippi Col., Clinton, MS

Abstract: On electroencephalography (EEG), an incorrect motor response is followed by a sharp negative deflection most prominent in the frontal and central cortex (likely originating from the anterior cingulate cortex). This error-related negativity (ERN) can be elicited whether or not the participant is consciously aware of the error and is thought to reflect either an error detection system or a more general conflict-monitoring system. Previous research has shown that the ERN is more pronounced in people with anxiety. The attentional control theory of anxiety posits that a decrease in top-down attentional control causes an increase in bottom-up attentional capture, and previous work in our lab has shown that this is true in students with test anxiety (TA). This study hypothesized that students with TA would have a larger ERN than students without TA and that the change in ERN would be larger in tasks requiring top-down attentional control. Participants were screened for TA using the blue-box stress test. EEG was measured from students with and without TA during a modified go-no go task. The modification was that half of the trials required top-down attentional processing (search condition) whereas the other half of trials required bottom-up attentional processing (salient condition). Interestingly, ERNs, as a whole, were smaller in participants with TA compared to participants without TA. In both groups, the ERN was larger in the salient condition compared to the search condition. Event-related spectral perturbations (ERSPs) over the central cortex in students without TA showed that committing an error caused a significant decrease in early theta power followed by a decrease in alpha power compared to correct trials; these differences were not seen in students with TA. On correct trials, students with TA had lower early theta power than

students without TA; on error trials, students with TA had decreased low-beta power compared to students without TA. In a separate exploratory analysis, there was a large negative deflection in the parietal lobes following the commission of an error; this parietal negativity was also much more pronounced in students without TA compared to participants with TA and was more prominent in the salient condition. Taken together, these data suggest that in students with TA, the conflict monitoring system of the anterior cingulate cortex may be hypofunctional and therefore goal-oriented behavior may be less amenable to correction. Alternatively, the parietal lobe deflection may suggest that the conflict-monitoring system includes the frontoparietal attentional network, a system known to be altered in TA.

Title: Pilot Results From a Brief, Remote Use, Cognitive Exam In COVID-19 Cases

Authors: *T. BERESFORD[1], D. HIPP[2], P. J. RONAN[3];
[1]RMRVAMC-SOM U Colorado, Aurora, CO; [2]Psychology, Univ. of Denver, Westminster, CO;
[3]Psychiatry and Basic Biomed. Sci., VA Research/USD Sanford Sch. of Med., Sioux Falls, SD

Abstract: Background: Early experience with the COVID-19 Pandemic has begun to elucidate brain function changes that may result in compromised cognition both acutely and during variable recovery periods. Reported cognitive assessment is often limited to orientation alone. Further assessment may seem an inappropriate burden in acute COVID-19 cases characterized by fatigue and confusion as well as examiner safety. Objective: To assess cognition in COVID-19 cases as comprehensively as possible in a brief format, all while observing safety; and to establish clear-face value of its external validity. Method: We adapted a brief cognitive assessment, previously applied to liver transplant candidates and medical/surgical inpatients, for remote use in patients hospitalized for COVID-19 treatment. Collecting quality assurance data from telephone-administered assessments, this report presents a series of six COVID-19 case vignettes to illustrate the 5-Minute Assessment use in diagnosis and treatment of brain effects. Primary medical teams referred the cases for neuropsychiatric consultation. Results: Varying over four decades in age, none were able to engage meaningfully with their surroundings on admission. On follow-up exam 6 to 10 days later, four of the six had recovered Working Memory, and only one had recovered calculation ability. Two were capable of complex Judgment responses while none of the cases completed frontal executive function testing in the normal range. Conclusions: Cognitive assessment in COVID-19 cases, using this remote examination, reveals patterns of cognitive recovery that vary among cases and are far more complex than loss of orientation. In this series, testing specific temporal, parietal, and three frontal lobe functions suggests that calculation ability, judgment, and especially frontal

executive functions, may characterize COVID-19 brain effects. Used widely, and serially, this exam method can potentially inform our understanding of COVID-19 brain effects with healing from the virus.

Title: A Preliminary Study to Evaluate Feasibility, Efficacy and Satisfaction of a mobile-based Cognitive Remediation Therapy (CRT) program for pediatric patients with chronic neurological disorders

Authors: *S. EOM[1], Y. LEE[2];
[1]Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [2]Univ. of Texas Dallas, Dallas, TX

Abstract: Pediatric patients with chronic neurological disorders have often problems in their nerocognitive function. Specially, the cognitive remediation therapy(CRT) may be beneficial for alleviating persisting neurocognitive deficits in pediatric neurological patients. This study aimed to evaluate the feasibility, efficacy and satisfaction of the developed mobile-based CRT program for cognitively dysfunctional pediatric patients. Based on the previous study results for investigating parents' concerns and necessity of CRT as well as various chief problems of pediatric neurological patients, a mobile-based CRT program for pediatric patients was developed, which was composed of 6 game-like friendly CRT programs for core neurocognitive training including auditory selective/sustained attention, auditory/spatial memory, and executive function. In addition, the executive web-dashboard for carrying out the study process of the patients' and their parents' participation in the CRT program was designed for providing the relevant information such as procedure manual and evaluating subjects' neurocognitive function at the pre & post CRT, and keeping a daily training log, as well as executing CRT program. For the feasibility, efficacy and satisfactory study of this CRT, one hundred adults were included in the study with a mean age of 23.5±3.5 years. Relating mobile-based neuropsychological tests of Digit Span, Stroop, Working memory and processing speed were also performed as the pre-and post-intervention evaluation. In addition, self-report for attention, impulsivity, meta-cognition, and satisfaction were administered at the time of pre-and post-intervention. Neuropsychological data and behavioral measure were analyzed as a within-subjects factor. The analysis of the feasibility test including compliance and participation rate demonstrate the high level of feasibility. Furthermore, neuropsychological and behavioral data including reaction time, accuracy, and interference ratio demonstrated the positive effect of mobile-based CRT on attention, working memory and executive function. And satisfactory results showed the high level of satisfaction. The pediatric patients-centered mobile-based CRT program and the executive web-dashboard were designed and produced, and the results of preliminary study suggest that the feasibility, efficacy and satisfaction of the CRT program are significantly good. With the availability of the executive web-

dashboard, hopefully CRT could be useful for a clinical study and a clinical intervention for cognitively dysfunctional pediatric patients as an evidence-based CRT intervention program.

Title: Conflict Control in Patients with Essential Tremor Pre-and Post- Deep Brain Stimulation.

Authors: *J. KANE[1], J. S. NEIMAT[3], S. WYLIE[1], P. HEDERA[4], F. PHIBBS[4], N. C. VAN WOUWE[2]; [2]Neurosurg., [1]Univ. of Louisville, Louisville, KY; [3]Neurosurg., Vanderbilt Univ., Nashville, TN; [4]Univ. of Louisville Sch. of Med., Louisville, KY

Abstract: Deep brain stimulation (DBS) of the regions known to be involved in the dysregulation of motor processes is a common treatment option for patients with Essential Tremor (ET), a movement disorder characterized by kinetic tremor and execution deficits. Disruptions in cerebellar-thalamo-cortical networks could affect inhibitory action control in ET, which is dependent upon the suppression of impulse and replacement of a more appropriate action. The current study investigated whether ET disrupts the proficiency of conflict control by having 41 ET patients (before DBS surgery) and 29 age-matched healthy controls (HC's) perform an action control task (SIMON task). A smaller subset of 8 ET patients [ongoing study] completed the task both pre- and post- DBS) surgery of electrodes in the thalamic ventral intermediate (VIM) nucleus. Patients completed blocks of the Simon task, which requires a left or right response to a feature (e.g., here arrow direction) of a spatially lateralized stimulus. When the action signaled by the spatial location and direction of the arrow are non-corresponding (i.e., induce conflict), the inappropriate action impulse must be suppressed. Overall, patient pre-DBS performance on non-corresponding (Nc) conflict trials was slower and less accurate than corresponding (Cs) trials in comparison to HC's. A focused analysis on fast impulsive response rates (accuracy in the fastest reaction time bin on Nc trials) showed that ET patients responded more erroneously compared to controls. In sum, these results suggest impaired conflict control in ET compared to HC's. When comparing preliminary results from pre and post DBS performance, we found no significant differences in patient's accuracy or reaction time (RT) pre- to post-DBS, however, there was a trend of overall faster reaction times post-DBS (p=.064). Lack of significant difference in performance may be due to greater surgical benefits on (gross) motor over cognitive performance, although data collection for this study continues as well. The larger number of pre-op impulsive errors in comparison to the HC could be explained by a reduction in performance monitoring potentially caused by cerebellar deficiencies in ET, since previous studies in patients with cerebellar damage have found that a reduction in performance monitoring could lead to more errors. Future studies should aim to investigate how cerebellar dysfunction in ET relates to action impulsivity and how this is affected by DBS.

Title: Buffer for boredom: A pilot investigation of the protective effects of exercise against mental fatigue

Authors: *B. TARI, M. SHIRZAD, M. HEATH;
Univ. of Western Ontario, London, ON, Canada

Abstract: Mental fatigue occurs after prolonged periods of sustained attention and results in increased ratings of exertion, decreased physical performance and slowed reaction times. Mentally fatigued individuals also perform worse than non-fatigued individuals on executive tasks (i.e., tasks requiring the ability to rapidly reconfigure attentional and motor goals). In contrast, executive function has been shown to be improved following a single bout of moderate-to-heavy-intensity exercise for as little as 10-min; however, whether a single bout of aerobic exercise can mediate the negative effects of mental fatigue is unknown. Here, participants completed separate 20-min sessions of rest (i.e., reading) and heavy-intensity (i.e., 80% of estimated maximum heart rate) aerobic exercise (via running or combination of running and walking) immediately prior to performing the psychomotor vigilance task (PVT) for 20-min. The PVT is a sustained-attention reaction-time task that measures the speed with which subjects respond to a visual stimulus and has been shown to reliably induce mental fatigue. Executive function was assessed prior to and immediately following the control-PVT and exercise-PVT sessions via the antisaccade task. Antisaccades are non-standard goal-directed eye-movements requiring that an individual look mirror-symmetrical to a target stimulus, and are mediated via similar frontoparietal networks modulated by aerobic activity and mental fatigue. Results demonstrate that the PVT elicited a greater degree of mental fatigue after rest than after exercise. In terms of executive performance, antisaccade reaction times (RTs) were lengthened following the rest-PVT session; however, antisaccade RTs were reliably shortened following the exercise-PVT session. Accordingly, evidence suggests that acute aerobic exercise may shield executive function against the deleterious effects of mental fatigue.

Title: Gray matter volumetric correlates of dimensional impulsivity traits in children: an adolescent brain cognition development project

Authors: *Y. CHEN[1], J. S. IDE[1], C. S. LI[1,3], W. WANG[1], S. ZHORNITSKY[1], S. CHAUDHARY[1], T. M. LE[1], S. ZHANG[1], C.-S. R. LI[1,2,4];
[1]Dept. of Psychiatry, [2]Dept. of Neurosci., Yale Univ. Sch. of Med., New Haven, CT; [3]Smith Col., Northampton, MA; [4]Inter-department Neurosci. Program, Yale Univ., New Haven, CT

Abstract: Previous research has investigated the cerebral volumetric correlates of impulsivity, largely in moderate-sized samples, and the findings varied extensively across studies. Further, few have examined the potentially distinct neural correlates of the various dimensions of impulsivity. Here, we followed published routines and performed voxel-based morphometry analysis of a data set (n=11,474; 5,452 girls, 9-10 years) curated from the Adolescent Brain Cognition Development project. Of the sample, 648 and 2,697 were identified as monozygotic twins and dizygotic twins/siblings, respectively. In a linear regression with all five subscores of the UPPS-P questionnaire as regressors and age in months, total intracranial volume, and scanner model as covariates, higher levels of lack of premeditation and sensation seeking were correlated with greater gray matter volumes (GMVs) in a wide array of cortical and subcortical regions that subserve impulse control, including the frontoparietal cortex, insula, thalamus, and dorsal striatum. In contrast, higher positive urgency was correlated with diminished GMVs in many of the same regions as well as the hippocampus and parahippocampus. Slope tests revealed that girls relative to boys showed stronger correlations of regional GMVs with sensation seeking and with positive urgency. The dimensional impulsivity traits were weakly to moderately heritable with lack of perseverance showing highest h^2 in girls and boys. The volumetric correlates were highly heritable in girls and boys combined, with those of sensation seeking and positive urgency showing highest h^2 in girls and in boys, respectively. These findings collectively suggest shared and distinct cerebral volumetric bases of dimensional impulsivity traits in children and may facilitate developmental neuroscience research of externalizing psychopathology.

Title: A step over the horse race model: study of inhibitory control of gait initiation by a stop signal task.

Authors: *L. FIORI[1,2,3], S. COLANGELI[1], A. RANAVOLO[3], F. DRAICCHIO[3], S. FERRAINA[1], E. BRUNAMONTI[1];
[1]Dept. of Physiol. and Pharmacol., [2]PhD Program in Behavioral Neurosci., La Sapienza, Rome, Italy; [3]Dept. of Occup. and Envrn. Medicine, Epidemiology and Hyg., INAIL, Rome, Italy

Abstract: Gait initiation triggers a chain of events leading our body to leave a stable position, in which the difference between the body's center of mass (COM) and the center of pressure (COP) is minimal. During the about 500 ms of anticipatory postural adjustments (APA), that precede the step onset, a set of muscles are recruited both to lift the foot and to stabilize the body as the difference between COM and COP increases. Then, it is during APAs that inhibitory commands should act for the interruption of the multisegmental control of the stepping. The Stop Signal Task (SST), requiring either to execute a movement in response to a go signal (Go trials) or to inhibit it, when a stop signal suddenly occurs after the go (Stop trials), is largely used to study action inhibition. The outcome in the task is accounted for by a model describing a race between Go and Stop process, triggered by go and stop signals respectively. In stop trials, movements are executed if the Go process runs sufficiently fast. This formulation of the model, mainly developed by studying movements completed in a very short period, as saccades or finger (key press) movements, approximates the occurrence of movements with the end of race. However, the overall process can be different for movements evolving in longer timescales, or requiring different steps, as gait initiation. We used an adapted version of SST to study gait inhibition and evaluate how well the race model accounts for its control. Nine healthy participants were tested, while the position of 31 markers fixed on their body, the ground reaction forces over 8 dynamometer platforms and the activation of 16 body muscles were simultaneously recorded. The recorded signals were used to compute the time course of COM and COP changes and to measure muscles activity modulations during APAs in Go (GT), Stop correct (SCT), and Stop error (SET) trials. Muscle activity was used to estimate trial by trial the reaction time to the go (GoRT) and to the stop (StopRT) signal. As predicted by the race model GoRTs in GT were longer than in SET. However, the difference between COM and COP, at the time of StopRT, resulted higher in SET than in SCT suggesting this as a further parameter to monitor for predicting gait inhibition. Our results suggest that the inhibitory command controlling postural adjustments before Gait initiation continues to be processed after muscular activation and that the inhibition of the programmed step takes place only if the COM-COP difference reaches a point of non-return. Our results suggest a revision of the go process for the race model that must account for the biomechanical variables influencing complex and multi-segmented movements.

Title: Neural Correlates of Emotional Working Memory in Nonsuicidal Self-Injury

Authors: *H. SHIN, G. KIM, H. MOON, J.-W. HUR;
Sch. of Psychology, Korea Univ., Seoul, Korea, Republic of

Abstract: There is strong evidence that emotional working memory may play a crucial role in processing emotional regulation. However, little is known about the neural correlates of emotional working memory of nonsuicidal self-injury (NSSI), which is associated with emotion dysregulation. The present study aimed to investigate the potential neurophysiological mechanism of emotional working memory in individuals who engaged in NSSI.Thirty-two individuals who have engaged in NSSI 5 or more times in the last year (NSSI group) and 28 age-, sex-, handedness-, socioeconomic status-, education-, and IQ-matched controls (control group) completed the Emotional Face N-back (EFNBACK) task during fMRI scanning. The EFNBACK task is a working memory task with emotional stimuli as distracters, and which consists of two different memory load conditions (i.e., 0-back, 2-back) and three emotional distracter type conditions (i.e., no picture, neutral face, or negative face). Whole-brain analysis revealed that the individuals with NSSI showed greater activity relative to controls in the left inferior and superior frontal areas during the high attentional demand conditions with negative-face distracters (2-back negative *versus* 2-back fixation contrast). The NSSI group also showed hyperactivation of the subcortical system, including the globus pallidus and caudate nucleus, in response to the 0-back negative *versus* 0-back fixation contrast. Moreover, within the NSSI group, a significant negative correlation was found between neural activity in the caudate and EFNBACK response times.These results are the first evidence of the altered neural response to the emotional working memory tasks in NSSI that has not been previously explored. These neural activity patterns to both the emotional distraction and the degree of attentional demand may provide new insights into the pathophysiology of NSSI.

Title: Longitudinal study of working memory in Neurocysticercosis

Authors: *L. BAQUEDANO SANTANA[1], E. G. BERNAL TERAN[2], A. D. DELGADO[3], M. VERASTEGUI[4];
[1]Univ. Nacional Mayor de San Marcos, Lima, Peru; [2]UNIVERSIDAD PERUANA CAYETANO HEREDIA, LIMA, Peru; [3]Infectious Dis. Lab. Research-LID, [4]Univ. Peruana Cayetano Heredia, Lima, Peru

Abstract: Neurocysticercosis (NCC) is a disease caused by the larval stage of the *Taenia solium* parasite located in the central nervous system. Seizures are the most common clinical manifestations; however,

patients with NCC often present cognitive impairment, including memory and learning alterations. The aim of this study was to evaluate memory in a rat model for NCC associated with neuronal damage in the hippocampus. Female and male rats 14 days old were intracranially inoculated with *T. solium* oncospheres. The T-maze test and Neurobehavioral scale were employed to evaluate spatial working memory and sensorimotor capacity. The H&E stain and the Anti-NeuN immunostaining allowed evaluating the hippocampal cells. NCC Male rats had short-term spatial memory losses in T-maze compared to control male rats at one year of follow-up. In contrast, NCC female rats displayed learning deficits and spatial working memory deficits at 9 and 12 months post-infection, compared to control female rats. Hippocampus neuronal cells density in NCC-infected rats with deficit memory was significantly different than the control group ($p<0.05$). Also, we reported seizures, paresis, and deficit sensorimotor. Overall, this study supports the relationship between NCC and cognitive impairment demonstrated by memory deficit.

Title: Vicarious trial and error during encoding of a spatial working memory task facilitates accurate decision-making

Authors: *A. E. GEORGE, J. J. STOUT, Jr., A. L. GRIFFIN;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Spatial working memory, the ability to encode, temporally maintain, and retrieve spatial information, is necessary for goal-directed navigation. Within a spatial working memory-dependent T-maze task, rats need to accurately retrieve information about a previous trial in order to make an informed decision about their next trajectory. When faced with these decisions at a choice point, rats will occasionally exhibit complex behaviors, such as pausing and sweeping their head back and forth. These behaviors, called vicarious trial and error (VTE), are thought to be a behavioral manifestation of deliberation (Redish, 2016). For this experiment, we examined VTE in adult male rats ($n = 18$) during asymptotic performance of a delayed non-match to position T-maze task, a task that experimentally separates memory encoding and retrieval into ‘sample’ and ‘choice’ phases. Interestingly, we observed that rats sometimes exhibit similarly complex behaviors during sample phase traversals, despite the fact that these trajectories are forced and thus do not require a decision. Using established methods to identify VTE (Redish, 2016), we found that VTE can be readily extracted from sample-phase traversals. We hypothesized that execution of sample phase VTE (sVTE) reflected the application of a strategy that was aiding rats in task performance. To explore this hypothesis, we analyzed the relationship between sVTE

and choice accuracy. We reasoned that, if sVTE aids the rat in making a correct decision, we should observe a higher proportion of sVTE to occur across trials in which the rat subsequently makes a correct choice when compared to the proportion of sVTE that occur on the sample phase of trials following a correct choice. As predicted, our results show that sVTE significantly tended to precede correct choices rather than follow them ($t(17) = 3.15$, $p < 0.01$). Surprisingly, the opposite effect was observed for incorrect trials - sVTE tended to occur more often on the sample phase of the trial following an incorrect decision ($t(17) = -4.13$, $p < 0.01$). Specifically, sVTE occurred most often on the sample phase of the trial after an incorrect choice when the next choice was correct ($t(17) = -2.25$, $p < 0.05$) - suggesting that, after an incorrect decision, the application of sVTE assists the rat in making a correct choice on the next trial. Together, these findings imply that VTE behaviors may serve various purposes during spatial working memory, depending on recent past experiences and whether encoding or retrieval is presently required.

Title: When Working Memory fails: mechanisms underlying memory accuracy and errors

Authors: *T. OÑA-JODAR[1], G. PRAT-ORTEGA[1], C.-Y. LI[2], J. DALMAU[1,3], A. COMPTE[1], J. DE LA ROCHA[1];
[1]IDIBAPS, Barcelona, Spain; [2]Inst. of Neurosci., Shanghai, China; [3]Hosp. Clin., Barcelona, Spain

Abstract: Working memory (WM) is an essential brain function, which is central for cognition and severely impaired in multiple brain disorders. To investigate the underlying mechanisms limiting WM we developed a two-alternative delayed response task in which head-fixed mice are presented with an acoustic stimulus coming from either a left or a right side speaker. Animals had to remember the prospective response during a variable delay (duration D=0, 1, 3 and 10s) after which, they had to lick the corresponding side port.To understand how the length of the delay period affected the mice's accuracy, we fitted a Generalized Linear Model that quantified the impact of the different factors on choice. The fitted model captured the forgetting process as a reduction of stimulus impact on choice as D increased. Mice also showed (1) an idiosyncratic fixed bias showing a side preference for one of the choices that was affected by the delay and (2) a repeating bias favoring the previously responded side that was independent of delay. Also, the repeating bias increased with trial index within a session whereas the interaction between stimulus and delay length was not affected. To recapitulate these findings, we propose a two-

state hidden Markov Model in which animals switch between two behavioral strategies: a WM and a history-based module (HB). The WM module is described as a double well potential where the planned response can be maintained in one of the two attractors and forgetting is captured by noise-driven escape transitions during the delay. Small asymmetries between the two wells can introduce a WM bias that increases with the delay. The HB one is a logistic function that only depends on previous responses and outcomes and is thus unaffected by the delay. Trial index results suggest that animals spend more time in the HB towards the end of the session. Moreover, pharmacological inactivation of NMDA receptors using NR2B antagonists caused a decrease of the stimulus weight and an increase of the repeating bias, without change in the stability of WM. Finally, we performed electrophysiological recordings in the anterolateral motor cortex (ALM) of behaving mice seeking to validate the proposed two-module model. We found that the stimulus selectivity degraded continuously during the delay period, establishing a neural correlate of the memory forgetting found behaviorally. Moreover, activity in ALM differed between inferred WM trials and HB trials. Our results show that the source of errors could be substantially different depending on the strategy that subjects are following: a memory trace decrease during the delay for WM related errors and a non-efficient repetition strategy for HB errors.

Title: Activation patterns underlying verbal working-memory maintenance and Cognitive Reserve

Authors: *C. HABECK[1], Y. STERN[2];
[1]Columbia Univ., New York, NY; [2]Cognitive Neurosience Division, Columbia Univ., New York, NY

Abstract: To identify an fMRI-pattern underlying working-memory rehearsal in a verbal Sternberg-task, we imaged 183 people with age coverage in the ranges 20-30 and 55-70. Beyond task performance, participants were characterized in terms of demographics, and neuropsychological assessments of crystallized verbal intelligence, episodic memory, perceptual speed, and abstract fluid reasoning. Participants studied an array of either 1, 3, or 6 upper-case letters for 3 seconds (=encoding phase), then rehearsed the letters sub vocally for 7 seconds facing a blank screen (=maintenance phase), to be probed with a lower-case letter to which they responded with a differential button press whether the letter was part of the studied array or not (=retrieval phase). For the current study we focused on the maintenance phase, and first performed OrT-CVA analysis (Habeck et al, 2005, Neural Computation) to identify an activation pattern showing memory-load increases in pattern score for all but 3 participants ($p < 0.0001$). The pattern showed positive loadings at mid-line supplementary motor and left inferior frontal areas, and negative loadings at Default-Node-Network areas. Load-related increases in pattern score correlated

positively with age, but negatively with mean cortical thickness, episodic memory, fluid reasoning, and perceptual speed, but load-averaged pattern scores were positively related to verbal intelligence. (All p-values less than 0.01). However, since the pattern revealed no relationship to task performance, we combined all load levels by averaging, and used PCA-regression in an additional analysis to derive a pattern to predict mean reaction time (p=0.002). The regional composition of the pattern was sparse and consisted of positive loadings (=faster reaction) in bilateral thalamus and left orbitofrontal areas, with negative loadings (=slower reaction) in right mid-frontal and angular-gyrus areas. Load-averaged pattern scores only displayed a positive association with perceptual speed (p=0.002). These results demonstrate that a necessary load-related activation pattern manifested greater efficiency (=lower slope) for younger age, thicker cortices, and better fluid cognition, but no relation to performance. Instead, there was an additional performance-related pattern, independent of age or brain structure. Because the performance relation was not confounded by brain structure or age, the pattern fulfills the postulates of Cognitive Reserve, and maps out a dimension different from usual proxies like crystallized verbal ability, leisure activity, or education.

Title: Emergence of population dynamics causally driving delayed paired associations working memory

Authors: *A. BELLAFARD, P. GOLSHANI;
UCLA, Los Angeles, CA

Abstract: While a number of brain regions vital for working memory have been identified, and persistent activity in these regions recorded during working memory tasks, how these activity patterns emerge and the necessity of these activity patterns for behavioral performance is poorly understood. To gain more insight into these problem, we have trained head-fixed mice to perform an olfactory paired association working-memory task, during which head-fixed mice made decisions depending on the sequential identity of two odors presented separated by 5 seconds. As the secondary motor cortex (M2) has been found to be essential for the performance of motor preparation tasks, we asked if the M2 was also critical for performance of complex working memory tasks requiring the comparison of two distinct stimuli separated in time. We therefore utilized a highly efficient soma-targeted Guillardia theta anion-conducting channelrhodopsin (stGtACR2) to perform optogenetic silencing at different time intervals while the animal was performing the task. Single-unit recordings demonstrated that stGTACR2 silencing was highly effective and did not result in abnormal activity patterns beyond the stimulation period. Silencing of M2 neurons during delay and reward periods dramatically worsened behavioral performance, while stimulation at other time intervals had no effect. Therefore M2 is both important for maintaining the

working memory during the delay period, as well as comparing the memory of the first stimulus with the second stimulus to drive decision making. Future work will determine the mechanisms that drive the development of delay activity with learning.

Abstract: It has been debated how attention and visual working memory (vWM) develop from childhood to adulthood. One prominent account has proposed that vWM capacity fully developed in late childhood as past research studies have reported children as early as 7 years old (or even younger) having a comparable level of vWM capacity similar to the adult level, distinct to the ability to filter out distraction which continues to develop throughout late childhood and adolescence. However, it has been argued that comparable working memory performance across children and adults could be due to the differences in experimental protocols used in different age groups. Moreover, recent research has shown that vWM continues to develop throughout adolescence. That said, it is still possible that vWM capacity could drop after late childhood and rise again during adolescence until it reaches a similar level in adulthood. Here, we measured the capacity of vWM and related EEG activity from typically developing children, teenagers, and healthy adults performing a delayed-matching-to-sample task where they selectively

remembered the colors of visual targets presented with and without distractors. Importantly, comparisons across age groups were performed using the data obtained from conditions where task parameters including encoding duration and set sizes of targets and distractors were carefully controlled. We found that vWM capacity continued to increase from late childhood to adolescence and adulthood in parallel with age-related improvement in selective filtering function. Moreover, the modulations of the contralateral delay activity and the frontal biasing EEG signals track the developmental trajectories of vWM capacity and filtering efficiency, respectively. Together, our data suggest that the continuing maturation of the parietal and frontal cortex plays a crucial role in supporting the parallel development of working memory and selective attention, which is extended throughout late childhood and adolescence.

Title: Flexible top-down control in the interaction between working memory and perception

Authors: *C. TENG[1], J. M. FULVIO[1], J. JIANG[2], B. R. POSTLE[1];
[1]Univ. Of Wisconsin–Madison, Madison, WI; [2]Univ. of Iowa, Iowa City, IA

Abstract: Working memory (WM) and perception are highly intertwined and interactive processes (e.g., Awh and Jonides, 2001; Chun, Golomb, Turk-Browne, 2011), and a considerable amount of research supports the idea that these two functions may rely on a common representational substrate (e.g., Teng & Kravitz, 2019; Teng & Postle, 2021). Here we examined how the interaction between WM and ongoing perception is controlled, by testing human performance on a dual-task that varied conflict between WM and perceptual representations. Subjects first viewed an orientation-grating memorandum, then performed orientation discrimination on a second item (the discriminandum), and then recalled the orientation of the memorandum. Congruity between memorandum and discriminandum was manipulated, and incongruent trials generated hallmarks of both proactive and reactive control in performance on the subsequent trial: The response-time cost of incongruity was reduced for the discrimination task (indicating increased proactive control) and the sign of the serial bias of the discriminandum on recall flipped, from attractive following congruent trials to repulsive following incongruent trials (a consequence of reactive control). A separate control experiment confirmed that the repulsive serial bias reflected top-down control (rather than, e.g., passive perceptual adaptation) because it was absent when the orientation of the discriminandum was made task-irrelevant. To formalize these observations, we fit the data using the Flexible Control Model (FCM; Jiang et al., 2014, 2015) and two model parameters were sensitive to trial-by-trial variation in conflict: fluctuation in “predicted conflict” quantified adjustments in the level of proactive control; the value of the “control prediction error” captured the strength of reactive control

recruited in response to memorandum-discriminandum congruity. Furthermore, the magnitude of the repulsive serial bias triggered by an incongruent trial was predicted by the magnitude of that trial's "control prediction error" (solidifying the link between repulsive bias and reactive control). Overall, these results illustrate that conflict between the current contents of WM and perception is governed by the flexible recruitment of two types of top-down control, proactive and reactive control. Model-based analysis of the results from a follow-up EEG experiment will investigate neural correlates of these two distinct forms of cognitive control.

Title: Impaired spatial working memory by TRPC4 channel knockdown in the hippocampus CA1 area

Authors: *B. SABER MAROUF[1], R. KAUSHIK[2], A. DITYATEV[2], M. SAUVAGE[3], M. YOSHIDA[4]; [1]ESF graduate school ABINEP, Med. Faculty, Otto-von-Guericke Univ., Magdeburg, Germany; [2]Mol. Abstract: Working memory requires a maintenance of information in a readily accessible form in various cognitive tasks. Persistent firing of neurons is believed to be one of the neurophysiological mechanisms to retain information during working memory. It has been reported that transient receptor potential canonical 4 (TRPC4) channels support persistent firing in individual hippocampal CA1 pyramidal cells. To study the role of hippocampal TRPC4 channels on the spatial working memory, shRNA technique was used to knockdown the TRPC4 channels in the hippocampal CA1 neurons. TRPC4 knock down efficacy was confirmed in primary neuronal cell culture. A spatial-delayed alternation task (T-maze) was used to study the effect of TRPC4 knockdown in mice (12 weeks old, C57BL/6J) spatial working memory. The results showed a significant performance attenuation in the TRPC4 knockdown group compared to the control group that was injected with a scramble shRNA virus. In conclusion, our data suggests an indispensable role of hippocampal TRPC4 channels in spatial working memory.

Title: Memory-guided continuous tracking reveals the spectrogram of working memory

Authors: *S. AHMAD[1], L. K. CORMACK[2], A. C. HUK[2];
[1]Inst. For Neurosci., Univ. Of Texas At Austin, Austin, TX; [2]Ctr. for Perceptual Systems, Univ. of Texas, Austin, TX

Abstract: Working memory is often studied in the laboratory using discrete items to be remembered, but in real life, continuous sensorimotor events are commonplace. We therefore developed a task in which subjects reconstruct a continuous (but noisy) visual trajectory from memory. We then adapted and extended the tools of continuous psychophysics (Bonnen et al, 2015) to analyze the effects of stimulus intensity and delay period on the accuracy of remembered trajectories. In our novel task, subjects used a mouse cursor to retrace the trajectory of a gaussian luminance blob after it moved in a one-dimensional random walk. The target's horizontal movement was specified by a sequence of gaussian white noise velocities that were cumulatively summed to generate the on-screen coordinates, while the vertical coordinates of the target and subject's cursor were defined by a constant rate. On each trial, subjects observed targets presented at 5% and 20% contrast levels travel trajectories of varying lengths (1, 2, or 4 s). Following each trajectory, the subject had an equivalent amount of time to retrace the previously seen path from memory. We adjusted the memory demand during the task by varying the length of the target trajectory. Longer trajectory lengths stressed the subjects mnemonic ability by increasing the amount of time between observing and reconstructing the target trajectory (delay period) as well as the amount of information to remember. Subjects were able to perform the task and completed a total of 162 tracking trials each. The spatial positions of the target and subject's cursor were used to compute trial-averaged cross-correlograms (CCGs) and measure the correlation between our target and response time series data as a function of the lag between them (Mulligan, Stevenson, & Cormack, 2013). Our CCGs showed that tracking performance on the task decreases when stimulus intensity is low and the delay length increases. We then generated time-frequency cross-correlation plots of the subject's response velocities to characterize the spectro-temporal representation of their memory-guided tracking performance and compare it to that of the target velocities. The resulting "spectrograms of memory" revealed the degree and time course to which coarser aspects of the target trajectory were remembered better than finer aspects of the trajectory. We found that the trajectories reconstructed from memory typically reflected frequencies below 10 Hz. This approach thus provides a means for characterizing more continuous aspects of working memory, and can do so in the context of a naturalistic behavior without requiring extensive task training.

Title: The effects of age on neural correlates of recognition memory: an fMRI study

Authors: *M. HOU, T. WANG, M. RUGG;
Ctr. For Vital Longevity, Utdallas, Dallas, TX

Abstract: Prior studies examining the effects of age on the neural correlates of recognition memory have yielded mixed results. In the present study, we employed a modified remember-know paradigm to compare the fMRI correlates of recollection and familiarity in samples of healthy young (n = 16, mean age = 20.3, age range = 18-25, 8 female) and older adults (n = 22, mean age = 69.1, age range = 63-77, 13 female). After studying a series of concrete words, participants underwent fMRI scanning during a test phase in which they responded "remember" to a test word if any qualitative information could be recollected about the study event. When recollection failed, participants signaled how confident they were that the test item had been studied. Young and older adults demonstrated statistically equivalent estimates of recollection and familiarity strength, while overall recognition memory accuracy was significantly lower in the older adults. Robust, age-invariant fMRI effects were evident in two sets of *a priori* defined brain regions consistently reported in prior studies to be sensitive to recollection (the 'core recollection network') and familiarity respectively. In addition, the magnitudes of 'familiarity-attenuation effects' in perirhinal cortex demonstrated age-invariant correlations with estimates of familiarity strength and memory accuracy, replicating prior findings. Together, the present findings add to the evidence suggesting that the neural correlates of recognition memory are largely stable across much of the healthy human adult lifespan.

Title: Cortical representations of decoded content in episodic memory encoding and reinstatement

Authors: *M. HEBSCHER[1,2], J. L. VOSS[1];
[1]Dept. of Neurol., [2]Neurol., Univ. of Chicago, Chicago, IL

Abstract: Everyday memory involves high overlap between the actors, locations, and objects of events. Such overlapping information can aid cueing of related memories or lead to memory interference. Little is known about how overlapping information is processed by different neural structures at the time of

encoding and how similarity between events affects their later recall. In the present study, we tested how the degree and content of similarity among naturalistic events affects how they are encoded and remembered. We used computational modeling to decode the content of naturalistic stimuli and measured the degree to which similarity between stimulus features predicts encoding and reinstatement by measuring multivoxel patterns of functional magnetic resonance imaging (fMRI) activity. Subjects (N=20) performed an episodic memory task in which they encoded and recalled naturalistic video stimuli in the fMRI scanner. Visual similarity between stimuli was assessed using a convolutional neural network and semantic similarity was measuring using a topic model applied to descriptive text of the videos. Visual similarity was found to positively predict multivoxel pattern similarity between stimuli at encoding in posterior temporal and occipital regions. Semantic similarity positively predicted pattern similarity at encoding in temporal and higher-level occipital regions, and negatively predicted neural similarity in lower-level occipital regions. These findings demonstrate that different event features derived from computational models map onto multivariate patterns of neural activity at the time of encoding in relevant cortical regions. We further found that greater pattern similarity at encoding was differentially related to later cortical reinstatement. Parietal and temporal regions tended to show a positive relationship, such that more neural similarity between stimuli at encoding predicted greater reinstatement of those stimuli. Occipital regions showed the opposite pattern, with greater neural similarity between stimuli at encoding negatively predicting later reinstatement of those stimuli. This suggests that greater neural similarity between events at the time of encoding, or integration, aids reinstatement in certain regions, while lower neural similarity, or differentiation, aids reinstatement in other regions. Together, these findings demonstrate that the degree and content of overlap between naturalistic events affects how they are encoded and reinstated by patterns of cortical activity.

Title: The Impact of Externally Induced Gamma Oscillations on Human Episodic Memory Formation

Authors: *D. WANG[1,2], K. L. SHAPIRO[2], S. HANSLMAYR[1,2];
[1]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom; [2]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Episodic memories are past experiences that usually contain rich multisensory information. Previous studies using rhythmic sensory stimulation (RSS) show that synchronising multisensory brain regions at theta frequency facilitates binding multisensory information into long-term memory. These findings suggest that effective associative memory depends on finely tuned timing between cortical inputs. One of such timing mechanisms is spike timing dependent plasticity (STDP). If a pre-synaptic

neuron fires within a short delay before a post-synaptic neuron, the connection from the pre-synaptic neuron to the post-synaptic neuron will be strengthened. If the temporal order of the two spikes is reversed, then the synaptic connection will be weakened. Such a time window for synaptic modification (< 50 ms) falls within the gamma frequency range and synaptic modification is an exponential function of delay. However, evidence on the causal role of synchronising neural inputs at gamma frequency in human episodic memory formation is lacking. We investigated this using RSS to entrain visual and auditory cortices at gamma frequency (37.5 Hz). Luminance of video clips and volume of sound clips were modulated by a 37.5 Hz sine wave with four phase offsets: 0°, 90°, 180° and 270°, which corresponds to the delay of 0 ms, 6.67 ms, 13.33 ms and 20 ms between visual and auditory inputs. In Experiment 1, 48 young healthy participants (both sexes) were asked to remember associations between the video-sound pairs and later recall the corresponding video when they were cued with a sound. Recall accuracy for the 0° condition was significantly better than the 270° condition, which has the longest delay between visual and auditory stimuli, suggested by a paired sample t-test. However, whether this memory effect was indeed driven by STDP is not clear with regard to the directionality of the synapses. To better formulate the role of STDP, we conducted Experiment 2 with a new group of 48 participants. The only difference from Experiment 1 was that the participants were cued with a video in the memory test and asked to recall the corresponding sound. Recall accuracy was predicted to decay exponentially as a function of the phase offset between visual and auditory inputs, if STDP is the driving force. In each experiment, EEG activity was recorded in 24 participants. EEG data is predicted to reveal that sensory regions are entrained to the respective frequency and phases. Our findings provide causal evidence with regard to the role of gamma oscillations in supporting human episodic memory formation, which supports the notion that STDP may play an important role in human learning and memory.

Title: Post-encoding reactivation binds episodic sequences in long-term memory

Authors: *X. WU[1,2,3], B. STARESINA[4], L. FUENTEMILLA[1,2,3];
[1]Dept. of Cognition, Develop. and Educational Psychology, [2]Inst. of Neurosciences, Univ. of Barcelona, Barcelona, Spain; [3]Cognition and Brain Plasticity Group, Bellvitge Inst. for Biomed. Res., Barcelona, Spain; [4]Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom

Abstract: Prior animal and human work have shown that post-encoding reinstatement plays an important role in the formation of a memory for the unfolding experience. Here, we test whether the integration of the elements of an episodic sequence is promoted via neural reinstatement after one-shot exposure. We recorded scalp electroencephalography (EEG) while participants encoded trial-unique combinations of

face-object-scene picture triplets that were subsequently recalled in a test. We used representational similarity analysis on EEG data and found evidence for rapid memory reinstatement the just encoded triplet sequence (i.e., ~500 ms after the offset) , and that the magnitude of the neural reinstatement predicted recollection in the test. We then used a time-resolved pattern classification approach to quantify the degree to which EEG neural activity elicited during picture encoding and at sequence offset discriminated between image categories. This analysis revealed statistically validated classifier fidelity at approximately 180ms - 500ms during image presentation, and this time window also coincided with significantly increased magnitude of discriminability of the classifier output throughout the offset period. More importantly, later remembered triplets showed reduced discriminability value across offset period comparing to the later forgotten triplets. Altogether these results provide important evidence that episodic offset memory reinstatement is a mechanism engaged to support integration of episodic elements in long term memory, and that such integration is achieved by overcoming the representational gap between separate encoding stimuli.

Title: Tracking encoding-retrieval transformations using EEG-based representational structures

Authors: *C. POSTZICH[1], J. LINDE-DOMINGO[2], M. WIMBER[1];
[1]Univ. of Glasgow, Glasgow, United Kingdom; [2]Ctr. for Adaptive Rationality, Max Planck Inst. for Human Develop., Berlin, Germany

Abstract: Episodic memories contain sensory information about the events we encounter, and it is commonly assumed that successful recall of the event is supported by the neural reactivation of such information. A growing amount of evidence, however, indicates that stimulus information during the initial encoding and the subsequent retrieval are not represented in the same cortical location, suggesting an encoding-retrieval transformation rather than a veridic reinstatement of the original information (Rissman, J., & Wagner, A. D., 2012, Annu. Rev. Psychol.). While most of the evidence comes from fMRI, the present EEG study uses second-order representational similarity analyses to investigate this potential transformation with high temporal resolution. In our task, subjects learned associations between words and objects in an encoding phase and were later cued with the word to retrieve the object, and to classify it according to its perceptual or semantic content (e.g., was it an animate or an inanimate object). The ability of a multivariate pattern classifier to distinguish different object classes (e.g., insects vs mammals) was used as a measure of the representational dissimilarity between classes of objects. Time series of representational dissimilarity matrices (RDMs) during encoding showed early differentiation along the perceptual dimension followed by differentiation along the semantic dimension, indicating a

forward stream of processing, in line with previous results (Cichy, R. M., Pantazis, D., & Oliva, A., 2014, Nat. Neurosci.). Encoding and retrieval RDM time series were then cross correlated, yielding a temporally resolved encoding-retrieval similarity measure that does not depend on the reactivation of the exact original features. Additionally, we employed a novel approach to delineate perceptual and semantic influences on this encoding-retrieval similarity measure, and this approach provided evidence for a reverse semantic-to-perceptual reactivation stream during retrieval (Linde-Domingo, J., Treder, M. S., Kerrén, C., & Wimber, M., 2019, Nat. Commun.). Finally, topographical analyses of the classifier performances indicate that different sets of sensors contribute to encoding and retrieval classification, adding to the notion that stimulus representations are transformed from initial learning to later remembering.

Title: Influence of dietary nutrient intake on episodic memory across the adult life span

Authors: *S. CANSINO[1], F. TORRES-TREJO[2], *C. ESTRADA-MANILLA[1], A. FLORES-MENDOZA[1], G. RAMÍREZ-PÉREZ[1], S. RUIZ-VELASCO[3];

Abstract: The aim of the study was to identify nutrients that have the ability to impact brain functioning and, as a consequence, influence episodic memory. In particular, we examined recollection, the ability to recall details of previous experiences, which is the episodic memory process most affected as age advances. A sample of 1550 healthy participants between 21 and 80 years old participated in the study. Nutritional intake was examined through a food frequency questionnaire and software developed to determine the daily consumption of 64 nutrients based on food intake during the last year. Recollection was measured through a computerized source memory paradigm. First, we identified which nutrients influence recollection across the entire adult life span. Then, moderator analyses were conducted by dividing the sample into young (21-40 years old), middle-aged (41-60 years old) and older (61-80 years old) adults to establish in which life stage nutrients influence episodic memory. Across the adult life span, recollection accuracy was shown to benefit from the intake of sodium, heme, vitamin E, niacin, vitamin B6, cholesterol, alcohol, fat, protein, and palmitic, stearic, palmitoleic, oleic, gadoleic, alpha-linoleic and linoleic acid. The effects of energy, maltose, lactose, calcium and several saturated fatty acids on recollection were modulated by age; in older adults, the consumption of these nutrients negatively influenced episodic memory performance, and in middle-aged adults, only lactose had negative effects.

Several brain mechanisms that support episodic memory were influenced by specific nutrients, demonstrating the ability of food to enhance or deteriorate episodic memory.

Title: Linear episodic chronometry in the macaque medio-posterior parietal cortex

Authors: *L. HUANG[1], L. WANG[1], Y. ZHENG[1], K. MAKOTO[2], S. KWOK[3,1,4];
[1]East China Normal Univ., Shanghai, China; [2]Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [3]Div. of Natural and Applied Sci., Duke Kunshan Univ., Kunshan, China; [4]Shanghai Key Lab. of Brain Functional Genomics, Shanghai, China

Abstract: Primate posterior parietal cortex (PPC) mediate memory consolidation and retrieval. While we previously reported that monkeys rely on a forward replay mechanism to support temporal-order judgement between cinematic events, it is unknown how PPC neurons deal with multiple events spanning across intertwined episodes. We recorded single-unit electrophysiology data from the monkeys PPC while having them learned 6 videos over 2 days and tested their temporal order judgement (TOJ) on third day: learning phase consisting of 3 10-s videos/day (in total 6 different videos), and testing phase on Day 3 consisting of TOJ trials without any video-watching. On day 3, they performed TOJ trials under three different conditions: (i) both frames from a single video; (ii) frames from two different videos learned within same day; (iii) frames from two different videos learned across two different days. We ran four 3-day sessions and recorded 61 neurons in total. We tested the hypotheses that (1) the animals recall the order of episodic events learned across the previous two days in a forward search, sequential manner, and (2) such a forward search retrieval mechanism is supported by PPC neurons. Behaviorally, a linear regression model showed that monkeys' response time for TOJ increased as a function of chosen frame location across the 6 videos spanning across the first two days (i.e., faster for video 1 and slower for video 6), with correct trials on Day 3: $r^2 = 0.018$, $p < 0.001$, suggesting that the six videos might have been integrated into a single temporal sequence and the animals retrieved the memory in a forward search sequential manner. Moreover, when considering the increment in RT between first and last chosen frame location, there is a compression factor of 2.14×10^{-6}. Correspondingly, the firing rate decreased significantly as a function of chosen frame location across the 6 videos spanning across the first two days (i.e., higher for video 1 and lower for video 6), with all neurons: $r^2 = 0.004$, $p < 0.001$, and with 36 out of 61 neurons showing this pattern. This result suggests firing rate of most of neurons are modulated by memory search. These results indicate that PPC neurons would reduce their firing rate when the memory search hit the memory target, suggesting that these neurons are involved in supporting the putative forward search. Altogether, our results suggest macaque monkeys can learn and maintain a linear, extended series of episodic experiences (over 48 hours), while PPC neurons are involved in supporting

this forward-replay memory search. These results support the presence of a memory chronometry for past episodes in the primate medio-posterior parietal memory system.

Title: Oligodendrocyte mechanisms in the anterior cingulate cortex but not the hippocampus are critical for episodic memory formation

Authors: *L. BARBOZA, B. BESSIÈRES, O. NAZARZODA, C. M. ALBERINI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The hippocampus and prefrontal cortex play an essential role in memory consolidation, the process by which an initially labile memory becomes stronger and resilient to disruption. While hippocampal biological mechanisms have been extensively investigated as the bases of memory consolidation, the biological changes in cortical areas contributing to memory consolidation and storage are less understood. Furthermore, while the hippocampus is generally known to play a transient, although critical, role in memory consolidation, cortical areas, and particularly the anterior cingulate cortex (ACC), is believed to be the site of long-term memory storage. Here we show that in the ACC, but not in the dorsal hippocampus (dHC), oligodendrocyte-specific transcripts are rapidly induced after a single episodic learning event and required for long-term memory formation. RT-qPCR time course analyses after inhibitory avoidance training in rats revealed a rapid upregulation of transcripts critical for oligodendrocyte differentiation and myelin biogenesis in the ACC but not the hippocampus. Western blot and immunohistochemistry analyses confirmed the upregulation of oligodendrogenesis-related proteins one day after training. ACC-targeted antisense-mediated knockdown of Myrf, a master transcription factor of oligodendrogenesis, impaired long-term memory retention but did not affect short-term memory. Likewise, either conditional global or ACC-targeted knockout of oligodendrogenesis in mice impaired long-term memory formation while dHC-targeted knockout had no effect. We conclude that oligodendrocyte-specific mechanisms are rapidly regulated and required for long-term memory formation in the ACC, but not the hippocampus.

Title: Flexible use of memory by food-caching birds

Authors: *M. C. APPLEGATE, D. ARONOV;
Columbia Univ., New York, NY

Abstract: A hallmark of human episodic memory is “flexibility” - the ability of a single memory to influence different behaviors in pursuit of different goals. It is unknown to what extent memory in other animals is similarly flexible. To address this question, we studied spatial behaviors of a specialist food-caching bird, the black-capped chickadee. These birds naturally pursue different goals at different moments in time as they explore an environment, cache food, and later retrieve caches. We designed a behavioral setup to engage these behaviors and track them automatically. In our apparatus, chickadees took seeds from a motorized feeder and cached them into one of 64 sites by peeling back a silicon flap. Site contents were invisible to the bird unless the flap was lifted. The contents and the bird’s interactions with each site were tracked through a transparent floor of the arena via a camera and real-time video processing. Our behavioral paradigm 1) allows birds to express their natural caching instincts, 2) permits high-throughput, automated behavioral tracking, and 3) is compatible with modern neuroscience techniques, such as awake-tethered recordings. We recorded chickadee behavior in two conditions: one in which they freely cached seeds throughout this arena, and one in which they retrieved previously made caches. We next used probabilistic modeling to disentangle the contributions of memory-guided and non-mnemonic strategies to the behavioral choices made by chickadees in these tasks. We first accounted for birds’ biases in their choice of sites (distribution over space, p_{bias}). We then considered the effect of three types of locations on subsequent site interactions: the previous site checked by the bird, sites already occupied by caches, and sites previously checked by the bird that are currently empty. We asked whether the probability of caching or checking at these locations, or nearby locations, was altered relative to p_{bias}. We found that chickadees use memories of the contents of individual cache sites in a context-dependent manner. During caching, chickadees are 3-fold more likely to avoid sites that already contain food, resulting in an even distribution of caches throughout the environment. During retrieval, they instead show a 2-fold propensity to return to occupied sites and obtain food. These effects are site-specific, long-lasting, and do not diminish as more seeds are cached. Thus, chickadees can use a single memory to achieve at least two unrelated behavioral goals. These results demonstrate memory flexibility in an animal in a tractable spatial paradigm.

Title: Pupil dilation as a proxy for implicit statistical learning in freely moving mice and humans

Authors: *A. ONIH, T. GEORGE, S. NIERVWETBERG, A. AKRAMI;
Sainsbury Wellcome Ctr., Univ. Col. London, London, United Kingdom

Abstract: Pupil dilation as a proxy for implicit statistical learning in freely moving mice and humansAdedamola Onih, Tom George, Svenja Nierwetberg, Athena Akrami Sensory events in natural environments are mostly patterned and structured. Different organisms have evolved to extract these structures efficiently and often without any explicit instruction. Previous studies have shown that by learning the statistical features of sensory inputs, humans can make predictions about future events, and when those predictions are violated, they exhibit a surprise response. In humans, multiple oddball paradigms have shown pupil dilation to be a reliable proxy for surprise in response to violations from predictable sensory events.. We developed a novel comparative behavioural paradigm, “X” detection, to investigate how mice and humans implicitly learn and generalise the statistics from their sensory world after a limited number of exposures. In this paradigm, subjects were exposed to task-irrelevant, structured auditory sequences while performing an auditory distractor task. Stimulus set is designed such that mere novelty detection can be distinguished from learning abstract rules. Tracking pupil diameter, we show that in both mice and humans, predictability of (task-irrelevant) auditory events correlates with the pupil size. This establishes pupil diameter as a reliable indicator of rule extraction over several sensory repeats. We use this paradigm to test the capacity of mice to learn auditory sequences of varied complexities, in comparison to human subjects, as well as computational models designed to learn different classes of regularities in unsupervised manners. We therefore establish mouse pupil size and the “X” detection task as a useful model for tracking the implicit extraction of statistics from the sensory world, and thus, a tool for further investigation into the neural correlates of statistical learning.

Title: Leveraging unsupervised behavioral segmentation to identify its neuronal correspondence during unconstrained behavior of macaques

Authors: *B. VOLOH[1], D. J. N. MAISSON[1], B. Y. HAYDEN[1], J. ZIMMERMANN[2];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Dept. of Neurosci., Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Rhesus macaques have been an invaluable animal model in determining the function and electrophysiology of the brain. Typical electrophysiological experiments are performed under highly unconstrained and unnatural conditions - such as "foraging" with eye movements. This raises doubt as to the ecological validity of neural inferences, and thus their external validity. A useful alternative would be to study behavior in freely moving unconstrained conditions. A key obstacle in the study of unconstrained behavior is behavioral segmentation, namely, the determination and annotation of behavioral states. To this end, we studied macaque behavior (N=2) in a large, open-field environment while they performed a foraging task. Pose reconstruction was achieved with a software tool we developed called OpenMonkeyStudio. For this study, we developed a data-driven, unsupervised behavioral segmentation pipeline, which takes in postural keypoints and embeds them in a lower, 2-dimensional space, in order to identify and cluster repeated occurrences of similar poses. Embedding poses resulted in well-formed, semantically meaningful clusters that could be identified by a human, such as "left stride", "right stride", and "sitting". Importantly, the structure of the embedding space was itself meaningful. Transitions tended to occur between nearby, rather than distant, clusters, suggesting a hierarchical organization of behavior. We further identified idiosyncratic sequences of poses (eg "walking" being composed of left and right stride poses) by embedding pose sequences on the basis of their circular edit distance. Finally, we re-embedded new pose data (from one subject) from sessions with simultaneous, large-scale, wireless neural recordings (128 channels spanning the prefrontal expanse, including dACC, DLPFC, OFC, VLPFC, and PM, among others). We found that across the population of all recorded neurons (n=5303), spike rates corresponded to specific postural states. This was true for all levels of cluster granularity of our embedding space, suggesting that neural responses track multiple time-scales of behavior. Taken together, these results provide a first insight into the neural basis underlying structured behavior during unconstrained foraging

Title: Anterior Cingulate Cortex Tracks the Distribution of Depleting Reward in Freely Moving Rhesus Macaques

Authors: *R. LOPEZ CERVERA, B. VOLOH, D. MAISSON, B. Y. HAYDEN, J. ZIMMERMANN; Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Foraging is a canonical decision-making behavior that has likely shaped functional neuroanatomy. Foragers in patchy environments are able to efficiently maximize their food intake by balancing the exploitation of resource patches with exploration for new patches. Making patch-leaving decisions requires the maintenance and integration of multiple forms of information. We have hypothesized that such decisions involve the generation and maintenance of a discrete continuous and abstract decision variable. The magnitude of this variable, which is presumed to be encoded in the dorsal anterior cingulate cortex, would be roughly akin to 'the current sum of evidence in favor of abandoning the current patch.' All past studies on this topic have been limited either by the use of virtual or chaired tasks on one hand, or the use of animal models with unclear prefrontal homology to humans on the other. To better understand foraging behavior in a more natural context, we developed a novel open field patch-leaving foraging task for rhesus macaques and recorded activity within dACC during task performance. We find that dACC neurons track the patch distribution of depleting reward. Furthermore, the relatively high firing rates that we observed when an animal depleted approximately half of a patch correlated with the relatively lower patch leaving rates for those same patch states. This novel signal may be one of several factors that subserve foraging computations.

Title: Dynamic tracking of social states in freely moving rhesus macaques

Authors: *J. K. MORROW, B. R. VOLOH, D. J. N. MAISSON, J. ZIMMERMAN, B. Y. HAYDEN; Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Primates, including humans, are fundamentally social creatures. Our social interactions take place in a rich, complex world that affords many dimensions of movement as well as opportunities for communication and physical interaction. This core aspect of social life - its embodiedness - is absent from nearly all of social neuroscience, due in part to the simple difficulty of rigorously measuring social behavior in open environments. We have developed a new experimental apparatus for eliciting and observing social interactions in rhesus monkeys, an important model organism for human neuroscience. The apparatus consists of a large (2.45 x 2.45 x 2.75 m) enclosure encircled by 62 machine vision cameras that continuously track the subjects as they freely interact within the space over several hours. We developed a system known as OpenMonkeyStudio that uses a deep neural network to predict the

positions of 13 body landmarks on the head, torso, and limbs to reconstruct 3-dimensional pose information for each monkey in the enclosure. Here, we describe extensions to OpenMonkeyStudio that allow for tracking of two monkeys at the same time. Specifically, we show that we can reliably individuate each animal, classify their individual actions over time, and generate proxemics for the pair (i.e., track the distance, angle, and orientation of one subject relative to the other). Hidden Markov modeling could then be applied to these data to estimate transitions between social states, that is, repeatedly observed, joint behavioral patterns expressed by the pair. In other words, we can determine how the actions of one animal affect the actions of the other, indicative of social engagement (or disengagement). This information has a myriad of uses including inferring dominance hierarchies or tracking how behavioral (e.g., exposing the animals to stressors) or pharmacological (e.g., transient inactivation of specific neural pathways) interventions impact social behavior. These results demonstrate the utility of our experimental design for tracking natural interactions between multiple animals. This paradigm could provide a powerful tool for assessing disorders that include social or affective deficits that are hard to track in traditional laboratory settings.

Title: Place-specific spatial encoding in the orbitofrontal cortex of freely moving rhesus macaques

Authors: *D. MAISSON, B. VOLOH, J. ZIMMERMANN, B. Y. HAYDEN;
Dept. of Neurosci., Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: There is growing interest in how the prefrontal cortex encodes a map of space. However, spatial coding in the primate prefrontal cortex, particularly in the orbitofrontal cortex (OFC), has remained largely unexplored. Investigating a prefrontal cognitive map has been limited by the ability to track the unrestrained movement of primates through an open field while recording neural activity. We developed a novel system, the Open Monkey Studio, which enables marker-less tracking and pose estimation of freely exploring rhesus macaques (Macaca mulatta). We coupled this new technology with a wireless recording system that makes use of a chronically implanted electrode array and stores neural data on a local data logger. Our recording environment is a cubic cage that is approximately 3 meters long on each dimension. In each session, there are 1-4 interactive computerized feeding stations, which represent "patches" in a foraging sense, and are available for the subject to forage from or ignore as they roam freely around the environment. To investigate spatial coding in the OFC, we tracked the movement of the monkey across time, while recording OFC neural activity, and estimated the animal's center of mass on 2 dimensions (length and width). To selectively investigate spatial coding in OFC, which is canonically a

core reward structure, we built a regression model to remove signature reward responses from the neural activity of each neuron. We then used the center of mass estimates to bin the reward-residualized neural activity into 30cm2 spatial bins. For each bin, we calculated a rate map, and computed the spatial information (bits/spike). To determine if the spatial information was significant, we shuffled the data 1000 times. For each shuffled set, we again computed spatial information. A neuron had significant spatial tuning, absent reward encoding, if its spatial information was greater than that of at least 95% of the shuffled sets. We found that the majority of neurons in OFC (n=194/302, 64.26%) encode spatial information. These results are consistent with the hypothesis that OFC contributes to the encoding of a broader cognitive map.

Title: Subject-to-subject and session-to-session variability in behavioural strategy for the International Brain Lab task

Authors: *C. FINDLING[1], P. DAYAN[2], A. POUGET[1], .. INTERNATIONAL BRAIN LAB[1];
[1]Univ. of Geneva, Geneva, Switzerland; [2]Max Planck institute for Biol. Cybernetcs, Tuebingen, Germany

Abstract: Most models of rodent behavior fit responses averaged across sessions and animals. Here, we ask instead whether different mice use different strategies and whether the same mouse uses different strategies on different sessions. Our analysis is based on a large cohort of mice (N=63), each performing 3-4 sessions of the International Brain Laboratory task. On each trial, mice earned liquid reward by turning a wheel to report whether a Gabor patch (of variable contrast) was on the left or right side of a screen. The prior probability that the stimulus appeared on the right switched in blocks between 0.2 or 0.8 in a random and uncued manner, with a nearly flat hazard rate. Here, we investigate different forms of variability in the behavior of the population using a 3 level hierarchical Bayesian model (HBM) which had a session level, nested within a subject level, itself nested within a population level. The session level captured the between-session variability within a subject; the subject level captured the between-subject variability. The HBM allowed L=4 candidate categories of behavioral strategies to which each session of each mouse could be attributed. The first category of optimal Bayesian agents implement the full generative process of the task, and so enjoy an explicit notion of block structure. The second category of stimulus-kernel strategies captures a local form of the bias within a block by low-pass filtering the sides on which stimuli were recently presented. The third action-kernel category is similar to the second but integrates over the sides that the mouse recently chose rather than over stimulus sides. The final fixed belief category maintains a fixed bias that does not change throughout the session. Inference was performed by combining variational Expectation-Maximization for session- and mouse-level parameters with type II maximum likelihood for population-level parameters (Piray et al. 2019). We found substantial between- and within-subject variability. For the former: the model fits favored action-kernel

strategies on at least one session for 71% of mice, optimal Bayesian strategies for 30%, fixed belief strategies for 19%, and stimulus kernel strategies for 13%. For within-subject variability, ~50% of the mice that performed 2 sessions or more were better explained by multiple strategies across sessions. Our results highlight the importance of not averaging across animals and sessions when analyzing rodent behavior. We are currently analyzing an additional, within-session level of strategy switching, and considering the representation of these various systematic differences in neural activity.

Title: A novel behavioral paradigm for parametric spatial working memory

Authors: *E. CHONG, L. CALCATERRA, A. AKRAMI;
Univ. Col. London, LONDON, United Kingdom

Abstract: Spatial working memory (SWM) is the short-term maintenance and update of spatial information. SWM is important for a broad range of cognitive tasks that involve reasoning about physical objects and spatially-organized information, even in abstract non-spatial contexts. What are the neural computations underlying SWM? We trained rats to perform a novel, parametric SWM task (PSWM), where 2D visual stimuli are projected onto the floor of a large behavioral arena, and animals learn to maintain stimulus locations in their working memory over a delay period. Our projection arena exploits the previously-reported tendency of rodents to attend to stimuli close to the ground, and their rapid acquisition of visual tasks involving such stimuli. Our paradigm additionally overcomes several key limitations of existing rodent SWM tasks: target location is continuous as opposed to discrete, and can be systematically controlled. It also spans a large space within animals' field of view, and mimics rodent naturalistic behavior. Animals were successfully trained to perform the task over several weeks, and we obtained a precise behavioral readout of the spatial precision of working memory in continuous spatial coordinates. Future experiments will involve the use of multiple tools to monitor and perturb brain activity during task performance, allowing the detailed investigation of the neural computations underlying PSWM behavior.

Title: Confidence-guided waiting as an evidence accumulation process

Authors: *T. BOYD-MEREDITH[1], A. PIET[2], C. D. BRODY[3];
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]Allen Inst., Seattle, WA; [3]Princeton Neurosci. Inst. and Dept of Mol. Biol., HHMI / Princeton Univ., Princeton, NJ

Abstract: When making decisions, we can improve our choice accuracy by combining multiple pieces of evidence that bear on the decision. In such an evidence accumulation process, choices are accompanied by a decision confidence signal, which estimates the probability of having chosen correctly. Confidence can be used to guide learning and subsequent actions. Investigation of the neural computations responsible for confidence estimates requires an accurate procedure for inferring the confidence of animal subjects. A post-decision wagering paradigm with randomly delayed reward delivery has recently been developed to simultaneously measure binary choices and graded estimates of decision confidence (Lak et al., 2014). In this paradigm, the length of time that an animal is willing to wait for reward before initiating a new trial is taken as a proxy for confidence. However, it is unclear what algorithm the animal uses to translate its decision confidence into a wait time decision. Here, we show that a post-decision drift diffusion to bound model can generate optimal wait time behavior. In this framework, each time step that the animal waits without receiving reward is taken as a piece of evidence favoring the unchosen option over the chosen option. The animal stops waiting for reward and starts a new trial once the balance of evidence crosses a fixed threshold. The decision to wait for reward results from the continued evolution of the latent variable used to determine initial choice. This unified view provides a parsimonious account of multiple decision processes previously studied separately. Moreover, this model can disambiguate patterns of waiting behavior produced by perturbation of the animal's initial confidence from patterns of waiting produced by perturbation of confidence-independent parameters of the wait time model. This improves the power of inactivation experiments to elucidate the role of different brain regions in generating confidence-guided waiting behavior. We trained rats to perform the wait time post decision wager after trials of the poisson clicks task. In the poisson clicks task, subjects must integrate and compare two trains of randomly-timed auditory clicks in order to choose correctly between two reward ports. This behavior is described by an extensively studied accumulation model (Brunton et al., 2013). We used the latent state at the final time point of the choice model as the initial point of a drift diffusion process controlling the wait time decision. Fitting the parameters of the accumulation process offers a concise explanation of rats' wait time distributions and provides a tractable strategy for an animal performing the task.

Title: Partial dopaminergic denervation of the globus pallidus produces short-memory impairment in rats

Authors: K. BARON-QUIROZ[1], M. GARCIA-RAMIREZ[2], *E. CHUC-MEZA[2];
[1]Unidad Profesional Interdisciplinaria de Biotecnología del IPN, Mexico City, Mexico; [2]Natl. Sch. Biolog Sci. IPN, Mexico city, Mexico

Abstract: Rats with low-level globus pallidus (GP) dopaminergic denervation can develop anxiety without any motor alterations (Avila et al. 2020). Besides, patients with unilateral or bilateral infarcts in the external GP show cognitive deficiencies, including amnesia and attention deficit (Jeon et al. 2002; Kim et al. 2008). In healthy subjects, on the other hand, the activity of the GP is enhanced during working memory tasks entailing the filtering of distractors and the storage of information (McNab & Klingberg, 2008). For these reasons the aim of this study was to evaluate the effect of low-level 6-OHDA-induced unilateral and bilateral GP lesions in male Wistar rats (n=8/group) on recognition memory, motor activity, and the number of TH+ neurons in the SNc. For unilateral- and bilateral-lesioned animals, there was a significant decrease in the number of TH+ neurons (27% and 42%, respectively) and in the object, location, and temporal order discrimination indexes of recognition memory tests. Motor activity was unaffected. Thus, GP dopamine denervation was detrimental to short-memory.

Title: Dynamic perturbation during retention alters human sequential working memory

Authors: *J. LI[1], Q. HUANG[2], Q. HAN[3], Y. MI[4], H. LUO[5];
[2]Sch. of Psychological and Cognitive Sci., [1]Peking Univ., Beijing, China; [3]Peking-Tsinghua Ctr. for Life

Sciences, Peking Univ., Beijing, China; [4]Ctr. for Neurointelligence, Sch. of Med., Chongqing Univ., Chongqing, China; [5]Dept. of Psychology, Peking Univ., Beijing, China

Abstract: Temporarily storing a list of items in working memory (WM) for subsequence goal-directed behavior is an important function in many cognitive processes. This ability has been posited to rely on dynamic representations during retention such as neural reactivations or a theta-gamma oscillation code. However, the causal evidence for the role of neural network dynamics in sequential WM is still lacking. We use a temporal-correlated "dynamic perturbation" approach to interfere with the underlying representations during retention and manipulate the relative memory strength of memory items. Six human behavior experiments confirm the validity of this manipulation approach. A continuous attractor model with short-term synaptic plasticity (STP) principles reproduces all the experimental results. The model indicates that the modification of multi-item synaptic efficacies accumulates over time and eventually leads to the changes in recall performance. Besides the manipulation of relative memory strength, this dynamic perturbation also manipulates the memory performance of order information in sequential WM task. Our results support the causal role of temporal dynamic neural network in mediating sequential WM and offer a promising, non-invasive method to manipulate WM.

Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [9]BCH / Harvard Med. Sch., Boston, MA

Abstract: An increasing body of literature suggests that cortical association areas play a crucial role in perceptual decision-making. Recent work in mice has shown that neurons in the posterior parietal cortex (PPC) exhibit activity predictive of behavioral choice. However, it remains unclear how this choice-specific behavior emerges from the underlying circuit connectivity in PPC. To investigate these structure-function relationships, we combined virtual reality behavior, *in vivo* calcium imaging, and large-scale electron microscopy in the same mouse to create a functional connectivity map of PPC neurons.
We used this multimodal dataset to analyze how synaptic connectivity of individual neurons relates to their cell type and choice-selectivity. We show that layer 2/3 excitatory and inhibitory neurons exhibit

choice-selective connectivity motifs, whereby neurons exhibit preferential connectivity to partners with similar choice-selectivity. These findings suggest that interneurons, as well as pyramidal neurons, exhibit choice-specific wiring, display choice-specific activity, and support decision-making computations and behaviors. This conclusion contrasts with the prevailing circuit models of primary visual cortex, where interneuron connectivity is essentially random, and suggests that critical aspects of connectivity may differ between sensory and association areas. To investigate the implications of these measurements, we performed circuit modeling to analyze how choice-specific wiring is constrained by network stability and contributes to computations such as amplification, feature competition, or winner-take-all. Taken together, these results provide an example for how synaptic connectivity motifs give rise to neuronal activity, which can contribute to a general understanding of how cortical circuits support complex behavior.

Title: The neural mechanism of the encoding of the familiar face in the primate striatum tail

Authors: *J. KUNIMATSU[1], H. AMITA[2], O. HIKOSAKA[3];
[1]Univ. of Tsukuba, Tsukuba, Japan; [2]Primate Res. Inst., Kyoto Univ., Inuyama, Japan; [3]Lab. Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: We can quickly find a familiar person in the crowd of people. This ability is necessary for our daily life, however, the underlying neuronal mechanism is still unclear. Recently, we found that neurons in the basal ganglia posterior circuit, including the striatum tail (STRt), encode values of visual objects stably based on the long-term memory (Yamamoto et al., 2013; Kunimatsu et al., 2019). Such stable value coding is useful for automatically and quickly finding good objects among many others (Hikosaka et al. Trends Cogn Sci 2013). We hypothesized that the long-term value coding neurons in STRt are involved in the detection of the socially familiar face. To address this question, we first studied whether striatal tail (STRt) neurons respond to face images by the passive-viewing task. In this task, the object was chosen randomly from twelve images, which were presented one at a time at the preferred position for the recorded neuron while the monkey fixed its gaze at the center. The images included three categories: 1) face images of socially familiar persons who take daily care of the monkeys for more than one year (familiar face), 2) face images of unknown persons (unfamiliar face), and 3) no reward associated fractal objects. We recorded 68 visual neurons in STRt, 30 of them (45%) showed a significant response to the face images. On the average, the response was stronger to familiar faces than unfamiliar faces in these neurons ($p < 0.05$). Next, we tested the object value (high-valued or low-valued) on long-term reward experiences for these face-responsive neurons. We found that these neurons also encoded the values of many fractal objects. Furthermore, the strength of neuronal modulation of social familiarity bias (familiar or unfamiliar) and object value bias (high-valued or low-valued) are positively correlated ($r = 0.43$, $p < 0.05$). These results suggested that the social familiarity and object value information are mediated by a common neuronal mechanism. The STRt may contribute to the quick detection of real-life familiar faces.

Abstract: Network Interactions during Long Term Memory-Guided versus Stimulus-Guided Attention in Humans
Isenburg K, Morin T.M., Rosen M.L., Somers D.C., Stern C.E.
Despite the remarkable capacity of human visual processing, we are limited in what we can pay attention to at a given moment. Recent work has identified differences between long term memory-guided attention (LTM-guided attention) and attention guided by external stimuli (STIM-guided attention), shedding light on large-scale brain network contribution to these two processes (Rosen et al., 2018). Given previous evidence of the Dorsal Attention Network (DAN) in the processing of external stimuli, and the Default Mode Network (DMN) in self-referential processing and memory retrieval, we examined whether these two networks would contribute differentially to STIM-guided vs LTM-guided attention. We hypothesized that the Cognitive Control Network (CCN), with posterior regions previously implicated in LTM-guided attention, would adapt connectivity with DMN and DAN based on LTM-guided vs STIM-guided attention. This analysis uses data previously collected from a neuroimaging study utilizing task-based functional Magnetic Resonance Imaging (fMRI) to compare connectivity differences between LTM-guided and STIM-guided attention in a block design (Rosen et al., 2018). 24 healthy controls (13 male) were enrolled and attended one training and one fMRI session, consisting of 12 scans. Brain activity was analyzed using a generalized Psychophysiological Interaction (gPPI) model implemented in Conn Toolbox. Connectivity results were analyzed based on the Schaefer 400 parcellation of the Yeo et. al (2011) 7-network brain atlas. Parcels of the DMN, DAN, and CCN were used to generate a connectivity matrix between all pairs (189 nodes) contrasting connectivity during LTM-guided vs. STIM-guided attention. Threshold Free Cluster Enhancement (TFCE) was employed to identify clusters where connectivity significantly differed across task conditions. Results showed 11 significant clusters of connections between Schaefer nodes. Preliminary findings showed stronger connectivity between the nodes of the posterior cingulate/medial prefrontal DMN with posterior nodes of the DAN and prefrontal nodes of the CCN during LTM-Guided attention. Additionally, connectivity decreased within the DMN, specifically between posterior cingulate nodes and prefrontal nodes. These results suggest that LTM-guided attention is supported by the postero-medial subdivision of the DMN (Karenback et al., 2018), gating network integration as they split off from the larger DMN and couple with nodes of the DAN and CCN.

Title: Anatomical connectivity between cortical brain areas and the anterior-posterior axis of the human hippocampus: new insights using quantitative fibre tracking.

Authors: *M. A. DALTON, A. D'SOUZA, J. LV, F. CALAMANTE;
Univ. of Sydney, Sydney, Australia

Abstract: Background. The hippocampus is central to a broad range of cognitive functions including episodic memory. To date, the anatomical connectivity of the human hippocampus is largely inferred from the results of studies conducted in the non-human primate brain. We know much less about how different regions along the anterior-posterior axis of the human hippocampus anatomically connect with cortical regions to support key functions such as memory. The aim of this study was to address this gap by assessing where along the anterior-posterior axis of human hippocampus different cortical brain areas preferentially connect. **Methods.** We combined high quality data from the Human Connectome Project (HCP) and cutting-edge quantitative fibre-tracking methods. Ten subjects were selected from the HCP 100 unrelated subject database. We implemented a Diffusion Weighted Imaging (DWI) pipeline specifically tailored to study hippocampal connectivity using MRtrix3. We combined our tailored pipeline with Track Density Imaging (TDI) to create 'endpoint density maps' which allowed us to quantitatively assess and visualise, for the first time in the human brain, where within the hippocampus different cortical brain areas preferentially 'connect'. **Results.** Patterns of anatomical connectivity generally aligned with predictions based on observations from the non-human primate literature. The results of group level analyses revealed that the hippocampus displayed preferential connectivity with discrete cortical areas in temporal, medial parietal, dorsal and ventral stream visual and early visual cortices. Strikingly, our results showed that each of these cortical areas displayed preferential connectivity with specific regions along the anterior-posterior and medial-lateral axes of the hippocampus. In parallel, circumscribed regions within the hippocampus were highly connected with multiple cortical areas. Intriguingly, we identified two 'hubs' of anatomical connectivity in the medial hippocampus; a posterior medial hub preferentially linked with visuospatial processing areas in parietal and early visual cortices and an anterior medial hub more broadly linked with temporopolar, inferotemporal, parietal and early visual areas. **Conclusions.** This study represents one of the most comprehensive *in-vivo* characterisations of structural connectivity between cortical brain areas and the human hippocampus to date. Our results contribute to ongoing efforts to characterise anatomical connectivity of the human hippocampus with implications for understanding functional differentiation along the long axis of the hippocampus.

Title: Single-neuron mechanisms of neural adaptation in the human temporal lobe

Authors: *T. P. REBER[1,2], S. MACKAY[2], M. BAUSCH[2], M. S. KEHL[2], V. BORGER[3], R. SURGES[2], F. MORMANN[2];

Abstract: A central function of the human brain is its ability to adapt to new situations based on past experience. Adaptation is reflected behaviorally by shorter reaction times to repeating or similar stimuli, and neurophysiologically by reduced neural activity in bulk-tissue measurements with fMRI or EEG. Several potential single-neuron mechanisms have been hypothesized to cause this reduction of activity at the macroscopic level. We here explore these mechanisms using an adaptation paradigm with visual stimuli bearing abstract semantic similarity. We recorded intracranial EEG (iEEG) simultaneously with spiking activity of single neurons in the medial temporal lobes of 25 neurosurgical patients. Recording from 4917 single neurons, we demonstrate that the reduced event-related potentials in the macroscopic iEEG signal is associated with a sharpening of tuning curves of single neurons in the amygdala as well as an overall reduction of single-neuron activity in the hippocampus, entorhinal cortex, and parahippocampal cortex. Together, these results identify the neuronal mechanism underlying neural adaptation in the human medial temporal lobe.

Title: Neurofeedback-supported mental imagery training selectively boosts the capacity of visual working memory and attention and reveals a causal role of contralateral delay activity and visual working memory capacity

Authors: M. MACHIZAWA[1,2], R. MIZUOCHI[1], S. YAMAWAKI[1], T. WATANABE[2];

Abstract: Brain training programs or intensive behavioral training techniques have been touted to improve our cognition. However, most of such approaches had been shown not to generalize and robustly enhanced our higher cognitive function, especially visual working memory (VWM) that is pivotal for our daily lives. Social demands are rising to break through the limited applicability of these approaches to improve our higher cognitive functions. Neurofeedback (NF) is one of the established methods to quantify and visualize our mental operations as a focused brain training. Here we propose a robust and novel neurofeedback training method that can improve the hardly-improved brain functions, attention and VWM. We have trained subjects with the contralateral delay activity (CDA), which is a robust neural substrate that can quantify the amount of our mental representation (Vogel & Machizawa, 2004) that also reflects the control of our selective attention (Vogel, McCollough & Machizawa, 2005). Twenty participants underwent a CDA NF training for five days, randomly assigned to the left- or right-lateralized training group (LHG and RHG, respectively), and blinded for the target neural marker. Each trial consisted of a baseline resting period followed by a mental imagery induction phase and feedback. Participants were asked to create mental imagery of their choice and try to improve the NF score. Their CDA amplitude relative to the baseline was computed and the feedback score was provided on a real-time basis. Their causal impact of the CDA NF was assessed by a test battery of attentional network and VWM capacity tasks at pre- and post-training days. The results revealed that the CDA NF equally improved their selective attention ability for both groups. Notably, the LHG but not RHG robustly improved VWM capacity with a high effect-size (Cohen's *d*: 0.94). The pooled outcome revealed left-lateralized CDA, but not right-lateralized CDA, correlated with the VWM improvement. Moreover, the individual variations in the behavioral and CDA changes revealed the causal role of the CDA for VWM capacity. Together with the evidence of the left-lateralized neuroanatomical relation of the capacity of VWM, our finding may elucidate a critical role of the functional neuroanatomy underlying VWM that may be applied for the prevention of dementia or attention deficiency.

Title: Single-neuron firing properties in the human amygdala predict subjective decisions on the delay discounting task

Authors: *M. OMIDBEIGI[1], J. GILL[4], Z. AGHAJAN[2], E. A. MANKIN[5], G. KALENDER[2], I. FRIED[6], N. A. SUTHANA[3], A. BARI[1];

Angeles, CA; [4]Univ. of California Los Angeles, Los Angeles, CA; [5]UCLA, Dept. of Neurosurg., Los Angeles, CA; [6]UCLA Sch. Med., Los Angeles, CA

Abstract: INTRODUCTION: The amygdala has long been described to be involved in emotion, especially fear-related processes. However, recent research has demonstrated its role in various decision-making in both humans and animals. A frequently used experimental paradigm to study human decision-making is the delay discounting task (DDT). DDT measures a subject's preference for larger hypothetical monetary rewards at variable delays compared to smaller immediate rewards. While the phenomenology of delay discounting and its relation to mental health has been studied in detail, little is known about its neural correlates in thedecision-making process. Here we hypothesized that the activity of the human amygdala is predictive of subject choice on the DDT. **METHODS:** We explored single neuronal activity from the amygdala in nine treatment-refractory epilepsy patients that were implanted with depth electrodes for seizure localization. We recorded from 12 amygdalas (5 left, 7 right) whilesubjects performed the DDT. In DDT, participants repeatedly chose between a small immediate reward (less than $10) and a larger delayed ($10 after either 2, 30, 180, 365 days) reward to estimate the discount rate for a reward of $10. Trials were compared between those in which the participant chose an immediate reward against trials in which subjects chose the delayed reward. We used the Wilcoxon rank-sum test in order to compare trials firing rate. **RESULTS:** We recorded the activity of 66 amygdala neurons from 9 patients. Neuronal discharge rates were examined During the time between stimulus onset and response time. During the DDT, 36 of 66 units (54.5%) differentiated immediate trials from delay trials by significant changes in firing rate 200-1000ms before the response. In population response of amygdala neuronal activity, we observed a significant (P value<.001, Wilcoxon rank-sum test) difference between immediate and delay trials. **CONCLUSION:** Our results uncover neural correlates of subjects' decisions between immediate and delayed reward during decision-making and suggest that amygdala neural firing rates can predict that decision.

Title: Alpha transcranial alternating current stimulation selectively modulates reward-dependent corticostriatal connectivity

Authors: *D. V. SMITH[1], Y. LIU[2], B. KREKELBERG[2];
[1]Temple Univ., Philadelphia, PA; [2]Cntr Molec Behav Neurosci, Rutgers Univ., Newark, NJ

Abstract: Receipt of reward evokes pleasure, alters pupillary responses, and increases activation within the striatum. Although much of the existing work on human reward processing has been limited to

correlative approaches such as neuroimaging, understanding how to manipulate reward processing with noninvasive brain stimulation could advance theories of reward processing and decision making and also have significant translational impact for disorders characterized by aberrant reward processing. Unfortunately, the striatum is buried deep inside the brain, making it inaccessible to approaches that manipulate function via noninvasive brain stimulation. We approached this problem by applying 10 Hz transcranial alternating current stimulation (α-tACS) to the ventrolateral prefrontal cortex (VLPFC) -- an area with dense projections to the striatum -- and a control site (temporal parietal junction). Stimulation was applied while participants underwent functional magnetic resonance imaging and received monetary reward and punishment. We hypothesized that alpha-tACS applied to VLPFC would alter reward processing, as indexed by pupillary responses and reward-dependent corticostriatal connectivity. We found that stimulation over VLPFC reduced the extent to which the receipt of reward constricted pupil size. VLPFC stimulation was also associated with enhanced VLPFC responses to reward and suppressed responses to punishment. In addition, we also found that VLPFC stimulation enhanced corticostriatal connectivity during the receipt of reward. These results suggest that tACS applied to prefrontal regions that are connected to the striatum can modulate reward-dependent corticostriatal connectivity. Understanding how tACS can be used to modulate reward-dependent corticostriatal connectivity may have important implications for psychopathologies associated with aberrant reward processing.

Title: The flow of information transformation across cortical networks during story listening

Authors: *C. H. C. CHANG, S. A. NASTASE, U. HASSON;
Princeton Neurosci. Inst., Princeton, NJ

Abstract: When listening to a spoken narrative, the listener's brain constantly synthesizes low-level input into higher-level representations along a cortical hierarchy with increasing temporal receptive windows. For example, the early auditory cortex processes rapidly-evolving acoustic features, early language areas synthesize the sounds into words, higher-order language areas synthesize the spoken words into sentences, while the default mode network synthesizes the spoken sentences to extract slow-evolving semantic features. This hierarchical processing architecture indirectly implies a temporal sequence of information transformation with longer temporal lags between regions farther apart in the cortical hierarchy. The current study directly examined the temporal lags between activities in different brain regions along the processing timescales hierarchy while subjects listened to a naturalistic spoken narrative.
We aggregated eight fMRI datasets acquired from 126 participants while they listened to spoken stories

and computed the inter-subject functional connectivity across areas along the processing hierarchy at varying lags (i.e. cross-correlation). For each seed-target pair, the lag with the peak correlation value was extracted as an estimate of the temporal lag between seed-target pairs. Regardless of the choice of the seed, we found the same order of peaks across the processing hierarchy, where early auditory peaked first, followed by ventral language areas, dorsal language areas, attention network, and lastly the default mode networks. This lag gradient was consistently found across intact stories but absent in resting-state and scrambled-story data, indicating a stimulus-driven flow of information transformation.
By simulating brain responses to narrative-like nested structure, we demonstrated that activation accumulation at varying granularity (e.g. word, sentence, and paragraph) can explain the lag gradient across networks. In addition, our simulation showed that the structural properties of natural narratives can account for the scale-free dynamics observed in the brain activity and the stronger low-frequency fluctuations in networks with longer temporal receptive windows.
In conclusion, this study revealed a novel lag gradient along the cortical hierarchy during story listening and illustrated how information is synthesized at different timescales along the processing hierarchy.

Title: The medial temporal lobe supports visual short-term memory precision

Authors: *W. XIE[1], M. CAPPIELLO[2], J. H. WITTIG, JR[1], S. INATI[3], M. A. YASSA[4], E. ESTER[5], W. ZHANG[2], K. A. ZAGHLOUL[1];

Abstract: Precision of information retained in short-term memory (STM) underlies our ability to pinpoint the exact details of a stimulus that we recently encountered. Imprecise STM has been associated with more variable neural representations and more variable recall behavior. However, the neural mechanisms supporting STM precision are yet fully understood. Here, we use converging evidence from multiple experimental modalities to test the hypothesis that STM precision relies on circuitry of the medial temporal lobe (MTL), a region commonly associated with the ability to distinguish similar information contents in long-term memory. First, using previously established neuroimaging methods, we find that MTL structures involved in discriminating the contents of long-term memory are also sensitive to task

demands on STM precision. Second, using intracranial electroencephalography (iEEG), we find that delay-period MTL activity retains precise item-specific information that is predictive of STM recall fidelity. Finally, we find that perturbing the MTL through electrical stimulation or surgical removal reduces STM precision. Collectively, these data provide correlational and causal evidence that the MTL makes an essential contribution to STM precision.

Title: Epigenetic mechanisms underlying reconsolidation-based memory updating

Authors: *C. W. SMIES, L. BELLFY, D. S. WRIGHT, M. W. URBAN, J. L. KWAPIS;
Biol., The Pennsylvania State Univ. - Univ. Park, State College, PA

Abstract: Memories are plastic records of experience that require maintenance in the form of updating to remain meaningful. The molecular mechanisms underlying memory formation have been heavily studied, whereas the mechanisms underlying memory updating have yet to be fully investigated. One key mechanism necessary for successful memory formation is histone acetylation, the addition of acetyl groups to histone tails, which typically enables gene expression necessary for memory formation. Enhancing histone acetylation by blocking histone deacetylase 3 (HDAC3, an enzyme that reduces histone acetylation) during memory consolidation enhances both gene expression and long-term memory formation in young and old mice (McQuown et al., 2011 & Kwapis et al., 2018). Recent work has suggested that histone acetylation is also important for reconsolidation-dependent updating, as broadly blocking histone acetylation disrupts both consolidation and reconsolidation of fear memories (Maddox et al., 2013), although the specific role of HDAC3 in reconsolidation-dependent updating is currently unclear. Here, we tested whether the HDAC3-specific inhibitor RGFP966 would improve reconsolidation-dependent memory updating in young and old male C57BL/6J mice using the novel Objects in Updated Locations (OUL) paradigm (Wright et al., 2020). In OUL, mice are trained on the locations of two identical objects. Next, this memory is updated by moving one object to a novel location. Finally, memory for both the original and updated locations is assessed during a test session, where memory is indexed by the time spent investigating the three familiar locations in relation to a novel location. Here, we report that systemically inhibiting HDAC3 immediately following memory updating ameliorates age-induced deficits in memory updating in the OUL task. In contrast, young mice that

receive RGFP966 immediately following the update session show intact memory for the updated information but decreased memory for the initial training information. Together, these data suggest that HDAC3 inhibition can enhance memory updating, but this enhancement may come at the expense of the original memory. In old animals that normally fail to update, HDAC3 inhibition enhances the updated information without affecting the original memory. In young animals that already show robust memory updating, HDAC3 seems to strengthen the updated information so that it outcompetes the original memory. Thus, the updated and original memories are tightly linked and may compete for expression.

Title: The role of circadian gene Per1 in gating contextual memory performance within the retrosplenial cortex

Authors: *C. A. BRUNSWICK, K. K. BODINAYAKE, D. S. WRIGHT, E. M. STUART, C. F. LO, A. C. HEIMANN, S. S. LAKHIA, J. L. KWAPIS;
Dept. of Biol., Penn State Univ., University Park, PA

Abstract: The link between the circadian system and memory performance is well-characterized and widely accepted. Circadian rhythms are endogenous cycles governed predominately by complex transcriptional patterns of circadian genes within the suprachiasmatic nucleus (SCN). Relatively little research has investigated the roles these genes play outside of the SCN. However, one such circadian gene—Period 1 (*Per1*)—has recently been implicated in gating memory formation independent of its role within the SCN. We investigated how *Per1* expression relates to memory performance in a memory-relevant cortical structure, the retrosplenial cortex (RSC). We sought to elucidate how *Per1* expression within the RSC is affected by a memory task, given the RSC's role in memory formation. First, male C57BL/6J mice were trained, during the day, in contextual fear conditioning and were then sacrificed at various timepoints following training (immediately, 30 min, 1 hr, or 2 hr post-training). We then performed qPCR on RSC tissue from these mice and determined that *Per1* expression was modulated by learning and peaked one hour after a learning event. Given *Per1*'s well-documented role in maintaining circadian rhythms, we next investigated how learning-induced expression of *Per1* changes across the circadian cycle and the link between *Per1* expression and memory performance. Two cohorts of male C57BL/6J mice were trained in a spatial memory task (object location memory, OLM) at six timepoints

spanning the circadian cycle (Zeitgeber Times: ZT1, ZT5, ZT9, ZT13, ZT17, ZT21). The first cohort of animals was used to investigate how performance in OLM varies throughout the circadian day. A second cohort was trained in the OLM task simultaneously and then sacrificed an hour later to analyze *Per1* expression. We found a significant effect of circadian timepoint on memory performance, with better memory for OLM observed during the day than at night. Learning-induced *Per1* expression within the RSC also varied with timepoint and peaked during the day. Notably, learning did not drive this same pattern of *Per1* expression within the SCN. These results confirm the role of *Per1* in modulating memory performance independent of the SCN's governance of the circadian system and demonstrate, for the first time, that *Per1* expression is induced by learning within the RSC in a circadian-dependent fashion. Furthermore, this induction of *Per1* expression by learning oscillates in tandem with memory performance across the circadian day/night cycle. Future experiments will directly manipulate expression of *Per1* in the RSC to determine how this impacts memory performance.

Title: Hippocampal Per1 and memory allocation both oscillate in tandem with memory performance

Authors: *L. BELLFY[1], C. W. SMIES[1], K. K. BODINAYAKE[1], A. R. BERNHARDT[1], E. M. STUART[1], D. S. WRIGHT[1], C.-Y. LO[1], J. L. KWAPIS[2];
[1]Dept. of Biol., Pennsylvania State Univ., University Park, PA; [2]Dept. of Biology, Ctr. for Mol. Investigation of Neurolog. Disord, Penn State Univ., University Park, PA

Abstract: Circadian rhythms influence many biological processes, including long-term memory formation. In mice, performance on behavioral paradigms varies dramatically depending on the time of day animals are tested, with better memory performance typically observed during the day compared to night. We used a dorsal hippocampus (DH)-dependent learning paradigm called Object Location Memory (OLM) to elucidate the molecular relationship between the circadian rhythm and memory. In this paradigm, young mice (around 3 months old) learn the location of two identical objects during a training session. During the test session 24 hours later, one of the objects is moved to a novel location. Memory for the training session is determined by the time the mouse spends investigating the object in the novel location. An outstanding question is how the molecular mechanisms of long-term memory are altered

across the day/night cycle. One mechanism that may regulate memory across the 24 hour day is the circadian gene *Period1* (*Per1*), which modulates memory formation directly in the DH independent of its role in the circadian clock in the brain's central pacemaker, the suprachiasmatic nucleus. Here, we tested whether *Per1* functions in the DH to regulate memory across the day/night cycle. First, we measured memory performance in OLM across the diurnal cycle. We found that mice show improved learning during the day compared to night, with peak and trough learning occurring at ZT5 and ZT17, respectively. Next, we assessed hippocampal *Per1* expression across the 24h day. We found that learning drove larger increases in hippocampal *Per1* during the day than at night. As *Per1* expression oscillated in tandem with memory performance, *Per1* may exert circadian control over hippocampal memory formation. Finally, we tested whether *Per1* may modulate hippocampal memory performance by regulating memory allocation, the process of determining which individual neurons across the brain encode a given memory. As *Per1* regulates the activity of the transcription factor CREB, a key mechanism controlling memory allocation, it is well-positioned to control memory allocation across the day/night cycle. Therefore, we monitored memory allocation across the diurnal cycle using *Arc* fluorescence in situ hybridization (*Arc* FISH) and found that a higher proportion of neurons are recruited to memory during the day (when both *Per1* levels and memory peak) than at night (when *Per1* and memory trough). *Per1* may therefore regulate hippocampal memory formation across the circadian day by controlling memory allocation. In conclusion, *Per1* may exert local control in the DH over memory formation by regulating memory allocation.

Title: Phosphorylation is a critical post-translational modification of 4EBP2 for memory dependent on sleep

Authors: N. BURKERT, I. SUCCI, L. GIVVINES, O. SKWIERAWSKI, E. WASH, ***J. C. TUDOR**; St. Joseph's Univ., Philadelphia, PA

Abstract: Sleep is critical for learning and memory formation. Five hours of sleep deprivation has been shown to impair memory in male mice by attenuating protein synthesis in the hippocampus. The mammalian target of rapamycin (mTOR) signaling pathway is a key regulatory pathway that is also affected by sleep deprivation. Eukaryotic translation initiation factor 4E binding protein 2 (4EBP2) is critical in this pathway for protein synthesis. To examine the role of 4EBP2 in sleep-dependent memory, we developed mutant 4EBP2 adeno-associated viruses (AAVs) with a CaMKII alpha promoter fragment to selectively express in excitatory neurons in the hippocampus. Point mutations to alanine residues at the

phosphorylation sites rendered the 4EBP2 protein phosphodefective, while point mutations to aspartate residues at the phosphorylation sites resulted in phosphomimetic 4EBP2. We found that mice infected with the phosphomimetic 4EBP2 AAV in the hippocampus were resistant to the memory impairments associated with sleep deprivation, while well-rested mice infected with the phosphodefective 4EBP2 AAV in the hippocampus had similar memory deficits to those associated with sleep deprivation. Further, phosphomimetic 4EBP2 prevented the deficits in protein synthesis in the hippocampus caused by sleep deprivation, while phosphodefective 4EBP2 lowered the amount of protein synthesis. Our findings support the role of phosphorylation as a critical post-translational modification of 4EBP2 for sleep-dependent memory formation. Work is continuing to examine whether this signaling pathway is also affected by sleep deprivation in female mice or if female hormones are protective to this effect.

Abstract: Maintaining appropriate levels of fear memory specificity is crucial for individual's survival and mental health, whereas overgeneralized fear commonly occurs in neuropsychiatric disorders, including posttraumatic stress disorder and generalized anxiety disorder. However, the molecular mechanisms regulating fear memory specificity remain poorly understood. The medial prefrontal cortex

(mPFC) is considered as a key brain region in fear memory regulation. Previous transcriptomic studies have identified that plexin-A1, a transmembrane receptor critical for axon development, was downregulated in the mPFC after fear memory training. In this study, we identified that learning-induced downregulation of the mRNA and protein levels of plexin-A1 specifically occurred in the inhibitory but not excitatory neurons in the infralimbic cortex (IL) of mPFC. Further studies of plexin-A1 by virus-mediated over-expression of functional mutants selectively in the IL inhibitory neurons revealed the critical roles of plexin-A1 for regulating memory specificity and anxiety. Moreover, our findings revealed that plexin-A1 regulated the distribution of glutamic acid decarboxylase 67, a GABA synthetase, which in turn modulated the activity of IL and its downstream brain regions. Collectively, our findings elucidate the molecular modifier of IL inhibitory neurons in regulating memory specificity and anxiety, and provide candidates for developing therapeutic strategies for the prevention or treatment of a series of fear generalization-related neuropsychiatric disorders.

Title: Bdnf and egr1 play doubly dissociable role in the consolidation and reconsolidation of first- and second-order fear memories in the basolateral amygdala complex

Authors: *A. SHVETCOV, R. F. WESTBROOK, N. M. HOLMES;
Univ. of New South Wales, Sydney, Australia

Abstract: We used rats to examine the roles of BDNF and EGR1 in consolidation and reconsolidation of first- and second-order fear memories in the basolateral amygdala complex (BLA). Rats were exposed to pairings of a light and foot shock to produce first-order conditioned fear of the light. They were then exposed to pairings of a tone and the conditioned light to produce second-order fear of the tone. The initial experiments examined the effect of infusing a BDNF antisense oligonucleotide (ASO) into the BLA on consolidation and reconsolidation of the first- and second-order fear memories. The BLA BDNF ASO infusion disrupted consolidation of the first-order (visual) fear memory when administered prior to pairings of the light and shock (Exp. 1); and disrupted consolidation of the second-order (auditory) fear memory when administered prior to pairings of the tone and the already conditioned light (Exp. 2). This infusion had no effect on reconsolidation of the first-order memory when administered prior to the tone-light pairings (Exp. 2) and no effect on reconsolidation of the second-order memory when administered prior to a brief re-exposure to the already conditioned tone (Exp. 3). The next experiments examined the effect of infusing an EGR1 ASO into the BLA on consolidation and reconsolidation of first- and second-order fear memories. The BLA EGR1 ASO infusion spared consolidation of the first-order (visual) fear memory when administered prior to light-shock pairings (Exp. 4). In contrast, this infusion disrupted retrieval of the first-order memory when administered before tone-light pairings; and thereby, acquisition

of the second-order fear memory (Exp.5). It also disrupted reconsolidation of the first-order fear memory when administered before the tone-light pairings (Exp. 5), and disrupted reconsolidation of the second-order fear memory when administered prior to a brief re-exposure to the conditioned tone (Exp. 6). Taken together, these results show that ERG1 and BDNF have doubly dissociable roles in the consolidation and reconsolidation of first- and second-order fear memories in the BLA. BDNF, but not ERG1, is critical for consolidation of both types of memory but is not needed for *re*consolidation of either. In contrast, EGR1 is critical for *re*consolidation of both types of memory but is not needed for consolidation of either.

Title: Activation of Rac1 GTPase in the basolateral amygdala leads to long-term fear memory impairment and neuronal morphological changes

Authors: *J. F. COSTA, M. DINES, R. LAMPRECHT;
Sagol Dept. of Neurobio., Univ. of Haifa, Haifa, Israel

Abstract: Evidence indicates that long-term memory-related processes such as consolidation, extinction, and forgetting involve changes in synaptic efficacy produced by alterations in neuronal transmission and morphology. Rac1 GTPase activity is regulated by synaptic activation and it can affect neuronal morphology by controlling actin-regulatory proteins. In this study, we have analyzed the role of Rac1 GTPase in the regulation of neuronal morphology and memory formation using a photoactivatable form of Rac1 (PA-Rac1). PA-Rac1 was expressed in mice basolateral amygdala (BLA) and photoactivated during fear conditioning. Mice in the control group were trained for fear conditioning but PA-Rac1 was not activated. Two days after fear conditioning, animals were tested for fear memory and their brains were removed immediately afterward and subjected to the Sca*l*eS clearing method to observe possible changes in neuronal morphology. We observed that activation of PA-Rac1 during fear conditioning impaired long-term fear memory. We also found significant changes in neuronal morphology in the PA-Rac1 activated neurons in the BLA two days after fear conditioning. We detected a small increase in the cell body sphericity but not its area or volume. Moreover, dendritic shafts presented a significant reduction in volume, area, mean diameter, and length, mostly in the dendrites that are proximal to the soma. We also observed alterations in terms of neuronal complexity such as an increase in dendritic branch points with a consequent increase of dendritic segments. Furthermore, we detected an increase in spine density in specific dendritic branches. These findings suggest that such alterations in neuronal morphology are involved in attenuating fear memory formation in the BLA.

Title: Evidence for tonically active presynaptic alpha-2 adrenoceptors and their modulation of NMDA receptor mediated release of catecholamines in rat brain slices

Authors: *Y. M. ALJOHANI, G. DEZFULI, K. J. KELLAR;
Pharmacol. & Physiol., Georgetown Univ., Washington, DC

Abstract: Maintaining optimal levels of catecholamine neurotransmission in the central nervous system is vitally important. These neurotransmitters modulate several crucial physiological processes, including aspects of arousal/attention, focus, neuroendocrine functions, and the sleep-wake cycle; in addition, they play complex roles in regulating cognition and affect. Previously, we demonstrated that in brain slices from aged Fischer 344 rats, there is an age-related decrease in glutamate-stimulated norepinephrine (NE) release in the cerebral cortex and hippocampus (Dezfuli et al., 2019) and a regionally specific decline in glutamate-stimulated dopamine (DA) release, with a deficit in the striatum but no significant reduction in the olfactory tubercle (Aljohani et al., 2021). We have begun to explore the modulation of this glutamate-stimulated release of neurotransmitters and now report that stimulation of alpha-2 adrenergic receptors with clonidine decreases the glutamate-stimulated NE release in a dose-dependent manner; while in contrast, blockade of these receptors with phentolamine, an alpha-1 and alpha-2 adrenergic receptor blocker or with idazoxan, a selective alpha-2 receptor blocker, markedly potentiates glutamate-stimulated NE release in cortical brain slices. These findings strongly indicate that alpha-2 adrenergic receptors modulate NE release in the cerebral cortex and that they are tonically active. Furthermore, these studies are consistent with a presynaptic location of alpha-2 receptors on NE axons, positioned to modulate the glutamate-stimulated release of NE and related behaviors (e.g., cognition and/or affective disorders). Results from the dopamine studies are ongoing and will be reported.

Title: The role of ciliary melanin concentrating hormone receptor 1 in cognitive functions in mice

Authors: *W. ALHASSEN[1], B. ROBBINS[1], H. NGUYEN[1], A. ALACHKAR[2];
[2]Pharmacol., [1]Univ. of California Irvine, Irvine, CA

Abstract: Primary cilia are microtubule-based sensory organelles that project from the surfaces of most cells and play crucial roles in cell signaling and communication through detecting and transducing external stimuli, and regulating the proper cell differentiation and migration. Primary cilia are involved in pathways such as the Sonic hedgehog, WNT, and cAMP mediated pathways. Alterations of neuronal primary cilia can cause abnormal neurogenesis and neural differentiation, leading to ciliopathies that may cause brain abnormalities, resulting in higher susceptibility to psychiatric disorders. MCHR1 is one of the few GPCRs that are selectively expressed on neuronal primary cilia. We have previously shown that MCHR1 mRNA levels are significantly lower in the PFC of subjects with schizophrenia and found that the disruption of the MCH system in mice led tobehavioral abnormalities including social and cognitive deficits. Thus we aim to establish the role that ciliary MCHR1 play in cognitive function by selectively removing MCHR1 by deleting IFT88 from neurons that express MCHR1. Animals that have loxP sites that flank the exons 4-6 of the intraflagellar transport 88 gene (IFT88) will be bred with our MCHR1CreER mice, which will result in the deletion of exon 4-6 in the tissues upon activation of the estrogen receptor expressed on Cre. Upon a tamoxifen injection i.p, tamoxifen-bound Cre-ER dissociates from HSP90, translocates into the nucleus, and carries out site-specific recombination between flanking loxP sites. Tamoxifen will be injected at 7 weeks old mice and at 8 weeks old were tested in cognitive behavioral assays. Animals where ciliary MCHR1 is removed displayed impaired working memory, recognition memory, spatial memory. In this study we show that the MCHR1 that localize specifically to cilia may be responsible for cognitive deficits seen in mice.

Title: Why our brain makes pauses when we speak: analyzing pauses in English (L1/L2), Spanish (L1/L2) and heritage Spanish

Authors: *N. ENRIQUEZ;
Univ. of Houston, Houston, TX

Abstract: Why our brain make pauses when we speak: Analyzing pauses in English (L1/L2), Spanish (L1/L2) and heritage Spanish We present a study on processing problem indicators in oral production in both Spanish and English in a simulated complaint task. Subjects are native English, native Spanish and heritage Spanish speakers. The aim was to describe the role of speech pauses as problem processing indicators in oral production as a communication strategy and their differences between groups of speakers and the language used in the simulation. Hypotheses: i) pauses are different quantitative and qualitatively depending on the speaker's competence; ii) results for heritage speakers will

be closer to L1 group than to L2; iii) cognitive load will be higher using a second language and iv) not only traditional parts of the brain involved in speaking (Wernicke, Broca) are going to be activated during a pause. In order to test these hypotheses, we gathered two different corpora. Recla/SP (10050 tokens) which consists of a sample of 30 dialogues in Spanish (10 native, 10 heritage and 10 non-native) and Recla/EN (9270 tokens) which contains 30 dialogues in English (10 native, 10 heritage and 10 non-native). We report preliminary findings on EEG data (32 channels, 500 Hz) during oral production. The bandpower in EEG data during 36 speech pauses was compared to baseline, where the subjects relaxed and looked at a blank paper in front of them for 1 min. The data was preprocessed by using the H-inf filter to remove eye-related artifacts, band-pass filtering the signal between 0.3 and 50 Hz, using the PREP pipeline for robust re-referencing, and ASR for removal of artefactual power bursts. At the onset of the speech pauses we found statistically significant ($p<0.01$) modulation in the left frontal areas for the delta band (1-4Hz), and activation of central-left regions in the alpha (8-12 Hz) and gamma (30-50 Hz) bands. The pattern was found both in English and Spanish speech production, with pre-frontal bandpower deactivation in the English task. Data confirms the role of pauses as indicators of the difficulty of the task itself and the linguistic difficulty in carrying it out in L2, hypothesis (i), (ii) and (iii). The study also reveals significant differences between native, heritage and non-native speakers, hypotheses (i) and (ii). In native speakers, pauses are indicators of difficulty in management decisions, while in non-native speakers indicate difficulties with syntax and verb inflection. As was stated in (ii) results for heritage are closer to L2. The cortico-basal ganglia-thalamo-cortical loop is highly involved in speaking, as well as, in pauses showing activation in L1 and L2 in all groups (iv).

Title: Effect of diet on the development of language-specific perception of phonemes in the infant's brain. An event-related potentials study

Authors: *G. C. ALATORRE-CRUZ[1,3], A. ANDRES[4], G. YUYUAN[5], H. DOWNS[5], D. R. HAGOOD[5], D. K. WILLIAMS[2,5], L. J. LARSON-PRIOR[6,3];

Abstract: Phonemic identification occurs early in cortical development. Infants can discriminate most tones at three months old and phonemic features by 5 - 6 months. Given that nutrition is fundamental to brain development, dietary intake may affect this early linguistic processing stage. A positive effect of breastfeeding has been reported for language encoding in infancy. However, no studies have addressed

the impact of other dietary choices on phonemic discrimination across early development. In this longitudinal study, 2-month-old infants were stabilized on one of three diets: breast milk (BF, 633 infants, 330 female), cow milk formula (MF,581 infants, 293 female), or soy-milk formula (SF, 607 infants, 273 female). Infants were assessed for their ability to discriminate phonemic sound differences at 3, 6, 9, 12, and 24 months. Infants were instrumented for brain electrophysiology (128 sensors, EGI) and tested with an oddball paradigm composed of frequent (/pa/ 80 %) and deviant (/ba/ 20%) auditory stimuli. The amplitude and latency of the mismatch negativity component (i.e., MMN, 300 - 500 ms) were compared between dietary groups in each age group. The differences between dietary groups were observed at 6, 12, and 24-months old. At 6-months old, the MMN amplitude was higher in the BF than MF and SF infants, while MMN latency was shorter for MF than the other two groups. Dietary groups also differed at 12-months old, the SF infants showed shorter MMN latency than BF and MF groups in the frontal left region, while at 24 months old, MF infants displayed longer MMN latency than the SF group. Given that the distinction between phonetic and phonemic features has been characterized as an increase in latency and amplitude of the MMN component, our results suggest that BF infants develop phonemic discrimination earlier than MF and SF infants. SF infants seem to have the slowest development of phonetic discrimination. Therefore, our results suggest that phonemic discrimination is differentially modulated by infant diet.

Title: Neural basis of Sign Language Proficiency Revealed by the Naturalistic fMRI Paradigm and Inter-subject Correlation Analysis

Authors: *Y. LIN[1], Y.-S. CHIU[3], W.-J. KUO[1,2];
[1]Inst. of Neurosci., [2]Brain Res. Ctr., Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan; [3]Dept. of Psychology, Fu Jen Catholic Univ., Taipei, Taiwan

Abstract: In this study, we used a naturalistic viewing paradigm together with fMRI to investigate neural basis of signlanguage proficiency of the hearing bilinguals with Mandarin as L1 and Taiwan sign language (TSL) as L2. 15 professional TSL interpreters and 15 TSL learners were recruited as participants. For naturalistic viewing in TSL, a story to describe local culture and events was translated into TSL by an expert and the connected TSL expression was videotaped. The participants were presented with the tape during MR scanning. The brain images were preprocessed with the standard procedure and analyzed with the inter-subject correlation (ISC) analysis to detect brain areas were showed correlated, synchronized BOLD activities during TSL comprehension. The ISC results of the two groups were further compared to reveal the sign language proficiency. By doing so, we found that the neural networks which work with reliable stability to encode TSL across individuals of the two groups was widely

distributed, including the ventral and dorsal visual pathways, bilateral inferior parietal cortex, bilateral premotor cortex, and left middle frontal gyrus. We further examined the ISC difference between two groups and found that the interpreter group showed brain regions with higher stability in the bilateral temporal cortex, the left inferior parietal cortex, and the left middle frontal gyrus. On the other hand, the learner group showed higher stability of their correlated brain activities in the visual dorsal processing stream and some sensorimotor regions. In sum, our results revealed that sign language proficiency in normal hearing participants was encoded in a widely distributed set of cortical networks which migrated from primary visuomotor brain areas and settled in brain areas which feature in processing human language and social/biological motion.

Title: Changes in the localization of functional activation to repetition sequences in infants across fNIRS studies

Authors: *J. GEMIGNANI[1], J. GERVAIN[1,2];
[1]Univ. of Padova, Padova, Italy; [2]Integrative Neurosci. and Cognition Ctr., Univ. of Paris, Paris, France

Abstract: Infants' ability to perceive repetition-based regularities plays a central role in language acquisition and has been long investigated, especially with functional near-infrared spectroscopy (fNIRS). However, exactly which brain areas are involved in processing repetitions and how this changes with development has received little attention. In this work, we explored how the pattern of functional activations elicited by different regularities changes across studies and age groups. We examined seven fNIRS studies conducted in three different labs; the final sample comprised data from 150 infants (72 M, 78 F; 91 newborns, 59 six month-olds). Stimuli included trisyllabic auditory sequences in the form of AAB or ABB as well as random sequences. fNIRS was measured with 24 channels distributed bilaterally to sample the fronto-temporal-parietal regions. Data analysis included pre-processing and block-averaging; then, for each study, cluster-based permutation tests were performed to compare changes in oxygenated hemoglobin (HbO) concentrations between conditions and identify clusters of active channels; in particular, paired t-tests compared (i) repetition sequences to a zero baseline (R>0), (ii) random sequences to a zero baseline (N>0) and (ii) repetition to random sequences. They were carried out within the time course of the hemodynamic response, for each channel; then, temporally and spatially adjacent pairs with a significant *t* value were grouped to form cluster candidates; clusters' significance was finally assessed with a permutation analysis, by comparing their *t* value to the null distribution of *t* values obtained by randomly relabeling data and carrying out the same paired t-test (1000 times). We found that newborns display a bilateral pattern of activation for the condition R>0, while no significant

activation was found in the left hemisphere for the N>0 comparison; by contrast, we found the clusters of the six months olds to be bilaterally distributed both for the R>0 and the N>0 comparison. Changes in the functional connectivity underlying these patterns are also being explored. Our results suggest that a permutation-based analysis provide a way to derive regions of interest from the data and assess their changes across dimensions of interest, e.g. age.

Title: Relationship between "tip-of-the-tongue" word retrieval errors and EEG spectral features

Authors: *E. A. RILEY[1], C. SANDBERG[2], D. J. MCFARLAND[3], D. GUPTA[3];
[1]Communication Sci. and Disorders, Syracuse Univ., Syracuse, NY; [2]Communication Sci. and Disorders, Pennsylvania State Univ., State College, PA; [3]Natl. Ctr. for Adaptive Neurotechnologies, Stratton VA Med. Ctr., Albany, NY

Abstract: *Background:* Temporary word retrieval failures that occur when a person cannot recall a specific word, but can recall information about the word (e.g., number of syllables) are known as "tip-of-the-tongue" (TOT) errors. TOT errors are common, especially in older adults. TOT errors are thought to involve inaccurate phonological retrieval after lexical selection has occurred, which may be similar to the underlying cause of word retrieval errors that some persons with aphasia (PWA) experience. Previous work has demonstrated that word retrieval in PWA can be predicted using EEG spectral features. The aim of the current study was to investigate the predictive relationship between word retrieval errors and EEG spectral features in healthy adults using a Famous People naming task (Middleton & Schwartz, *J Speech Lang Hear Res*, 2013).
Method: Eighteen healthy adults (mean age = 57 yrs; 3m/15f) participated in this study, which included a behavioral screening session and 4 EEG sessions. Data were collected with informed consent and PSU IRB approval. Participants who advanced beyond screening produced error responses for at least 10% of the items and were able to recognize at least 250 pictures from a set of 704. In EEG sessions, the subject-specific stimuli set (pictures recognized in the screening) presented in the first 2 sessions was repeated in the last 2 sessions. Stimuli were displayed for a maximum of 5s/picture, during which the participant verbally named the person in the picture while a microphone recorded their responses. Scalp EEG (32 channels) was acquired at 1000 Hz (BrainAmp DC (Brain Vision, LLC)) referenced to FCz. NCAN BCI2000 software was used to present the stimuli, and to acquire and synchronize EEG data with the spoken response. All trial responses were scored by two researchers independently on an 8-point rating scale that encoded responses as correct, nil, or various errors.
Analysis & Results: EEG data were notch filtered (55-65Hz), common-average referenced and epoched (-

2s to 2s) relative to the speech onset. Noisy epochs were rejected using trial statistics. Automated speech onset detection was performed to detect onset of spoken response. Multi-taper spectral analysis (0.5-45Hz) was performed. Response analysis, normalized to total number of stimuli per person, showed a significant increase in number of correct responses in the first stimuli exposure vs. second exposure ($p < .05$). A mean speech response time of 2.3s+/-0.2s was observed; significantly lower for correct responses (2.2s+/-0.17s) vs. incorrect (2.6s+/-0.32s); $p < .01$. Preliminary results of EEG analyses are promising and spectral differences between error types will be discussed.

Title: Representations of Linguistic Information at Different Timescales in the Human Brain During Reading and Listening

Authors: *C. CHEN, T. DUPRE LA TOUR, J. L. GALLANT, D. KLEIN, F. DENIZ;
Univ. of California Berkeley, Berkeley, CA

Abstract: Natural language contains information at different timescales. For example, syntactic structure occurs at relatively short timescales, while discourse structure occurs at longer timescales. Some evidence from functional neuroimaging experiments suggests that different brain regions may be specialized for processing linguistic information at these different timescales. However, previous neuroimaging studies have not directly compared how linguistic information at different timescales is represented across stimulus modalities.
Here, we study the representation of linguistic information at different timescales and modalities in the brain. We examined fMRI data collected in two previous studies from our lab, in which subjects listened to and read the same set of natural language narratives (Huth 2016, Deniz 2019). We used voxelwise encoding models to determine the selectivity of each voxel to linguistic information at each timescale and modality. First, we transformed the stimuli into timescale-specific feature spaces. To do this, we projected each stimulus word into an embedding space that encodes the meaning of words as vectors. We then applied linear filters to the resulting embedding to decompose the embedding into timescale-specific feature spaces. These feature spaces range from high-frequency components that capture quickly-changing information such as syntactic structure, to low-frequency components that capture slowly-changing information such as discourse structure. Then, for each subject and modality, we used regularized regression to estimate a mapping from each timescale-specific feature space to brain responses in each voxel. We used the estimated mapping to predict brain responses to a held-out narrative, and we used the prediction performance on the held-out narrative to determine the selectivity of

each voxel to linguistic information at each timescale and modality.
We find that short-timescale models predict well in different primary and secondary sensory regions for reading (visual cortex) and listening (auditory cortex). In contrast, long-timescale models predict well in amodal regions distributed across prefrontal, temporal, and parietal cortices for both modalities. For both modalities, voxelwise timescale-selectivity follows a spatially smooth gradient from modality-specific representations of short-timescale information in sensory regions, to modality-general representations of long-timescale information in higher-level cortical regions.

Title: Specificity in sound-to-meaning correspondences in spoken language

Authors: K. MATTHEWS[1], A. HOFFMAN[1], S. A. LACEY[2], L. NYGAARD[1], *K. SATHIAN[3]; [1]Emory Univ., Atlanta, GA; [2]Penn State Col. of Med., Hershey, PA; [3]Milton S. Hershey Med. Ctr. & Penn State Col. of Med., Hershey, PA

Abstract: The relationship between the sound of a word and its meaning has long been assumed to be primarily arbitrary; thus, the sounds of language are assumed to bear no necessary resemblance to properties of their referents. Despite this arbitrariness assumption, mounting evidence suggests that non-arbitrary , or sound-symbolic correspondences, exist in natural languages and that language users recognize and use these associations to infer word meaning. Few studies, however, have systematically addressed the range of possible meanings that may be involved in sound-symbolic correspondence and the degree to which sound-symbolic mappings are specific to particular meanings (e.g., pointy) or rather rely on mappings to common abstract domains (e.g., arousal). The current study assessed the relative specificity of sound-symbolic mappings by examining the features of speech sounds associated with fourteen adjectives representing the categorical opposites across each of seven different meaning domains, including the perceptual attributes of shape (round, pointy), size (big, small), luminosity (bright, dark); weight (light, heavy), and texture (soft, hard); and the affective attributes of arousal (calming, exciting) and valence (good, bad). Native English-speaking listeners were presented with 537 (consonant-vowel-consonant-vowel) pseudowords that sampled from the acoustic-phonetic feature space of American English and rated each item from 1 to 7 on each of the fourteen different adjectival scales (e.g., 1= not round, 7 = very round). Average ratings were analyzed as a function of both consonant (manner, voicing, and place of articulation) and vowel (roundedness, height) features for each scale. The results revealed some commonalities across meanings such that similar clusters of speech sound types were associated across particular word meanings. For example, voiced consonants and rounded vowels were both

associated with higher ratings of bigness and heaviness. Some feature-to-meaning mappings were found to be scale-specific, with constellations of different features associated with each meaning. For example, while some phonetic features associated with ratings of pointedness were similar to those of heaviness (e.g., stops), other features differed across the two scales (e.g., vowel roundedness). Further, features associated with perceptual attributes did not map uniformly onto either the arousal or valence dimensions. These findings suggest that sound-symbolic correspondences vary across meaning domains and may reflect the instantiation of meaning-specific, cross-modal associations within natural languages.

Title: Neural substrates for socio-emotional processing via mood-indicating linguistic morphemes: An fMRI study

Authors: *S. KIYAMA[1], Y.-W. SUNG[2], K. XIONG[1], M. MAKUUCHI[3], S. OGAWA[4];
[1]Tohoku Univ., Sendai, Japan; [2]Kansei Fukushi Res. Inst, Tohoku Fukushi Univ., Sendai-Shi, Japan; [3]Natl. Rehabil. Ctr. for Persons with Disabilities, Tokorozawa, Japan; [4]Kansei Fukushi Res. Inst., Touhoku Fukushi Univ., Sendai-shi, Japan

Abstract: Language plays a role in expressing the socio-emotional states of language users, as well as propositional contents. Through language, users perceive another user's emotions and experience their own. However, it is difficult to distinguish how the emotional and propositional aspects of language are regulated, since the emotions are typically expressed with prosody or nonverbal behavior, concurrently with the proposition. We focus on Japanese sentence-final particles (SFPs), as they are function words with no proposition, and users can freely attach SFPs to the sentence to indicate their mood. To examine neural bases for socio-emotional processing with language, we conducted an fMRI study with a mood regulation task in conversation. In the experiment, native Japanese speakers read hypothetical dialogs with either the self-oriented SFP "-yo" or the other-oriented "-ne," in either a self- or other-oriented proposition in the context. We compared the BOLD signals while participants processed the two types of SFP, depending on the two types of context. We estimated the appropriate participant number to be 30 based on a power analysis to obtain a medium effect size ($0.7\ {}_p\eta^2$) in a repeated measures 2 x 2 ANOVA. We then obtained 32 participants' data (21 male, average age was 21.6±1.5), and confirmed no significant sex differences in the following results (FDR corrected $p < .05$, Fig.1). Subsequently, stronger activity was induced for processing the self-oriented "-yo" than the other-oriented "-ne" when the moods of the SFP and context were inconsistent rather than consistent, in the right supplementary motor area, the left anterior dorsal cingulate, the left inferior frontal gyrus pars triangularis, and the right insular lobe.

Contrarily, the left middle temporal gyrus was more strongly activated when the moods of the SFP and context were consistent. Further, the left temporal pole yielded a stronger activation in other-oriented contexts for both SFPs. It suggests that socio-emotional regulation via language requires a wide network of language, motor, social cognition, and emotion areas.

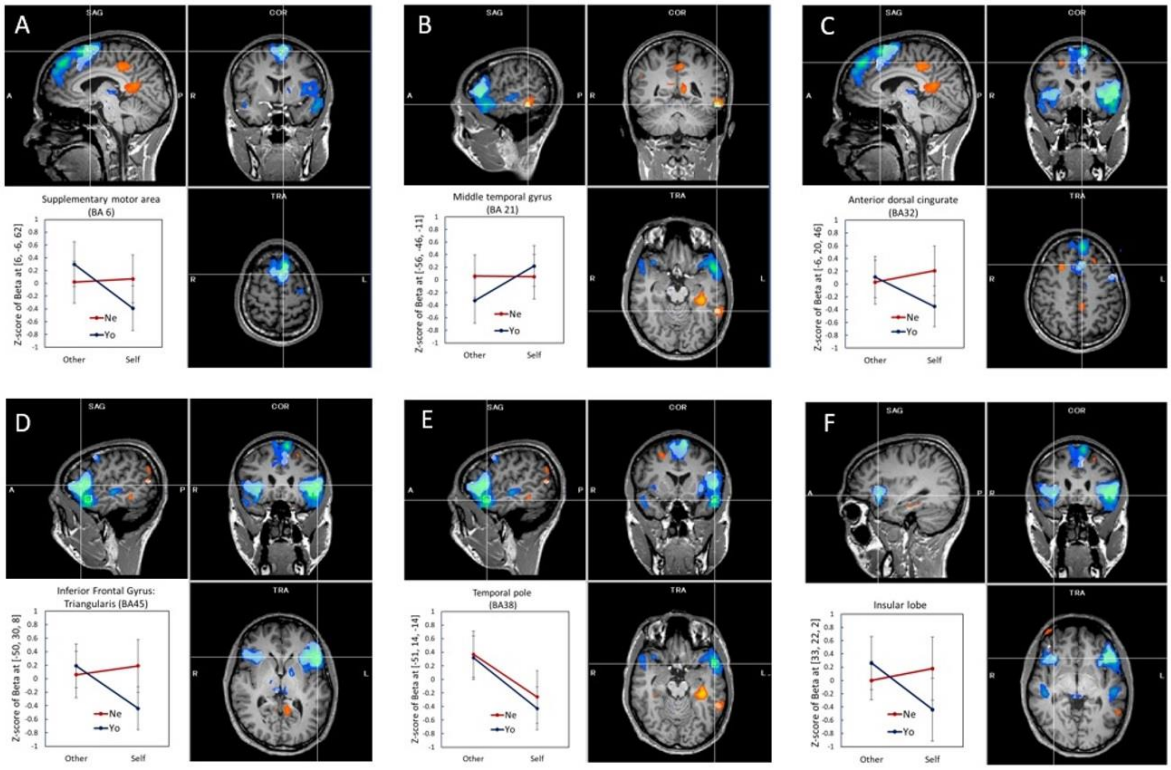

Fig. 1. Overlap fMRI activation of contrasts during processing Japanese mood-indicating sentence-final particle (SFP) '-yo' and the interaction of the two types of SFP ('-yo', '-ne') and Context (other-oriented, self-oriented) by native Japanese speakers (N = 32). All p < 0.05 (FDR corrected). Error bars indicate 95% confidence intervals. Numbers in brackets indicate coordinates of the peak voxel in Talairach space.

Title: Using tract-tracing studies in non-human primates to delineate the anatomic connections that underlie resting-state functional connectivity changes after amygdala neurofeedback in humans

Authors: *L. TRAMBAIOLLI[1], C. BIAZOLI[2], S. N. HABER[3];
[1]McLean Hosp. - Harvard Med. Sch., Belmont, MA; [2]Sch. of Biol. and Chem. Sci., Queen Mary Univ. of London, London, United Kingdom; [3]Univ. of Rochester, Rochester, NY

Abstract: Functional magnetic resonance imaging (fMRI)-based neurofeedback is an emerging therapeutic tool for neurological and psychiatric conditions. Resting-state functional connectivity (rsFC) studies in clinical samples suggest fMRI neurofeedback induces neural plasticity. rsFC is highly correlated with structural connections which might be used to select neurofeedback target candidates. However, *in vivo* diffusion imaging, the current technique to determine structural connections in humans, is error-prone. This study aimed to evaluate whether non-human primate (NHP) anatomic connections determined using the gold-standard method of tract-tracing can be used to explain rsFC the connections that underlie changes due to neurofeedback training. Specifically, we focused on protocols targeting self-regulation of the blood-oxygen-level-dependent (BOLD) signal in the left amygdala. In the first set of analyses, we collected meta-data from three studies reporting rsFC regions-of-interest (ROIs) changes associated with amygdala self-regulation. We registered these ROIs to the human Regional Mapping (RM) parcellation. This parcellation allows direct comparisons between homologous regions of the NHP and human brains. We used the Cocomac tract-tracing database to determine the connectivity strength of amygdalar projections to each RM parcel. The real connectivity strength of each rsFC ROI was calculated and compared with 10^4 ROIs randomly sampled from the human template. Confidence Interval analyses show that more than 60% of intra-hemispheric rsFC associated with neurofeedback training are explained by connections of moderate strength in the NHP data. In the second set of analyses, we placed an anterograde tracer injection in the left amygdala of a macaque monkey. Under darkfield microscopy, we evaluated the NHP regions homologous to the areas with amygdala-cortical rsFC changes after neurofeedback in humans. We identified dense axonal projections in four out of eight intra-hemispheric locations, suggesting a monosynaptic anatomic link to the rsFC changes. In sum, the results show that the precision of NHP neuroanatomy can help understand connections that underlie rsFC changes due to neurofeedback training in humans. This approach can help identify new neurofeedback targets to specific symptoms and conditions.

Title: Nmda antagonism disrupts gamma frequency auditory steady state response (assr) as well as harmonics in female sd rats

Authors: *M. RAZA[1], D. V. SIVARAO[2];
[1]Dept. of Pharmaceut. Sci., Bill Gatton Col. of Pharm., Johnson City, TN; [2]Dept. of Pharmaceut. Sci., Bill Gatton Col. of Pharm., Johnson city, TN

Abstract: **Background**. Schizophrenia patients show dysfunction in processing sensory inputs including a reduction in cortical entrainment to steady-state auditory click stimuli delivered ~ 40 Hz, called the auditory steady-state response (ASSR). Deficits in 40 Hz ASSR are attributed to a reduction in NMDA-mediated neurotransmission within the cortical neural networks. Indeed, acute administration of NMDA antagonists to healthy human subjects or laboratory animals can reproduce many sensory and cognitive deficits seen in schizophrenia patients, including a reduction in 40 Hz ASSR. Click sounds are spectrally complex and carry not only the driving frequency (f_0) but also its integer multiples ($n*f_0$), called harmonics. Harmonics play a pivotal role in sound recognition, a domain in which schizophrenia patients perform poorly relative to controls. Spencer et al. reported that evoked power and phase-locking factor (PLF) to a 20 Hz driving frequency were intact in first-episode psychosis patients but its 40 Hz harmonic was disrupted (Biol. Psychiatry 2008). In the current study, we tested the hypothesis that the NMDA antagonist MK801, would attenuate 40 Hz ASSR, but will only affect harmonics of a 20 Hz click train. **Methods**. Female Sprague-Dawley rats were implanted with epidural (vertex/cerebellum) EEG recording electrodes. Rats were administered vehicle, 0.025, 0.05, and 0.1 mg/kg MK-801 (sc), using a Latin square design; at least 3 days were allowed between treatments. Auditory click trains were presented at 10, 20, 40, 80, and 160 Hz (65dB), 60 minutes post-treatment; 75 trials were recorded. Time-frequency analysis was performed using Windows-based software (EMSE Data Editor, Cortech Solutions). **Results**. MK-801 dose-dependently reduced the PLF for 40, 80, and 160 Hz ASSR only. Evoked power was reduced at 40 and 80 Hz only; dose-dependent increases in power were noted at 160 Hz ASSR. Lastly, while PLF for 20 Hz ASSR was unaffected, dose-dependent reductions in 40 and 80 Hz harmonics were noted. For evoked power, only the second harmonic (ie., 40 Hz) showed a significant decrement. **Conclusion**. NMDA antagonism not only attenuated gamma frequency ASSR but also disrupted the harmonics of 20 Hz ASSR. These findings are reminiscent of observations made in first-episode psychosis patients as well as in chronic schizophrenia (Tsuchimoto et al., Schiz Res., 2011), highlighting the potential of this acute pharmacological model for translational research.

Title: Brain age prediction in gray matter volume, cortical thickness and white matter integrity across different durations of illness in schizophrenia using machine learning approach

Authors: *J.-D. ZHU[1], S.-J. TSAI[1,2], A.-C. YANG[1,3,4];
[1]Inst. of Brain Science, Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan; [2]Dept. of Psychiatry, Taipei Veterans Gen. Hosp., Taipei, Taiwan; [3]Digital Med. Center, Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan; [4]Dept. of Med. Research, Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Brain age prediction is a novel approach to assessing accelerated aging of the brain in different diseases. However, most brain-age studies combined the average brain age gap of individuals with schizophrenia with different durations of illness for comparison with healthy controls. Therefore, this study investigated whether the declined brain structures as reflected by the brain age gap may be present in schizophrenia in terms of gray matter volume, cortical thickness, and white matter integrity across different durations of illness. We recruited 194 individuals with schizophrenia and 330 healthy controls. We extracted gray matter volume, cortical thickness, and white matter integrity from healthy controls and used these features to train three brain-age prediction models using Gaussian process regression, respectively. Three models were applied to predict brain age in individuals with schizophrenia and calculated the brain age gap. Compared with healthy controls, the gray matter volume and cortical thickness models revealed that individuals with schizophrenia had a larger brain age gap across different durations of illness. In addition, gray matter volume and white matter integrity progressively deteriorated in individuals with schizophrenia from approximately 19 and 20 years, respectively, after disease onset, whereas the rate of cortical thickness decline was relatively consistent over the whole disease course. Our findings suggested that schizophrenia differentially affected the decline of different brain structures during the disease course. Moreover, the different trends of decline in thickness and volume-based measures suggest a differential decline in dimensions of brain structure throughout the course of schizophrenia

Title: Smartwatch digital phenotypes relate to positive and negative psychotic symptom variation in a longitudinal monitoring study (e-Prevention) of patients with psychosis

Authors: E. KALISPERAKIS[1], T. KARANTINOS[1], T. KARANTINOS[1], P. FILNTISIS[2], M. LAZARIDI[1], A. ZLATINTSI[2], N. EFTHYMIOU[2], A. MANTAS[1], L. MANTONAKIS[1], V.

GARYFALLI[1], P. TSANAKAS[2], P. MARAGOS[2], *N. SMYRNIS[1];

Abstract: Monitoring and relapse prevention in psychotic disorders is critical but at the same time challenging due to the difficulty in observing patients outside the clinic and the lack of well-established objective measures of human behavior. One of the proposed solutions to this are digital phenotyping techniques such as recording passive data from sensors in smartphones and wearables. During the ongoing e-Prevention project we record digital phenotypes using a specially modified commercial smartwatch including: a) motion via accelerometer (linear acceleration) and gyroscope (angular velocity); b) heart activity via photoplethysmography including heart rate (HR) (beats per minute) and inter-pulse (PP) intervals measuring heart rate variability (HRV) c) measures extracted from specialized smartwatch algorithms including time spent sleeping and awake as well as steps covered during wakefulness. 35 patients suffering from psychotic disorders (20 with schizophrenia and 15 with bipolar disorder) were monitored for a period of up to 14 months. During the same period patients were assessed monthly for psychopathology using the PANSS scale. Linear mixed model analysis was used to assess the relation of mean and variance of each digital phenotype for each subject and each month to psychopathology. Positive psychopathology was positively correlated with mean HR in both wakefulness and sleep (t_{150}=3.27, p=0.001 and t_{208}=2.86, p=0.005 respectively). Negative psychopathology was negatively correlated to the mean HRV (t_{183}=-2.69, p=0.008) and positively correlated to the variance of HRV (t_{225}=2.81, p=0.005) during wakefulness and positively correlated to time spent sleeping (t_{91}=2.74, p=0.007). The results indicate that digital phenotypes and especially measures of heart rate activity, are sensitive to changes in psychopathology over time and could be possibly used as input variables in expert systems that could aid the clinician in the monitoring of these patients and to the timely prediction of symptom relapse.

Title: Functional connectivity-based stratification biomarker for major depressive disorder with replicability and predictivity of antidepressant responses

Authors: *Y. KASHIWAGI[1,2], T. TOKUDA[2], Y. TAKAHARA[1,2], Y. SAKAI[2], J. YOSHIMOTO[2,3], A. YAMASHITA[2,4,5], T. YOSHIOKA[2], S. MOMOSAKI[1], K. OGAWA[1], M. KAWATO[2,6], O. YAMASHITA[2,6];
[1]SHIONOGI & CO., LTD., Osaka, Japan; [2]Advanced Telecommunications Res. Inst. Intl., Kyoto, Japan; [3]Nara Inst. of Sci. and Technol., Nara, Japan; [4]Boston Univ. Sch. of Med., Boston, MA; [5]VA Boston Healthcare Syst., Boston, MA; [6]RIKEN, Tokyo, Japan

Abstract: Major depressive disorder (MDD) is highly heterogeneous in terms of symptom presentations, disease trajectories, treatment responses, and underlying biological mechanisms. Identification of biologically homogeneous subtypes of MDD is expected to promote the development of precise diagnoses and effective treatments. Several studies have shown to identify clinically useful subtypes of MDD by data-driven approaches based on clinical features and/or biological substrates, but almost all those stratifications have not sufficiently been replicated in an independent validation cohort. To develop the functional connectivity (FC)-based biomarker for MDD stratification with replicability, we applied the hierarchical supervised/unsupervised approach. In our group, some generalizable diagnostic markers which distinguish healthy controls and MDD patients have been developed based on whole brain FCs by supervised learning algorithms. In this study, the FCs with larger contribution on those diagnostic markers were applied to an unsupervised clustering method for identification of MDD subtypes. Two independent multi-site datasets of resting-state fMRI data were analyzed in this study: One dataset consisted of 138 MDD patients collected from 3 sites, and the other consisted of 181 MDD patients collected from different 4 sites. As an unsupervised method, multiple co-clustering algorithm was individually applied to these 2 datasets. This algorithm is powerful in clustering with high-dimensional data and can identify clustering patterns of subjects based on FCs in specific brain areas. We could confirm the high similarity of the clustering solutions between datasets, which indicates that the approach enables replicable subtyping. To examine clinical usefulness of the subtyping, we applied the multiple co-clustering to all MDD patients (N = 319) and analyzed treatment responsiveness of each subtype with MDD patients who have longitudinal clinical data (before and after 6 week-treatment of antidepressant, N = 96). As a result, we found some characteristic subtypes with high or low responsiveness to antidepressant treatment. These subtypes were defined by distinct patterns of FCs between the thalamus and pre/post central gyrus. We have shown the usefulness of the hierarchical supervised/unsupervised approach and multiple co-clustering method for replicable subtyping, and the subtyping based on the thalamic connectivity with sensorimotor area may be useful for prediction of antidepressant treatment outcomes. In the future study, we are planning prospective clinical researches to validate the clinical characteristics of the MDD subtypes.

Title: Discovery of positive modulators of the T-type calcium channel Cav3.3 to treat the sleep spindle deficits observed in schizophrenia patients

Authors: *S. P. MORAN, A. GHOSHAL, J. R. COLEMAN, Jr, M. FITZGERALD, D. BAEZ-NIETO, E. YU, L. YANG, J. GALE, L. A. WANG, N. KURA, N. G. SHUART, Y.-L. ZHANG, M. WEIWER, F. F. WAGNER, J. Q. PAN;
Stanley Ctr. for Psychiatric Res., Broad Inst. of MIT and Harvard, Cambridge, MA

Abstract: Schizophrenia is a debilitating disorder that lacks effective treatments for the negative symptoms (e.g., social withdrawal) and cognitive disruptions (e.g., working memory deficits) in patients. Recently, large scale human genetics studies including genome wide association studies (GWAS) and exome sequencing studies have identified many replicable genomic loci for schizophrenia risk. Cacna1I, was identified as one of these schizophrenia risk genes and it encodes the functional core, α1 subunit, of $Ca_V3.3$ voltage-gated calcium channels. $Ca_V3.3$ channels are expressed in a subset of neurons including GABAergic neurons of the thalamic reticular nucleus (TRN) where they regulate neuronal excitability. The TRN has emerged as a crucial brain nucleus in the generation of sleep spindles, sleep dependent memory, focused attention, and cognitive flexibility, all of which are impaired in patients with schizophrenia. Our group and others have demonstrated that loss of $Ca_V3.3$ dramatically alters TRN neuronal firing in mice, and this altered firing corresponds with reduced sleep spindles occurrences, a phenotype also found in schizophrenia patients. Based on these genetic and biological evidence, we hypothesize that $Ca_V3.3$ potentiators could benefit patients with schizophrenia by rescuing sleep spindle deficits and improving sleep dependent cognitive function. However, there is a lack of selective and potent $Ca_V3.3$ small molecule potentiators. We therefore set out to identify highly selective, potent and brain penetrant Cav3.3 potentiators. We first established a novel primary high-throughput screening (HTS) fluorescence-based assay to capture the increased calcium influx mediated by $Ca_V3.3$ in HEK cells. After completion of a HTS campaign of ~77,000 compounds, we identified 5 validated $Ca_V3.3$ potentiators. We then selected two hits to perform medicinal chemistry. From these efforts, we report a novel set of potent and highly selective $Ca_V3.3$ potentiators that enhance $Ca_V3.3$ function in both cell-based molecular pharmacology and high throughput patch clamp electrophysiology as well as modulating a known $Ca_V3.3$ mediated hyperpolarization induced rebound bursting phenomenon in acute mouse brain slices containing TRN. Taken together, these studies identified selective $Ca_V3.3$ potentiators that can modulate $Ca_V3.3$ channel activity relevant for sleep spindles and sleep dependent cognition and represent an exciting step towards the development of a novel class of potential therapeutics for the treatment of sleep disturbances and cognitive deficits in patients with schizophrenia.

Title: MRGPRX4, a target of interest in drug development for mental disorders. Towards the identification of active molecules from ethnopharmaceuticals

Authors: *C. GALLO[1], G. POLETTI[1], R. ROJAS[1], J. ALBÁN[2], A. VAISBERG[1];
[1]Univ. Peruana Cayetano Heredia, Lima, Peru; [2]Univ. Nacional Mayor de San Marcos, Lima, Peru

Abstract: Mas-Related G protein-coupled receptor, member X4 (MRGPRX4) was first identified among a family of GPCRs related to the MAS1 oncogene. The MRGPRX4 gene is conserved in chimpanzee, Rhesus monkey, mouse, and rat, and is expressed in primary sensory neurons. Recently, it has been shown that MRGPRX4 is activated by bile acids-and bilirubin and may have a role in cholestatic itch. Altered nociception, including itch, has been reported in schizophrenia/psychosis, affective disorders as well as in other mental disorders. Although an interplay between central and peripheral regulatory processes is suspected, the exact nature of the biological mechanisms implicated is still unknown. Even though there is no clear link between MRGPRX4 and mental disorders yet, a potential contribution of this GPCR to the underlying biological mechanisms is feasible. Consequently, the identification and isolation of specific ligands or interacting molecules will be important for a better understanding of its role in the development of these diseases. Rescuing traditional medicine practices is one of the possible avenues to discover novel pharmacological approaches. We have a repository of 477 extracts from an equal number of plant collections corresponding to 265 species from 87 different plant families used in Peruvian traditional medicine for brain disorders. The collections were done in several localities and geographic regions of Peru. We have identified 20 extracts with high activity (either agonist or inverse agonist) for MRGPRX4 through a functional Gq calcium mobilization assay performed at the NIMH Psychoactive Drug Screening Program (PDSP) - University of North Carolina, Chapel Hill. These extracts are used in Peruvian traditional medicine for treating diverse behavioral conditions defined either in formal (depression, schizophrenia, anxiety, insomnia) and informal (“sadness”, “madness”, “aching heart”, “fright”) terminology. The extracts are currently being fractionated to isolate and characterize the active molecules.

Abstract: CXCR4 and CXCR7(ACKR3) belong to the chemokine GPCR family and are receptors for CXCL12 (also called SDF-1 alpha). Stimulation of CXCR4 triggers a classical GPCR cascade. CXCR7 instead, functions as a scavenger receptor for CXCL12, and can form heterodimers with CXCR4. Either CXCR7 or the CXCR4/CXCR7 complex induce β-arrestin-mediated internalization and lysosomal degradation of CXCL12-bound receptors. CXCR4 and CXCR7 are expressed in both developing and mature CNS. High co-expression of these receptors has been observed in the globus pallidus, the paraventricular and supraoptic hypothalamic nuclei, in the medial habenula and in the choroid plexus of the lateral ventricles. CXCR4 and CXCR7 have been involved in neurodevelopment, inflammation, neurogenesis, angiogenesis, and in immune cell activation and recruitment, supporting a potential role in the interaction between the nervous and immune systems. CXCR4 has only one synthetic partial agonist and several small molecule antagonists, such as AMD 3100 and T140, among others. CXCR7 is activated by the peptidomimetic TC1402 as well as by the small molecules CCX771 and AMD-3100. No antagonist molecule has been reported yet for CXCR7. AMD 3100 is the only FDA-approved small molecule drug acting on CXCR4/CXCR7; consequently, the identification of novel agonists for CXCR4 and agonist or antagonists for CXCR7 is of high interest. Rescuing traditional medicine practices is one of the possible avenues to discover novel pharmacological approaches. We have a repository of 477 extracts from an equal number of collections corresponding to 265 species from 87 different plant families used in Peruvian traditional medicine for treating brain disorders. We have identified 5 extracts with high activity for CXCR4 and 53 with high activity for CXCR7(ACKR3) through a functional Tango-beta-arrestin assay performed at the NIMH Psychoactive Drug Screening Program (PDSP) - University of North Carolina, Chapel Hill. The active extracts are used in Peruvian traditional medicine for treating diverse behavioral conditions defined either in formal (depression, insomnia) and informal (“sadness”, “madness”, “aching heart”, “nervousness”) terminology. The top 20 extracts are currently being fractionated to isolate and characterize the active molecules. The isolated molecules will be pivotal not only to explore the potential of CXCR4 and CXCR7 as drug targets for mental disorders, but to advance in the understanding of the pathologic mechanisms involved in their occurrence.

Title: Multimodal conversational technology for remote assessment of symptom severity in people with schizophrenia

Authors: *H. KOTHARE[1], M. NEUMANN[1], O. ROESLER[1], J. LISCOMBE[1], D. PAUTLER[1], D. SUENDERMANN-OEFT[1], C. YAVORSKY[2], A. KHAN[3], J.-P. LINDENMAYER[3], V. RAMANARAYANAN[1];
[1]Modality.AI, Inc., San Francisco, CA; [2]Valis Biosciences, Inc., Berkeley, CA; [3]Nathan S. Kline Inst. for Psychiatric Res., Orangeburg, NY

Abstract: The causes of schizophrenia are complex and largely unknown. Current treatments focus on the management of positive or psychotic symptoms. However, negative symptoms like lack of facial and verbal expression, monotone speech, social withdrawal and isolation affect people with schizophrenia on a day-to-day basis and are harder to recognize and interpret. A shortage of mental health services in parts of the world makes it difficult to provide care and support to people with schizophrenia. Additionally, the COVID-19 pandemic exposed the pressing need for clinicians to be able to monitor treatment and symptoms in psychiatric disorders remotely. We present an exploratory study highlighting the feasibility of a novel multimodal conversational platform with real-time automated extraction of speech and facial metrics to assess symptom severity in people with schizophrenia.
Eight participants diagnosed with schizophrenia took part in this study. Their symptom severity was evaluated in clinic using standard clinical psychometric instruments like the Positive and Negative Syndrome Scale (PANSS) and the Brief Negative Symptom Sale (BNSS) along with cognitive assessments like the Wide Range Achievement Test -4 (WRAT-4) Reading. They were then guided by a virtual conversational agent through an interactive session on a cloud-based multimodal dialogue platform that included a battery of tasks to elicit speech and facial behaviours like syllable repetitions, read speech and spontaneous speech. An audio-visual analytics module automatically extracted a variety of measures capturing speech acoustic properties, facial landmark positions and articulatory kinematics during these tasks.
We found that articulation rate (r^2=0.64 p=0.02), loudness(r^2=0.67 p=0.01), internal silence (r^2=0.63 p=0.02) and lip aperture (r^2=0.61 p=0.02) correlated highly with WRAT-4 Reading scores. Vertical position of the eyebrows (r^2=0.89 p<0.01) correlated positively with the PANSS positive subscale whereas measures like cepstral peak prominence (r^2=0.57 p=0.03) and mouth surface area (r^2=0.63 p=0.02) correlated negatively with the PANSS general psychopathology subscale. Metrics like cepstral peak prominence (r^2=0.66 p=0.01) and lower lip velocity (r^2=0.56 p=0.03) also correlated with the BNSS total score.
The small sample size notwithstanding, these observed correlations between standard clinical assessments and speech and visual analytics suggest that audio-visual measures extracted through multimodal conversational interfaces could be an effective tool for remote monitoring of symptoms and the efficacy of treatment strategies in people with schizophrenia.

Title: Selectively driving nigrostriatal dopamine transmission impairs cognitive function

Authors: *N. A. MOYA, S. YUN, M. M. MARTIN, J. G. PARKER;
Physiol., Northwestern Universtiy, Chicago, IL

Abstract: Altered dopamine signaling is implicated in psychosis in mental disorders like schizophrenia. In particular, excess nigrostriatal (NS) dopamine signaling is thought to underlie hallucinations, delusions, and thought disorders, symptoms of psychosis that respond to antipsychotic drug treatment. Cognitive impairment, such as a deficit in working memory, is also prevalent in schizophrenia, but is resistant to current treatments. Antipsychotic drugs preferentially block D2 dopamine receptors, which are enriched within the striatum. These observations question whether excess striatal dopamine contributes to cognitive impairment in schizophrenia. However, excess striatal dopamine also impacts D1 receptor signaling in the striatum. Moreover, the striatum is directly and indirectly connected to other brain structures like the prefrontal cortex, with which it may compete for cognitive resources. Therefore, striatal hyperdopaminergia could disrupt cognitive function, but this idea has never been explicitly tested. Here we asked whether excess D1R signaling in the dorsomedial striatum (DMS) might impair cognitive function. To test this idea, we selectively re-expressed the excitatory cation channel TRPV1 in the SNc dopamine neurons of TRPV1 knockout mice. Treating these mice with the TRPV1 agonist capsaicin

increased dopamine release in the striatum but not prefrontal cortex as measured by dLight fluorescence via dual-site, *in-vivo* fiber photometry. This approach improves upon traditional antipsychotic drug screening tools like amphetamine treatment, which increases dopamine transmission throughout the brain and fails to recapitulate the regional dopamine imbalance observed in schizophrenia. Driving NS dopamine transmission induced both increases in locomotion and decreases in cognitive function in an assay of working memory. We are currently using calcium imaging and chemogenetic approaches to dissect the striatal circuit dysfunction underlying these behavioral deficits with the goal of identifying novel therapeutic targets to treat the cognitive symptoms of disorders like schizophrenia.

Title: Modulating D1 rather than D2 receptor-expressing spiny-projection neurons corresponds to optimal antipsychotic effect

Authors: *S. YUN, B. YANG, M. M. MARTIN, N.-H. YEH, A. CONTRACTOR, J. G. PARKER; Physiol., Northwestern Univ., Chicago, IL

Abstract: Excess dopamine transmission in psychosis is predicted to unbalance striatal output via D1- and D2-dopamine receptor-expressing spiny-projection neurons (SPNs). Antipsychotic drugs are thought to re-balance this output by attenuating striatal D2-receptor signaling. Here we imaged D1- and D2-SPN Ca^{2+} dynamics *in vivo* to determine whether they can predict antipsychotic effect. Initially we compared effective (clozapine and haloperidol) to ineffective (MP-10) antipsychotic treatments. Clozapine and haloperidol normalized hyperdopaminergic D1-SPN ensemble dynamics, while MP-10 only normalized D2-SPN activity. Only clozapine, haloperidol or chemogenetic manipulations of D1-SPNs all also normalized sensorimotor gating. Given this link between D1-SPN modulation and antipsychotic effect, next we evaluated compounds selectively targeted to D1-SPNs. D1R partial agonism, antagonism, or positive modulation of M4 cholinergic receptors all normalized the levels of D1-SPN activity, locomotion, and sensorimotor gating. Our results suggest that D1-SPNs are a more relevant therapeutic target than D2-SPNs in psychotic disorders and adjudicate basic strategies for doing so.

Title: Redundancy in cerebellar circuits facilitates rapid online learning

Authors: *A. PEREZ ROTONDO, D. RAMAN, T. O'LEARY;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The cerebellum is critically involved in motor control, refining trajectories as movements are being executed. This requires fast, online learning from limited information. What features of cerebellar circuit structure make it particularly suited to online learning? The cerebellum has a distinctive circuit architecture in which each mossy fibre input typically projects onto 250 granule cells, which themselves comprise over half of the neurons in the brain. Each granule cell forms 4 synapses with mossy fibres. The main hypotheses for this sparse input expansion are that it facilitates pattern separation and smooth function approximation. However, we currently lack a theory that explains why this architecture is suited to online motor learning. We show that the large input expansion effectively trades time for space, allowing rapid and accurate learning in an online context. We consider a cerebellar-like network, with sparse connections that map low-dimensional inputs into a high-dimensional internal, 'granule cell' layer. The network is tasked with simultaneously learning an internal model of a motor system, and using this model to better control motor output. Learning happens concurrently with trajectory execution, using a biologically plausible learning rule to adapt synaptic weights. Learning online introduces a narrow time window that severely limits the information available for synaptic plasticity mechanisms to appropriately adjust synaptic weights. We find that the effect of having limited information depends on the spread of the eigenvalues Hessian of the task error. As the number of granule cells increases, the spread decreases. Hence the geometry of the error surface becomes more favourable for online learning, diminishing the effect of information error and allowing for faster learning. This suggests that the large energy cost associated with maintaining the majority of the brain's neurons might be an inevitable cost of precise, fast, motor learning. Our result fills gaps in the understanding of how cerebellar structure is optimised for online learning of motor tasks.

Title: Modeling of signaling mechanisms underlying cooperative and competitive formation of synaptic plasticity

Authors: *R. AMANO[1], M. NAKAO[1], K. MATSUMIYA[1], F. MIWAKEICHI[2];
[1]Grad. Sch. of Information Sci., Tohoku Univ., Sendai-Shi, Japan; [2]Dept. of Statistical Modeling, The Inst. of Statistical Mathematics, Tachikawa-Shi, Japan

Abstract: Several studies have reported clustered formation of synapses, which is thought to be a neurophysiological substrate of synaptic plasticity. Synapse clustering may be achieved by intracellular signaling mechanisms involving synaptic tagging and capture (STC) and plasticity-related proteins (PRPs), synthesized in a synaptic activation-dependent manner. STC may signal to induce cooperative plasticity clustering proximal synapses activated synchronously. In contrast, PRPs are captured through competitiveness among synapses to complete synaptic plasticity. In this study, a model of synaptic plasticity was constructed to examine how the temporal structure of the synaptic input sequence affects the resulting spatial pattern of synaptic formation in the presence of a cooperative and competitive signaling mechanism of plasticity. Firstly, a possible mechanism of cooperative LTP formation was simulated based on STC signaling. Then, the capture mechanism of PRPs was additionally incorporated to simulate synaptic clustering in the presence of cooperative and competitive signaling of plasticity. The present study investigated the cluster formation through these simulations depending on the temporal structure of synaptic input. The simulation results showed that STC facilitated cooperative induction of plasticity over synapses coactivated with close timings, and in contrast, competitive capture of PRPs selectively induced plasticity depending on the temporal relationship between synaptic activations. In addition, the results showed that the competitive mechanism enhances the cooperative induction of plasticity associated with the intensity of synaptic activation. Thus, these results suggest that memory engram represented on the temporal structure of synaptic input sequences is carved as a cluster pattern of synapse formation through the cooperative and competitive induction mechanism of plasticity involving STC and PRPs.

Title: Using Spiking Neuronal Networks to solve Reinforcement Learning control problems

Authors: D. HASEGAN[1], D. D'ONOFRIO[4], S. GRUNBLATT[4], M. DEIBLE[2], S. CABY[3], H. HAZAN[5], H. ANWAR[4], S. A. NEYMOTIN[4,6];

Abstract: While Spiking Neuronal Networks (SNNs) have been successfully used to model biological phenomena, their use in solving Reinforcement Learning (RL) problems remains limited. In contrast, Artificial Neural Networks (ANNs) have successfully solved many RL problems while remaining biologically implausible. In this study, we work towards understanding and improving the performance of SNNs solving RL control challenges.

We use the NEURON simulator and NetPyNE to create an SNN interfaced with environments from OpenAI's Gym, such as CartPole. In CartPole, the goal is to balance a vertical pole by moving left/right on a 1-D plane. Our SNN model contains multiple populations of neurons organized in three layers: sensory layer, association/hidden layer, and motor layer, where each neuron is connected by excitatory (AMPA, NMDA) and inhibitory (GABA) synapses. The association and motor layers contain one excitatory population and two inhibitory populations with different synaptic time constants. Each neuron is an event-based integrate-and-fire model with plastic connections between excitatory neurons. We explore the modulation of these plastic connection weights through both evolutionary strategies (ES) and a Reinforcement Learning algorithm that employs Spike Timing-Dependent Plasticity (STDP). An ES update consists of adding together many random perturbations of the connection weights, where each set of random perturbations is weighted by the total episodic reward (e.g., how long the model can keep the pole balanced in Cartpole) it is able to achieve when applied independently. We compare both algorithms' performance against commonly used algorithms (deep reinforcement learning) for solving RL control problems.

In our SNN, the environment activates sensory neurons tuned to specific features of the game state. We split the motor neuronal population into subsets representing each movement choice. The subset with more spiking over an interval determines the action. Note that motor neurons do not receive explicit feedback on how they contributed to action generation. Using RL, we supply intermediary evaluations (reward or punishment) of each action by judging the effectiveness of a move (e.g., moving the CartPole to a balanced position).

Training our model on Cartpole demonstrates effective learning of balancing capabilities by moving the cart left and right, keeping the pole vertical. We are expanding our model's learning in additional control tasks. The model opens up new capabilities for SNNs in RL and could serve as a testbed for neurobiologists aiming to understand learning mechanisms and dynamics in neuronal circuits.

Title: Heavy-tailed correlations emerge from Hebbian plasticity

Authors: *C. LYNN[1,2], S. E. PALMER[3], C. HOLMES[1];
[1]Joseph Henry Labs. of Physics, Princeton Univ., Princeton, NJ; [2]Initiative for the Theoretical Sci., City Univ. of New York, New York, NY; [3]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: In networks of neurons, correlations and synaptic strengths are heavy-tailed, with a small number of neurons interacting much more strongly than the vast majority of pairs. Yet, it remains unclear whether, and how, such heavy-tailed connectivity can emerge from simple underlying mechanisms. Building upon recent advances in neuroimaging, here we show that the correlations between thousands of neurons in the mouse visual cortex admit heavy-tailed distributions spanning three decades in strength. Moreover, we find that these distributions are robust to variations in the visual stimuli, even persisting during spontaneous activity. To explain these heavy-tailed correlations, we propose a simple model of synaptic change based on Hebbian plasticity: synapses are pruned at random, and the synaptic weight is redistributed throughout the network by either (i) adding weight to existing synapses in a Hebbian fashion or (ii) creating new synapses. Importantly, our model contains only a single parameter $0 \le p \le 1$, which represents the probability of Hebbian growth relative to new synaptic growth. We demonstrate, both analytically and numerically, that the model generates scale-free distributions of connectivity strength, with a power-law exponent $\gamma = 1 + \frac{1}{p}$ that depends only on the probability of Hebbian growth. Our results indicate that heavy-tailed distributions of correlations and synaptic weights may be governed by robust self-organizing principles that do not depend on the biophysical particulars of different neural systems.

Title: Ultrafast large-scale simulations of biophysically realistic neurons using deep learning

Authors: *V. J. OLAH, M. J. M. ROWAN;
Dept. of Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Understanding the activity of the mammalian brain requires an integrative knowledge of circuits at distinct scales, ranging from ion channel time constants to synaptic connection probabilities. To understand how multiple parameters contribute synergistically to circuit behavior, neuronal computational models are regularly employed. A major limitation of currently employed models containing anatomically and biophysically realistic neurons is the computational demand when scaled to the size of local circuits. To overcome this limitation, we trained several artificial neural net (ANN) architectures to model the activity of realistic, multicompartmental neurons. We identified a single ANN that accurately predicted both subthreshold and action potential firing, and correctly generalized its responses to previously unobserved synaptic input. Furthermore, ANNs are able to forecast several different facets of neuronal

behavior with high fidelity, such as ionic current dynamics. Importantly, when scaled, processing times were orders of magnitude faster compared with traditional approaches. In order to demonstrate the versatility of our approach, we have constrained our ANN architecture on all major cell classes of the visual cortex from a publicly available database and demonstrated that further training of specific cell types can be significantly accelerated and stabilized by taking advantage of the currently modeled repertoire of cells and transfer learning. Thus, our ANN approach allows for rapid, detailed network experiments using inexpensive, readily available computational resources.

Title: Effect of multiple timescale adaptation in a Hodgkin-Huxley neural network

Authors: *T. J. RICHNER, B. N. LUNDSTROM;
Neurol., Mayo Clin., Rochester, MN

Abstract: Excitatory neurons are known to exhibit spike rate adaptation in response to stimuli. We've previously shown that spike rate adaptation in single neurons is comprised of multiple time constants and approximates fractional differentiation. We hypothesized that multiple timescale adaptation (MTA) would alter, and possibly stabilize, network dynamics. Further, we were interested to find signatures of MTA that could be measured in human subjects with epilepsy.
We modeled a network of 256 Hodgkin-Huxley neurons in which MTA could be enabled or disabled for comparison. The neurons were partitioned 80% excitatory (AMPA & NMDA) and 20% inhibitory ($GABA_A$ & $GABA_B$). Neurons were arranged into a 2D grid and synapse strengths were probabilistically based on distance, which allowed for positive feedback loops. Network input was low amplitude exponentially-filtered Gaussian noise. As excitatory-to- excitatory synaptic strengths were increased, seizure-like dynamics resulted in the network lacking MTA. In contrast, the network with MTA was resistant to sustained seizures. MTA dampened positive feedback loops among excitatory neurons thereby preventing seizures.
In order to find potential electrophysiological biomarkers of MTA, we analyzed the power spectra and spiking statistics of the network with and without MTA. The average membrane voltage was used to approximate the local field potential. MTA decreased overall spectral power while also increasing power in low frequencies (< 3 Hz). MTA had the most pronounced effect on the interspike intereval (ISI) histogram. MTA flattened the ISI histogram, decreasing counts at short intervals (<50 ms) and increasing counts at longer intervals (>200 ms). We are continuing to explore novel stimulus waveforms that can be used to assay MTA. Further, we are analyzing invasive EEG recordings, microwire recordings, and cortico-cortical evoked potentials from human subjects for biomarkers of MTA.

Title: Theta-gamma phase amplitude coupling in a hippocampus CA1 interneuron network.

Authors: *A. PONZI, M. MIGLIORE;
Inst. of Biophysics, CNR, Palermo, Italy

Abstract: Theta nested gamma oscillations are well known to occur in the hippocampus, but their origin is not clear. Here we construct a CA1 network circuit using detailed multi-compartment cell models optimized to match the electro-physiological properties of OLM, PVBC and PYR cells, with reconstructed 3D dendritic morphologies [1]. Cells are connected in appropriate dendritic domains using facilitating and suppressing synapses with strength and probability matching experimental findings [2,3]. We first validate the circuit properties against experimental findings on fast onset and late persistent synaptic response data [4] on the selective routing of information by OLM and PVBC cells in CA1. By driving the circuit with Schaffer collaterals inputs, we found that theta nested slow and fast gamma oscillations emerge within physiologically plausible parameter regimes. We investigated the mechanism for generation of theta nested gamma oscillations. We find that OLM cells and PYR cells generate gamma oscillations by the network PING mechanism. When OLM cells are close to firing threshold PING occurs in bursts at theta frequency. During PING bursts most of the cells in the network spike synchronously at gamma frequency. Each PING burst lasts three or four gamma cycles. PING bursts are separated by longer periods of irregular spiking activity in the PYR cells and very low activity in the OLM cells. PING bursts are initiated when a few OLM cells cross firing threshold. They spike inhibiting a few PYR cells which recover together after one gamma time scale. This generates synchronized PYR excitation which in turn synchronizes more OLM cells, which in turn further synchronizes more PYR

cells. This PING burst does not continue indefinitely because, besides synchronizing the PYR spiking activity, the increased OLM activity also suppresses the PYR average firing rate. This reduces the excitation onto the OLMs which drop below threshold and the PING burst ends. Slowly OLMs revert to threshold until a few cross threshold initiating the next PING burst. The timescale of OLM reversion to threshold sets the slow theta timescale. It depends on the OLM membrane time constant as well as the PYR to OLM synapses which can show slow facilitation. We show how the theta and gamma timescales depend on network, cellular and synaptic parameters and discuss the relevance to cognitive function of CA1.

Title: A nonlinear calcium-based plasticity rule explains long-term stability of synapses

Authors: *B. WANG[1], J. ALJADEFF[2];
[2]Dept. of Neurobio., [1]UCSD, San Diego, CA

Abstract: Activity dependent synaptic plasticity is considered to be a primary mechanism underlying learning and memory. Yet it is unclear whether plasticity rules such as STDP measured in vitro apply in vivo. Network models with STDP predict that activity patterns (e.g., place-cell spatial selectivity) should change much faster than observed experimentally. We address this gap by investigating a nonlinear calcium-based plasticity rule fit to experiments done in physiological conditions. In this model, LTP and LTD result from calcium transients arising almost exclusively from synchronous coactivation of pre- and postsynaptic neurons. We analytically approximate the full distribution of nonlinear calcium transients as a function of pre- and postsynaptic firing rates, and temporal correlations. This analysis directly relates activity statistics that can be measured in vivo to the changes in synaptic efficacy they cause. Our results highlight that both high-firing rates and temporal correlations can lead to significant changes to synaptic efficacy.
The tractability of the single synapse model allows us to systematically explore its network-level implications. Using a mean-field theory, we show that the nonlinear plasticity rule, without any fine-tuning, gives a stable, unimodal synaptic weight distribution characterized by many strong synapses which remain stable over long periods of time, consistent with electrophysiological and behavioral studies. Moreover, our theory explains how memories encoded by strong synapses can be preferentially stabilized by the plasticity rule. We confirmed our analytical results by simulating a spiking recurrent network. While most synapses are weak and undergo rapid turnover, the fraction of strong synapses are

sufficient for supporting realistic spiking dynamics and serve to maintain the network's cluster structure. Our results provide a mechanistic understanding of how stable memories may emerge on the behavioral level from an STDP rule measured in physiological conditions. Furthermore, the plasticity rule we investigate is mathematically equivalent to other learning rules which rely on the statistics of coincidences, so we expect that our formalism will be useful to study other learning processes beyond the calcium-based plasticity rule.

Title: Real time, low latency removal of ballistocardiogram artifacts during simultaneous EEG-fMRI

Authors: *J. LEVITT, Z. YANG, L. D. LEWIS;
Boston Univ., Boston, MA

Abstract: Simultaneous EEG-fMRI is an attractive technique for imaging the brain, as it provides the high temporal resolution of EEG and the high spatial resolution of fMRI. Developing real-time analysis of EEG-fMRI signals could expand the applications of this technique to enable closed-loop neurofeedback experiments. However, its application is limited by the presence of ballistocardiogram (BCG) artifact in the EEG signals, caused by subtle movements of the EEG electrodes through the magnetic field of the MR scanner with each heartbeat. Techniques do exist for the post-hoc removal of these artifacts, including the use of an electrically insulated BCG reference layer that records noise signals directly, or by the use of an optimal basis set algorithm (OBS) that models noise locked to each heartbeat. However, these methods are not well suited to closed-loop experimental designs, because they cannot be implemented in real time with low latency and high efficacy. Here, we propose and validate a novel method for removing BCG artifacts in real time using a Kalman filter in combination with a BCG reference layer. To validate our method, we used simulated EEG-BCG data with ground truth signal and noise, created by adding EEG data collected from healthy adults outside the MR scanner to BCG reference layer data (i.e., noise) from the same subjects collected inside the MR scanner. We then tested whether we could recover the original EEG signal using our real-time Kalman filter methodology and compared this to recovery using current gold-standard algorithms. Our results show that the Kalman filter recovers the original EEG waveform and delta wave phase significantly better than OBS, and as well as BCG reference layer regression. Additionally, the Kalman filter also recovered EEG power spectral

density (PSD) better than OBS, and as well as reference layer regression, for frequencies below 15 Hz, though there was no difference for higher frequencies. We then conducted a proof-of-concept experiment demonstrating the efficacy of this method in practice during live recordings with a visual task and found that we could display cleaned EEG data in real time with low latency (typically less than 20ms). An open-source MATLAB-based application is under development to make this method accessible to the neuroscience community. These results show that our method is practical and effective for real-time applications and will enable EEG-fMRI neurofeedback experiments at low latencies, opening the door to investigations of the neural circuit basis of neurofeedback interventions.

Title: Source space reconstruction from simultaneously acquired EEG-fMRI via a multi-level deep transcoder

Authors: *X. LIU[1], P. SAJDA[2];
[2]Biomed. Engin., [1]Columbia Univ., New York, NY

Abstract: Simultaneous EEG-fMRI is a neuroimaging modality which focuses on capturing both high spatial and temporal resolution brain activity, though a current challenge is how to combine the two measures to infer a high resolution spatiotemporal source space. Here we report on a method for symmetrically fusing the two modalities using a multi-level deep transcoder to reconstruct a 2mm x 10ms resolution source space. The approach is completely data-driven and does not require structural images, models of hemodynamics response functions nor lead field models. At the core of the approach is a cyclic convolutional transcoder which maps from EEG to fMRI and vice versa. After training, our model can reconstruct/infer a source space from only EEG and/or fMRI data, namely it solves the EEG source separation/fMRI deconvolution problem and extracts forward/inverse head models and hemodynamic response functions from the data. Source reconstruction results from simulated simultaneous EEG-fMRI data show good correlation with the ground truth, with average correlation coefficients of 0.66±0.0045/0.59±0.0017 for oscillation/sparse sources estimated from fMRI alone and 0.76±0.0017/0.41±0.0011 for oscillation/sparse sources estimated from EEG alone. Compared to classical techniques for EEG sourcing, our transcoding approach has higher correlation with ground-truth even when the ground-truth lead field matrix is used for the classic method. We also evaluated the approach for real simultaneous EEG-fMRI data. Specifically we used data from a simultaneous EEG-fMRI experiment

where subjects performed an auditory odd-ball task. We trained transcoders via a leave-one-subject-out approach and generated a source space for the left out subject. In the group source space we found: 1) prolonged deactivation across regions making up the default mode network (e.g. prefrontal cortex, posterior cingulate cortex, and temporal pole) after both standard and oddball stimuli, 2) activations were observed only after odd-ball stimuli in parieto-occipital lobe/300~350ms post stimulus, 3) activations in the source space where seen in the left and right primary motor cortex/400ms only after oddball trials and these activations were followed by activations in left and right somatosensory cortex/450ms coinciding with right hand index finger button pressing which was the behavioral response required for detection of odd-ball stimuli. In summary, the completely data-driven source space recovered by our approach is consistent with the known spatiotemporal brain dynamics for this task.

Title: EEG theta and ERP responses to congruent versus incongruent brands

Authors: *H. DINI[1], A. SIMONETTI[2], L. BRUNI[1], E. BINGE[2];
[1]Dept. of Architecture, Design, and Media technology, Aalborg Univ., Copenhagen, Denmark; [2]Dept. of Marketing and Market Res., Univ. of Valencia, Valencia, Spain

Abstract: Neuroimaging and behavioral studies have shown that brands convey meaning to consumers. How the brain immediately reacts to brand logos followed by either congruent or incongruent pictorial brand cues can deepen the understanding of the semantic processing of brands. Previous studies on linguistics have found different brain responses to congruent vs incongruent stimuli, which was attributed to the process of error monitoring. Our study investigated whether brands lead to the same brain reactions. Thirty-two participants (13 female, mean age 26.84 ± 4.33) performed the task, wearing a 32-channel EEG cap. Forty congruent and forty incongruent 2D brand-related image sequences were shown through a virtual reality headset. Each sequence comprised three images implying a brand, a question, and the brand logo. The congruence manipulation happened in the brand logo. Then, preprocessed signals of the last image were first averaged among each condition to obtain ERP activity, and then the time-frequency activity of each trial was calculated using the Welch method. Time-frequency analysis was implemented on the theta frequency band (4-7 Hz), and time interval of 700 to 1200 ms after stimulus starts. The analyses were implemented on central region electrodes based on literature, and a two-dimensional permutation test was conducted to test the statistical significance. The ERP analysis showed a significant difference between the two conditions (congruent > incongruent) in the N400 component (p= 0.04, effect size= 0.54), in which the incongruent condition had a larger negative peak. The results showed that theta activity of congruent (versus incongruent) condition is significantly lower (p= 0.01, effect size= -0.69).

This study showed that brain response to congruent versus incongruent brand logos differed in both time (ERP) and time-frequency domains. Studies in linguistic field have suggested that difference in the central and mid-frontal region due to stimuli congruence is related to error monitoring process. This study replicated their findings. Thus, we argue there is a higher processing difficulty in mismatched (versus matched) brand logos, leading to a larger error monitoring. Therefore, error monitoring process could be extended to other forms than linguistic, such as images and brands. Moreover, the theta band difference occurred in 700-1200 ms while ERP difference occurred in N400 component. This finding suggests that these two methods capture different aspects of brain activity.

Title: A machine learning alternative to identifying contrasts during cognitive tasks

Authors: *B. BLIDARESCU[1], C. PISTOL[1], I. OANE[1], A. BARBORICA[1], I. MINDRUTA[2], C. DONOS[1];
[1]Physics Dept., Univ. of Bucharest, Bucharest, Romania; [2]Neurol. Dept., Emergency Univ. Hosp. Bucharest, Bucharest, Romania

Abstract: Motivation: The study of contrasts from event related potentials (ERP) obtained from stereo-EEG (SEEG) is usually performed using permutation cluster analysis (PCLA) in order to find intervals with amplitude differences that reach statistical significance. The sites exhibiting such contrast are considered to have a preferential response for one of the task conditions. However, a major drawback of this approach is that it requires a sufficiently high signal to noise ratio (SNR) to highlight a contrast between the conditions, this in turn requiring an increase in the number of trials per experiment, which is often not feasible in a clinical environment. We propose a novel approach that uses machine learning (ML) to identify the SEEG contacts exhibiting different activation patterns between conditions.**Methods:** 10 patients undergoing presurgical evaluation with intracranial electrodes performed a cognitive task where they were shown angry and happy faces for 1.5s and they were instructed to push a button to classify them. The raw data was notch filtered, common averaged, down-sampled to 256Hz, cropped to [-0.3, 1.0] s, baseline corrected, low-passed with a Savitzky-Golay filter at 15Hz and 45Hz for the ML and PCLA, respectively. We compared the outcome of two analyses: permutation cluster tests between the ERPs of the two conditions, a ML classifier trained on statistical moments (mean, standard deviation, median absolute deviation, skewness and kurtosis) computed on 3 intervals: [0.2,0.4] s, [0.4,0.8] s, [0.8,1] s. The best ML model per contact was chosen by a Hyper-optimization algorithm (Bayes Search) from two types of classifiers (Multi-Layer Perceptron and Random Forest Classifier) that were evaluated using

the Matthews Correlation Coefficient (MCC) metric.**Results:** The PCLA revealed on average 16.3% ± 7.3% contacts per subject with significant contrasts ($p<0.05$). The ML classifier identified on average 26.3% ± 6.6% contacts per subject that allowed better than chance classification (MCC>0.2, equivalent of >60% accuracy). The average Jaccard similarity coefficient per subject was 0.21 ± 0.07 for SEEG contacts exhibiting the angry-happy contrast, and 0.53 ± 0.17 for the brain structures containing contacts exhibiting contrasts.**Conclusion:** Both methods identified contacts located in the brain structures hypothesized by the Pessoa and LeDoux models of facial emotions processing, but also contacts that are not usually associated with facial emotion processing. Further validation on simulated trials with various SNR may disambiguate which method is more resilient to low SNR.

Title: Multivariate pattern analysis identifies brain networks in sparse intracranial EEG recordings

Authors: *C. DONOS[1], B. BLIDARESCU[1], C. PISTOL[1], I. OANE[1], I. MINDRUTA[2], A. BARBORICA[1];
[1]Physics Dept., Univ. of Bucharest, Bucharest, Romania; [2]Neurlogy Dept., Emergency Univ. Hosp. of Bucharest, Bucharest, Romania

Abstract: Introduction: The study of cognitive processes using intracranial EEG (iEEG) usually relies on the identification of brain locations where statistically significant differences are observed between two or more task conditions. Multiple brain locations that are activated during the task as considered to be part of the brain network involved in the task realization. In practice, we often do not have enough trials to reach a good signal-to-noise ratio (SNR), and the brain locations where we record iEEG varies from patient to patient. We propose a method for identifying brain networks from sparse iEEG recordings, based on multivariate pattern analysis (MVPA).
Methods: We recorded iEEG using depth electrodes from 10 epilepsy subjects while they were performing a face recognition task. The subjects were shown happy and angry faces and they were asked to push a button to indicate the emotion on the faces. iEEG was epoched, common averaged, filtered with a Savitzky-Golay filter at 15Hz, cropped to [-0.3, 1] s interval and baseline corrected. For each subject and for each contact we first trained a random forest classifier to discriminate the task condition (angry vs happy) and computed the Matthews Correlation Coefficient (MCC). Contacts that had MCC > 0 (better than chance) were preselected for training two MVPA models. The first model aggregates data across contacts and time, while the second model aggregates data across channels and employs time

generalization (trains one model per time sample).
Results: For the first model, the classifier performed above chance level for all subjects, and the mean MCC during cross-validation was 0.45±0.16. For the second model, we optimized the iEEG channels used for classification by adding them to the classifier one by one, starting with the ones that performed best during the random forest screening step. The subset of channels that resulted in the largest area under the curve (AUC) during the training of the second model was considered to outline to brain network observed during the cognitive task. The mean AUC was 0.63±0.07.
Conclusion: As opposed to identifying brain networks by finding individual iEEG channels that exhibit significant contrasts between conditions, we developed a method that identifies the brain networks finding the subset of channels that provide the best classification score.

Title: A standardised framework for re-referencing strategies of human intracranial electrophysiological data

Authors: *G. PARISH[1], F. ROUX[1], L. KOLIBIUS[1], R. CHELVARAJAH[2], D. ROLLINGS[2], V. SAWLANI[2], H. HAMER[3], S. GOLLWITZER[3], G. KREISELMEYER[3], M. TER WAL[1], B. STARESINA[1], M. WIMBER[4], S. HANSLMAYR[4];
[1]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [2]Queen Elizabeth Univ., Birmingham, United Kingdom; [3]Universitätsklinikum Erlangen, Erlangen, Germany; [4]Univ. of Glasgow, Glasgow, United Kingdom

Abstract: In recent years human electrophysiological studies, particularly intracranial and human single neuron studies, have become increasingly popular as the field grows in funding and stature. It is important, therefore, that there is some form of standardisation that enables comparison between studies and findings. Such studies inherently rely on the analysis of electrical signals that are emitted by the combined neural circuitry of the brain. These signals must be recorded in relation to some grounding signal, meaning that the reference signal will play a large role in the resultant waveforms that are ultimately recorded. At the point of recording, there is a general understanding that typical grounding sources will help to minimise surrounding electrical interference whilst not removing much of the original signal. For this reason, grounding references are often situated around the periphery of the head or a specifically purposed impedance wire. However, studies often employ another step of re-referencing, whereby a single or amalgamation of electrodes or micro-wires are selected as an additional grounding reference. In theory, this is pursued to further increase the signal to noise ratio. However, it is often the

case that a re-referencing strategy is chosen to remove signals that are undesirable for the hypothesis in question. Re-referencing might be achieved in any number of ways that are currently preferred by the field, whether it is the subtraction of an average set, an independent-component, or a particular electrode of interest, amongst others. Preferred strategies are often employed on a case-by-case basis, rather than being prescribed from a standardisation of re-referencing methods. We feel that this can murky the underlying theory behind secondary re-referencing, potentially leading to disagreements and an inability to reproduce findings across studies. As such, we here explore a human episodic memory paradigm to assess the effect of a variety of popular re-referencing techniques on resultant oscillatory signals and spike-field coherence, using intracranial EEG data collected from 18 subjects. We comparatively analyse time-frequency space and the degree to which spikes conform to oscillatory signals, with a focus on theta and gamma frequencies. We also examine whether re-referencing strategies maximise cognitive effects in relation to our episodic memory paradigm. Overall, we hope to provide a standardised framework for human intracranial re-referencing methods, such that the field can engage in more transparent and comparable experimentation.

Title: Intracranial artifact classification for cognitive neuroscience research applications

Authors: *S. LONG[1], M. BRUZZONE[2], S. MITROPANOPOULOS[2], A. GUNDUZ[1];
[1]Biomed. Engin., [2]Neurol., Univ. of Florida, Gainesville, FL

Abstract: Introduction: Intracranial electroencephalography (iEEG) presents a unique opportunity to extend findings from cognitive studies utilizing non-invasive techniques. However, iEEG data are recorded from patients with drug resistant epilepsy who display EEG containing physiological activity, non-cerebral artifacts, and transient pathological activity including interictal epileptiform discharges (IEDs) or high frequency oscillations (HFOs). IEDs are known to disrupt proper cognitive processes, potentially confounding results in cognitive iEEG studies. In this study, we developed, tested, and validated an automated artifact classifier for continuous task-based iEEG.
Methods: We utilized a large public dataset (DS1) of iEEG data from depth and subdural iEEG electrodes to train and test a random forest classifier (RFC) using a 70/30 cross validation approach. DS1 was collected at St. Anne's University Hospital (Brno, Czech Republic) and Mayo Clinic (Rochester, Minnesota) and contains 3-second data segments (fs =5,000Hz) classified as non-cerebral (n=73,902), pathological (n=67,797), or physiological (n=151,290). Features were extracted to train a RFC to

distinguish events as non-cerebral, pathological, or physiological. Segments were filtered, down sampled to 1200Hz, and processed to extract 66 features related spectral characteristics, morphological shape, anatomical location, and brain state. Performance was validated on continuous iEEG data. Dataset 2 (DS2), collected at Motol University Hospital (Prague, Czech Republic), contains 5-min of continuous recordings (fs =1,000Hz) with expert IED annotations for 2 subjects. Dataset 3 (DS3), collected at the University of Florida Neuromedicine Hospital (Gainesville, FL), contains 8-min of continuous recordings (fs=1200Hz) with expert annotations for 3 subjects.
Results: On DS1, our RFC had class specific performances of 91.9% | 90.6% | 91.36% (physiology), 96.3% | 98.0% | 93.197% (pathology), and 94.6% | 96.6% | 89.9% (non-cerebral artifacts) for accuracy, specificity, and precision. On DS2, our classifier had a sensitivity of 85.1% and specificity of 84.3% for annotated IEDs (pathology). These results suggest that our RFC is capable of successfully classifying iEEG data into three distinct classes with high levels of accuracy, precision, sensitivity, and specificity. Additionally, our classifier was able to achieve similar performance levels on datasets collected at a lower sampling rate not involved in training, suggesting its generalizability.

Title: Machine learning approach to assess the severity of neuropsychiatric symptoms of dementia based on electroencephalography signal

Authors: *H.-Y. CHIEN[1], A.-C. YANG[1,2,3];
[1]Inst. of Brain Science, Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan, Taipei City, Taiwan; [2]Digital Med. Center, Natl. Yang Ming Chiao Tung Univ., Taipei City, Taiwan; [3]Dept. of Med. Research, Taipei Veterans Gen. Hosp., Taipei City, Taiwan

Abstract: Dementia is a neurodegenerative disease in which no cure is available. Current treatments can only help improve some of the symptoms and slow the progression of the disease. Therefore, it is important to diagnose and treat the symptoms associated with dementia early by effectively evaluating symptoms profiles and severity to help maintain the cognitive function and life quality of the patient. The diagnosis of dementia requires extensive observation of clinical history and multiple assessments of clinical questionnaires. However, objective assessment involving other physiological signals or neuroimage remains limited. Therefore, the diagnosis of dementia is subjective, time-consuming and

costly. It is also relatively vague in assessing the severity of the psychological and behavioral symptoms of dementia (BPSD). We aim to use electroencephalogram (EEG) to assist clinical evaluation of dementia severity to reduce the time and resource consumption, and to establish an objective method for automatic detection of BPSD. In this study, we analyzed the EEG data of 108 Alzheimer's disease (AD) (59 women, 49 men) and with a mean age of 78.0 years (SD: 8.6). EEG data from all subjects were further divided into 999 10-second segments. The EEG were first analyzed with 5 sub-frequency bands using a Butterworth filter, and each sub-band was extracted for multiple features, including frequency and nonlinear domain metrics. The extracted EEG features were then used to predict Neuropsychiatric Inventory (NPI) scores associated with EEG segments using machine learning models. Finally, the relationship between the severity of dementia and EEG changes was investigated by searching for significantly correlated features and brain regions in the model. We divided the demented patients into two groups according to the cut-off of NPI score at 14, which is related to the outcome of dementia. Among the models trained using MATLAB, the best performance was achieved by k-nearest neighbors (KNN) with an accuracy rate of 86.4%. The model was further trained using the support vector machine (SVM) and bagging tree algorithm, and the accuracy rate was 83.4% and 85.9% in the validation dataset. Using the KNN method, we established individual model for each EEG channels, and we found the accuracy of Cz, Pz and F8 to be 83.9%, 79.9% and 79.4% respectively. It is evident that the features captured in this study are effective in assessing the severity of neuropsychiatric symptoms of AD. In the future, we hope to assist the clinical assessment of BPSD in patients with dementia with a rapid, non-invasive, low-cost, objective and reliable method.

Title: Grammatical, syntactic, and semantic error identification in single-trial brain-computer interface sentence construction using evoked frequency content and machine learning strategies

Authors: *A. W. L. CHIU, C. L. KOUTSOUMPAS, **E. J. WHITESIDE**, E. B. DRONG;
Biomed. Engin., Rose-Hulman Inst. of Technol., Terre Haute, IN

Abstract: Brain-computer interface (BCI) spellers are currently a means of communication for those with severe neuromuscular deficiencies. These spellers allow users to construct and edit sentences through visually evoked EEG signals. However, the ability of the user to make the necessary corrections when errors occur is a tedious process. For this study, we aim to identify important EEG features and develop machine learning strategies to quickly classify different types of errors in BCI spellers. An OpenBCI 16-channel Ultracortex Mark IV headset with the Cyton and Daisy board setup was used for data acquisition. Subjects were presented with 240 sentences (ranging from 6 to 15 words in length) using an optimal

recognition point (ORP) paradigm where each word was shown in rapid succession (60 words per minute) to simulate the use of a BCI speller in sentence construction. Each sentence had an equal probability of containing either a semantic error (SM), a syntactic error (SY), a spelling error (SP), or no error (Control). Subjects were instructed to press one of two buttons for each trial: a green button for Control or a red button if any error was perceived. EEG features such as ERP (P300, N400, P600 intensities), as well as frequency band power (alpha and theta) were extracted. A linear discriminant analysis (LDA) method was developed to classify these four possible outcomes using 180 randomly selected sentences as the training set. Using only the alpha band as the main feature, we were able to achieve a classification accuracy of 67.8% for Control vs SM; 65.6% for Control vs SP; and 68.9% for Control vs SY. Using only the theta band as the main feature, we were able to achieve a classification accuracy of 57.8% for Control vs SM; 61.2% for Control vs SP; and 62.3% for Control vs SY. This result is promising since this process simulates the real-time error detection procedure in a typical BCI spelling session where decisions are made based on single-trial data without any trial rejection techniques nor aggregated analysis. Further improvement can be achieved by incorporating additional features into the training set, along with other nonlinear boundary conditions.

Title: An interpretable EEG latent space captures inter- and intra-individual variability in a team flow task

Authors: *Q. WU[1], S. SHIMOJO[2], M. SHEHATA[2,3];
[1]Div. of Humanities & Social Sci., [2]Div. of Biol. & Biol. Engineering/Computation & Neural Systems, California Insititute of Technol., Pasadena, CA; [3]Electronics-Inspired Interdisciplinary Res. Inst., Toyohashi Univ. of Technol., Toyohashi, Japan

Abstract: Introduction: Brain signals reflect individual traits and states. Traditionally, many studies have been using EEG data to recognize individual identities and predict behaviors or cognitive abilities. However, most of these studies adopted complicated models that focused on prediction performance, sacrificing interpretability (black box). Here, we identified individual differences in a musical team flow task via extracting latent features from EEG data in a highly interpretable, lower-dimensional space to maximize inter-individual and intra-individual variability. To facilitate interpretation of the latent space, we analyzed its relationship to a psychological space, establishing connections between neural data and subjective experiences. **Methods:** We analyzed data collected in a previous study (Shehata et al., 2020).

Briefly, 15 subjects (5 males; age: 18-35 years) forming ten pairs (5 participants were paired twice) played a music rhythm game under three conditions creating three states (team flow, team only, and flow only states). EEG hyperscanning and subjective ratings were collected. We calculated EEG power spectral density (PSD) of four frequency bands (theta, alpha, beta, and low-gamma) at each of the 128 channels. First, we extracted ten principal components (PC) from each frequency band through the principal component analysis (PCA) and then conducted linear discriminant analysis (LDA). The latent dimensions (LD) were determined based on the classification accuracy of each subject and their states (10-fold cross-validation). Finally, we constructed a psychological space based on subjective ratings and conducted a representational similarity analysis (RSA) with the EEG latent space. **Results:** We successfully identified 3 LDs that achieved 100% classification accuracy. Plotting the EEG data in the 3D latent space revealed two levels of segregation. A macrosegregation captured inter-individual differences, and microsegregation captured intra-individual states. Using RSA, we found a significant correlation (Pearson's $r = 0.308$, $p < 0.001$ by permutation) of the trial-by-trial similarity representations between the latent space and the psychophysical space, indicating shared similarity structures between the brain signals and behavioral characteristics. **Conclusion:** Using LDA, we demonstrated both inter- and intra-individual segregations of EEG characteristics in a 3D latent space and mapped the similarity structures in this space onto behavioral traits. Future research would benefit from this approach and look for latent brain features associated with psychophysical traits and states.

Title: Involvement of GluN2B-containing NMDA receptors in the elimination of cortico-motoneuronal synapses during development

Authors: *T. OHNO[1], ***T. OHNO**[1], S. FUKUDA[1], N. MURABE[1], K. SAKIMURA[2], T. HAYASHI[1], M. SAKURAI[1];
[1]Teikyo Univ. Sch. Med., Tokyo 173-8605, Japan; [2]Dept Cell. Neurobiol, Brain Res. Institute, Niigata Univ., Niigata, Japan

Abstract: We previously showed in our *in vitro* slice co-culture model of the corticospinal (CS) projections that CS axons extend over the spinal gray matter during early stages of development but later regress from the ventral side (Ohno et al., 2004). This elimination was further found to be dependent on GluN2B-containing NMDA receptors (Ohno et al. 2010, Isoo et al., 2016). We found *in vivo* that CS axons make direct and transient connections with motoneurons (MNs) at an early postnatal stage in rodents, which had been believed to be present only in higher primates (Maeda et al., 2016; Murabe et al., 2018). We further studied the time course of ratio of cortico-motoneuronal (CM) monosynaptic connections. Positive ratio of CM-EPSCs were shown to reach plateau at postnatal day (P) 8 (65%), then decreased from P14 toward P21 and disappeared thereafter (Ohno et al., 2021). Here, we studied the

involvement of GluN2B-containing NMDA receptors, which we found to be involved in axonal regression from the ventral spinal cord *in vitro*. To conditionally knockout (KO) the GluN2B gene (*Grin2b*) from the forearm MNs, we employed GluN2B-floxed mice and adeno-associated virus encoding Cre recombinase gene (AAV-Cre). Intramuscular injection of AAV-Cre into the forearm muscles of GluN2B-floxed mice at P1 made it possible for AAV-Cre to infect the axon terminals of MNs projected to the forearm muscles and to selectively KO *Grin2b* of those MNs. We clamped GluN2B-KO MNs to +40 mV and recorded NMDA components of EPSCs evoked by electrical stimulation of the posterior funiculus at P9-10. We measured the reduction in the amplitude of the GluN2B component of EPSCs by the application of GluN2B inhibitor, ifenprodil (3 μM) and Ro25-6981 (3 μM). In wild-type MNs, the EPSC amplitudes were inhibited by 78.4 ± 8.5% (mean ± S.E.M.), whereas in conditional GluN2B-KO MNs, EPSC amplitudes decreased by only 16.9 ± 8.5%, indicating that this method successfully KOs GluN2B in the MNs. We then examined the developmental change of the positive ratio of CM-EPSCs on conditional GluN2B-KO MNs. CM direct connections were present in about 30 % of GluN2B-KO MNs even after P21 and preserved at least until P48. These results suggest that CM synapse elimination is dependent at least partly on synaptic activity and post-synaptic GluN2B-containing NMDA receptors.

Title: Neuronal SIRPα temporally enables microglia activation and synapse refinement during development

Authors: *D. JIANG[1], C. BURGER[1], N. ALBRECHT[2], P. ANDRADE[1], R. D. MACKIN[1], V. AKHANOV[1], J. H. LIANG[1], M. A. SAMUEL[3];
[2]Neurosci., [3]Dept. of Neuroscience, Huffington Ctr. on Aging, [1]Baylor Col. of Med., Houston, TX

Abstract: Microglia activation is dynamic, and periods of increased activation precisely align with the window in which developmental neural pruning proceeds. Little is known about the neuron-derived signals that permit microglia activation during these periods and restrict it as synapses mature. Using the murine retina, we show that signal regulatory protein alpha (SIRPα) produced by neurons acts as a permissive cue that temporally enables microglia activation. During developmental synapse pruning, neurons are the dominate developmental source of SIRPα. SIRPα is also temporally regulated: high levels are present during synaptic refinement while lower levels are present in adults. Nanoscopic imaging reveals that SIRPα localizes to the synaptic cleft where it structurally overlaps with its binding partner CD47. Using cell type-specific deletion methods, we show that while microglia-derived SIRPα is

dispensable for microglia activation and synapse engulfment, neuronal SIRPα is required. Deletion of SIRPα from retinal neurons dramatically restricts microglia activation, limits engulfment, and increases synapse number. Conversely, prolonging neuronal SIRPα expression extends the window in which microglia are active. Together, these data identify a neuron-derived cue that enables microglia activation and synapse remodeling and reveal a temporal switch that permits microglia activation at the appropriate developmental time.

Title: The involvement of CD47 and the complement protein C3 in synaptic elimination in sensory-motor circuits during normal development.

Authors: *D. FLOREZ-PAZ, G. Z. MENTIS;
Ctr. for Motor Neuron Biol. and Disease, Depts. of Pathology and Cell Biol. and Neurol., Columbia Univ., New York, NY

Abstract: Proper assembly of sensory-motor circuits requires synapse formation between appropriate neurons for the normal function of the nervous system. Synapse formation requires the activation of different genetic pathways that regulate the number and function of synapses with the appropriate postsynaptic neurons. We previously reported, that C1q is involved in synaptic refinement and elimination of proprioceptive sensory synapses (VGluT1+) on spinal motor neurons. Here, we explored the role of complement protein C3 in synapse engulfment and the interaction of C1q with CD47 as counterpoise signals in synapse development of spinal motor circuits. We systematically quantified the number of VGluT1+ synapses on motor neuron somata and synaptic density in their dendrites, at different ages (P0, P5 and P10) in WT, C1qKO, C3KO, and CD47KO animals. In C3KO animals, we observed an increase in VGluT1+ synapses at P5 compared to WT. Surprisingly, we also found an increase in synapses in CD47KO mice compared to controls at P5 and P10. Using immunohistochemistry, we studied the expression of CD47 in C1qKO and C3KO animals; starting at P5 there was an upregulation of CD47, tagging more synapses in Cq1KO and C3KO animals compared with WT. To investigate a possible protecting role of CD47 in synaptic pruning, we studied the interaction between C1q and C3 with CD47 using quadruple staining against ChAT, C1q or C3, CD47 and VGlut1, showing that at P0 and P5, ~10% of synapses in motor neurons were tagged by both C1q and CD47. Further, we also stained microglia using Iba1, and we confirmed that VGlut1 synapses are engulfed by microglia when tagged by both, CD47 and C1q starting at P0, suggesting that CD47 is not sufficient to protect synapses from engulfment when is also tagged by C1q. To reveal the CD47 source in the spinal cord, we performed RNAscope

experiments and found that CD47 is only expressed in motor neurons, but not in microglia or astrocytes. Together, these results confirm a role of C3 in synapses elimination, but raising the possibility that that CD47 does not provide a synaptic-protecting role for sensory synapses in the spinal cord, as was previously described in other circuits, and likely plays a role in signaling for engulfment of synapses by microglia.

Title: Depletion of microglia with PLX5622 in adulthood reverses developmental pruning of the rat glossopharyngeal nerve

Authors: *A. J. RIQUIER, S. I. SOLLARS;
Univ. of Nebraska At Omaha, Omaha, NE

Abstract: The removal of excess synapses, or 'pruning' is a well-established phenomenon of the developing brain. The central projections of the gustatory glossopharyngeal nerve form a terminal field (IX) of synapses with neurons of the nucleus of the solitary tract. The IX reduces in volume by approximately 66% between postnatal day 15 (P15) and P25 (Mangold & Hill, 2008), yet this pruning can be experimentally reverted later in life (Skyberg et al., 2017; Sun et al., 2018), suggesting this reduction may not be a discrete occurrence, but a continuous maintenance throughout the lifespan. The central nervous system macrophages microglia are known to perform synaptic pruning in other sensory systems (e.g. Paolicelli et al., 2011; Schafer et al., 2012; Stevens et al., 2007) including the other gustatory nerves in mice (Sun et al., 2019). To determine if microglia are responsible for pruning and maintenance of the IX, we used daily intraperitoneal injections of the colony-stimulating factor 1 receptor inhibitor PLX5622 to deplete microglia at various points of the rat lifespan, then labeled the IX with a biotinylated dextran amine and quantified its volume. In vehicle-treated control rats, the IX was largest at P14, reduced in volume by approximately 66% by P25 ($p < .01$), then remained at that reduced size through P68 ($p > .1$). In contrast, when microglia were removed from P1-P40 no pruning of the IX occurred; indeed, the IX was statistically identical in size to those of pre-pruning P14 rats ($p > .1$). When PLX5622 treatments were then ceased at P40, microglia returned within three days and pruning resumed; by P68 the volume of the IX had reduced to sizes comparable to adult controls ($p > .1$). These results indicate that microglia are necessary for IX developmental pruning and are capable of such well outside the typical pruning period. To test if normally occurring developmental IX pruning could be reversed, we next took adult control rats whose IX had already pruned and depleted their microglia from P40-P68, which resulted in the IX

expanding to pre-pruning sizes typical of the neonatal rat ($p > .1$). To see if this was a generalizable phenomenon, we repeated the analyses with the somatosensory IX fibers that project to the spinal trigeminal nucleus (SpV). As expected, SpV IX fibers underwent developmental pruning ($p < .01$) and removing microglia during development prevented this pruning ($p > .1$). However, when microglia were allowed to return in adulthood, pruning did not resume; by P68, SpV IX fibers remained at pre-pruning volumes ($p > .1$). Taken together, these data show that microglia continuously maintain the gustatory IX at a reduced size at least several weeks after pruning typically occurs.

Abstract: Valproic acid (VPA) exposure during a critical developmental period in Xenopus tadpoles results in local neural circuit hyperexcitability in the optic tectum, abnormal dendritic development as well as associated behavioral abnormalities, such as lack of schooling, sensory hypersensitivity and increased seizure susceptibility. VPA is a common anti-seizure medication, and prenatal exposure to VPA results in a higher incidence of Autism spectrum disorders (ASD) in humans, and causes brain abnormalities associated with ASD in other organisms. Previous microarray studies from the lab have shown that VPA exposure results in remarkable alterations in gene expression, including a greater than two-fold increase in matrix metalloproteinase 9 (MMP9). MMP9 is a secreted endopeptidase targeting extracellular matrix proteins, creating permissive environments for neuronal development and plasticity. Developmental dysregulation of MMP9 is implicated in development of neurodevelopmental disorders (ND). Here we test the hypothesis that chronically elevated MMP9 activity during early neurodevelopment is responsible for neural circuit hyperconnectivity observed in *Xenopus* tadpoles after early exposure to VPA, a known teratogen associated with ND in humans. We found that overexpressing MMP9 in the Xenopus tectum mimics effects of VPA on synaptic connectivity, and blocking MMP9 activity pharmacologically or genetically reverses effects of VPA on physiology and behavior. We further show that during normal neurodevelopment MMP9 levels are tightly regulated by neuronal activity and

required for structural plasticity. These studies show that MMP9 plays a critical role in both normal and abnormal development.

Title: Cell-type specific deletions of Neuroligin 2 reveal a vital role of synaptic excitation-inhibition balance in mice

Authors: *C. M. LONGLEY, J. E. MESSIER, Z.-L. CAI, J. PARK, W. CHEN, M. XUE;
Baylor Col. of Med., Houston, TX

Abstract: The spatiotemporal relationship between synaptic excitation (E) and inhibition (I) orchestrates the patterns of neuronal activity in the brain. Excitation and inhibition stay relatively proportional to each other over different temporal and spatial scales. This proportionality, often referred to as E-I balance, is thought to be critical for neuronal functions, and disruption of E-I balance has been hypothesized as a key etiology of many neurodevelopmental and psychiatric disorders. However, causal evidence demonstrating the importance of E-I balance has been scarce. Here we show that Neuroligin 2 (Nlgn2), a postsynaptic cell adhesion molecule exclusively expressed at inhibitory synapses, selectively regulates GABAergic inhibition without affecting glutamatergic excitation in mouse cortical excitatory and inhibitory neurons. Deletion of Nlgn2 early in development from pyramidal neurons, somatostatin (Sst)-expressing, parvalbumin (Pv)-expressing, or vasoactive-intestinal peptide (Vip)-expressing interneurons leads to a cell-autonomous reduction in synaptic inhibition onto each of these neuron types, thereby disrupting the E-I balance. Even though constitutive Nlgn2 knockout mice are viable, conditional deletion of Nlgn2 in either glutamatergic or GABAergic neurons unexpectedly causes postnatal lethality, indicating an essential role of E-I balance in survival. Simultaneous loss of Nlgn2 in both glutamatergic and GABAergic neurons results in viable mice with developmental delay, suggesting that re-establishing E-I balance partially restores neuronal functions. Together, our results indicate that Nlgn2 plays a critical role in the development of inhibitory synapses onto both excitatory and inhibitory neurons and provide evidence for a vital role of maintaining a proper E-I balance in brain functions and organism survival.

Title: Input and output connectivity mapping reveals integrating properties of corticoclaustral and intraclaustral circuits

Authors: *A. M. SHELTON, D. K. OLIVER, S. J. BUTT, A. M. PACKER;
Physiology, Anatomy, & Genet., Univ. of Oxford, Oxford, United Kingdom

Abstract: The claustrum is highly interconnected with many other structures in the brain. However, our knowledge of the organizing principles governing extra- and intra-claustral connectivity remain incomplete. The present study investigates the architecture of circuits between the claustrum and neocortex and within the claustrum itself. Immunohistochemistry, retrograde tracing, *in vitro* whole-cell patch-clamp electrophysiology, dual-color optogenetic circuit mapping, and *in vivo* calcium imaging of neural activity were used to assess the extent to which claustrum neurons receive common input from multiple cortical areas. We determined that individual claustrum neurons frequently integrate inputs from more than one cortical site, most commonly between regions of the frontal cortex. Additionally, we found that neurons in the claustrum receive inputs from an array of sensory and associative cortical areas, albeit to a lesser extent. Retrograde labelling further demonstrated that the degree of input integration from frontal cortical regions depends on the output target of claustrum neurons. Finally, optogenetic mapping revealed that intraclaustral connectivity was found to be far more frequent than previously reported in coronal slices, particularly among neurons that did not share the same output target. Our findings shed light on the organizing principles of claustrum input and output connectivity, demonstrating the relationship between cortical projections, local claustral connectivity, and claustral outputs. Claustrum projection neurons pool inputs from multiple sites around the brain and display a high degree of connectivity with each other that is influenced by output target. This work provides mechanistic evidence of the claustrum as an intrinsically integrative structure with the capacity to perform local transformations of cortical input via distinct intraclaustral pathways.

Title: Cortex layer 5 innervates the thalamic reticular nucleus

Authors: *B. CARROLL[1], V. SAMPATHKUMAR[2], N. B. KASTHURI[2], S. SHERMAN[3];
[2]Neurobio., [1]Univ. of Chicago, Chicago, IL; [3]Dept Neurobiol, Univ. Chicago, Chicago, IL

Abstract: A major cortical efferent and the primary source of inhibition to dorsal thalamus, the thalamic reticular nucleus (TRN) is well-positioned to regulate corticothalamic communication. Whereas cortical inputs had been previously thought to originate solely in layer 6 of cortex (L6), we recently demonstrated with light microscopy that axons of cortical layer 5 (L5) cells also produce varicosities in TRN. Our experiments employed viral tracing in the genetic mouse line Rbp4-Cre, which selectively expresses Cre-recombinase in L5. Using injections of Cre-dependent adeno-associated viruses (AAVs) in cortex, we labelled L5 neurons and examined the nature of their labelled varicosities in the somatosensory domain of TRN. First, we used light microscopy and a Cre-dependent AAV encoding the fluorescent label enhanced yellow fluorescent protein (EYFP) to localize the resulting label in TRN and demonstrate that varicosities arising in L5 are restricted to edge regions of TRN, where resides a subpopulation of inhibitory cells projecting to higher-order thalamus. In contrast, L5 varicosities are absent in TRN's core, containing cells that project to first-order thalamus; we also showed through labelling of corticofugal axons from both L5 and L6 with EYFP expression independent of Cre that these core cells receive L6 inputs. Second, we used electron microscopy and Cre-dependent AAVs encoding enhanced ascorbate peroxidase (APEX2) to test that these varicosities include bona fide terminals onto TRN cells. We delivered two APEX2 viruses, one to label mitochondria in L5 cells of primary somatosensory cortex and the other to label cytoplasm in L5 cells of primary motor cortex. By doing so, we established that L5 from these areas provides synaptic innervation of TRN cells. Together, these experiments established evidence that cortical afferents to TRN include L5, and that these L5 inputs impact inhibition of higher-order, but not first-order, nuclei in dorsal thalamus.

Title: Spatiotemporal mapping of extracellular field potentials in different layers of mouse somatosensory cortex

Authors: *V. JAIN, M. FORSSELL, P. GROVER, M. CHAMANZAR;
Electrical and Computer Engineering, Carnegie Mellon Neurosci. Inst., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: ***Background:*** Somatosensory cortex mediates and transforms sensory information across different layers. While the laminar organization of the neural circuit structure in the somatosensory cortex is well characterized, the complex dynamics of functional integration within these layers still remains elusive. Electrophysiological response has been to elucidate the neuronal circuit connections under different pathological states or stimulation conditions. Here we report the results of a systematic study based on a series stimulation-recording experiments to detect extracellular field potentials in different layers of the somatosensory cortex in response to electrical stimulation in each layer. ***Method:*** Coronal brain slices were prepared from 3-6 weeks old C57BL6 mice of either sex. Each layer of the somatosensory cortex was stimulated using a Pt-Ir bipolar electrode. A single biphasic pulse (cathodic phase first) with 200µs pulse width was applied as the extracellular stimulation signal to each layer of the somatosensory cortex and the local field potentials (LFPs) were recorded in different layers at different locations within the somatosensory cortex within a 1 mm lateral range. The amplitude of the stimulation signal was chosen such that the effect of volume conduction is minimized, ensuring local stimulation of the cortical layer of interest. ***Results:*** The results from the present study revealed a widespread activation of neural circuits in different layers on stimulating layer 5 which is in accord with the laminar organization whereas stimulation of Layer 1, Layer 2/3 and Layer 6 evoked a confined response in nearby layers. Interestingly, Layer 4 stimulation leads to comprehensive activation of Layer 2/3 and Layer5. ***Conclusion:*** In conclusion, current work divulges network connections across the cortical laminae mediated through synaptic transmission, which can be used to better understand information processing in neuronal networks and as a baseline to study the impaired neural signal transmission under different pathological conditions.

Title: Rapid homeostatic modulation of transsynaptic nanocolumn rings

Authors: *P. MUTTATHUKUNNEL[1], P. FREI[2], S. PERRY[3], D. DICKMAN[3], M. MÜLLER[2]; [1]Dept. of Mol. Life Sci., [2]Univ. of Zurich, Zurich, Switzerland; [3]Univ. of California, Department of Neurobiology, CA

Abstract: Robust neural information transfer relies on a delicate molecular architecture of chemical synapses and even subtle changes in the molecular organization of synapses may profoundly affect synaptic transmission and animal behavior. Neurotransmitter release is controlled by a specific arrangement of proteins within presynaptic active zones. How the specific presynaptic molecular architecture relates to postsynaptic organization, and how synaptic nano-architecture is transsynaptically regulated to achieve stable synaptic transmission remains enigmatic. Using STED microscopy, we here discovered that presynaptic nano-rings formed by the active-zone cytomatrix protein scaffold Bruchpilot (Brp) precisely align with glutamate receptors (GluRs) nano-rings composed of ~6 GluR clusters at the *Drosophila* NMJ. Individual rings harbor ~5 transsynaptically-aligned Brp-GluR 'nanocolumns'. Transsynaptic nanocolumn rings are partially masked by unaligned GluR clusters. Genetic manipulations of GluR subunits and the auxiliary GluR subunit Neto revealed a GluR subtype-specific nano-organization: While GluRs containing the GluRIIA subunit predominantly localize to nanorings, GluRIIB 'nanoclusters' can be found both, inside and outside of nanorings. Intriguingly, acute GluR impairment rapidly triggers the formation of new transsynaptic nanocolumns on the minute time scale during homeostatic plasticity. We reveal distinct phases of structural transsynaptic homeostatic plasticity, with postsynaptic reorganization preceding presynaptic modulation. Finally, the auxiliary GluR subunit Neto promotes structural and functional homeostatic plasticity. Thus, transsynaptic nanocolumns arrange in stereotypic rings that are rapidly modulated during homeostatic plasticity to stabilize synaptic efficacy.

Abstract: Heterogeneity in the etiopathology of autism spectrum disorders (ASD) limits the development of generic remedies, requires individualistic and patient-specific research. Recent progress in human-induced pluripotent stem cell (iPSC) technology provides a novel platform for modeling ASDs for studying complex neuronal phenotypes. In this study, we generated telencephalic induced neuronal (iN) cells from iPSCs derived from an ASD patient with a heterozygous point mutation in the *DSCAM* gene. The mRNA of DSCAM and the density of DSCAM in dendrites were significantly decreased in ASD compared to control iN cells. RNA sequencing analysis revealed that several synaptic function-related genes including NMDA receptor subunits were downregulated in ASD iN cells. Moreover, NMDA receptor (R)-mediated currents were significantly reduced in ASD compared to control iN cells. Normal NMDA-R-mediated current levels were rescued by expressing wild-type DSCAM in ASD iN cells, and reduced currents were observed by truncated DSCAM expression in control iN cells. shRNA-mediated DSCAM knockdown in control iN cells resulted in the downregulation of an NMDA-R subunit, which was rescued by the overexpression of shRNA-resistant DSCAM. Furthermore, DSCAM was co-localized with NMDA-R components in the dendritic spines of iN cells whereas their co-localizations were significantly reduced in ASD iN cells. Levels of phospho-ERK1/2 were significantly lower in ASD iN cells, suggesting a potential mechanism. A neural stem cell-specific *Dscam* heterozygous knockout mouse model, showing deficits in social interaction and social memory with reduced NMDA-R currents. These data suggest that *DSCAM* mutation causes pathological symptoms of ASD by dysregulating NMDA-R function.

Title: Dars2-related leukoencephalopathy: possibility of dysregulated noncanonical functions of mitochondrial aspartyl-trna synthetase?

Authors: *S. GUANG[1,2], C. L. NEMETH[1,2], M. YING[1,2], A. FATEMI[1,2];
[1]Kennedy Krieger Inst., Baltimore, MD; [2]Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: DARS2-related leukoencephalopathy, also called Leukoencephalopathy with Brainstem and Spinal cord involvement and Lactate elevation (LBSL), is a rare disorder with a wide phenotypic spectrum. Classic LBSL is characterized by childhood-onset slowly progressive spasticity, cerebellar ataxia and dysfunction of the dorsal column. Early onset cases with cerebral hypoplasia and early demise, as well as mild adulthood-onset cases, were also reported. LBSL is caused by mutations in the *DARS2* gene, which encodes mitochondrial aspartyl-tRNA synthetase (mt-AspRS). mt-AspRS is synthesized in cytosol and transported to mitochondria, responsible for attaching aspartate to its corresponding tRNA. Nearly all patients are compound heterozygous for *DARS2* mutations, of which, one is most frequently a splice mutation in intron 2, which causes exon 3 skipping, a frameshift, and a premature termination codon. A subset of point mutations have been studied regarding aminoacylation activity, architecture, localization and solubility. None of them cause gross structural or functional perturbations, except for the R263Q mutant, which impairs enzyme activity. Altogether, the housekeeping aminoacylation activity seems not be the major target, pointing to the possibility that mt-AspRS moonlights in the cells by performing noncanonical functions such as regulating splicing or translation, as has been reported for several cytosolic aminoacyl-tRNA synthetases. We generated cerebral organoids for seven LBSL patients and three controls using an unguided protocol and performed SMARTseq2. After quality control, 809 cells were used for downstream analysis. At least six cell identities were found in our dataset. We uncovered two patient subgroups which presented unique profiles of differentially expressed genes. Patients carrying at least one missense mutation showed downregulated expression of genes related to mRNA processing and splicing, which was exacerbated in neuronal cells. Patients carrying two splice site mutations showed upregulated genes related to RNA splicing and translation. Inspired by these findings, we identified some genes, such as *LGMN*, *SLIRP*, *CAST* and *PDCD4*, which were spliced differently across LBSL patient groups. Furthermore, transcript analyses of *DARS2* showed decreased levels of normal transcripts in LBSL patients and transcripts skipping exon 3 coexist with normal transcripts within individual control cells, but LBSL cells might express solely abnormal transcripts within an individual cell. A full understanding of these findings may help to reveal noncanonical functions of *DARS2* and the identification of therapeutic targets.

Title: Modeling Glut1 Deficiency Syndrome at the Human Blood-Brain Barrier In Vitro Using CRISPR-Cas9 Edited Induced Pluripotent Stem Cells

Authors: *I. PERVAIZ[1], F. ZAHRA[2], C. M. MIKELIS[2], A. J. AL-AHMAD[2];
[1]Texas Tech. Univ., AMARILLO, TX; [2]Texas Tech. Univ., Amarillo, TX

Abstract: Background: Glucose represents one of the major energy sources for the central nervous system (CNS). Glucose uptake is mostly occurring across the blood-brain barrier (BBB), via the involvement of glucose transporters (GLUTs). At the BBB, such transport is mostly mediated via GLUT1 also known as solute carrier family 2, facilitated glucose transport member 1. In addition to the importance of glucose for neuron metabolism, there is growing evidence that brain microvascular endothelial cells (BMECs) lining the BBB are highly glycolytic. Yet our current understanding of glucose metabolism at the BBB remains limited. GLUT1 deficiency syndrome (G1D) is an autosomal dominant childhood form of epilepsy affecting GLUT1 activity. It is often characterized by early onset of seizures, gait disorders, and intellectual disability. A major issue is the lack of a robust *in vitro* model of G1D to understand the pathophysiology of the BBB. The aim of this study is to develop and characterize G1D-BMECs by gene editing using induced pluripotent stem cells (iPSCs). **Methods:** Heterozygous *SLC2A1*+/- iPSC (IMR90)-c4 were produced by the CRISPR-Cas9 method. Such iPSCs were differentiated into BMECs using established protocols. Cell phenotyping, barrier function, glucose uptake, and metabolism were assessed in the system. **Results:** *SLC2A1*+/- iPSCs were viable and showed no significant differences in terms of phenotype or growth, compared to unedited iPSCs. Differentiated *SLC2A1*+/- BMECs showed similar *SLC2A1* expression, at mRNA level to the control, but showed reduced GLUT1 expression at the protein level, as well as reduced glucose uptake. A decreased barrier function was observed in these cells, without any major changes in tight junction complex and glucose metabolism, as well as impaired angiogenesis. **Discussion:** Our data suggest that *G1D-BMECs* display reduced GLUT1 expression and glucose uptake, reduced barrier tightness, and angiogenesis thus, recapitulating findings documented *in vivo*. Taken together, our data suggest that G1D-BMECs can be a potential tool to model G1D at the BBB *in vitro*.

Title: Contribution of GABA-A receptor subunit deletions to human Angelman syndrome neuronal phenotypes

Authors: T. M. ROBINSON[1], C. L. SIROIS[2], S. J. CHAMBERLAIN[2], ***E. S. LEVINE**[1];
[1]Neurosci., [2]Genet. and Genome Sci., Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: Maternal deletion of chromosome 15q11-q13 causes Angelman syndrome (AS), a genetic disorder in which individuals present developmental delays, language impairment, intellectual deficits, motor ataxia, and seizures. The gene located in this region that is primarily responsible for AS is UBE3A, which encodes a ubiquitin protein ligase. This gene is normally imprinted in the brain, and expression in neurons is only from the maternal allele. Thus, a maternal deletion of this region, which is the most common cause of AS, results in a complete loss of UBE3A expression in neurons. Several non-imprinted genes in the region are also affected, including a cluster of GABA-A receptor subunit genes (GABRB3, GABRA5, and GABRG3), which encode the β3, α5, and γ3 subunits, respectively. AS can also be caused by loss of function mutations of UBE3A. When AS results from mutations of UBE3A, the symptoms of affected individuals pertaining to cognition, motor function, and seizures are less severe compared to the symptoms caused by a maternal deletion. This suggests that in 15q11-q13 deletion patients the loss of other genes in the region contribute to AS pathophysiology. We have previously shown that human AS neurons containing a maternal 15q11-q13 deletion have impaired maturation of resting membrane potential (RMP) and action potentials (APs), increased excitability, and decreased GABA-mediated synaptic transmission compared to neurons derived from unaffected controls. In the present studies, we used novel isogenic iPSC lines derived from a patient with a UBE3A mutation and a CRISPR-corrected counterpart to examine the contributions of UBE3A and the GABA-A receptor subunits to AS neuronal phenotypes. Maturation of RMP and AP firing were affected in UBE3A mutation neurons to a similar extent as AS deletion neurons. UBE3A mutation neurons also displayed increased excitability, but of a lesser magnitude than seen in AS deletion neurons. Spontaneous inhibitory synaptic activity was not altered in UBE3A mutation neurons, in contrast to the decreased frequency and amplitude of spontaneous inhibitory synaptic currents seen in AS deletion neurons. We hypothesize that the hemizygous loss of the GABA-A receptor subunit cluster contributes to the more severe cellular phenotypes in AS deletion neurons. Ongoing experiments are exploring whether decreasing the expression of these genes in UBE3A mutation neurons using antisense oligonucleotides (ASOs) will mimic the cellular phenotypes seen in AS deletion neurons, including decreased inhibitory synaptic signaling and neuronal hyperexcitability. These studies may identify novel targets for therapeutic development in AS.

Title: Novel discoveries for warburg micro syndrome protein rab3gap1 in modulation of neurite outgrowth and interactions with axon elongation and an ER Golgi trafficking factor

Authors: *J. VACHARASIN[1], P. S. GHATE[2], D. NOWLING[1], S.-H. CHEON[1], M. H. COWEN[3], V. KAY[1], M.-K. LAWLOR[1], M. MCCORD[1], E. CHUKWURAH[4], M. WALLA[1], S. B. LIZARRAGA[1];

Abstract: Mutations in Rab3Gap1 are known to cause Warburg Micro syndrome, a neurodevelopmental disorder that results in delayed motor development, hypoplasia, and other abnormalities. However, the neuronal function of Rab3Gap1 is not well defined. We find that knockdown of RAB3GAP1 leads to a reduction in neurite outgrowth in human stem cell derived neurons. Using a combination of mass spectrometry, co-immunoprecipitation, and colocalization analysis we identified two novel interactors of RAB3GAP1: the axon elongation factor Dedicator of cytokinesis 7 (DOCK7) and the TATA modulatory factor 1 (TMF1) a modulator of Endoplasmic Reticulum (ER) to Golgi trafficking. DOCK7, TMF1, and Rab3GAP1 are expressed during fetal stages of brain development. To further understand the function of Rab3GAP1 its interactors, we used genome editing to target exon 7 of Rab3GAP1. This is an exon that is commonly mutated in patients with Warburg Micro syndrome. We find that the subcellular localization of TMF1 and DOCK7 to the ER-Golgi compartment is altered in RAB3GAP1 mutant cells. The ER-Golgi compartment is important in autophagy and Rab3Gap1 has been previously shown to be important in the formation of the autophagosome. We find that the induced exon 7 mutation in Rab3GAP1 also leads to alterations in autophagy. Taken together our work identifies a novel role for Rab3GAP1 in neurite outgrowth and two novel interactors of Rab3GAP1 which could provide additional mechanisms that underlie the pathogenesis of Warburg Micro Syndrome.

Title: Function of the Trinucleotide (CGG) Repeats Within the FMR1 Gene in Human Neurons

Authors: *C. L. SIROIS, M. LI, Y. GUO, T. KORABELNIKOV, Y. XING, B. LEVESQUE, A. BHATTACHARYYA, X. ZHAO;
Waisman Ctr., Univ. of Wisconsin-Madison, Madison, WI

Abstract: The 5’ UTR of the *FMR1* gene contains trinucleotide CGG repeats, that, when expanded beyond a certain threshold, can lead to one of several disorders depending on the length of the repeats. Repeats that range from 55 to 200 CGGs lead to either Fragile X Tremor and Ataxia Syndrome (FXTAS) or Fragile X Primary Ovarian Insufficiency (FXPOI), while repeats beyond 200 CGGs lead to silencing of the FMR1 gene and cause Fragile X Syndrome (FXS), a neurodevelopmental disorder that causes 2-5% of all autism cases. Recent research has shown that repeats below 55 CGGs are also correlated with certain health conditions, leading to CGG repeat lengths to be further subdivided into low zone (less than 24

CGG), normal (24-42 CGG), and gray zone (42-54) categories. To investigate the function of these CGG repeats *FMR1* in human neurons, we generated two human embryonic stem cell (hESC) lines lacking the CGG repeats in FMR1 (H1ΔCGG, H13ΔCGG) using genome editing and differentiated these cells into neurons. We found that removal of the CGG repeats does not affect *FMR1* expression at the mRNA or protein level in either hESCs, neural progenitors, or early post-mitotic neurons. Interestingly, *FMR1* mRNA in neurons lacking CGG repeats exhibit altered localization. Our results demonstrate that CGG repeats in *FMR1* may have a function in early neural development, which may have important implications for CRISPR-based gene therapy approaches that aim to remove the expanded CGG repeats from the *FMR1* gene.

Title: Identifying Cellular Phenotypes of Dup15q syndrome Using CRISPR-edited Human iPSC-derived neurons

Authors: *M. ELAMIN[1], A. DUMARCHEY[2], C. STODDARD[2], S. J. CHAMBERLAIN[2], E. S. LEVINE[1];
[1]Neurosci., [2]Genet. and Genome Sci., Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: Dup15q syndrome is a neurodevelopmental disorder caused by maternal, but not paternal, duplications in the 11.2-13.1 region of the long arm of chromosome 15. Affected children typically exhibit intellectual disability, developmental delay, autism, and epilepsy. It is thought that *UBE3A*, the gene encoding the ubiquitin protein ligase E3A, underlies many Dup15q behavioral phenotypes because it is the only imprinted gene that is expressed solely from the maternal allele. Nevertheless, the exact role of *UBE3A* is yet to be determined. To identify cellular phenotypes in human Dup15q neurons, we used an induced pluripotent stem cell (iPSC) line derived from an individual with an isodicentric 15q duplication. This iPSC line was also edited using CRISPR technology to generate an isogenic line with the extra genetic material completely removed. Whole-cell patch-clamp recordings revealed a hyperexcitability phenotype in Dup15q neurons characterized by an increased voltage-gated sodium current, larger action potential amplitude, greater firing frequency, and increased excitatory synaptic transmission compared to isogenic control neurons. Normalizing *UBE3A* gene expression throughout in vitro development with the use of antisense oligonucleotides (ASO) prevented these cellular phenotypes, indicating that increased *UBE3A* expression is necessary for the establishment of these cellular phenotypes. A later treatment with

the *UBE3A* ASO was only partially effective at reversing these cellular deficits. Overexpression of *UBE3A* in an iPSC line from an unaffected individual with a paternal 15q duplication was achieved by using an ASO targeting the antisense transcript that is responsible for silencing paternal *UBE3A*. We found that *UBE3A* overexpression affected sodium currents, action potential amplitude, and firing rate, similar to the cellular phenotypes observed in Dup15q neurons. Increased expression of *UBE3A* was not sufficient, however, to affect excitatory synaptic transmission, suggesting a contributing role for other genes in the duplicated region. Elucidating the functional relevance of *UBE3A* and other genes to Dup15 cellular phenotypes will enrich our knowledge of the pathophysiological mechanisms underlying this disorder and aid in the development of novel therapeutics.

Title: Investigation into the disease mechanism of Leukoencephalopathy with Spinal Cord and Brain Stem Involvement and Lactate Elevation (LBSL) using patient iPSC-derived motor neurons

Authors: *S. BAEK[1], C. L. NEMETH[1,3], B. O'BRIEN[1], S. GUANG[1], M. YING[2], A. FATEMI[1,3]; [1]Moser Ctr. for Leukodystrophies, [2]Hugo W. Moser Res. Inst., Kennedy Krieger Inst., Baltimore, MD; [3]Dept. of Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Leukoencephalopathy with Brainstem and Spinal Cord involvement and Lactate Elevation (LBSL) is an autosomal recessive disorder characterized by dorsal column dysfunction which results in slowly progressive gait difficulty, spasticity, ataxia, and proprioceptive deficits. Hallmark MRI shows progressive loss of white matter volume unique to dorsal columns and lateral corticospinal tracts of the spinal cord, and select regions of the brainstem and cerebral cortex. Most of the individuals diagnosed with LBSL are compound heterozygote for mutations in the *DARS2* gene, which encodes mitochondrial Aspartyl-tRNA Synthetase that conjugates the amino acid aspartate to its cognate tRNA during protein translation within mitochondria. Established knockout mouse models have been studied but fail to recapitulate the human condition. We utilized induced Pluripotent Stem Cells (iPSCs) reprogrammed from peripheral blood mononuclear cells (PBMCs) of patients to further investigate the pathological manifestation of the disease. Using a rapid differentiation protocol, we derived patient iPSCs into motor neurons and show reduced neurite outgrowth and reduced spontaneous firing in LBSL cells compared to control using IncuCyte live cell imaging and electrophysiological analysis, respectively. Our western blot analysis indicates reduced DARS2 in motor neurons compared to iPSCs in both control and LBSL patients; however, LBSL cells show a greater reduction of DARS2 in both conditions compared with controls. Despite reduced DARS2 protein, translation of mitochondrial proteins appears intact within

LBSL neurons. Finally, analysis of mitochondria using the Seahorse XFe96 Cell Mito Stress Test reveals reduced baseline oxygen consumption as well as spare capacity of LBSL patient cells suggesting an overall reduction of mitochondrial flexibility and fitness. Interestingly, these findings suggest that mitochondrial impairment and neuronal growth deficits are independent of mitochondrial translation. This model may serve as a useful testbed for future therapeutics aimed at understanding LBSL disease mechanism.

Title: Investigation of CDH13's role in neurodevelopmental disorders using a set of generated isogenic induced pluripotent stem cell lines (iPSC) and iPSCs carrying different CDH13 variants in a functional intronic SNP rs2199430

Authors: *M. VITALE, J. ZÖLLER, K. LESCH;
Div. of Mol. Psychiatry, Ctr. of Mental Health, Univ. Hosp. Würzburg, Germany, Würzburg, Germany

Abstract: CDH13 has been identified as a risk gene for various neurodevelopmental disorders and is involved in cell migration, neurite outgrowth, and axon guidance. CDH13 is predominantly in parvalbumin and somatostatin interneurons. This indicates that CDH13 functions at the inhibitory synapse thus implying an involvement in neuronal network activity. A well-functioning neuronal network activity is controlled by interaction between a certain excitation (E) and inhibition (I) ration via balanced synaptic communication between the glutamatergic and GABAergic neurons. Since it is known that the disruption of the E/I balance is present in many neurodevelopmental disorders, impact on the E/I balance by CDH13 particularly in the modulation of inhibitory synaptic activity is possible. The aim is to investigate CDH13's role in the E/I balance by using induced pluripotent stem cell (iPSC) lines.
We are using iPSCs from healthy individuals carrying a GG, AA and AG genotype in the SNP rs2199430 and we generated a $CDH13^{+/-}$and a $CDH13^{-/-}$cell line using CRISPR/Cas9. The CRISPRed lines and the unmodified iPSCs are then differentiated into three neuronal subtypes: serotonergic, glutamatergic, and GABAergic neurons. These subtypes are generated by using a small-molecule a or a transcription-based reprogramming differentiation approach.CDH13 levels will be compared I) between neuronal subtypes derived from the same iPSC line and II) between neuronal subtypes derived from different iPSC cell lines and finally III) in the co-cultures experiments. Since previous studies have shown that CDH13 is an inhibitor of neurite outgrowth, we would like to investigate this in our cell line as we expect that the

$CDH13^{-/-}$ and $CDH13^{+/-}$ will enhance neurite outgrowth. This will be assessed using microfluidics devices and a neurite outgrowth assay (Thermofisher).To explore the neuronal network activity, experiments using the microelectrode array (MEA) will be done. For this reason, the glutamatergic and GABAergic neurons will be co-cultured to mimic the E /I imbalance: the aim is to co-culture different combinations of GABAergic and glutamatergic neurons derived from the different CDH13 genotype iPSCs.This would allow us to comprehend if the different genotypes affect the neuronal activity in distinctive ways. In conclusion, CDH13's role in the E/I balance and its cellular mechanism is far from being understood. Using different CDH13 SNP variants and the isogenic iPSC lines with a gene dose-dependent deficiency of CDH13 will facilitate investigation of CDH13's mechanism and elucidate the role of CDH13 in the etiopathogenesis of a wide spectrum of neurodevelopmental and psychiatric disorders.

Title: Methylene chloride alters morphological development in zebrafish larvae

Authors: *C. OWENS, S. GAREY, A. EASKER, N. TITERA, B. CARTER;
Univ. of Wisconsin-Eau Claire, Eau Claire, WI

Abstract: Methylene chloride is a volatile organic compound commonly used as a solvent in paints, in the production of pharmaceuticals, and as an extraction solvent in the food industry. In epidemiological studies, environmental exposure to methylene chloride has been associated with increased Autism Spectrum Disorder (ASD) prevalence. How this chemical impacts brain formation and general embryonic development is not known. Our objectives were to (1) determine how methylene chloride can affect development in zebrafish using dose-dependent titrations and (2) identify phenotype-concentration thresholds in zebrafish larvae for morphological and behavioral analyses. In these experiments, methylene chloride was emulsified with ethanol into embryo solution. Unsexed zebrafish larvae were treated with methylene chloride at 10 hours post-fertilization (hpf) with concentrations from 0 to 500 parts per million (ppm). Larvae were imaged using brightfield microscopy between 24hpf and 120hpf for several morphological features: mortality, length, spinal curvature, eye size, cardiac edema, yolk edema, head edema. DanioScope software (Noldus) was used to quantify these features. R studio was used for performing ANOVA and post hoc testing for significant differences between means. Methylene chloride treatment resulted in dose-dependent morphological changes in zebrafish embryos across the time course of observation; the lowest observable adverse effect level (LOAEL) was measured to be 200ppm. Long-term, characterizing the impact of methylene chloride on brain development may contribute to improvement of understanding ASD and inform data-driven environmental regulations.

Title: The organization of the gravity-sensing system in zebrafish

Authors: *Z. LIU[1], D. G. C. HILDEBRAND[3], J. L. MORGAN[2], N. SLIMMON[1], M. W. BAGNALL[1]; [1]Neurosci., [2]Ophthalmology, Washington Univ. in St. Louis, Saint Louis, MO; [3]Lab. of Neural Systems, The Rockefeller Univ., New York, NY

Abstract: Motor circuits develop in sequence from those governing fast movements to those governing slow. Here we examine whether upstream sensory circuits are organized by similar principles. Using serial-section electron microscopy in larval zebrafish, we generated a complete map of the gravity-sensing (utricular) system from the inner ear to the brainstem. We find that both sensory tuning and developmental sequence are organizing principles of vestibular topography. Patterned rostrocaudal innervation from hair cells to afferents creates a directional tuning map in the utricular ganglion, forming segregated pathways for rostral and caudal tilt. Furthermore, the mediolateral axis of the ganglion is linked to both developmental sequence and temporal kinetics. Early-born pathways carrying phasic information preferentially excite fast escape circuits, whereas later-born pathways carrying tonic signals excite slower postural and oculomotor circuits. These results demonstrate that vestibular circuits are organized by tuning direction and kinetics, aligning them with downstream motor circuits and behaviors.

Title: Elucidating the role of PAX-6 transcription factor in C. elegans neuronal asymmetry

Authors: *A. KELLY, R. XIONG, Y.-W. HSIEH, C.-F. CHUANG;
Dept. of Biol. Sci., Univ. of Illinois At Chicago, Chicago, IL

Abstract: Brain asymmetry has been observed in many organisms including humans at multiple levels such as molecular and functional. Reduced or reversed brain asymmetry is associated with specific neurological disorders and diseases like dyslexia and autism. Understanding the molecular mechanisms underlying brain asymmetry will provide insight in the development of strategy for treating associated neurological disorders. However, investigating brain asymmetry directly in humans is difficult. Thus model organisms like the nematode *C. elegans* provide the opportunity to study a system that has functionally similar mechanisms to our own. This study focuses on investigating the role of an ortholog of human PAX6 transcription factor in asymmetric development of one olfactory neuron pair in *C. elegans*. This neuron pair further undergoes differentiation into two subtypes that each enables the *C. elegans* nematode to sense different chemicals in their environment. To dissect the structure and function relationship of the PAX-6 protein in neuronal asymmetry, we crossed fluorescent markers of this neuron pair into various *C. elegans* mutants of the human PAX6 ortholog and analyzed neuronal asymmetry phenotypes using fluorescence microscopy techniques. Our results suggest that the PAX6 ortholog is required for the asymmetrical development of the olfactory neuron pair. Additionally, the neuronal asymmetry phenotype in *pax-6* mutants correlates with defects in axon connection that is essential for the specification of normal neuronal asymmetry. Since PAX6 plays a major role in the development of the human eye, central nervous system, and pancreas, an important prospect of this project is that it could provide insight to diseases and disorders that occur in some of these structures.

Title: Cellular and molecular mechanisms of mok-1 function in left-right neuronal asymmetry

Authors: *R. XIONG[1], X. WANG[2], C.-F. CHUANG[1];
[1]Univ. of Illinois at Chicago, Chicago, IL; [2]Div. of Developmental Biol., Cincinnati Children's Hosp. Res. Fndn., Cincinnati, OH

Abstract: The developing nervous system generates a large diversity of cell types with distinct patterns of gene expression and functions. One way to establish neuronal diversity is to specify neuronal subtypes across the left-right axis. The *C. elegans* left and right AWC olfactory neurons communicate to specify asymmetric subtypes, AWC^{OFF} and AWC^{ON}. The default AWC^{OFF} is specified by a Ca^{2+}-regulated kinase cascade that is activated by influx of Ca^{2+} through the voltage-gated Ca^{2+} channel UNC-2/UNC-36. Intercellular communication between the two AWC neurons and other neurons through the NSY-5/innexin gap junction network antagonizes *unc-2/unc-36* Ca^{2+} signaling in the induced AWC^{ON} cell. Our recent data suggest that voltage- and calcium-activated SLO BK potassium channels *slo-1* and *slo-2* acts redundantly downstream of *nsy-5* to inhibit *unc-2/unc-36* Ca^{2+} signaling in the specification of AWC^{ON}. To identify the genes required for *slo-1* function in inhibiting *unc-2/unc-36* Ca^{2+} signaling for promoting AWC^{ON}, we performed a non-biased forward genetic screen to isolate *mok* (modifier of K^+ channel) mutants that suppress the *slo-1(gf)* $2AWC^{ON}$ phenotype. *mok-1*(*vy11)* is one of the mutants identified from this screen. The $2AWC^{OFF}$ phenotype of *mok-1*(*vy11)* mutants is suppressed by loss-of-function mutations in the Ca^{2+} channel gene *unc-36*, suggesting that *mok-1* acts upstream of the *unc-2/unc-36* Ca^{2+} signaling pathway. Together, our results suggest a model in which *nsy-5* inhibits *unc-2/unc-36* Ca^{2+} signaling through *slo-1* and *mok-1*. We identified the mutation responsible for the *vy11* phenotype using whole genome sequencing with the help of Alex Boyanov in the Oliver Hobert lab. Further genetic analysis and behavior analysis of the *vy11* mutant, as well as molecular characterization of *mok-1* will be presented in the meeting.

Title: Competition and refinement in a developing sensorimotor circuit

Authors: *B. MCFARLAND[1], H. JANG[1], Y. KURMANGALIYEV[2], T. A. GODENSCHWEGE[3], A. NERN[4], C. R. VON REYN[1,5];
[1]Sch. of Biomed. Engineering, Sci. and Hlth. Systems, Drexel Univ., Philadelphia, PA; [2]Dept. of Biol. Chem., UCLA, Los Angeles, CA; [3]Biol. Sci., Florida Atlantic Univ. - John D MacArthur Campus, Jupiter, FL; [4]Janelia Res. Campus, Ashburn, VA; [5]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Sensorimotor neurons may receive inputs from multiple sensory neuron cell types that have to be integrated across space and time and transformed into an appropriate behavioral response. Many factors influence the output of sensorimotor neurons including the number of pre-synaptic partners, the location and density of synapses, and underlying intrinsic properties. Few sensorimotor circuits, however, have been fully characterized across development. Understanding how wiring and intrinsic properties develop is important in understanding sensorimotor circuit function and is also clinically relevant as miswired sensorimotor circuits are thought to underlie multiple neurodevelopmental disorders. Here, we investigate developmental wiring and intrinsic properties in a well-established sensorimotor escape circuit (the Giant Fiber circuit) in *Drosophila melanogaster*. We first investigate the timecourse of circuit formation focusing on visual projection neurons (VPNs) as they compete for space on the dendrites of a shared post-synaptic partner, the Giant Fiber (GF). We find one VPN, LC4, first makes contact at a proximal location on GF approximately 24 hours puparium formation (hAPF). A second VPN, LPLC2, contacts distal GF dendrites approximately 24 hours later. This segregation is maintained across development. We also find that during this partner matching period, a third VPN, LPLC1, contacts GF during development but does not maintain connections into adulthood. Next, using RNA-sequencing data generated for all three VPNs across development, we investigate the timecourse of synaptic and ion channel genes that determine intrinsic properties. We find that many synaptic genes and ion channels are upregulated by 60hAPF, a time when contacts between GF and all VPNs peak. Finally, we investigate how the early loss of LC4 leads to anatomical and functional compensation in the GF circuit. We find that early expression of Kir2.1, an inward-rectifying potassium channel, results in ablation of the majority of LC4 input. We perform whole-cell current-clamp electrophysiology on head-fixed adult flies while presenting visual stimuli known to elicit escape behaviors through the GF circuit, a looming stimulus mimicking an object approaching on a direct collision course. Surprisingly, following LC4 ablation, we find that GF output is different from previous data showing GF output when LC4 is still present but silenced, suggesting LC4 ablation causes circuit level changes that effect output function. Overall, our data suggests inputs to the GF circuit are segregated, and that the circuit adapts to developmental perturbation to preserve function.

Title: EphrinAs and EphAs are expressed in lingual epithelium and repel gustatory and somatosensory neurites

Authors: M. AKSU[1], A. J. GEORGE[1], K. H. DOSHI[2], D. CHO[3], M. RUSSO[4], J. HWANG[5], R. W. TREFFY[6], J. WONG[1], A. JENNINGS[1], M. K. L. PILON[7], *M. ROCHLIN[1];

Abstract: Ephs and ephrins are cell surface proteins that act as ligands and receptors for one another, initiating signaling cascades that can cause repulsion, arborization, or growth promotion of axons. EphrinAs are lipid-linked and interact primarily with EphAs, whereas ephrinBs are transmembrane and interact primarily with EphBs. In embryonic day 14.5 (E14.5) mouse tongue, when gustatory afferents have just entered fungiform papillae (FP) epithelium, *in situ* hybridization and immunostaining revealed that ephrinA1, A3, A4, and A5 are broadly distributed in the dorsal epithelium and present at a higher level than observed in the mesenchyme. The FP epithelium and the papilla core tissue traversed by afferents exhibited lower levels of ephrinAs than surrounding epithelium. At E16.5, ephrinA mRNA levels are higher throughout the dorsal lingual epithelium compared to E14.5, and more clearly excluded from the nerve path within papillae. A variety of EphAs are also expressed in the epithelium at these stages. In E14.5 geniculate ganglia, EphA/ephrinA expression varies in intensity and localization, with some restricted to Phox2B-positive (oral sensory, mostly gustatory) neurons and others restricted to Prrxl1-positive neurons (aural somatosensory) neurons. Rat geniculate and trigeminal neurites are repelled dose-dependently by stripes of ephrinA-Fc as well as EphA-Fc fusion proteins in vitro, demonstrating that both forward signaling (via axonal EphAs) and reverse signaling (via axonal ephrinAs) can occur. We are examining Phox2b-Cre::tdTomato mice to determine if triple knockout mice lacking ephrinA1, A3, and A4 exhibit aberrant innervation within lingual FP. Our data also raise the possibilities that reverse signaling guides geniculate axons, and that Eph/ephrin signaling among dorsal lingual epithelial cells contributes to their organization.

Title: Thalamic contributions to sensory processing in developing somatosensory and motor cortex

Authors: *L. J. GÓMEZ[1], J. C. DOOLEY[2], G. SOKOLOFF[4], M. S. BLUMBERG[3];
[2]Dept. of Psychological and Brain Sci., [3]Dept Psychol, [1]Univ. of Iowa, Iowa City, IA; [4]Psychological and Brain Sci., The Univ. of Iowa, Iowa City, IA

Abstract: Primary somatosensory (S1) and motor (M1) cortex interdependently process sensory input throughout life. Previous studies of sensory processing in adult animals have indicated that M1 relies on

S1 for sensory input; however, in developing animals this is not always the case. Specifically, we recently demonstrated in postnatal day (P)12 rats that S1 and M1 process sensory inputs differently depending on submodality: Whereas tactile inputs are conveyed to M1 via S1 (congruent with the classical model), S1 and M1 receive proprioceptive input in parallel from an unknown common source. Parallel proprioceptive input to S1 and M1 is likely important for shaping somatotopy and connectivity within and between them; thus, establishing the source of this input will better inform our understanding of their development. To determine the structures that convey proprioceptive input to cortex, we first performed retrograde tracing from the forelimb representation of S1 and M1 at P12 using wheat germ agglutinin. We found that both the ventral posterolateral (VPL) and posterior medial (POm) thalamic nuclei project to S1 and M1 at this age; we did not detect projections to both S1 and M1 from any other thalamic or extra-thalamic structure, suggesting that VPL and/or POm are the best candidate sources of proprioceptive input. To assess their contributions to proprioceptive processing in S1 and M1, we are recording extracellular activity in S1 and M1 at P12 in response to proprioceptive stimuli. Following a baseline period of recording, we pharmacologically inactivate VPL or POm and measure changes in proprioceptive responses in S1 and M1. We also test the possibility that both VPL and POm convey proprioceptive inputs to cortex by inactivating the two structures simultaneously. By delineating the pathways through which S1 and M1 receive parallel sensory input in early development, these experiments will help clarify how sensory input contributes to their functional development.

Title: Neurogenesis and fate of olfactory bulb granule cells

Authors: *T. LIBERIA, K. HAN, C. A. GREER;
Dept Neurosurg., Yale Univ., New Haven, CT

Abstract: In most regions of the mammalian CNS neurogenesis occurs embryonically and decreases quickly after birth. However, neurogenesis of granule cells (GCs) targeted to the olfactory bulb (OB), the largest population of interneurons in the OB, begins embryonically but continues robustly throughout life. GCs constitute a heterogeneous population based on timing of neurogenesis, location of their somata in the granule cell layer (GCL), regionalization of their progenitors, morphological variability and differential gene expression, among other characteristics. The apical dendrites of GCs establish reciprocal dendrodendritic synapses with lateral dendrites of mitral/tufted cells (MC/TC) in the external plexiform layer (EPL). Interestingly, the distribution of GC somas in the GCL may play a role in establishing these

local circuits in the EPL. It has been suggested that superficial GCs preferentially contact TC dendrites in the superficial EPL, while GCs localized to deeper laminae within the GCL establish synapses predominately with MC dendrites. As shown previously, the timing of neurogenesis is a key determinant of the location of GC somata in the GCL. GCs generated postnatally are preferentially incorporated into the deeper regions of the GCL, while those born embryonically are integrated into superficial portions of the GCL. Despite the importance of timing, the precise organization of GCs generated at specific time points is not fully understood. Similarly, their integration into EPL synaptic circuits depending on the timing of neurogenesis is uncertain. We have used CD1 mice (males & females) to address these questions. First, we inject BrdU i.p. to specifically label GCs born at embryonic day (E)17, postnatal day (P)0, P7, P21, P55, P175 and analyze their distribution within the GCL. Second, we study the integration of new GCs into the circuitry by electroporating GC progenitor cells at P0 with pUbC-tdTomato to specifically label future GCs, and immunohistochemistry to analyze the temporal expression of synaptic markers in those labeled GCs. Our results demonstrate that GC somata have different distribution patterns depending on their birthdate, but they do not differ between sexes. Interestingly, this applies not only when we compare embryonic with postnatal stages, but when we compare among postnatal timepoints. Our results thus far show that the heterogeneous organization of GCs persists throughout their neurogenesis in both embryonic and postnatal periods. Currently we are digging deeper into how sublaminar location in the GCL and timing of neurogenesis may be reflected in the expression of synaptic markers at the dendrodendritic synapses.

Title: Experience-dependent actin organization specifies dendritic properties in cortical interneurons

Authors: *X. HOU[1], M. MORISHIMA[2], J. SUGI[1], K. SAKIMURA[3], Y. KAWAGUCHI[2,4], S. SUGIYAMA[1];

Abstract: The cell-type specific properties and connectivity of inhibitory neurons underlie their ability to spatiotemporally shape information processing. Despite much progress in parsing information on interneuron diversity, the mechanisms of differentiation have not been elucidated. We demonstrated the first determinants that specified dendritic properties via experience-dependent actin organization. Cell-type specific expression and membrane-associated distribution of actin-binding proteins allowed interneurons to select their unique dendritic morphologies from a variety of multipolar and bipolar shapes. Morphological transdifferentiation in the juvenile visual cortex affected physiological properties, and hence cortical function and plasticity, to enable visual acuity.Therefore, actin organization activated by individual experience modified dendritic morphology and increased the heterogeneity of intracortical circuits to enable functional individuality.

Title: Oxytocin excites pyramidal neurons of the rat ventral subiculum

Authors: *J. R. HOWARD, S. W. HARDEN, C. J. FRAZIER;
Pharmacodynamics, Univ. of Florida, Gainesville, FL

Abstract: Central oxytocin receptors (OTRs) are involved in the regulation of fear, anxiety, and advanced social behaviors, but much remains unknown about the neurons that express OTRs, the effects of OTR activation at a cellular level, or the extent to which these vary at different stages of development. The ventral subiculum (vSB), a primary output center of the hippocampus, plays an important role in fear association, and is known to express OTRs with high density in both rodents and humans. This study uses whole-cell patch clamp recordings from acute brain slices of Sprague Dawley rats (p16-p40) to characterize the electrophysiological effects of OTR activation in vSB pyramidal neurons. Glutamate and GABA receptor antagonists were continuously applied to reduce influence of synaptic inputs. Voltage-clamp experiments performed at -60 mV demonstrated that acute exposure to a low concentration of selective OTR agonist [Thr4,Gly7]-oxytocin (TGOT, 10 nM) produces an excitatory shift in holding current which is prevented by exposure to selective OTR antagonist (L-368, 1 μM). We found the excitatory effect of OTR activation was significantly greater in juveniles (p16-p27) than adults (p28-p40). When pyramidal neurons were categorized as burst firing (BF) or regular spiking (RS), the excitatory effects of TGOT were found to be the same between both types of neurons in juvenile rats but greater in BF neurons of adult rats. Current-clamp experiments in juvenile rats demonstrate that OTR activation by 10 nM TGOT raises resting membrane potential and increases spontaneous firing rate. Using current-clamp ramps to investigate action potential dynamics we found that OTR activation significantly

decreased action potential rheobase (without affecting threshold) and reduced peak amplitude. Together these findings demonstrate that low concentrations of OTR agonists can robustly excite vSB neurons in an age and cell-type dependent manner.

Title: Cellular and molecular mechanisms of NK3 receptor-mediated excitation of basolateral amygdala neurons

Authors: *S. LEI, B. HU;
Univ. of North Dakota, Grand Forks, ND

Abstract: The tachykinins refer to two peptides encoded in rodents by the Tachykinin 1 (Tac1) and Tac2 (TAC3 in humans) genes, which are involved in neurotransmission and neuromodulation in the central nervous system. Tac1 encodes a precursor protein that produces two peptides, substance P (SP) and neurokinin A (NKA), whereas Tac2/TAC3 encodes neurokinin B (NKB). SP, NKA and NKB bind to three G-protein-coupled receptor subtypes, NK1, NK2, and NK3, respectively. NKB is an endogenous high-affinity agonist for NK3 receptors, which couple to $G\alpha_{q/11}$ to activate PLCβ, resulting in the production of IP_3 to facilitate intracellular Ca^{2+} release and diacylglycerol to activate PKC. While high density of NK3 receptors was distributed in the basolateral nucleus of amygdala (BLA), the effects and involved mechanisms of NK3 receptor activation have not been determined. Here, we used the in vitro slice recording techniques and found that activation of NK3 receptors by application of the selective NK3 agonist, senktide, increased the excitability of BLA principal neurons in rat amygdala slices. NK3 receptors excited BLA neurons by activating a cation channel and depressing an inwardly rectifying K^+ (Kir) channels. Further pharmacological experiments indicated that G protein-gated inwardly rectifying K^+ (GIRK) channels were involved in NK3 receptor-induced excitation of BLA neurons. NK3 receptor-mediated excitation of BLA neurons required the function of PLCβ, but was independent of intracellular Ca^{2+} release and PKC activity. PLCβ-elicited depletion of PIP_2 was required for NK3-induced excitation of BLA neurons. Our results may provide one of the cellular and molecular mechanisms to explain the physiological functions of tachykinins in the amygdala.

Title: Neuromedin B excites neurons of the lateral nucleus of the central amygdala by a PLCß and PKC-dependent inhibition of inwardly rectifying K^+ channels

Authors: *C. BOYLE, S. LEI;
Univ. of North Dakota, Grand Forks, ND

Abstract: Neuromedin B (NMB) is a mammalian orthologue of the bombesin family of neuropeptides first isolated from the porcine spinal cord. NMB is a neuroendocrine modulator that activates the hypothalamic-pituitary axis and modulates stress, fear, and anxiety-like behaviors. In the mammalian brain, the amygdala is composed of a collection of nuclei that are critically involved in these behaviors with its central division considered the behaviorally relevant output nuclei. NMB activates G-protein coupled receptors in the central division of the amygdala and leads to the activation of phospholipase Cβ (PLCβ) that generates the secondary messengers inositol trisphosphate (IP3) and diacylglycerol (DAG). The release of IP3 and DAG leads to an increase in intracellular calcium and the activation of protein kinase C (PKC), respectively. However, it remains unknown how activation of NMB-induced intracellular signaling regulates neuronal activity in the central amygdala. Here we show using *in vitro* whole-cell patch-clamp techniques that NMB increased neuronal activity in the lateral subdivision of the central amygdala. NMB induces significant potentiation of action potential firing that was dependent upon functional G-proteins, PLCβ, and PKC. NMB depolarized resting membrane potentials that were specific to the NMB receptor as well as elevated membrane time constants. Current-voltage traces before and after the treatment with NMB support the involvement of inwardly rectifying potassium channels, likely GIRK2/3. The activity of G-proteins, PLCβ, and PKC were required for the inhibition of the GIRK2/3 channels. These results suggest that NMB can modulate neuronal activity in the central amygdala, which may explain NMB involvement in fear and anxiety related disorders.

Title: Group II and III metabotropic glutamate receptors regulate long-term potentiation via the Gβγ-SNARE pathway

Authors: *Z. ZURAWSKI[1], S. HUYNH[1], M. POTCOAVA[1], C. DELBOVE[3], H. HAMM[4], S. T. ALFORD[2];
[2]Dept. of Anat. and Cell Biol., [1]Univ. of Illinois at Chicago, Chicago, IL; [3]Neurobio., Univ. of Chicago, Chicago, IL; [4]Pharmacol., Vanderbilt Univ., Nashville, TN

Abstract: Long term potentiation (LTP) is a form of synaptic plasticity that represents a critical step in learning and memory. Following LTP induction, the density of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors (AMPARs) located postsynaptically in synapses and which mediate synaptic transmission is increased. The higher the density of AMPARs, the greater the excitatory postsynaptic current (EPSC) underlying the synaptic response. Thus, the insertion of AMPARs into the postsynaptic membrane is necessary for maintaining LTP. AMPA receptor insertion is mediated through the fusion of trafficking vesicles with the postsynaptic plasma membrane, a type of exocytosis. The exocytosis of AMPARs is facilitated by SNARE protein complexes consisting of proteins such as SNAP-25. Gβγ, as liberated by Gi/o-coupled G-protein coupled receptors (GPCRs), such as Group II metabotropic glutamate receptors (mGluRs) can inhibit exocytosis through binding to SNAREs such as SNAP25, competing with fusogenic calcium sensors. These interactions have mainly been studied presynaptically. The effect of Gβγ on the exocytosis and insertion of AMPARs into the postsynaptic membrane is unknown. To test whether Gβγ can regulate and more specifically inhibit the exocytosis of AMPAR bearing vesicles, a combination of extracellular field recording and whole cell recording of mice hippocampus slices was used. By comparing the effects of LTP on wild type mice vs SNAP-25Δ3 mice, whose mutant SNAP-25 protein is unable to bind Gβγ, we can test whether Gβγ can regulate the exocytosis of AMPAR bearing vesicles through binding to the SNAP-25 t-SNARE complex. From extracellular field recordings, we show that the use of a group II mGluR agonist can inhibit LTP in wild type but not SNAP-25Δ3 mice. From whole cell recording, we show that LTP is able to increase the amplitude of post LTP mini EPSCs while having no effect in wild type mice. Previously, SNAP-25, syntaxin1A, syntaxin3, syntaxin4, and VAMP2 have been shown to be implicated in the process of exocytosis of AMPAR bearing vesicles. In vitro functional studies show that Gβγ can inhibit synaptotagmin and SNARE-dependent lipid mixing in reconstituted systems containing SNAP25, syntaxin1A, and syntaxin3, but not syntaxin4. Thus, we show that Gβγ from Group II mGluRs can inhibit the insertion of AMPA receptor-bearing vesicles with the postsynaptic plasma membrane by binding to a SNARE complex containing SNAP-25.

Title: Noradrenaline-dependent regulation of serotonin and non-serotonin neurons in the dorsal raphe

Authors: *J. KHAMMA[1], D. COPELAND[1], H. HAKE[2], S. GANTZ[1];
[1]Univ. of Iowa, Iowa City, IA; [2]Univ. of Washington, Seattle, WA

Abstract: Serotonin neurons are implicated in a variety behavioral processes, such as alertness and mood regulation. The dorsal raphe is the primary location of serotonin neurons in the brain, and it receives noradrenergic input that is excitatory via activation of Gαq protein-coupled alpha 1-adrenergic receptors ($\alpha1\text{-}A_R$). However, it is unclear if the excitatory effects of noradrenaline are present in both serotonin and non-serotonin dorsal raphe neurons. In the present study, we assayed the presence of $\alpha1\text{-}A_R$ in serotonin and non-serotonin dorsal raphe neurons using fluorescent *in situ* hybridization (RNAscope), tryptophan hydroxylase (TpH) immunostaining, and whole-cell patch-clamp recordings in dorsal raphe brain slices from adult male and female C57bl/6j mice. In neuronal populations containing serotonin reuptake transporter (SERT) and vesicular GABA transporter (vGAT) mRNA, to identify serotonin and GABA neurons respectively, we assayed mRNA levels for two $\alpha1\text{-}A_R$ isoforms: $\alpha1a\text{-}A_R$ and $\alpha1b\text{-}A_R$. The majority of serotonin (97%) and GABA (85%) neurons contained at least one of the two $\alpha1\text{-}A_R$ isoforms, and many had both. Of the neurons that had a single isoform, serotonin neurons predominately expressed $\alpha1b\text{-}A_R$ while GABA neurons expressed $\alpha1a\text{-}A_R$, suggesting serotonin and GABA neurons are biased towards a specific $\alpha1\text{-}A_R$ isoform. Additionally, we assayed mRNA levels for the ion channel responsible the $\alpha1\text{-}A_R$-dependent synaptic current, glutamate delta 1 receptor ($GluD1_R$). $GluD1_R$ mRNA levels were comparable between serotonin and GABA neurons, suggesting both neuron populations have the ion channel to produce the $\alpha1\text{-}A_R$-dependent synaptic current. To confirm if both neuronal populations had an $\alpha1\text{-}A_R$-dependent synaptic current, whole-cell patch-clamp recordings were made using an internal solution containing biotin. Brain slices were fixed in 4% paraformaldehyde for 1 hour at room temperature prior to immunostaining. Most neurons immunostained for TpH (TpH+, 72%) while 28% neurons were TpH-. Electrical stimulation of the brain slice evoked an $\alpha1\text{-}A_R$-dependent synaptic current in nearly all recorded TpH+ neurons (96%). In contrast, the $\alpha1\text{-}A_R$-dependent synaptic current was not observed in TpH- neurons (0%). Thus, activation of $\alpha1\text{-}A_R$ by synaptically released noradrenaline may be a distinct characteristic of serotonin neurons. Taken together, the data provide evidence that serotonin and GABA dorsal raphe neurons are differentially regulated by noradrenaline, which may consequently affect how these population of neurons respond to anxiogenic or threatening stimuli.

Title: Subcellular localization of alpha1-adrenergic receptors in the locus coeruleus

Authors: Z. LUYO[1], *D. A. MITRANO[2];
[1]Program in Neurosci., [2]Mol. Biol. and Chemistry; Program in Neurosci., Christopher Newport Univ., Newport News, VA

Abstract: The locus coeruleus (LC) is the major source for norepinephrine (NE) in the brain. The LC projects to areas involved in learning and memory, reward, arousal, attention, and autonomic functions related to stress. There are three types of adrenergic receptors that respond to NE, alpha1-, alpha2-, and beta-adrenergic receptors. Previous works has shown that the alpha1-adrenergic receptor (AR) to be present in the LC, however, with some confounding functional studies. For example, it was shown that alpha1-ARs in the LC are involved in some of the motivational effects of stimulation of the medial forebrain bundle, which was reduced by injection of the alpha1-AR antagonist terazosin (Lin et al., 2007). Another study showed that during novelty-induced behavioral activation, the alpha1-AR antagonist prazosin reduced c-fos expression in brain regions known to contain motoric alpha1-ARs, except for the LC, where c-fos expression was enhanced (Stone et al., 2006). Despite new research delineating more specific connectivity of the neurons in the LC, and some roles of the adrenergic receptors, the alpha1-ARs have not been localized at the subcellular level in the LC. Therefore, in order to try and gain a greater understanding of the behavioral pharmacological studies, we used immunohistochemistry at the electron microscopic (EM) level to determine more specifically what types of cells contain the alpha1-AR in the LC and when in neurons, what neuronal elements contain the receptor. We hypothesized, based on previous work in the nearby ventral periaqueductal gray area (Porter-Stransky et al., 2019), that the alpha1-AR would be found mainly presynaptically in axon terminals, and possibly glial elements. Single labeling immunohistochemistry at the EM revealed that about 38% of labeled elements that contained the alpha1-AR were glial elements, while approximately 50% of the labeled elements were axon terminals or small unmyelinated axons in the LC. Currently, we are using double labeling immunohistochemistry at the EM level to determine whether the alpha1-ARs are found in astrocytes or other types of glial elements, and further, the neurochemical identity of the axon terminals the receptors are found on. This neuroanatomical study will hopefully shed light on how the alpha1-ARs are modulating activity of the LC.

Title: Cb_1-receptor contributes to anandamide inhibition of voltage gated sodium channels in neocortical neurons

Authors: *L. J. STEIGER[1], G. B. MATTHEISEN[3], S. M. SMITH[2];
[2]Pulmonary and Critical Care Med., [1]VA Portland Healthcare Syst. and Oregon Hlth. &, Portland, OR;
[3]PCCM, OHSU, Portland, OR

Abstract: Voltage-gated sodium channels (VGSCs) generate action potentials and are therefore essential for inter- and intracellular communication in excitable cells. VGSC function is regulated by endogenous molecules indicating their modulation is of physiological importance. Additionally, VGSC current inhibition is a mechanism for a wide range of effective therapeutics. It has been proposed that endocannabinoids inhibit multiple VGSC isoforms through a direct mechanism independent of the major central cannabinoid receptor, CB_1. Here, in patch-clamped murine neocortical neurons expressing VGSC α-subunits Nav1.1, 1.2, 1.3 and 1.6, we present evidence that the endogenous cannabinoid, anandamide (AEA), inhibits VGSC currents indirectly via CB_1-receptor signaling. Inhibition by AEA was strong and ubiquitous, occurring in >99% of neurons tested (n > 200). AEA (10 μM) almost completely blocked VGSC currents in voltage-clamped recordings. In current clamp recordings, AEA decreased repetitive action potential firing in response to stepwise current injections. These effects were concentration dependent with a half maximal reduction in action potential firing occurring at 3.3 ± 0.5 μM (n = 7) AEA. Prior reports indicate that AEA-mediated inhibition of VGSC currents occurs independent of the canonical cannabinoid signaling pathways. However, AEA inhibition of sodium channels was strongly attenuated in neurons from CB_1-null mutant mice. CB_1 null-mutant neurons had significantly lower block after 1000 seconds of AEA application versus their wild-type sister cultures (32 ± 7%, n = 7 versus 91 ± 4%, n = 6, $P < 0.0001$). Like other indirect VGSC blockers, the time course of inhibition by AEA was well described by f(t) = a+(b*exp(-(x/tau)^2)) where t, T, and A & B, represent time, the time constant, and constants respectively. In the absence of a functional CB_1 receptor copy, T increased from 555 ± 94 s to 2245 ± 618 s ($P = .0008$). To further explore the role of G-protein coupled receptor signaling in this inhibitory pathway, we utilized GDPβS, which inhibits G-protein cycling. Whereas AEA (10 μM) inhibited VGSC current by 71 ± 7% (n = 8), measured 250 s after onset of application, inclusion of GDPβS (2 mM) in the recording pipette led to only 3 ± 3% inhibition (n = 6, $P < 0.0001$). Taken together, these results indicate that CB_1 is a major player in the mechanism by which AEA inhibits VGSC currents and that other GDPβS sensitive components also contribute. The role of CB_1 described here indicates that modulation of VGSCs should be considered as a potential mechanism underlying the AEA-mediated retrograde signaling that regulates synaptic plasticity.

Title: Chronic activation of Gp1 mGluRs leads to distinct refinement of neural network activity through non-canonical p53 and Akt signaling

Authors: *Y. YOOK[1], D.-C. LIU[2], S. SORIANO[2], S. LIZARAZO[1], D. E. EAGLEMAN[1], N.-P. TSAI[1,2];
[1]Mol. and Integrative Physiol., [2]Neurosci. program, Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Group 1 metabotropic glutamate receptors (Gp1 mGluRs), including mGluR1 and mGluR5, are critical regulators for neuronal and synaptic plasticity. Dysregulated Gp1 mGluR signaling is observed with various neurological disorders, including Alzheimer's disease, Parkinson's disease, epilepsy, and autism spectrum disorders. It is well established that acute activation of Gp1 mGluRs leads to elevation of neuronal intrinsic excitability and long-term synaptic depression. However, it remains unknown how chronic activation of Gp1 mGluRs can affect neural activity and what molecular mechanisms might be involved. In the current study, we employed a multielectrode array (MEA) recording system to evaluate neural network activity of primary mouse cortical neuron cultures. We demonstrated that chronic activation of Gp1 mGluRs leads to elevation of spontaneous spike frequency while burst activity and cross-electrode synchronization are maintained at the baseline. We further showed that these neural network properties are achieved through proteasomal degradation of Akt that is dependent on the tumor suppressor p53. Genetically knocking down p53 disrupts the elevation of spontaneous spike frequency and alters the burst activity and cross-electrode synchronization following chronic activation of Gp1 mGluRs. Importantly, these deficits can be restored by pharmacologically inhibiting Akt to mimic inactivation of Akt mediated by p53. Together, our findings reveal the effects of chronic activation of Gp1 mGluRs on neural network activity and identify a unique signaling pathway involving p53 and Akt for these effects. Our data can provide insights into constitutively active Gp1 mGluR signaling observed in many neurological and psychiatric disorders.

Title: Lidocaine suppresses cell proliferation and induces apoptosis of myofibroblasts

Authors: *T. MATSUMURA, S. MAEDA;
Tokyo Med. and Dent. Univ., Bunkyo-ku, Tokyo, Japan

Abstract: Lidocaine inhibits nerve conduction as a sodium channel blocker, as well as suppressing proliferation and inducing apoptosis in fibroblasts. The induction of apoptosis by lidocaine is mediated by G-protein-linked receptors and involves the activity of cAMP and PKC. Myofibroblasts, a differentiated form of fibroblasts, produce extra-cellular matrix molecules (ECM) that regulate tissue strength and

resilience. However, imbalanced ECM secretion leads to tissue fibrosis. Although myofibroblasts serve an important role in wound healing and nerve regeneration after surgical procedures, the effects of lidocaine on myofibroblasts are not known. In the present study, we investigated the effect of lidocaine on cell proliferation and induction of apoptosis in myofibroblasts. Normal human dermal fibroblasts (NHDF, Promo Cell GmbH, Germany) were grown in culture, and stimulated with 5 ng/ml of TGF-β, which induced differentiation of dermal fibroblasts into myofibroblasts. The cell counting kit-8 (CCK-8) (#96992, Sigma) was used to investigate cell viability of fibroblasts and myofibroblasts after adding lidocaine (0.1 and 1 mg/ml). For detection of apoptosis, 24 h after seeding, cells were treated with lidocaine (at 0.001, 0.01 and 0.1 mg/ml) and, at three days post treatment, tested with the Apoptotic/ Necrotic/ Healthy Cells Detection Kit (#ab176749, abcam). Significant reduction in proliferation of fibroblasts and myofibroblasts was seen with 1 mg/ml lidocaine compared with untreated controls on day 3 ($p < 0.001$: Dunnett test). Apoptosis was detected in myofibroblasts as well as fibroblasts 3 days after administering 0.1 mg/ml lidocaine. We showed that lidocaine also suppresses cell proliferation and induces apoptosis of myofibroblasts. Further studies are needed to confirm which biochemical pathways in myofibroblast apoptosis were modulated by lidocaine. Conclusively, lidocaine might be a therapeutic agent for wound repair and reinnervation after surgery through the utilization of physiochemically tuned myofibroblasts.

Title: Local antagonism of α2 adrenergic receptors in the primary motor cortex blocks vagus nerve stimulation induced motor map plasticity.

Authors: *C.-T. TSENG[1], C. A. THORN[2];
[1]The Univ. of Texas At Dallas, Richardson, TX; [2]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Vagus nerve stimulation (VNS) paired with rehabilitation training has been shown to promote the recovery of motor function following stroke. Recent studies have shown that VNS enhanced recovery of motor function following stroke relies on VNS facilitated reorganization of the somatotopic cortical motor map. In addition, noradrenergic innervation in the primary motor cortex (M1) has been shown to be critical for this form of VNS-driven neural plasticity to occur. However, the mechanisms underlying noradrenergic regulation of VNS-dependent cortical plasticity remain unclear. In M1, noradrenergic α2 receptors (α2-ARs) are widely expressed and are known to play a role in synaptic communication and plasticity. In this study, we examined whether local activation of α2-ARs in rat M1 is required for VNS-induced motor map plasticity. Twenty-nine female Sprague-Dawley rats, 10-12 weeks old at the start of

behavioral training, were trained to perform a lever pressing task with their right forelimb. Once criterial performance was reached, rats were implanted with VNS electrodes around the left cervical vagus nerve along with intracortical cannula targeted to the M1 forelimb area contralateral to the trained limb. After surgical and behavioral recovery, subjects were randomly assigned to a treatment group and received a final ten training sessions in which intracortical infusions of either α2-AR antagonists (yohimbine or RS79948) or control vehicle were administered, and VNS or sham stimulation was paired with correct lever press performance (veh|sham: n = 7; veh|VNS: n = 6; drug|sham: n = 6; drug|VNS: n = 10). Twenty-four hours after the final treatment session, intracortical microstimulation was used to examine the reorganization of the cortical motor map. Consistent with previous studies, we found that VNS paired with forelimb training resulted in the enlargement of the map representation of task-relevant musculature in M1. Intracortical α2-AR antagonism blocked this VNS-driven reorganization of the motor map. Our results suggest that local activation of α2-ARs is necessary for VNS-induced plasticity in the motor cortex, providing insight into the noradrenergic neuromodulatory mechanisms that may underlie VNS-dependent cortical plasticity.

Title: Voltage-gated calcium channels at peripheral Trpv1-lineage nerve endings contribute to local calcium dynamics linked to heat hypersensitivity

Authors: *R. Y. MEIR[1], E. J. LOPEZ SOTO[1], D. M. DUBREUIL[2], S. DASTE[1], A. FLEISCHMANN[1], D. LIPSCOMBE[1];
[1]Dept. of Neurosci., Brown Univ., Providence, RI; [2]Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Voltage-gated calcium (Ca_V) channels play a critical role in transmitting information about noxious stimuli, and they regulate excitation-dependent calcium entry and transmitter release at presynaptic afferents in spinal cord dorsal horn. Intrathecal $Ca_V2.2$ channel block reduces sensory transmission and alleviates neuropathic pain in humans. The bifurcating axon of nociceptors support signal detection in peripheral organs and central transmission of nocifensive information in the spinal cord. Axon endings at peripheral sites innervate target organs including skin where they detect sensory stimuli. A feature of sensory nerve endings is their ability to rapidly alter sensitivity to sensory stimuli,

for example, following injury. Transient sensory hypersensitivity is an important adaptive response, whereas prolonged hypersensitivity can lead to chronic pain. Our lab recently showed that peripheral $Ca_V2.2$ channels are essential for transient heat hypersensitivity in skin; intradermal ω-conotoxin MVIIA (ω-CgTx MVIIA), a highly selective $Ca_V2.2$ channel inhibitor, occluded capsaicin-induced transient, heat hypersensitivity *in vivo*, whereas intradermal ω-agatoxin IVA, a selective $Ca_V2.1$ channel inhibitor, had no effect (DuBreuil et al., 2021). Here we present evidence that $Ca_V2.2$ channels in *Trpv1* nerve endings in skin are activated by intradermal capsaicin. Sensory axon endings in skin are generally inaccessible to electrophysiological analyses, and highly specific antibodies for immunostaining for $Ca_V2.2$ protein are not available. We therefore applied 2-photon imaging of *Trpv1*$^{GCaMP6f+/-}$ mice, along with vascular labeling by intravenous Texas Red dextran, to measure intracellular calcium signals evoked by capsaicin in *Trpv1* nociceptor nerve endings. We co-imaged blood vessels to use as a reference both during image acquisition and post-acquisition motion correction. Data acquisition and analyses were performed masked to the experimental conditions. Capsaicin injection caused motion distortion that we could not correct at early time points, but GCaMP6f signals at 5, 15, and 30 mins post injection were recorded. At 15 mins, nerve endings treated with ω-CgTx MVIIA showed significantly reduced capsaicin-induced Ca^{2+} signals as compared to capsaicin alone indicating the presence of functional $Ca_V2.2$ channels (n = 122 nerves, 3 mice capsaicin alone; n = 146 nerves, 3 mice capsaicin with ω-CgTx MVIIA). These data suggest a critical, yet underappreciated role for peripheral $Ca_V2.2$ channels in mediating local calcium dynamics at *Trpv1*-nociceptor nerve endings in skin under conditions that trigger heat hypersensitivity.

Abstract: Voltage-gated $Ca_V2.2$ channels are important for the transmission of noxious stimuli centrally, in the dorsal horn of the spinal cord and, recently shown by our lab, for robust, transient capsaicin-induced heat hypersensitivity in peripheral Trpv1 nociceptor nerve endings in skin (DuBreuil et al., 2021). The lab also showed that the P2X7 receptor blocker, A438079, reduces capsaicin-induced heat hypersensitivity implicating ATP in this signaling cascade and its likely release from Trpv1 nociceptors. Further, we find that intradermal injections of a P2X7 receptor agonist (BzATP) alone can elicit heat hypersensitivity, within 30 mins, in both wild type (WT; n=6) and in $Ca_V2.2$ global knockout (KO) mice (n=7). P2X7 receptors are expressed by non-neuronal cells suggesting that the activation of P2X7 receptors in capsaicin-induced hypersensitivity depends on neuroimmune signals. Here, we show that interleukin-1α (IL-1α) is detected in the interstitial space in mouse hindpaw within 15 minutes of intradermal capsaicin injection. At this time point, mice exhibit maximum levels of hypersensitivity to heat and mechanical stimuli. In $Ca_V2.2$ KO mice, IL-1α levels induced by intradermal capsaicin are reduced by 70% compared to wild type (6-8 animals per group; p =0.0400). These data suggest that IL-1α is released in skin in response to capsaicin activation of Trpv1 nerve endings, and that block of neuronal $Ca_V2.2$ channel activity blunts this transient neuroimmune response. To assess the role of $Ca_V2.2$ channels in prolonged, maladaptive forms of neurogenic inflammation, we compared paw withdrawal behavioral responses in WT and $Ca_V2.2$ KO mice following intraplantar injection of Complete Freund's Adjuvant (CFA). We observed reduced heat hypersensitivity in $Ca_V2.2$ KO mice 1 day and up to 5 days following CFA treatment when compared to WT mice (p= 0.005) .These findings support other data from our lab showing marked reductions (60%) in levels of IL-1 spontaneously released from hindpaw skin explants from $Ca_V2.2$ KO animals (n=3) when compared to WT controls (n= 3; p = 0.006) (DuBreuil et al., 2021). Our data suggest that $Ca_V2.2$ channels are necessary for neuroimmune signaling in skin under conditions that trigger both transient and long-lasting heat hypersensitivity.

Title: $Ca_v2.3$ R-type calcium channels in the thalamus modulate visceral nociception

Authors: S. M. GHODSI[1], S. M. JOKSIMOVIC[2], T. TIMIC STAMENIC[1], S. MAKSIMOVIC[1], V. JEVTOVIC-TODOROVIC[3], J. HEINSBROEK[1], *S. TODOROVIC[1];
[1]Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [2]Childrens Hosp. of Philadelphia, Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Aims: All sensory tracts from the spinal cord innervate in the ventrobasal thalamus (VB) and relay to the cortex. Reticular thalamic nucleus (RTN) is the main source of GABAergic input to the

thalamus and is thought to regulate nociception by influencing activity of thalamocortical VB neurons. Previous studies have shown the role of $Ca_v2.3$ channels in tuning the firing mode of RTN. Herein, we used *in vivo* calcium imaging paired with mouse genetics, patch-clamp electrophysiology *ex vivo* and behavior assays to interrogate the role of thalamic $Ca_V2.3$ channels in visceral pain transmission in real time. **Methods**: Male C57Bl/6J mice were stereotaxically injected with AAV1-CaMKII-GCaMP6f plasmid followed by implanting a 0.6-mm diameter GRIN lens tangent to the border of RTN and VB. Visceral pain is induced by intraperitoneal injection of 0.6% acetic acid and scoring writhing reflex for 30 minutes. *In vivo* calcium imaging sessions were performed by placing the mouse in a novel open-field arena and recording baseline (30 min) followed by 30 min of pain behavior. Spontaneous inhibitory postsynaptic potentials (sIPSPs) were interrogated using patch-clamp recordings in acute brain slices from CACNA1E null and control mice. **Results:** Initial behavior assays show that $Ca_V2.3$ deficient mice have significantly higher writhing scores compared to WT littermates. Although the bulk analysis of calcium transients shows no significant difference between the baseline and pain assay, event-dependent analysis of calcium signals shows a significant increase in the activity of VB neurons paired with pain reflexes in the subjects of about 2-fold. Recordings of sIPSCs in VB thalamus from WT and mutant mice showed no differences in average decay and amplitude. However, the average frequency of sIPSCs was decreased in $Ca_V2.3$ KO animals more than 2-fold (WT: 7.35 ± 1.12 Hz; $Ca_V2.3$ KO animals: 2.78 ± 0.50 Hz). **Conclusions:** Our *in vivo* calcium imaging data determined the direct involvement of VB in visceral nociception. Moreover, our pain behavior assays and patch-clamp data show that the thalamic $Ca_V2.3$ R-type calcium channels play a critical role in regulating visceral pain relay to the cortex. We have also demonstrated that $Ca_V2.3$ null subjects have less inhibitory GABAergic input to VB, likely causing thalamic neurons to fire in the tonic mode rather than rebound bursting which results in lower pain threshold in the $Ca_V2.3$ KO subjects.

Title: $Ca_V3.1$ T-type calcium channels regulate activity of the dorsal subiculum by supporting burst firing

Authors: *S. JOKSIMOVIC[1], S. GHODSI[2], J. A. HEINSBROEK[2], S. M. TODOROVIC[3];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Anesthesiol., Anschutz Med. Campus Univ. of Colorado, Denver, CO; [3]Anesthesiol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Aims: The subiculum is the main output structure of the hippocampal formation. Using *ex vivo* patch-clamp electrophysiology, we previously showed that the $Ca_V3.1$ isoform of T-type calcium

channels (T-channels) has a crucial role in regulating burst firing of subicular neurons. Here, we aimed to confirm and further explore these findings using more selective *in vivo* imaging and genetic approaches focused on the dorsal subiculum (dSub), which is critically involved in spatial memory processing. **Methods**: Adult male C57BL/6J mice were stereotaxically injected with AAV1-CaMKII-GCaMP6f followed by implanting a 1-mm diameter GRIN lens tangent to the dSub. *In vivo* calcium imaging sessions were performed at baseline and 20 min after intraperitoneal injection of vehicle, 5 and 7.5 mg/kg TTA-P2 (pan-selective T-channel antagonist) by placing the mouse in an open-field arena. The target gene silencing was conducted by injecting AAV vectors expressing shCa_V3.1 (AAV2-GFP-U6-mCACNA1G-shRNA) or control (scrambled shRNA) into the dSub. Spontaneous action potential (AP) firing and intrinsic excitability were assessed using patch-clamp recordings in acute brain slices from shCa_V3.1 and control mice. **Results:** Successful GCaMP transfection and lens implantation were confirmed by immunohistochemistry in each subject 10-12 weeks post-surgery. The dose-dependent decrease in calcium transients' amplitude after i.p. injection of relatively low doses of TTA-P2 demonstrates the critical role of T-type calcium currents in the dSub activity. Specifically, we noted a 35% decrease in the average calcium amplitude after the injection of 7.5 mg/kg TTA-P2, as compared to the vehicle ($P<0.001$, one-way ANOVA followed by Tukey's test). Importantly, the calcium activity after the vehicle injection was not different from the baseline measurement. The firing frequency did not follow the same pattern: even the dose of 7.5 mg/kg did not significantly affect the calcium event frequency. Regarding patch-clamp experiments, we detected a drastically lower AP firing frequency in shCa_V3.1 GFP+ neurons ($P=0.002$ vs. control GFP+ neurons). As expected, the bursting properties were also compromised in these neurons, as assessed with a lower number of APs per current injection ($P=0.023$, two-way RM ANOVA) and per burst ($P=0.011$) in the shCa_V3.1 group. **Conclusions:** Based on our *in vivo* calcium imaging and patch-clamp data in the dSub-specific Ca_V3.1 knock-down mice, as well as our previous *in vitro* results, we propose that Ca_V3.1 T-channels are the main driving force behind the bursting activity of dSub neurons, and are thus able to modulate cognitive functions mediated by the subicular circuitry.

Abstract: Presynaptic calcium channels are key components for the transmission of information between neurons. Their kinetic properties as activation state and conductivity but also their spatial arrangement are critical parameters shaping the release probability of synapses. P/Q-channels ($Ca_V2.1$) are essential for many synapses in the mammalian brain, where they represent the main population of voltage-gated calcium channels. Within the presynaptic membrane $Ca_V2.1$-channels are found in a clustered organization. Multiple binding sites to scaffold proteins as well as their C-terminal involvement in phase separated scaffold clusters are discussed to cluster calcium channels in the synapse. Here, we asked the question, whether these clusters are formed in a synapse-specific manner and whether they adopt to the activity history of the synapse? We used single-particle tracking photoactivation localisation microscopy (sptPALM) to directly monitor the endogenous population of $Ca_V2.1$-channels under different conditions of network activity. The strong confinement of $Ca_V2.1$-channels within the active zone (AZ) as well as their intrinsic local mobility suggest an ongoing reorganisation. Investigating the $Ca_V2.1$ channel population in glutamatergic and GABAergic synapses uncovered differences in their organisation. In glutamatergic synapses, most $Ca_V2.1$-channels are concentrated within one central nanocluster, defined by a steep increase in channel density. Whereas in GABAergic synapses, $Ca_V2.1$-channels are organized at least in two smaller nanoclusters. Artificial clustering of $Ca_V2.1$-channels by photoactivatable cross-linkers did not induce a growth of these clusters, as expected, but a shrinkage. This indicates a defined freedom of local mobile channels within the cytomatrix of the AZ. Inducing acute changes in the activity of synapses by electrical or chemical manipulations affected this previously described local organisation of $Ca_V2.1$-channels and thus promotes the idea that local rearrangements in the molecular environment are essential for fast changes in synaptic activity. Concluding, the organization of the endogenous $Ca_V2.1$-channel population within the presynaptic membrane probed by single-molecule imaging let argue that channel nanoclusters are probably formed by two mechanisms, molecular crowding within the presynaptic membrane and liquid phase separation of presynaptic scaffold proteins where $Ca_V2.1$-channels are linked to.

Title: Role of presynaptic Ca_V2 channels in regulating synaptic vesicle release

Authors: *P. VEERARAGHAVAN[1], R. GORAL[1], D. GUERRO-GIVEN[2], C. THOMAS[2], P. VALINO RAMOS[1], N. KAMASAWA[2], S. M. YOUNG, Jr[1];
[1]Univ. of Iowa, Iowa City, IA; [2]Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: The efficiency of synaptic transmission relies on the levels and localization of voltage-gated Ca^{2+} channels (VGCCs) at the presynaptic active zone (AZ). Ca_V2 channels, a subset of VGCCs, includes $Ca_V2.1$, $Ca_V2.2$ and $Ca_V2.3$ that are primarily expressed in mammalian central nervous system synapses. Among them, $Ca_V2.1$ is most efficient in triggering action potential (AP)-mediated synaptic vesicle (SV) release. During development, many fast firing presynaptic terminals modify from having mixed Ca_V2 subtypes to either $Ca_V2.1$ dominant or exclusive. Further, to achieve AP temporal precision and fast firing rate, Ca_V-SV coupling (relative positioning of Ca_V channels to SVs) switches from microdomain (loosely coupled) at immature stage to nanodomain (tightly coupled) SV release at mature stage. However, it is still unknown if these SV release states depend on the Ca_V2 subtype. Calyx of held (calyx), a fast firing presynapse like many central synapses transforms from having mixed Ca_V2 subtypes to $Ca_V2.1$ and switches its release state form micro- to nanodomain during development. Therefore, to understand the relation between Ca_V2 subtype and SV release states we conditionally knocked out (CKO) $Ca_V2.1$ or both $Ca_V2.1/2.2$ at calyx using either $Ca_V2.1^{fl/fl}$ mouse or using our novel mouse model, $Ca_V2.1^{fl/fl}/2.2^{fl/fl}$. We examined the changes in calcium current (I_{Ca}), readily releasable pool (RRP), SV release kinetics and AZ ultrastructure during development. We observed a partial compensation of I_{Ca} in both $Ca_V2.1$ and $Ca_V2.1/2.2$ CKO calyces. However, we found distinct changes in RRP size and SV release kinetics in either $Ca_V2.1$ or both $Ca_V2.1/2.2$ ablated calyces without altering AZ ultrastructure during both micro- and nanodomain release state. Hence, we propose that Ca_V2 channels play differential role in SV release states during development. This study will highly impact our current understanding on how different Ca_V2 channels regulate release in a native neuronal circuit.

Title: The C-terminus of $Ca_V2.1$ alpha$_1$ subunit is a key regulator of Ca_V2 subtype abundance at the presynaptic terminal

Authors: *J. LI[1], S. M. YOUNG, JR[2];
[2]Dept. of Anat. and Cell Biol., [1]Univ. of Iowa, Iowa City, IA

Abstract: The C-terminus of $Ca_V2.1$ α1 subunit is a key regulator of Cav2 subtype abundance at the presynaptic terminal Jianing Li[1], Samuel M. Young, Jr[1,2]1.Department of Anatomy and Cell Biology, Cell& Developmental Biology Program, University of Iowa, Iowa City, IA 52242, USA2.Department of Otolaryngology, Iowa Neuroscience Institute, Aging Mind Brain Initiative, University of Iowa, Iowa City, IA 52242, USAIn the central nervous system (CNS), there are multiple subtypes of voltage-gated calcium channels (VGCCs). Synaptic transmission in CNS is mainly mediated by Ca_V2 family, and $Ca_V2.1$ is more efficient in triggering neurotransmitter release compared to $Ca_V2.2$ and $Ca_V2.3$ due to its higher abundance and closer proximity to synaptic vesicles (SV). Moreover, the presynaptic terminals become increasingly $Ca_V2.1$ dominant during development. However, molecular mechanisms regulating presynaptic Ca_V2 subtype abundance remains unknown. Cytoplasmic domains in Ca_V2 α_1 subunit are implicated in controlling presynaptic Ca_V2 subtype abundance. To determine which cytoplasmic regions controlling Ca_V2 subtype abundance at the presynaptic terminal, we expressed Ca_V2 hybrid construct: $Ca_V2.1/2.3$ II-III loop+ C-terminus hybrid, $Ca_V2.1/2.3$ II-III loop hybrid, $Ca_V2.1/2.3$ C-terminus hybrid, in a $Ca_V2.1$, $Ca_V2.2$ null background at the calyx of Held presynaptic terminal. We identified that cytoplasmic C-terminus plays a key role in regulating Ca_V2 subtype abundance at the presynaptic terminal. Our research shed light on molecular mechanisms regulating presynaptic Ca_V2 subtype abundance and neuronal circuit output.

Title: Activity-dependent clustering of L-type calcium channel complexes with Shank3 and CaMKII

Authors: *Q. YANG[1], L. HU[1], J. C. QUAY[1], K. R. ERICKSON[1], R. J. COLBRAN[2];
[1]Vanderbilt Univ., Nashville, TN; [2]Dept Molec Physiol & Biophysics, Vanderbilt Univ. Sch. Med., Nashville, TN

Abstract: Neuronal excitation-transcription (E-T) coupling induces new mRNA transcription and is essential for normal learning and memory. One major pathway that initiates E-T coupling is initiated by the activation of voltage-gated L-type Ca^{2+} channels (LTCCs) in the plasma membrane. LTCC-dependent E-T coupling increases phosphorylation of the nuclear CREB transcription factor, which can be induced by local Ca^{2+} increases within a nanodomain close to the channel, without requiring Ca^{2+} increases in the bulk cytosol or nucleus. Formation of this LTCC nanodomain may involve clustering of the major neuronal LTCC α1 subunits ($Ca_V1.2$, $Ca_V1.3$), but the molecular basis for LTCC clustering is poorly understood. Previous studies in our lab found that LTCC-dependent E-T coupling requires direct binding of the $Ca_V1.3$ α1 subunit N- and C-terminal domains (NTD and CTD, respectively) to Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII), a major neuronal signaling protein, and to Shank3, a scaffolding

protein, respectively; as well as a novel CaMKII-Shank3 interaction[1,2]. We hypothesized that these three protein-protein interactions contribute to LTCC clustering. Preliminary data indicate that neuronal depolarization increases the size of $Ca_V1.3$ LTCC clusters in rat primary cultured hippocampal neurons. A series of co-immunoprecipitation (co-IP) experiments from transfected HEK293T cell lysates indicate that Shank3 can assemble multimeric $Ca_V1.3$ LTCC complexes under basal conditions. Moreover, activated, but not inactive, CaMKII can assemble homo-multimeric $Ca_V1.3$ LTCC complexes, as well as heteromeric $Ca_V1.3$-$Ca_V1.2$ complexes in this co-IP assay. We also used fluorescence microscopy to examine $Ca_V1.3$ clustering in the plasma membrane of transfected HEK293T cells. The co-expression of Shank3, but not CaMKII, enhances $Ca_V1.3$ cluster size under basal conditions. However, the addition of an LTCC agonist (BayK8644) to cells co-expressing CaMKII increased the size of $Ca_V1.3$ clusters. Ongoing studies are examining the dynamics of LTCC cluster formation. Taken together, our findings reveal novel molecular mechanisms contributing to neuronal LTCC clustering that may be required to initiate long-range signaling to the nucleus during learning and memory. 1. Abstract: L-type voltage gated Ca^{2+} channels (LVGCC) are transmembrane proteins that allow influx of Ca^{2+} into excitable cells. Of the four LVGCCs, $Ca_v1.2$ is most highly expressed in the brain. $Ca_v1.2$ has roles in dendritic development, synaptic plasticity, neuronal survival, and cognitive and affective behaviors. The $Ca_v1.2$ alpha subunit is encoded by *CACNA1C*. Genetic studies have linked single nucleotide polymorphisms (SNPs) and rare variants within *CACNA1C* with neuropsychiatric disorders including autism, bipolar disorder, and schizophrenia. While there is evidence that $Ca_v1.2$ is involved in cognitive and affective function, it is unclear whether $Ca_v1.2$'s primary role is in neurons or glia. $Ca_v1.2$ haploinsufficient mice exhibit antidepressant-like phenotypes, hypoactivity, anxiety-like behaviors, increased fear responses, and social deficits; and mice lacking $Ca_v1.2$ in neural progenitors (Nestin-Cre) exhibit cognitive deficits in learning tasks. Furthermore, loss of $Ca_v1.2$ has been shown to reduce maturation of oligodendrocytes and growth of myelin, and overexpression of $Ca_v1.2$ increases myelin expression, so it is clear that $Ca_v1.2$ plays an important role in myelination. However, it is unclear if the deficits in these mice are due to loss of $Ca_v1.2$ from neurons or other derivatives of neuronal progenitor cells: astrocytes or oligodendrocytes. We have investigated the effects of loss of $Ca_v1.2$ from Synapsin1

expressing cells, which should target most CNS neurons but not glia. Previous work with Synapsin1 Cre (Syn-Cre) $Ca_v1.2$ knockout mice ($Ca_v1.2$ cKO) identified a significant deficit in extinction of fear learning and a shift in inhibitory/excitatory balance in the lateral amygdala. No abnormalities in motor function or anxiety were found in the open field test and light dark box. Our behavioral data indicates that $Ca_v1.2$ cKO mice have normal baseline motor function though female KOs display impaired motor learning on the rotarod task. Latency to float on the forced swim test was significantly higher in the cKO mice and this effect appears to be driven largely by the female cKOs. On the social preference/recognition task, the male cKO mice were impaired, but no effect was seen in females. Similar to previous work, no effects of genotype were identified on the elevated zero maze, thigmotaxis, or sucrose preference. We conclude that the antidepressant, motor, social, and learned fear-related phenotypes in $Ca_v1.2$ mutant mice may be driven at least in part by changes in neuronal function as a result of loss of neuronal $Ca_v1.2$, whereas basal anxiety-like phenotypes in $Ca_v1.2$ deficient mice may be occurring through changes in astrocytes or oligodendrocytes.

Title: Using induced pluripotent stem cell-derived neurons to evaluate the role of $Ca_V1.2$ in the pathogenesis of autism spectrum disorder.

Authors: *K. G. HEROLD, M. A. BAMGBOYE, D. C. O. VIEIRA, D. DISILVESTRE, J. O. OWOYEMI, A. L. MEREDITH, I. E. DICK;
Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Autism spectrum disorder (ASD) is a neurological disorder characterized by repetitive, restricted behaviors, interests, and activities along with a range of challenges in communication skills and social interaction. Pathway and genetic analyses have indicated a strong connection between ASD and the dysregulation of Ca^{2+} signaling. In particular, the L-type Ca^{2+} channel (LTCC) has been repeatedly identified as associating with ASD in multiple GWAS and functional studies, and genetic mutations within this channel family have been shown to be causative of ASD. In fact, mutations within the $Ca_V1.2$ LTCC have been identified as one of the few monogenic causes of ASD, resulting in a multisystem disorder known as Timothy syndrome (TS). TS patients harbor a single *de novo* point mutation within $Ca_V1.2$, which causes severe cardiac arrhythmias, long-QT syndrome and ASD. TS is one of the most penetrant genetic forms of ASD, making it an ideal model system with which to gain traction on

understanding the role of Ca^{2+} dysfunction in ASD. Interestingly, preliminary results from our lab have demonstrated marked differences in channel gating due to distinct TS mutations. Such differences may underlie the differential phenotypes of select $Ca_V1.2$ mutations. To probe the effects of these mutations on neuronal function, we utilized human induced pluripotent stem cell (iPSC)-derived neurons harboring select $Ca_V1.2$ mutations. Patch clamp recordings of these cells yield distinct LTCC currents enabling evaluation of the biophysical properties of wildtype and mutant channels in the context of a human neuron. In addition, these cells enable robust recordings of neuronal action potentials with distinct AP morphologies. Pharmacological dissection enables the evaluation of the relative contribution of the mutated channel and select Ca^{2+} dependent proteins on the electrical properties of the membrane. Overall, as Ca^{2+} disruption may be a recurrent feature of ASD, studying rare mutations such as TS, may provide insight into the pathogenesis of ASD beyond TS.

Title: Characterization and opioid sensitivity of nucleus accumbens interneurons expressing neuropeptide y

Authors: *C. L. RETZLAFF, P. E. ROTHWELL;
Neurosci., Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Mu opioid receptor (MOR) agonists such as morphine and fentanyl are known to regulate the activity of GABAergic interneurons in the ventral tegmental area and hippocampus, both areas known to be important for reward processing. Though the nucleus accumbens (NAc) is a critical structure in the reward circuit, the effects of MOR agonism on interneurons in this brain region are not well understood. We sought to characterize MOR expression and function within the NAc specifically in the low threshold spiking interneurons (LTSIs). While it is understood these cells participate within local circuitry of the striatum and can synapse with medium spiny neurons (MSN) to modulate their output, the understanding of how opioid receptors modulate these cells has never been explored. Using fluorescent *in situ* hybridization, we identified LTSIs based on co-expression of neuropeptide Y (NPY) and somatostatin (SST) and found that a large majority (87%) also expressed the MOR in both male and female mice between 6 and 16 weeks of age. There was a small number of NPY cells that did not express SST, known as neurogliaform interneurons. These interneurons were in lower abundance in NAc than dorsal striatum and it was difficult to find and record these cells using electrophysiology, so this subpopulation was not studied further. We were able to examine the functional consequences of MOR expression in LTSIs using electrophysiology. Cell attached and whole cell current clamp recordings were used to assess intrinsic

excitability and revealed decreases in evoked or spontaneous action potential spiking after bath application of DAMGO, a MOR specific agonist. Through optogenetic experiments to examine synaptic output from LTSIs to MSNs, we found DAMGO application reduces GABAerigic output by more than 40% to both populations of MSNs, those expressing D1 or D2 dopamine receptors. All electrophysiological experiments were done in both male and female mice of 6-12 weeks in age. These data indicate that while LTSIs only comprise about 1% of neurons in the NAc they have opioid sensitive synaptic transmission that can alter the overall function of NAc circuitry.

Title: Riluzole Improves Glucose Metabolism and Confers Long-term Procognitive Effects in Alzheimer's Disease Mice

Authors: *C. A. FINDLEY, S. A. MCFADDEN, K. N. HASCUP, E. R. HASCUP;
Neurology, Neurosci. Institute, Ctr. for Alzheimer's Dis., Southern Illinois Univ. Sch. of Med., Springfield, IL

Abstract: Background: It is well established that glutamatergic neurotransmission plays an essential role in learning and memory. In Alzheimer's disease (AD), glutamate dynamics shift with disease progression, inciting cognitive impairment and further perpetuating disease pathology. Several studies have demonstrated procognitive effects in male AD mice with prodromal administration of a glutamatergic modulator (riluzole). The current study aimed to investigate the short- and long-term effects of prodromal riluzole treatment in two AD mouse models. Methods: Male and female C57BL/6 (littermate control), AβPP/PS1 (transgenic), and $APP^{NL-F/NL-F}$ (knock-in) mice received either vehicle- (1% sucrose) or riluzole- (356 μM) treated drinking water (voluntary oral administration) between 2-6 months of age. Separate cohorts of mice were assayed either immediately following treatment cessation (6 months of age) or 6 months post-treatment (12 months of age). Insulin and glucose tolerance testing (ITT, GTT) were performed to examine metabolic function, followed by Morris water maze (MWM) to determine cognitive ability. Results: Riluzole-treated male $APP^{NL-F/NL-F}$ (n=18) and littermate control (n=12) mice showed significantly improved peripheral glucose tolerance compared to genotype-matched vehicle-treated controls ($p<0.05$, 0.01, respectively). No significant differences were observed for insulin sensitivity with treatment. Riluzole did not have a long-term impact on peripheral glucose or insulin tolerance. MWM results indicated that spatial learning was not significantly different at either time point.

However, riluzole significantly improved long-term spatial memory in 12-month-old $APP^{NL-F/NL-F}$ and AβPP/PS1 male mice compared to genotype-matched vehicle-treated controls on measures of platform entries, latency to first entry, and duration in platform proximity ($p<0.05$). No effects were observed in female mice with riluzole treatment. Conclusions: Besides known glutamatergic modulatory effects, riluzole also improves peripheral glucose metabolism, a potentially beneficial effect as metabolic syndrome is a risk factor for AD. Procognitive effects were also observed 6 months post-treatment in both $APP^{NL-F/NL-F}$ and AβPP/PS1 male mice. These findings highlight the importance of peripheral glucose homeostasis on cognitive function in AD mouse models. Further, sex differences in responsiveness to riluzole treatment potentially indicate differing glutamatergic pathologies with disease progression.

Title: Acute ethanol in basolateral amygdala modulates GABA circuits and anxiety-like behavior in male, but not female, rats

Authors: S. MUNSHI[1], L. ALBRECHET-SOUZA[2], N. W. GILPIN[2,3], J. G. TASKER[1,3];
[1]Tulane Brain Institute, Dept. of Cell and Mol. Biol., Tulane Univ., New Orleans, LA; [2]Dept. of Physiology, Sch. of Med., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [3]Southeast Louisiana VA Healthcare Syst. (SLVHCS), New Orleans, LA

Abstract: Accumulating evidence suggests sex-dependent behavioral changes following alcohol administration. The basolateral amygdala (BLA) plays a critical role in the development of alcohol use disorder (AUD). Although earlier studies have shown that corticotropin releasing hormone (CRH) and ethanol increases the central amygdala GABAergic transmission, the role of the BLA CRH system in ethanol effect is unknown. We previously observed that ethanol increased GABA release onto BLA principal neurons via activation of parvalbumin-positive interneuron axons. In the present study, we tested the hypotheses that the acute ethanol modulation of GABA inhibitory inputs to BLA principal neurons (i) has a higher threshold in females, (ii) is dependent on CRHR1 activation, and (iii) causes differential dose-dependent anxiety-related behaviors in males and females. Using *ex vivo* whole-cell patch-clamp recordings from BLA pyramidal neurons in amygdala slices from adult Wistar rats, we found that ethanol caused a dose-dependent increase in spontaneous IPSC (sIPSC) frequency, with a threshold of 22 mM, in principal neurons from male rats; ethanol had no effect on sIPSCs at non-toxic concentrations in female rats, and increased the sIPSC frequency only at the toxic non-physiological concentration of 88 mM, revealing a striking sex difference in acute alcohol sensitivity. In slices from male rats, the CRHR1 antagonist (R121919, 2 μM) reduced, but did not abolish completely, the effect of ethanol on sIPSC frequency. *In vivo* bilateral intra-BLA injections of 22 mM ethanol, but not 44 mM,

produced anxiolytic effect in males tested in the elevated plus maze; intra-BLA ethanol had no effect at either concentration in females. Due to the inverted U-shaped dose-dependent anxiolytic effect observed in males, we further determined whether ethanol changes the inhibition-to-excitation balance in the BLA by testing for an acute ethanol effect on excitatory transmission; however, ethanol (44 mM) had no effect on excitatory postsynaptic currents, suggesting that the observed behavioral change in males is not due to a change in the excitation-inhibition balance in the BLA. Taken together, these data suggest a sex-difference in the ethanol regulation of anxiety-like behavior that is mediated by modulation of inhibitory synaptic circuits in the BLA. This finding may provide a neurobiological substrate that contributes to the differential susceptibility and behavioral manifestations of AUD in males and females.

Title: Novel $Ca_V2.1$-modulators to treat Hemiplegic Migraine

Authors: *M. IZQUIERDO-SERRA[1], S. A. SERRA[1], S. E. WARD[2,3], P. J. BESWICK[2], J. M. FERNÁNDEZ-FERNÁNDEZ[1];
[1]Univ. Pompeu Fabra, Barcelona, Spain; [2]Univ. of Sussex, Brighton, United Kingdom; [3]Cardiff Univ., Wales, United Kingdom

Abstract: Human mutations in the *CACNA1A* gene, encoding the pore-forming α_{1A} subunit of the voltage-gated $Ca_V2.1$ calcium channel, cause most of the familial and sporadic hemiplegic migraine (FHM/SHM) cases. Hemiplegic Migraine (HM) mutations induce a gain of $Ca_V2.1$ channel activation that specifically enhances cortical excitatory transmission to favor initiation and propagation of cortical spreading depression, a key process in migraine pathophysiology. Accordingly, there are pharmacological evidences suggesting that reduction of $Ca_V2.1$ activity can provide a new therapeutic approach for the treatment of HM and the relief of common migraine. Currently the only truly $Ca_V2.1$-selective inhibitors are peptide toxins of the agatoxin family, which are not suitable therapeutic tools: their mode of inhibition can give rise to undesirable side effects and peptides have limited utility for *in vivo* studies. Therefore, low-molecular-weight compounds that selectively modulate $Ca_V2.1$ activity could emerge as new drugs to treat migraine.

Here we have employed a high-throughput study using automated patch clamp to identify novel selective $Ca_V2.1$-inhibitors. From an initial set of 80 compounds recognized as potential $Ca_V2.1$ blockers *in silico*, our results highlighted six novel small organic molecules with higher selectivity for $Ca_V2.1$ inhibition (over $Ca_V2.2$ and $Ca_V1.2$ blockade) as prospective elements to develop HM therapeutic tools. Next, in a low-throughput evaluation of the compounds, we studied their effect on the wild-type "healthy" and gain-of-function FHM mutant $Ca_V2.1$ channels. We identified novel potent and selective inhibitors of $Ca_V2.1$ capable of preventing the excessive activity of $Ca_V2.1$ channels produced by human mutations leading to HM, with minor effects on the wild-type channel (in order to reduce/prevent potential side effects). In addition, to validate the potential therapeutic use of the best candidates, we tested if the reduction of excessive $Ca_V2.1$ activity was sufficient to prevent hyper-excitability on cortical networks observed in HM mouse model, a gain-of-function $Ca_V2.1$ knock-in animal. Interestingly, our study featured a selective $Ca_V2.1$ inhibitor that diminished excitability of the aberrant neuronal network with minor effects on the healthy cortical neuronal network from wild-type mice. This novel molecule that modulates the $Ca_V2.1$ channel activity and reverts its pathological gain-of-function effect may contribute to the development of a new, effective and safe treatment for both hemiplegic and common migraine.

Title: Dopamine Autoreceptor Functioning is Attenuated Following Chronic Blockade of Dopamine Transporters

Authors: *R. L. PACE, P. A. NALAN, D. B. LESTER;
Psychology, Univ. of Memphis, Memphis, TN

Abstract: Extracellular dopamine levels are mediated in part by dopamine transporters (DATs) and dopamine autoreceptors (DARs). DATs are responsible for the reuptake of dopamine into the presynaptic terminal, and DAR activation inhibits dopamine release. Using in vivo fixed potential amperometry in anesthetized mice, the current study sought to better understand whether these two neural mechanisms work collectively or independently. Stimulation parameters specifically designed to assess DAR functioning were applied during nucleus accumbens (NAc) dopamine recordings following chronic administration of the DAT inhibitor cocaine (20 mg/kg i.p. daily for 7 days). Dopamine recordings took place 24 hours after the last cocaine administration, and DAR functioning was assessed before and after an in-test injection of cocaine (8th injection for the cocaine group and 1st injection for the control group). DAR functioning was significantly attenuated in mice that received chronic cocaine (-37% compared to control mice). The in-test cocaine injection had opposing effects on DAR functioning in the chronic cocaine mice and controls, with DAR functioning increasing 20 min post-injection in the chronic cocaine mice and decreasing in control mice. These results highlight compensatory mechanisms employed at the

level of the presynaptic membrane to counteract chronic blockade of dopamine reuptake and increased levels of extracellular dopamine. A better understanding of the interactions between DATs and DARs may lead to improved treatments for dopamine-related disorders such as ADHD, depression, and substance use disorder.

Title: Altered $GABA_A$ receptor subunit configuration in drug-resistant epilepsy (DRE): A possible cause of benzodiazepine resistance

Authors: *J. BANERJEE[1], D. SHARMA[2], A. B. DIXIT[6], S. DEY[2], M. TRIPATHI[3], R. DODDAMANI[2], M. C. SHARMA[4], S. LALWANI[5], P. CHANDRA[2];

Abstract: Benzodiazepines (BZDs), positive allosteric modulators at $GABA_A$ receptors, are widely used an anti-convulsant for the treatment of patients with severe forms of epilepsies. A large number of patients with drug-resistant epilepsy (DRE) do not respond to BZDs. BZDs bind at the classical benzodiazepine binding site located at the interface of α-and γ- subunit of the $GABA_A$ receptors. The selectivity of benzodiazepine responsiveness is primarily determined by the type of the α subunits, with α1-, α2-, α3-, and α5-containing $GABA_A$ receptors being sensitive to BZDs. While α3-, and α5-containing $GABA_A$ receptors are insensitive to BZDs. This study was designed to investigate if altered configuration of $GABA_A$ receptor subunits could contribute to BZD-resistance in patients with DRE. Brain specimens were obtained from patients with various DRE pathologies like mesial temporal lobe epilepsy, focal cortical dysplasia, Rasmussen's encephalitis, dysembryoplastic neuroepithelial tumor and ganglioglioma undergoing resective surgery. Region matched cortical tissues from patients with mature healthy brain, who underwent autopsies for causes other than brain pathology, were used as controls. Resected cortical samples obtained from surrounding areas of brain tumors during surgical resection in patients with low-grade gliomas without any history of seizures were used as non-seizure controls for electrophysiological studies. Differential gene and cellular expression of $GABA_A$ receptor subunits were evaluated and validated using qPCR and immunohistochemistry. Whole cell patch-clamp recordings were performed on pyramidal neurons of resected cortical samples obtained from patients with DRE to measure the spontaneous $GABA_A$ receptor activity. We observed upregulation of α4-subunit containing $GABA_A$ receptors both at mRNA and protein level in DRE samples as compared to controls, while α1-subunits containing $GABA_A$ receptors did not show any significant changes. Treatment with flumazenil, a BZD

binding site antagonist, did not affect the kinetics of GABAergic events in samples obtained from patients with DRE pathologies. However, flumazenil significantly reduced the frequency and amplitude of spontaneous GABAergic activity recorded from pyramidal neurons of non-seizure control samples. Our results demonstrated that enhanced expression of α4-containing $GABA_A$ receptors may contribute to benzodiazepine resistance in patients with DRE.

Title: Risperidone Mitigates Enhanced Excitatory Neuronal Function and Repetitive Behavior Caused by an ASD-Associated Mutation of SIK1

Authors: *M. BADAWI[1], T. MORI[1,2], T. KURIHARA[1], T. YOSHIZAWA[3], K. NOHARA[1], E. KOUYAMA-SUZUKI[1], T. YANAGAWA[4], Y. SHIRAI[1], K. TABUCHI[1,2];

Ctr. for Supports to Advanced Science, Shinshu Univ., Matsumoto, Japan; [4]Dept. of Oral and Maxillofacial Surgery, Fac. of Medicine, Univ. of Tsukuba, Tsukuba, Japan

Abstract: Six mutations in the salt-inducible kinase 1 (SIK1)-coding gene have been identified in patients with early infantile epileptic encephalopathy (EIEE-30) accompanied by autistic symptoms. Two of the mutations are non-sense mutationsthat truncate the C-terminal region of SIK1. It has been shown that the C-terminal truncated form of SIK1 protein affects the sub-cellular distribution of SIK1 protein, tempting to speculate the relevance to the pathophysiology of the disorders. We generated SIK1-mutant (SIK1-MT) mice recapitulating the C-terminal truncated mutations using CRISPR/Cas9-mediated genome editing. SIK1-MT protein was distributed in the nucleus and cytoplasm, whereas the distribution of wild-type SIK1 was restricted to the nucleus. We found the disruption of excitatory and inhibitory (E/I) synaptic balance due to an increase in excitatory synaptic transmission and enhancement of neural excitability in

the pyramidal neurons in layer 5 of the medial prefrontal cortex in SIK1-MT mice. We also found the increased repetitive behavior and social behavioral deficits in SIK1-MT mice. The risperidone administration attenuated the neural excitability and excitatory synaptic transmission, but the disrupted E/I synaptic balance was unchanged, because it also reduced the inhibitory synaptic transmission. Risperidone also eliminated the repetitive behavior but not social behavioral deficits. These results indicate that risperidone has a role in decreasing neuronal excitability and excitatory synapses, ameliorating repetitive behavior in the SIK1-truncated mice.

Title: Characterization of oxygen-level dependent isoflurane effects on proximal vs distal dendritic excitatory inputs using a high-flow brain slice chamber

Authors: *S. KLEIN, R. A. PEARCE;
Anesthesiol., Univ. of Wisconsin, Madison, WI

Abstract: Background: Isoflurane is a commonly used anesthetic with multiple targets in the brain. It has been shown to differentially modulate ascending vs. descending excitatory synapses in neocortex.[1] Here, we sought to characterize its effect on the analogous distal temporoammonic (TA) relative to the proximal Schaffer Collaterals (SC) pathways. Recent findings also indicate that isoflurane affects excitatory synaptic transmission by targeting mitochondrial complex I. Therefore, we also tested effects at differing oxygen levels to stress ATP production. **Methods:** Coronal hippocampal brain slices (400 μm) prepared from 2-4 month old C57BL/6J mice were perfused in a high flow chamber (Scientific Systems Design) at 16 mL/min with aCSF (32°C) aerated with high O_2 (95%O_2-5%CO_2) or low O_2 (70%O_2-25%N_2-5%CO_2) levels. Field EPSPs (fEPSPs) were measured in stratum radiatum in response to SC stimulation at the CA1/CA2 border and stratum lacunosum-moleculare in response to TA stimulation at CA1/subiculum border. Slices were stimulated either once per 20 s (alternating pathways) or 20 stimuli at 50 Hz every 60 s (SC only). **Results:** Isoflurane (100-850 μM) suppressed the SC fEPSP to a greater degree than the TA fEPSP, in a concentration-dependent manner, with no significant O_2 level-dependent differences. Following a 30-min application, isoflurane was removed, and responses recovered quickly (20 min), but to a steady state fEPSP slope that was smaller than the original baseline. We term this unexpected, persistent decrease in fEPSP slope, “isoflurane-induced long-term depression” (iso-LTD). The amplitude of iso-LTD was greater at high O_2 levels, for both TA and SC pathways. To further stress the energy-intensive synaptic machinery, we applied trains of 20 stimuli (50 Hz) every 60 s. fEPSP depression during repeated stimulation was increased during isoflurane application (425 μM), to equal

degrees at low and high O_2 levels, and at low O_2 levels the depression persisted following isoflurane washout. **Conclusions:** Isoflurane acutely suppressed SC more than TA responses, independent of O_2 level. By contrast, iso-LTD was O_2 level-dependent and affected both pathways equally. Finally, O_2 level-dependent recovery was the reverse for trains vs single stimuli applied to the SC pathway. **References:** 1. Raz, *Front Syst Neurosci* **8**:191 (2014); 2. Title: Generation of transgenic tools to delineate striatal neurabin function

Authors: *W. COREY[1], A. J. BAUCUM, II[1,2,3];
[1]Biol., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [2]Pharmacology/toxicology, [3]Stark Neurosci. Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Amphetamine abuse in the US has been steadily increasing, and in some areas poses a greater threat than the opioid crisis. A key brain region involved in drug seeking and drug taking is the striatum. The dorsal and ventral subdivisions of the striatum work in concert to mediate the reinforcing and motor behavioral effects of amphetamine. Therefore, understanding how amphetamine alters striatal function is a key component in devolving novel therapeutics for drug abuse and addiction. The main output neurons of the striatum are GABAergic, medium-spiny neurons (MSNs), and striatal functionality is mediated by neuroplastic changes in MSN activity. Within MSNs, dopaminergic receptor activation triggers a cascade of reversable phosphorylation, which is facilitated by the activation of specific protein kinases and inhibition of specific protein phosphatases. In comparison to abundant protein kinase expression, only four serine/threonine protein phosphatases are expressed in the striatum. However, serine/threonine protein phosphatases, such as PP1, gain their target specificity by interacting with phosphatase-targeting proteins. Within the striatum, the neurabins, termed neurabin and spinophilin, are the most abundant PP1 targeting proteins in dendritic spines. Spinophilin's expression in the striatum has been strongly characterized, and spinophilin has been shown to regulate striatal-dependent motor-skill learning and amphetamine-induced locomotor sensitization. In contrast to spinophilin, neurabin's expression within the striatum and its involvement in these striatal-dependent behaviors has not been fully probed. We found that neurabin expression in the striatum is not sex-dependent but is age-dependent. In addition to this data, we also present validation of a new global neurabin knock-out mouse model and preliminary data on the generation of a conditional knock-out mouse model. These mice will be utilized to probe neurabin's involvement in striatal-dependent motor-skill learning and amphetamine-dependent locomotor sensitization. Understanding neurabin's expression in the striatum, and its role in these key striatal

behaviors could, along with spinophilin, provide a druggable target for therapeutics designed to address drug abuse and addiction.

Title: $Gaba_A$ receptors containing the α4 subunit modulate emergence/recovery following anesthesia with different general anesthetics in mice

Authors: *M. T. MANSOURI, P. S. GARCIA;
Dept of Anesthesiol., Columbia Univ. Irving Med. Ctr., New York, NY

Abstract: Introduction: Transitions into conscious states are partially mediated by inactivation of sleep networks and activation of arousal networks. Our previous work demonstrated that the GABA Type A receptor ($GABA_AR$) antagonist, flumazenil, can promote wakefulness in patients with idiopathic hypersomnia. Also, we reported that intravenous flumazenil could hasten EEG and behavioral correlates of emergence from isoflurane anesthesia in rats. **Objective:** As the $GABA_AR$ mediates the clinical effects of many common general anesthetics, we aimed to evaluate the role of $GABA_ARs$ containing the alpha-4 subunit (GABRA-4) in emergence and recovery from three different anesthesia regimens: inhaled isoflurane, injected ketamine/xylazine and injected ketamine in mice. **Methods:** Age-matched, adult male (n=32; 26-30 g) mice genetically manipulated to knock-out (KO) the gabra4 gene and wild-type (WT) littermates were used. Following the administration of isoflurane (1.5%, 90 min), ketamine/xylazine (K/X, 90/5 mg/kg, intraperitoneal) and ketamine (90 mg/kg, intraperitoneal), loss of righting reflex (LORR), minimal alveolar concentration (MAC), emergence (return of righting reflex; RORR) and recovery (sticky dot notice) were recorded. Cognitive performance was also evaluated using spontaneous Y-maze alternation test. **Results:** We demonstrated that genetic ablation of GABRA-4, hastens emergence from anesthesia from each tested anesthetic regimen without significant changes in recovery characteristics. The cognitive performance of mice in a working memory assessment (Y-maze) was not different among these groups. Although loss of righting reflex appears to be delayed in α4 knockout animals, the minimal alveolar concentration of isoflurane to suppress movement was not different between the two groups, indicating α4 $GABA_ARs$ in the spinal cord are not key mediators of anesthetic-induced immobility. Pharmacologic studies with a gaboxadol (a preferred GABRA-4 agonist) confirm these specific effects occur during emergence from anesthesia via α4-containing $GABA_A$ receptors without an associated change in recovery and/or cognitive performance. **Conclusion:** We conclude that there are important differences in the neural substrates mediating emergence and recovery. These findings confirm that α4-containing $GABA_A$ receptors are involved in hastening wakefulness.

Title: Neuron glia interactions in adult hormone modulated plasticity in male and female canaries (Serinus canaria)

Authors: P. A. MASSA[1], A. P. BOGARD[1], E. E. SANDMAN[1], G. F. BALL[2], *F. N. MADISON[1]; [1]Dept. of Biol., Hope Col., Holland, MI; [2]Univ. of Maryland, College Park, MD

Abstract: In temperate zone species such as canaries (Se*rinus canaria*) the neural circuitry regulating song behavior undergoes well-defined changes across the seasons. In males, increased daylengths in the spring initiates an increase in gonadal volumes and circulating testosterone driving marked changes in brain morphology and song frequency. Females given exogenous testosterone in adulthood, also demonstrate male-like changes in brain morphology and song behavior. More specifically, the telencephalic nucleus HVC (acronym is proper name), a key nucleus for song production, undergoes well-defined seasonal changes in neuroplasticity with a high rate of neurogenesis mediating marked changes in HVC volume. Much is known about the neural circuitry driving song behavior, however, the mechanisms underlying the morphological changes in adult hormone-modulated brain plasticity remain to be elucidated. In mammals, astrocytes, specialized glial cells that promote neuron migration and survival, have been shown to mediate maturation and plasticity of neuronal networks. In male songbirds, astrocytes parallel seasonal plasticity, suggesting that astrocytes may play a role in hormone-modulated neurogenesis. We therefore sought to investigate the role of astrocytes in adult hormone modulated neuroplasticity in male and female canaries. Males were castrated and females were photoregressed and housed in our aviary on short days (8L:16D) for at least 6 weeks. Birds were surgically implanted with either a 10 mm testosterone-packed Silastic implant or an empty implant as a control for 7 days. Brains were extracted, sectioned, and HVC volumes were quantified in Nissl stained sections. Brain sections were also double-labeled via immunohistochemistry for glial fibrillary acidic protein (GFAP) and neuronal nuclear protein (NeuN). Both males and females treated with testosterone had larger HVC volumes compared to controls. Preliminary evidence demonstrates increased GFAP-immunoreactivity in the ventricular and neurogenic subventricular zone suggesting that astrocytes may play a role in the guidance and survival of new neurons migrating to HVC in both male and female canaries.

Title: Astrocyte dependency of synchronous activities in the neonatal hippocampal networks

Authors: *R. IDE, Y. SHINDO, K. HOTTA, K. OKA;
Biosci. and Informatics, Keio Univ., Yokohama-Shi, Japan

Abstract: The dynamics of the mammalian central nervous system change dramatically around the first week after birth. During this period, immature neurons extend their neurites and establish large number of synapses to form a functional neuronal network. The formation of this network in the mammalian brain depends on not only genetic programs but its neural activities. Neural activities in the neonatal hippocampal neurons are regulated by their principal neurotransmitters: GABA and glutamate.Synchronized activities in the neural network is a typical characteristic on the neonatal period. They were observed only in the immature networks when GABA behaves as an excitatory neurotransmitter (Yamanaka et al. 2018). Although excitatory GABA and glutamate are thought to trigger the synchronous network events, the details of their mechanism remain unclear. In particular, the contribution of astrocytes to these events is largely unknown. Previous paper has stated astrocytes synchronized local neuronal activity via extra-synaptic NMDA receptors (Carmignoto et al. 2006). However, it is not clarified how astrocytes orchestrate the synchronization of large population of neuronal activities.Astrocytes generate spontaneous and evoked Ca^{2+} transients. The density of astrocytes and the number of gap junctional coupling between astrocytes increases during the first postnatal week. Moreover, astrocytes change their protein expression profiles in the same period. Astrocytes also regulate synapse formation and extracellular ion concentrations through these changes in properties.In this work, we studied the mechanism of synchronous network events and the role of astrocytes in these events. We observed the cellular events of each neuron by Ca^{2+} imaging to examine its contribution to the synchronous network events. These events were transient; they disappeared until the second postnatal weeks *in vitro*. They were mediated by activation of $GABA_A$ receptors because the inactivation of $GABA_A$ receptor abolished them. Synchronization was observed in networks with/without astrocytes, and there was a trend of negative correlation between the frequency of synchronized network events and the number of astrocytes. The networks with high percentage of astrocytes show more neurons with sporadic activities. However, the ratio of astrocytes did not change the fraction of neurons participating in synchronized network events. These results suggest that the activities of GABAergic neurons cause synchronized network events, and astrocytes contribute to network events indirectly via synapse formation, rather than through direct involvement including the release of glutamate.

Title: Astrocyte to neuron reprogramming for spinal cord repair

Authors: *A. NICEFORO[1], T. A. FORTINO[2], Y. SHAH[2], L. V. ZHOLUDEVA[4], L. QIANG[3], M. A. LANE[3];
[1]Drexel University-College of Med., Philadelphia, PA; [2]Neurobio. & Anat., [3]Drexel Univ., Philadelphia, PA; [4]Gladstone Inst., San Francisco, CA

Abstract: Traumatic spinal cord injury (SCI) results in the loss of neurons and glia with accompanied reactive gliosis and tissue scarring, preventing significant endogenous repair. A potential, innovative therapeutic strategy that can be used to target these reactive astrocytes is direct cellular reprogramming by overexpression of neurogenic transcription factors (TFs) or microRNAs (miRs) that controls cellular fates. Here we used a rat model of cervical SCI to test the hypothesis that activated resident astrocytes known to partition the cavity that develops after injury, can be reprogrammed into neurons by inducing the expression of either *Ascl1,* an early expressed neurogenic TF, or a combination of *miR124* and *miR9/9**. Primary astrocyte cultures were generated from postnatal days 2-3 (P2-3) rat cortex and spinal cord, and activated with TGFβ (Transforming growth factor beta) one day prior to doxycycline-inducible lentiviral transduction. Doxycycline was added for 15 days to induce TF expression, prior to extended culture to facilitate neuronal maturation. Immunocytochemistry revealed glial-derived neurons positive for neuronal markers (e.g., MAP2, NeuN and TAUR1) and negative for the astrocytic markers (e.g., GFAP). Neuronal activity was measured using multielectrode arrays (MEAs) in reprogrammed cells compared to scramble virus-treated astrocytes. Anatomical, behavioural and electrophysiological outcome measures were used to assess the effects of the reprogramming strategies *in vivo,* post-cervical SCI. While anatomical evidence confirmed *in vivo* reprogramming of resident astrocytes into neurons, behavioural and functional outcomes showed no significant differences in respiratory function. Advances in cellular reprogramming are providing novel ways to manipulate the cytoarchitecture of the injured cervical spinal cord. This ongoing research is highlighting a novel therapeutic approach for promoting anatomical repair.

Title: Transplanting glial restricted progenitor cells for repair

Authors: *M. CUSIMANO;
Drexel Univ., Manayunk, PA

Abstract: *Marissa Cusimano[1,2], Alessia Niceforo[1,2], Tara Fortino[1,2], Indigo VL Rose[4], Lyandysha V. Zholudeva[3], Shane Liddelow[4,5,6], Liang Qiang[1,2], Michael A. Lane[1,2]*
1.*Department of Neurobiology & Anatomy, Drexel University College of Medicine, Philadelphia, USA* 2.*Spinal Cord Research Center, Drexel University College of Medicine, Philadelphia, USA*3.*Gladstone Institutes, San Francisco, California, USA*4.*Neuroscience Institute, NYU Grossman School of Medicine, New York, NY, USA*
More than half of all spinal cord injuries (SCIs) occur at the cervical level resulting in persistent, life-threatening respiratory deficits. Respiratory compromise and associated secondary complications remain a leading cause of morbidity and mortality in patients suffering from cervical SCI. While spontaneous improvements in respiration have been reported clinically and experimentally, this spontaneous recovery alone remains insufficient to significantly improve respiratory function. Given the limited capacity for self-repair in the spinal cord, there has been a significant research effort toward promoting neural repair post-SCI. One promising approach with continued pre-clinical and clinical interest, is transplantation of neural precursor cells that have been shown to survive, integrate and even facilitate neural repair. One component of these donor cells is glial restricted progenitors (GRPs), that have been shown to reorganize the cytoarchitecture of the injured internal milieu and promote and support axonal growth. Preclinical studies have demonstrated that GRPs transplanted into SCI, migrate into host tissue, reduce glial scar formation and inflammation, while promoting axon growth post-SCI. However, several pre-clinical studies have yielded variable or only limited functional recovery. Therefore, we propose that GRPs alone require additional components, such as endothelial cells (ECs) to enhance cell survival, integration, and tissue repair. Our preliminary studies demonstrate that transplantation of ECs at the site of injury contribute to vascular repair. Phenotypic analysis (immunocytochemistry, gene expression) is used to define phenotype of donor cells prior to and following transplantation. Particular attention is given to the pro-reparative phrenotypes of these donor cells. Ongoing work tests the efficacy of transplanted cells to anatomically and functionally integrate with injured vasculature and phrenic spinal pathways, and their contribution to improved phrenic function post-SCI.

Title: Synergistic interactions among intrinsic, synaptic, and structural heterogeneities drive synaptic plasticity profiles in dentate gyrus granule cells

Authors: *S. SHRIDHAR[1], P. MISHRA[2], R. NARAYANAN[1];
[1]Indian Inst. of Sci., Bangalore, India; [2]MOLECULAR BIOPHYSICS UNIT, INDIAN INSTITUTE OF SCIENCE, BANGALORE, India

Abstract: Granule cells (GC) in the dentate gyrus exhibit pronounced heterogeneities in their intrinsic properties and synaptic connectivity, with these heterogeneities further amplified by the expression of adult neurogenesis. The impact of such heterogeneities on synaptic plasticity rules has not been quantitatively analyzed. Here, we assessed the ramifications of the expression of intrinsic, synaptic, and structural heterogeneities on synaptic plasticity profiles induced through two protocols: the BCM-like 900-pulses protocol and the theta-burst stimulation (TBS) protocol. First, we addressed the impact intrinsic heterogeneities had on plasticity profiles obtained with both induction protocols, with a fixed baseline synaptic strength across models. We found that heterogeneities in intrinsic properties resulted in heterogeneities in the modification threshold of the BCM-like protocol and the amount of plasticity induced by TBS. However, pair-wise correlations between these plasticity measurements and any of the intrinsic measurements or parameters were weak ($|r|<0.4$). Next, we examined the relationship between excitability properties and synaptic strength and showed that similar plasticity profiles could be obtained across all models with different synaptic strengths, thereby demonstrating plasticity degeneracy whereby the impact of heterogeneities in intrinsic properties could be counterbalanced by heterogeneities in synaptic strength. However, we did not find strong pair-wise correlations between synaptic strength and any intrinsic measurement or parameter governing the model. We then explored the role of neurogenesis-induced structural heterogeneity, by progressively altering the diameter of the model neurons, mimicking maturation-induced increase in GC surface area. When synaptic strengths were fixed, we found a progressive rightward shift in the plasticity profile with an increase in diameter. Importantly, in immature neurons with extremely small diameters, the plasticity profile manifested no long-term depression for a large range of baseline synaptic strength values. Finally, when the plasticity profiles were tuned to be similar by altering synaptic strengths, we found the emergence of plasticity degeneracy involving intrinsic, structural, and synaptic parameters. Together, our analyses provide a biophysical framework for understanding the role of various heterogeneities and the synergistic interactions among them in engram cell formation, in effectuating the maturation-induced switch in synaptic plasticity regimes, and in the emergence of plasticity degeneracy.

Title: Hippocampal and thalamic afferents form distinct synaptic microcircuits in the mouse infralimbic frontal cortex

Authors: *K. GRAHAM[1], N. P. SPRUSTON[2], E. B. BLOSS[1];
[1]The Jackson Lab., Bar Harbor, ME; [2]HHMI Janelia Res. Campus, Ashburn, VA

Abstract: Neural circuits within the frontal cortex support the flexible selection of goal-directed behaviors by integrating input from brain regions associated with sensory, emotional, episodic, and semantic memory functions. From a connectomics perspective, determining how these disparate afferent inputs target their synapses to specific cell types in the frontal cortex may prove crucial in understanding circuit-level information processing. Here, we used monosynaptic retrograde rabies mapping to examine the distribution of afferent neurons targeting four distinct classes of local inhibitory interneurons and four distinct classes of excitatory projection neurons in mouse infralimbic cortex. Interneurons expressing parvalbumin, somatostatin, or vasoactive intestinal peptide received a large proportion of inputs from hippocampal regions, while interneurons expressing neuron-derived neurotrophic factor received a large proportion of inputs from thalamic regions. A more moderate hippocampal-thalamic dichotomy was found among the inputs targeting excitatory neurons that project to the basolateral amygdala, lateral entorhinal cortex, nucleus reuniens of the thalamus, and the periaqueductal gray. Together, these results show a prominent bias among hippocampal and thalamic afferent systems in their targeting to genetically or anatomically defined sets of frontal cortical neurons. Moreover, they suggest the presence of two distinct local microcircuits that control how different inputs govern frontal cortical information processing.

Abstract: A core network of ubiquitously expressed glutamate-synapse-associated proteins mediates activity-dependent synaptic plasticity throughout the brain, but the specific proteomic composition of synapses differs between brain regions. Here, we sought to classify the diversity of activity-dependent remodeling across brain regions using quantitative multiplex co-immunoprecipitation (QMI). This novel proteomic technique allows for the simultaneous and quantitative measurement of the amount of co-association between large numbers of proteins in shared complexes.We first compared the response of cultured neurons to distinct stimuli, and defined PIN parameters that differentiate input types. We next

compared the response of three different brain regions maintained alive in vitro to an identical stimulus, and identified three qualitatively different PIN responses. Finally, we measured the PIN response following associative learning tasks, delay and trace eyeblink conditioning, in three brain regions, and found that the two forms of associative learning are distinguished from each other using brain-region-specific network mechanisms. We conclude that although the PIN of the glutamatergic post-synapse is expressed ubiquitously, its activity-dependent dynamics show remarkable stimulus-specific and brain-region-specific diversity.

Title: Interrogating modulatory effects of CA2 on CA1 plasticity in mice hippocampus

Authors: *M. BIN IBRAHIM, N. KOH, S. SAJIKUMAR;
Natl. Univ. of Singapore, Singapore, Singapore

Abstract: The hippocampus plays an integral role in episodic memory formation and storage, particularly by neurons in its CA1 subfield. Beyond the circuitry is the CA2 region. While not directly involved in the hippocampal loop and episodic memory, the CA2 region is implicated in social memory. There also exists monosynaptic connections from CA2 innervating CA1. The functional relevance of the CA2-CA1 connections has yet to be uncovered, suggesting possible modulation of CA1 by CA2. Unravelling this will shed light on how different forms of memory – episodic and social – interact with one another in the hippocampus. Hence, it is likely that these connections could play a role in memory persistence of episodic memory in the CA1 via activation during social interaction.We aimed to interrogate how the CA2-CA1 connections can modulate synaptic plasticity of the Schaffer collateral (SC)-CA1 synapses. Field electrophysiology of hippocampal slices from young male C57BL/6 mice was utilised to measure synaptic modification via long-term potentiation (LTP), a cellular correlate of learning and memory. Weak stimulation of SC-CA1 synapses exhibit early-LTP but not late-LTP in SC-CA1 synapses. Besides that, the weak stimulation of CA2 neurons does not lead to any modification in synaptic strength in SC-CA1 synapses. However, when preceded by a weak stimulation of CA2 neurons, SC-CA1 synapses exhibit a late phase of LTP upon weak stimulation. This ‘priming’ phenomenon is also shown to be protein synthesis-dependent and time-dependent.Following this, we investigated the associativity of the CA2-primed late-LTP via the synaptic-tagging-and-capture hypothesis (STC), a model for associative plasticity. Using field electrophysiology, CA2-primed late-LTP is unable to participate in STC. When a

second set of SC-CA1 synapses is weakly stimulated following CA2 priming, both the first and second population of SC-CA1 synapses can only exhibit early-LTP. This preliminary set of results demonstrate that CA2 connections onto CA1 can influence the synaptic plasticity of CA1, suggesting possible implications of how social behavioural states can modulate persistence of memory. Our next steps will involve analysing the molecular pathways and players involved in plasticity and signalling, and replicating the electrophysiological result using behavioural models.

Title: Seizure onset is stochastic at the single neuron level

Authors: *L. A. LAU, K. P. LILLIS, K. J. STALEY;
Massachusetts Gen. Hosp., Boston, MA

Abstract: Acquired epilepsies are characterized by spontaneous, recurrent seizures that emerge following injury. The unpredictable nature of seizures is one of the most disabling features of epilepsy. Understanding seizure initiation, or ictogenesis, is critical for developing mechanistically based treatments for medically refractory epilepsy. However, ictogenesis is difficult to study, due to the spontaneous nature of seizures and poor spatial sampling available for capturing seizure onset in vivo. Here, we developed novel techniques for chronic cellular resolution imaging of neuronal activity in the hippocampal organotypic slice culture model of post-traumatic epilepsy to analyze seizure onset at the single neuron level. Hippocampal slice cultures generate spontaneous seizure-like events following slicing injury. With this preparation, it is feasible to image the entire network, ensuring that the earliest pathological activity is captured (as no outside inputs exist). Pan-neuronal GCaMP7 expression was paired with DLX-cre-targeted tdtomato labeling of interneurons to separate the calcium activity of principal cells and interneurons. We used a custom imaging system to observe undisturbed organotypic hippocampal slice cultures over several weeks to capture the calcium activity across dozens of seizures. Chronic calcium imaging of the entire hippocampal network, with paired electrophysiology, revealed 3 patterns of seizure onset: low amplitude fast activity, sentinel spike, and spike burst + low amplitude fast activity onset. These patterns recapitulate common features of human seizure onset, including low voltage fast activity and spike discharges. We also used this preparation to track the activity of individual neurons and test whether a subpopulation of neurons consistently initiates seizure activity. Our cellular level tracking revealed that neuronal onset sequences were highly variable seizure-to-seizure and lacked a repeatable population of neuronal activators at seizure onset. These results argue against seizure initiation by a small number of neuronal drivers, such as hub cells, and is rather consistent with transitions to seizures driven by state changes that allow for re-entrant seizure activity in non-stereotyped sequences.

We further explore how individual neurons contributed to the overall population signal during ictal onset and frank seizure. Interestingly, the large population signal during frank seizure is due to both synchronous re-activation of neurons that were recruited during onset and increased intra-cellular calcium amplitude.

Title: Establishing a human iPSC-derived neuron model of SLC35A2-associated epilepsy

Authors: *D. LAI[1], D. WILLIAMS[2], P. SOSICKA[3], A. K. RESSLER[2], H. H. FREEZE[3], M. BOLAND[2], E. L. HEINZEN[1];
[1]Univ. of North Carolina, Chapel Hill, NC; [2]Columbia Univ., New York, NY; [3]Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA

Abstract: *SLC35A2* encodes a Golgi-localized UDP-galactose transporter that is essential for protein glycosylation. Variants in *SLC35A2* cause a congenital disorder of glycosylation that is associated with intractable seizures, as well as epileptic encephalopathies. Our lab was the first to identify post-zygotically acquired *de novo*, loss-of-function (LOF) variants in *SLC35A2* in 17% of individuals with intractable non-lesional focal epilepsy – a finding now corroborated by two other groups. Despite this clear association with epilepsy, it is unknown how *SLC35A2* variants contribute to epileptogenesis. In this study, we develop a human induced pluripotent stem cell (iPSC) derived neuron model to investigate how *SLC35A2* variants disrupt neural activity and neural connectivity using whole-cell patch clamp electrophysiology and multielectrode array (MEA), respectively.
We have established iPSCs (isogenic control) CRISPR-edited to harbor a pathogenic missense variant (p.Ser304Pro; SLC35A2$^{S304P/Y}$) and a frameshift indel (SLC35A2$^{-/Y}$), all of which express the pluripotent markers NANOG and SOX2 using immunofluorescent (IF) staining. Both *SLC35A2* missense and indel variants encode LOF proteins, which is validated using a MALI lectin binding assay that showed reduced binding in SLC35A2$^{S304P/Y}$ and SLC35A2$^{-/Y}$ protein lysates compared to the isogenic control. Loss of transporter activity can be attributed to reduced protein expression and loss of Golgi-localization when assessed on IF staining. To investigate the consequence of *SLC35A2* variants on neural network activity, iPSCs were differentiated into glutamatergic neurons using dual smad inhibition and plated for MEA analysis. Over six weeks of recordings, synchronous activity was only detected in isogenic control neural networks compared to those formed by SLC35A2$^{S304P/Y}$ and SLC35A2$^{-/Y}$ neurons as quantified by mutual information (P-value <0.01) and the spike train tiling coefficient (P-value <0.01). Whole-cell patch clamp electrophysiology recordings also reveal differences in excitability between *SLC35A2* variants compared

to the isogenic control when action potential (AP) characteristics (e.g., AP duration, rheobase, etc.) and passive membrane properties (e.g., resting membrane potential, capacitance, etc.) are assessed. Together, these findings demonstrate that neurons harboring *SLC35A2* variants lead to aberrant neuron function and network activity, which may be contributing to the epileptogenic phenotype. Further characterization of the underlying mechanisms of *SLC35A2*-associated epileptogenesis and evaluations across an allelic series in this model system are underway.

Title: Role of Functional Network Formation in Epilepsy

Authors: *U. BODDETI[1], M. BACHANI[1], J. OWOTADE[1], M. MOYER[1], R. SERRA[1], H. P. ZAVERI[2], K. ZAGHLOUL[3], A. KSENDZOVSKY[4];
[1]The Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Dept. of Neurol., Yale Univ., New Haven, CT; [3]NIH, Bethesda, MD; [4]Dept. of Neurosurg., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Introduction: Despite surgical resection of a defined epileptogenic focus (EF), about 50% of patients go on to have refractory seizures[1]. Recently, focal epilepsy is being redefined as a network disorder[1] and studies have demonstrated that resection of nodes outside the EF may contribute to better surgical outcomes[1]. Additionally, our group has shown higher interictal connectivity between nodes involved in seizure onset in a cohort of epilepsy patients, further suggesting the presence of an underlying distributed epileptogenic network in focal epilepsy[1].
Objective: To characterize seizure network formation in a novel *in vitro* culture model of cortical epilepsy.
Methods: Primary mixed cultures of cortical neurons from P1 rat pups were cultured on 96-well multi-electrode array (MEA) plates with eight active electrodes per well for stimulation and recording. We developed an *in vitro* stimulation model of cortical epilepsy to study epilepsy network formation using a biphasic tetanic stimulation at 50 or 100 Hz, 500 μV, 250 μA applied for one hour daily for ten days.
Results: Four-days of daily *in vitro* stimulation demonstrated significant increases in neuronal baseline bursting, modeling kindled seizures. Tetanic stimulation with 50Hz had the highest elevation in neuronal busting. In order to compare distributed network connectivity, we calculated and ranked coherences (13-32Hz) across all electrode pairs (n=24) and identified the top 15% for comparison to control. The average coherence across the top connected pairs was significantly higher in stimulated wells compared to controls (0.27 vs. 0.17, p=0.0002). Furthermore, coherence across the highest-ranking electrode pair was

strengthened with daily stimulation. This was not seen in control electrodes.
Conclusion Statement from Research Findings: Our data suggests that daily stimulation with 50Hz strengthens connectivity and increases overall neuronal bursting *in vitro* thereby potentially recapitulating *in vivo* seizure networks.
Conclusion: Similar to human data, this *in vitro* model suggests an elevated interictal coherence among electrode pairs involved in seizure formation. Next, we aim to characterize the structural nature of this network quantifying axonal boutons and dendritic spines. Ultimately, our work aims to enable a better understanding of network formation in epilepsy that will inform future epilepsy surgery decision making.

Title: In vitro oscillation patterns of distinct areas of hippocampal formation in animal model of epilepsy

Authors: J. RIGHES MARAFIGA, M. VENDRAMIN PASQUETTI, *M. CALCAGNOTTO; Biochem., NNNESP Lab-UFRGS, Porto Alegre, Brazil

Abstract: Introduction: Hippocampal network oscillations are useful to pursue brain activity in temporal lobe epilepsy (TLE). However, the dynamics of underlying oscillation pattern during the epileptogenesis throughout the hippocampal formation in TLE is not clear. Here, we characterized the *in vitro* oscillatory patterns within the hippocampal formation of adult epileptic male rats at two different stages of epileptogenesis, 30 and 60 days after pilocarpine-induced *Status Epilepticus* (*SE*). Material and Methods: Extracellular pair recordings were performed in CA1, CA3, dentate gyrus (DG) and entorhinal cortex (EC) of hippocampal formation slices of epileptic (n = 19) and aged-matched control (n = 20) animals, under either 4-Aminopyridine (4-AP)-induced hyperexcitability or spontaneous network activity condition, without 4-AP. Local field potentials were analyzed and power spectral densities (n_{epoch} = 30-50) and phase coherence (n_{epoch} = 20-25) were computed in 5s-epochs between interictal epileptiform events (IEDs) and 5s-epochs of spontaneous network activity using MATLAB. Data were analyzed by either Student's *t*-test (parametric) or Mann-Whitney U test. (non-parametric) with significance level of $p<0.05$. All animal procedures were performed according the Ethics Committee on Animal Use-UFRGS (approval # 33274). Results: At 30 days post-*SE*, 4-AP bathed slices from epileptic animals had increased ictogenesis in CA1; higher power of slow and/or middle gamma in EC, CA1 and CA3; and high-

frequency oscillations (HFOs) in CA3. Phase coherence was higher in middle gamma between CA1-CA3 and EC-CA1, and in HFOs between EC-CA1. At 60 days post-*SE*, we observed increased ictogenesis in EC and DG; higher power of slow and/or middle gamma in CA1, CA3 and DG, HFOs in EC, CA3 and DG; and higher phase coherence in HFOs between CA1-CA3. Under spontaneous network activity at 30 days post-*SE,* slices from epileptic animals, already had higher power of slow and/or middle gamma in all recorded regions, and HFOs in EC. At 60 days post-*SE*, they had higher power of slow and/or middle gamma in EC, CA3 and DG, higher power of HFOs in DG; and higher phase coherence in fast ripples oscillations between DG-CA3, when compared to controls. Conclusion: We found, region- and stage-dependent specific changes in gamma and HFOs within the hippocampal formation of epileptic animals under a second insult of hyperexcitability and during the spontaneous network activity, without epileptiform activity. Taken altogether, our results reinforce the role of gamma and HFOs within the hippocampal formation in ongoing pathological processes of network reorganization, crucial to the epilepsy establishment.

Title: Use of a submerged chamber for new insights into spreading depolarization in hippocampal slices

Authors: *Y.-L. LU[1], H. E. SCHARFMAN[1,2];
[1]Ctr. for Dementia Res., The Nathan Kline Inst. for Psychiatric Res., Orangeburg, NY; [2]Departments of Child & Adolescent Psychiatry, Physiol. & Neuroscience, and Psychiatry, New York Univ. Langone Hlth., New York, NY

Abstract: Spreading depolarization (SD) is sudden and synchronized depolarization of principal cells followed by depression of activity, which slowly propagates across brain regions like cortex or hippocampus. SD is considered to be mechanistically relevant to migraine, epilepsy, and traumatic brain injury. Interestingly, research into SD, especially SD that occurs spontaneously, is not as common as SD using models of focal stimulation. Here we optimize an in vitro experimental model allowing us to record SD without focal stimulation. This method uses electrophysiological recordings and imaging of intrinsic optical signals in slices. The method is also relatively easy and inexpensive. Acute hippocampal slices from mice or rats were prepared and used for extracellular and whole-cell recordings in area CA3. Recordings were made in a submerged-style chamber which allowed flow of artificial cerebrospinal fluid (aCSF) above and below the slices. Flow was fast (>5ml/min), and temperature was 32°C. ACSF

containing 0 mM Mg^{2+} and 5 mM K^{+} (0 Mg^{2+}/5 K^{+} aCSF) was used. Two major types of activity were observed: SD and seizure-like events (SLEs). Although both mouse and rat slices showed SLEs, only mouse slices developed SD in the first hour of 0 Mg^{2+}/5 K^{+} aCSF exposure. Intrinsic optical imaging showed that most SDs initiated in CA3 and propagated into CA1 and dentate gyrus. In dentate gyrus, SD propagated in two separate waves: into hilus and into granule cell/molecular layers. This optimized in vitro model can be used to better understand the mechanisms and relationship between SD and SLEs. It could also be applied in preclinical drug testing.

Title: Selective modulation of vCA1 rescues social memory in chronic epileptic mice.

Authors: *A. M. GOODMAN[1], J. B. KAHN[3], A. M. BERNAL[4], D. A. COULTER[2];
[1]Pediatrics Div. of Neurol., Children's Hosp. of Philadelphia, PHILADELPHIA, AL; [2]Pediatrics Div. of Neurol., Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Univ. of Pennsylvania, Philadelphia, PA; [4]Haverford, Philadelphia, PA

Abstract: Temporal lobe epilepsy (TLE) is the most common form of epilepsy in adults and is associated with high rates of comorbidities including cognitive, behavioral, and affective disruptions. These comorbidities are not only detrimental to quality of life but are not corrected - and may even be exacerbated - by existing therapies for TLE. Central to chronic TLE are dysfunctional hippocampal circuits which, when healthy are critical for appropriate function of several types of learning, memory, and related cognition, making them prime targets for therapeutic intervention. Since this epilepsy-associated behavioral dysfunction is presumably based on hyperexcitable aggregate circuit properties, our overarching goal is to modify the activity of these circuits, thereby correcting behavioral dysfunction. Our previous work used chemogenetic DREADDs in vCA1 to demonstrate that circuit-level manipulation of activity was able to rescue performance in a social memory discrimination (SMD) task in a 22q11.2 deletion syndrome mouse model of psychiatric disorders. We also showed that DREADD mediated inhibition of dentate gyrus granule cells in a pilocarpine (pilo) mouse model of TLE was sufficient to rescue spatial object recognition performance in a region-dependent manner. In this study, we first identified that epileptic (pilo) mice had deficient social memory, assessed with the SMD task. We next determined the role of vCA1 pyramidal neurons in mediating this behavioral deficiency. Inhibitory DREADDs (hM4Di/KORD) recruitment in vCA1 excitatory neurons was sufficient to rescue SMD (p=0.043, RM 1-way ANOVA). Cre-dependent vCA1 DREADDs together with CaV2-Cre infusion into the mPFC were used to selectively modulate mPFC projecting vCA1 pyramidal neurons to determine the

role of the subnetwork in SMD deficiency. Selective inhibition of mPFC projecting vCA1 pyramidal neurons was also able to rescue SMD (p=0.012, paired t-test). In summary, hyperexcitable vCA1 neurons are critical mediators of epilepsy associated deficits in social memory. These results further demonstrate that circuit-specific modulation may be a viable therapeutic strategy to correct multiple behavioral comorbidities. We extend this conclusion by showing that subnetwork specific circuit modulation may be used to provide specific, targeted correction of behavioral comorbidities.

Title: Not all signals are created equal: spectral differences between brain regions in epilepsy

Authors: *D. REICH[1], P. SALAMI[2], S. CASH[2];
[1]Neurol., Brigham and Women's Hosp., Boston, MA; [2]Neurol., Massachusetts Gen. Hosp., Massachusetts, MA

Abstract: Intracranial EEG (iEEG) is used both clinically and increasingly for research into questions of basic neuroscience; over the last few decades, scientists have relied on iEEG recordings to study the role of different brain regions in various cognitive tasks. While the majority of this research has been performed in epileptic brain, it is unclear how such pathology affects the physiological activities of each brain region. In this study, we seek to address this question by evaluating how the epileptogenicity of a region impacts its regular neural dynamics, as measured through the spectral power estimates of the iEEG signal.
Five-minute interictal periods of awake (n=99) and asleep (n=98) data from patients (n=33) with medically refractory focal epilepsy who underwent presurgical evaluation with iEEG were analyzed. The spectral power in six frequency bands (delta, theta, alpha, beta, low gamma, and high gamma) was evaluated and compared across seven brain regions (hippocampus, lateral temporal, frontoparietal, cingulate, amygdala, occipital, and insula). The analyzed data were classified into four groups: hippocampus (n=19), lateral temporal (n=7), frontoparietal (n=5), and occipital (n=2) lobes, depending on the seizure onset zone (SOZ) of each patient. The power in each frequency band in each region was then averaged over the interictal data in each SOZ group. Within each SOZ group, the average power was compared for all region pairs within each frequency band, using Kruskal-Wallis tests to identify significance (p=0.05).
We found that for hippocampus SOZ, the hippocampus had significantly larger power compared to other regions (non-SOZ) across all bands ($p<0.05$). This trend was also apparent for frontoparietal SOZ, where the frontoparietal lobe had the largest or second to largest power across all bands compared to other

regions. Interestingly, this trend was not conserved for lateral temporal and occipital lobe seizure onsets. For lateral temporal SOZ, the occipital lobe had the largest power across all bands, and for occipital onset, the hippocampus had the largest power across bands. Furthermore, for all SOZs except lateral temporal, the hippocampus had the largest absolute power.
Our findings demonstrate that the relationship between the SOZ and spectral power magnitude is complex. In the hippocampus and frontoparietal lobes, the effect of epileptogenicity on neural dynamics is much more apparent, while less obvious in lateral temporal and occipital lobes. This variability in signals has implications for identifying SOZ for epilepsy, but also more broadly for informing how future analyses and comparisons may need to account for these differences.

Abstract: Alzheimer’s disease (AD) is the most common cause of dementia in the United States and 14 million Americans are expected to develop AD by 2060. Despite the acceleration of AD prevalence, there are no effective treatments, and many recent clinical trials have failed. To identify disease-altering targets, a deeper understanding of the pathophysiology of this devastating illness is needed. Expanding our understanding of the pathophysiology of AD requires knowledge of changes in protein kinase signaling networks. We hypothesize that changes in protein kinase signaling networks are perturbed in AD. Using the PamGene12 Kinome Array platform, we deployed a novel bioinformatics workflow where we identified kinases that are under and overrepresented in the disease using postmortem dorsolateral prefrontal cortex (DLPFC) in AD. Adenosine monophosphate activated protein kinase (AMPK) was identified as a “hit” kinase between control, Mild Cognitive Impairment (MCI), and AD subjects, suggesting that AMPK may be implicated in the transition from MCI to AD. To confirm our bioinformatic findings, we performed AMPK activity assays. AMPK activity was decreased in male and female AD DLPFC. Moreover, we found lower AMPK activity in MCI vs controls, and even lower AMPK activity in AD vs MCI. Inspired by our changes in enzyme activity, we measured changes in transcript expression. Transcript expression of the regulatory subunits of AMPK were changed.

Transcripts for canonical upstream activators of AMPK (Tak1, LKB1, and OGT) were increased. To mechanistically study the phosphorylation profile of AMPK, we knocked down AMPKα1 and AMPKα2 using siRNA (25 pmols) ± AICAR [1 mM], an allosteric activator of AMPK, in primary murine astrocytes. With the PamGene12 Kinome Array, we identified 15 peptides where the peptide phosphorylation was simultaneously increased in the activated cultures and decreased in the AMPK-KD cultures. These 15 peptides were significantly enriched for key metabolic signaling pathways. Examination of these 15 peptides in human postmortem brain as well as astrocytes derived from familial human AD iPSCs revealed differential activity of the AMPK network. Interestingly, increased phosphorylation was observed at Laminin-B1 (LMNB1), a reporter peptide of AMPK, in both male and female subjects as well as astrocytes derived from iPSCs, potentially serving as a novel biomarker of the disease. AMPK and its network represent a potential key node in the pathogenesis and pathophysiology of Alzheimer's Disease. Further work will explore the subunit-specific role of AMPK in driving the Alzheimer's phenotype.

Abstract: Measurement of PIM1 Kinase Activity in Alzheimer's DementiaAuthors: Jacob B. Rethman, Abdul-rizaq Hamoud, Khaled Alganem, Ali S. Imami, Elizabeth S. Shedroff, Nicholas D. Henkel, and Robert E. McCullumsmithAlzheimer's dementia (AD) is the most common cause of dementia in the United States and 14 million Americans are expected to develop AD by 2060. Despite the acceleration of AD prevalence, there are no effective treatments, and many recent clinical trials have failed. To identify disease-altering targets, a deeper understanding of the pathophysiology of this devastating illness is needed. PIM1 is a proto-oncogene serine/threonine-protein kinase involved in the mTOR signaling pathway. This kinase phosphorylates PRAS40 which regulates activity of the mTORC1 protein complex. Accumulating evidence suggests this signaling pathway intersects with AD pathophysiology. Using the PamGene12 Kinome Array, we measured protein kinase activity for the serine-threonine kinome in AD and control postmortem DLPFC. Using our novel bioinformatic pipeline, we identified PIM1 as an overrepresented kinase "hit" in AD. Furthermore, data from the platform

suggests a decrease in PIM1 activity. We will confirm these findings using a luciferase-based kinase assay for PIM1 activity. PIM1 kinase activity will be measured in dorsolateral prefrontal cortex (DLPFC) homogenates from AD (N=20) and control (N=20) samples. Additionally, PIM1 kinase activity will be measured in schizophrenia (N=20) and control (N=20) samples to access disease specificity. These experiments will be conducted with a specific PIM1 inhibitor to quantify PIM1 activity levels. This data will determine if changes in PIM1 activity are AD-specific or broadly related to disorders of cognitive dysfunction in neuropsychiatric disorders. Furthermore, these findings will validate PIM1 as a "hit" on the kinome array platform. **Keywords:** Alzheimer's Disease, Schizophrenia, PIM1, postmortem, DLPFC

Title: Transcriptomic analyses revealed conserved and divergent molecular pathways in various neurodegenerative diseases

Authors: *A. V. ISLAS BUSTAMANTE GUTIÉRREZ[1,2], A. VARELA-ECHAVARRÍA[2], V. Y. MULEY[2];

Abstract: Neurodegeneration is any pathological condition that primarily affects neurons leading to loss of their structure and function, and ultimately death. The onset of neurodegeneration is exceptionally well associated with aging and often triggers in older adults. Neurodegeneration manifests in clinically and pathologically recognizable phenotypes referred to as neurodegenerative diseases (ND). ND represent a group of neuropathologies that affect specific neurons in certain anatomical parts of the brain. Multiple neuropathologies co-exist in older adults more often than by random chance, and each neuropathology contributes differently to the cognitive impairments and motor functions among affected individuals. Molecular mechanisms underlying such clinical features and differences among ND are largely unknown. There is still a lack of knowledge about the conserved and divergent genetic pathways among ND. In this study, we have analyzed microarray expression datasets from 18 independent studies, available through the GEO database. Each dataset represents expression in degenerative brain tissues from ND patients and healthy tissues and covers all major ND such as Alzheimer's (AD), Parkinson's (PD), Huntington's (HD), and Frontotemporal dementia (FTD), along with rare conditions such as pick disease, progressive supranuclear palsy, and Creutzfeldt-Jakob Disease. The differential gene expression between healthy and each ND was performed and the differentially expressed genes (DEGs) were analyzed for their enrichment in Gene Ontology terms. Consistent with previous studies, DEGs in AD were heterogeneous depending on the disease stage and the tissue source from specific brain regions. Interferon-gamma

signaling pathways were up-regulated in asymptomatic, incipient, and moderate AD patients irrespective of the brain region, and also in patients with neurofibrillary tangles, FTD associated with Progranulin gene mutation. This suggests that the neuronal loss in these patients was induced by JAK/STAT signaling. In contrast, FTD without Progranulin mutation affected muscle contraction and blood pressure pathways. Many DEGs from most ND were enriched in neurotransmitter transport and synaptic organization related pathways. Overall, our results provide evidence on convergence of dysregulated inflammatory immune response and synaptic signal transmission pathways in most ND, and a highly heterogeneous functional landscape in AD patients. These results are being validated using publicly available RNA-sequencing datasets and also analyses being carried out for many rare ND.

Abstract: Motivation: Alzheimer’s disease (AD) is a devastating illness with a great need for highly effective disease modifying therapies. Determining molecular pathways that are driving disease at distinct stages of disease progression in antemortem brain samples is impractical and unethical. To identify stage

specific molecular disease drivers, we apply a machine learning approach to learn a trajectory of disease progression based on whole proteome expression variation in post mortem AD samples.
Methods: We performed whole proteome quantification via mass spectrometry using a data-independent acquisition protocol. We profiled 62 samples derived from superior medial temporal gyrus tissue from three studies (Adult Changes in Thought, University of Washington ADRC, and DIAN) for 24 autosomal dominant AD, 18 sporadic AD, 11 high AD neuropathologic change controls, and 9 low AD neuropathologic change controls. We applied a manifold learning approach (DDRTree) to the proteome data (40,346 peptides from over 5,000 genes across samples) to learn a lineage of disease progression from healthy aging to late stage disease.
Results: Based on the topology of the learned proteome disease lineage, we identify two distinct late stage disease subtypes of AD that are shared across sporadic and mutant PSEN AD cases. One subtype is characterized by loss of expression of 909 (FDR<0.05) proteins involved in intracellular trafficking (e.g. intracellular protein transport GO:0006886, adjusted P-value=$6.865x10^{-3}$) whereas the other subtype is characterized by loss of expression of 670 proteins (FDR<0.05) involved in synaptic function (e.g. synaptic vesicle exocytosis GO:0016079, adjusted P-value=$1.642x10^{-7}$). We demonstrate that genes that are predictive of these subtypes overlap with previously published subtype associated genes from RNA-seq data in sporadic AD cases ($P<1x10^{-3}$) based on a study from the Accelerating Medicine Partnership in Alzheimer's Disease consortium.
Conclusions: Molecular heterogeneity as revealed by proteome variation can help disentangle the molecular etiology of the disease at clinically relevant disease stages. The shared proteomic expression signatures across sporadic and mutant PSEN cases suggests common late stage disease mechanisms - within subtype - between autosomal dominant and sporadic disease. Our results suggest that there are common subtypes of AD characterized by either synaptic dysfunction or intracellular trafficking deficits.

Title: Psychosis in Alzheimer's Disease is Associated with Increased Expression of Ubiquitin Ligases

Authors: *M. R. DECHELLIS-MARKS[1], R. SALISBURY[1], Y. WEI[3], Y. DING[3], J. KRIVINKO[1], O. LOPEZ[1], J. KOFLER[2], M. MACDONALD[1], R. SWEET[1];

Abstract: Psychosis in Alzheimer's disease (AD+P) is a phenotypic variant that affects 40 – 60% of all AD subjects. AD+P is associated with more rapid deterioration compared to AD without psychosis (AD-P). The neurobiological basis of psychosis in AD is poorly understood. Neuroimaging studies which compared AD+P to AD-P have found decreased synaptic indices in the dorsolateral prefrontal cortex (DLPFC). Previously, we reported that the presence of multiple neuropathologies is a minor fraction of the risk of psychosis in AD. However, we found that canonical synaptic proteins levels in cortical gray matter are reduced in AD+P compared to AD-P, suggesting that vulnerability to psychosis may be, in part, driven by loss of synaptic proteins. To determine if protein level differences were driven by transcriptional changes we performed RNA sequencing, finding only a mild correlation between synaptic transcript and protein levels (DeChellis-Marks., *In Review).* We further found altered mRNA expression of genes involved in multiple posttranscriptional pathways Taken together, these results suggests that the synaptic proteome in AD+P is differentially perturbed by post-transcriptional mechanisms that alter protein availability.
In this study we asked (1) if gray matter proteins are differentially abundant and (2) which post-transcriptional pathways may be driving the synaptic protein availability differences between AD-P, AD+P, and controls. We evaluated the proteome of 129 subjects (Neuropathological Controls: 19; AD-P: 49; AD+P: 61) by lysing DLPFC tissue. We performed TMT labeling and high-pH reverse phase fractionation to increase depth and resolution of the proteome. We quantified more than 3,000 proteins at 90% present call. Our preliminary analysis also identified 186 proteins that were nominally significantly differentially expressed in AD+P compared to AD-P (uncorrected p-value < 0.05). 137 (74%) of these proteins were upregulated in AD+P relative to AD-P. Interestingly, functional annotation identified the proteins altered in AD+P to be enriched for the protein ubiquitination pathway (uncorrected p = 3.42E-10; B-H corrected p = 1.59E-7). Altered protein ubiquitination pathway activity suggests that the relative decrease in synaptic protein levels in AD+P may be a result of protein degradation.

Abstract: Dendritic spines are highly dynamic structures enriched with actin, which undergoes activity dependent modification to control the synaptic and cognitive functions. The dynamic equilibrium between globular and filamentous actin modulates the spine morphology and synaptic plasticity. The rapid turnover of actin during assembly/disassembly is finely regulated by several actin binding proteins at the synapse. We have shown that perturbation of F-actin and total dendritic spines in one month old APP/PS1 mice and primary cortical neurons. However, the molecular mechanisms involved in F-actin loss in synaptosomes, the underlying factors and the functional consequence needs to be elucidated. Thus, characterizing the actin interactome from synaptosomes of wildtype and APP/PS1 mice delineates molecular mechanisms involved in the synaptic dysfunction during AD. Here, we isolated synaptosomes, F-actin and G-actin fractions from synaptosomes, performed immunoprecipitation followed by LC-MS/MS analysis. We detected 1053 proteins in WT and 988 proteins in APP/PS1 mice at the age of six months in synaptosomes. We detected 350 common actin interacting proteins in synaptosomes of WT and APP/PS1 mice. Additionally, we found that 209 proteins in WT and 256 proteins in APP/PS1 are uniquely associated with actin. From F-actin fraction, we identified 130 proteins specific to WT and 70 proteins specific to APP/PS1. We also found 224 common proteins interacting with actin in F-actin fraction. Our proteomic analysis of actin interacting proteins in the synaptosomes isolated from six month old WT and APP/PS1 mice revealed proteins with significant differences in actin interactome with respect to proteins involved in synapse organization, protein translation and energy metabolism.

Title: Age-dependent hippocampal proteomics in the APP/PS1 alzheimer mouse model by directDIA

Authors: *S. J. F. VAN DER SPEK, M. A. GONZALEZ-LOZANO, F. KOOPMANS, S. S. M. MIEDEMA, I. PALIUKHOVICH, A. B. SMIT, K. LI;

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder. Currently a cure is lacking, and the cause remains largely unknown. However, toxic effects of amyloid beta are believed to play a major role in AD pathogenesis. These toxic effects are in part recapitulated in the Amyloid Precursor Protein swe/Presenelin 1 dE9 (APP/PS1) mouse model of AD. In the current study, we analyzed the proteome of a hippocampal synapse enriched fraction obtained from APP/PS1 mice and their wildtype controls at 6 and 12 months of age. For the analysis, we performed label free-quantification proteomics by data independent acquisition (DIA). First, we compared the use of a classical DIA analysis with a recently improved directDIA workflow, that does not require the use of a project specific spectral library. Subsequently, directDIA was applied to the 6- and 12-months APP/PS1 datasets and differential expression analysis was performed using the Mass Spectrometry Downstream Analysis Pipeline (MS-DAP). Strongest regulation of proteins was observed at 12-moa. Especially proteins involved in amyloid beta homeostasis and microglial-dependent processes, like synaptic pruning and immunoreactivity, including APOE, CLU and C1CA-C.

Title: Early impairments of fear memory extinction and amygdala plasticity in the TgF344AD rat model of Alzheimer's disease are distinct from impairments in non-pathological aging

Authors: *C. M. HERNANDEZ, N. L. JACKSON, M. E. BAGLEY, L. L. MCMAHON;
Cell, Developmental and Integrative Biol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Alzheimer's disease (AD) is accompanied by cognitive impairments affecting several memory domains. One such domain, emotional memory, is supported by a vast network of medial temporal lobe structures which are negatively impacted in AD. Human studies suggest the inability to acquire aversive emotional (fear) memories may be an early sign of AD that occurs prior to measurable cognitive impairments. The transgenic Fischer344 AD (TgF344AD) rat model recapitulates many aspects of human AD. The current study used behavioral and electrophysiological approaches in TgF344AD rats to define the contributions of genotype and age to fear memory impairments in AD. Young adult (YA, 6 mo) and middle-aged (MA, 14 mo) non-Tg (nTg) and TgF344AD (Tg) rats were trained on a contextual fear conditioning paradigm consisting of acquisition (tone, CS; shock, US), extinction (CS), retrieval (CS),

and renewal (CS) with a 24-hr delay between each test. At least 3 weeks post-testing, rats were sacrificed for *ex-vivo* slice electrophysiology to record extracellular field potentials from the basolateral amygdala. Synaptic physiology experiments included measuring the strength of basal excitatory transmission in input/output curves, and the magnitude of long-term potentiation (LTP) induced by high-frequency stimulation.In YA adult rats, there was no effect of genotype on acquisition, although, YA Tg rats showed extinction impairments that carried over to retrieval and renewal testing. These extinction impairments in YA Tg rats may be due to increased strength of basal transmission, synaptically driven hyperexcitability, and attenuated LTP magnitude. In MA nTg rats, there were acquisition and extinction impairments relative to young nTg rats. While there were no differences in the input/output relationship of peak field potential amplitudes, hyperexcitability and attenuated LTP magnitude was observed in MA nTg rats relative to nTg. Interestingly, MA Tg rats showed an enhanced ability to extinguish fear expression to the CS relative to MA nTg. However, MA Tg rats continued to show impairments in retrieval and renewal. Enhanced extinction in MA Tg rats may be associated with BLA compensatory mechanisms, as MA Tg rats showed attenuated field peak amplitudes, while having greater hyperexcitability, with no difference in LTP relative to MA nTg rats. These data recapitulate early deficits in human AD patients and further suggest deficits in AD manifest distinctly from nonpathological aging.

Title: Investigating the effects of increasing O-GlcNAc in the TgF344-AD Alzheimer’s disease rat model

Authors: *M. L. GARCIA, B. M. LANGNER, N. L. JACKSON, L. L. MCMAHON;
Univ. of Alabama, Birmingham, Birmingham, AL

Abstract: Alzheimer’s disease (AD) is currently ranked as the sixth leading cause of death in the United States, with more recent estimates indicating that it may rank up to third in older populations. In 2020 alone, it is projected that AD directly cost Americans over $300 billion, with this number growing exponentially every year. This is because the greatest risk factor for developing AD is aging, and as our aging population is expected to rise, so too will the incidences of AD. Current estimates by the Center for Disease Control and Prevention (CDC) expect AD cases to reach over 14 million cases by 2060. Unfortunately, there are few advances in treatment options, and this is further complicated by limitations in rodent models that recapitulate human AD both at the level of histopathology and behavioral phenotypes. One of the earliest regions of pathological change in humans with AD is the Locus Coeruleus

(LC), with accumulationof hyperphosphorylated Tau (pTau). The LC is critically important as it is the only source of noradrenergic (NA) input into forebrain region, specifically the hippocampus. It has been known for several decades that the NA input is vital to many physiological processes, and has been shown to be required for spatial learning and memory as well as contextual fear. One treatment receiving robust attention is O-GlcNAcylation, the O-linked attachment of the β-N-acetylglucosamine (O-GlcNAc) to serine/threonine residues. Importantly O-GlcNAcylation competes with phosphorylation on Tau at key serine residues. Accordingly, pharmacologically increasing O-GlcNAcylation using an inhibitor of O-GlcNAcase, Thiamet-G, decrease pTau levels in transgenic mice (add the mouse type) as well as improve spatial learning and memory.. Currently several OGA inhibitors are in clinical trials for other tauopathies as well AD, however; it is not known how a chronic increase in O-GlcNAcylation will affect other pathology or immune systems. Our study tests the hypothesis that an increase in O-GlcNAc will decrease overall histopathological markers in a novel rat model of AD, the TgF344-AD. This model exhibits many features of early onset pathology in human AD including pTau accumulation in LC and degeneration of noradrenergic fibers in hippocampus. To test this hypothesis we will treat WT and Tg animals with Thiamet-G, an O-GlcNACase inhibitor, to chronically increase O-GlcNAcylation. We will then assess markers of AD pathology, including amyloid-beta and pTau, as well as other inflammatory markers. This novel work will investigate the possible mechanisms/pathways that are improved by increasing O-GlcNAc.

Title: Disrupting the Dkk1-LRP6 interaction attenuates synapse loss reduces beta-amyloid production and preserves cognition

Authors: *J. D. JACKSON[1,2], C. ELLIOTT[3,4], G. WILLIAMS[4], N. ASHTON[4], J. FINDLAY[3,5], M. ULMSCHNEIDER[6], A. HYE[4], C. BALLARD[6], M. HARTE[7], R. AL-SHAWI[8], G. BAILLIE[3], P. SIMONS[8], R. KILLICK[4], W. XIA[1,2];

London, London, United Kingdom

Abstract: Loss of central synaptic connectivity is a central to the etiopathology of Alzheimer’s disease. The underlying mechanisms driving synapse loss remain poorly understood. However, increasingly evidence point to a disruption in Wnt signalling playing a major, if not central role. This disruption is most likely the result of the ability of β-amyloid (Aβ) to induce Dickkopf-1 (Dkk1). Dkk1 binds to LRP6,

removing it from the Frizzled co-receptor complex and, in so doing, antagonises the canonical arm of Wnt signalling, whilst concomitantly enabling activity in the non-canonical, or β-catenin-independent, arms of Wnt signalling to proceed. We have shown that in neurons this process leads not only to the loss of synapses but to further Aβ production too. We hypothesised that by disrupting the binding of Dkk1 to LRP6 synapses would be protected, and Aβ production reduced. Here we report the mapping of the Dkk1-LRP6 interaction by peptide array and the development of a disruptor peptide derived from Dkk1 which reversibly binds LRP6 with high-affinity. This disruptor peptide restores Wnt-β-catenin activity in the presence of Dkk1 in a dose dependent manner. In primary rat neuronal cultures it protects against Dkk1-driven reduction in dendritic spines and lowers the concomitant production of endogenous $A\beta_{1\text{-}38,\ 1\text{-}40}$ and $_{1\text{-}42}$. Following intracerebroventicular administration the peptide preserves cognitive performance in an acute rat model of oligomeric $A\beta_{1\text{-}42}$ mediated memory impairment. These new data further support the contention that the induction of Dkk1 and its effects on LRP6 are an important element of Alzheimer's disease neuropathogenesis, and establish Dkk1 as a therapeutic target through which one might combat this intractable disease.

Title: Axonal Aβ stress induced tau mislocalization causes retrograde synaptic defects within a compartmentalized in vitro model system.

Authors: *T. NAGENDRAN[1], J.-H. TSENG[2], T. J. COHEN[3], A. M. TAYLOR[1];
[1]Xona Microfluidics, Inc., Durham, NC; [2]Neurosci. Ctr., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Neurol., Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Tau protein tangles and brain atrophy are hallmarks of Alzheimer's Disease (AD). An early cellular event in the progression of AD is the mislocalization of pathological tau from the axon to the somatodendritic compartment of affected neurons. Following this mislocalization, pathological tau is released and taken up by adjacent neurons and cells. However, the molecular mechanisms that regulate tau mislocalization and how neuronal function is affected, remains unclear. To test whether exposure of axons to Aβ challenge regulates tau mislocalization and leads to synaptic defects, we cultured E18.5 rat hippocampal neurons in compartmentalized microfluidic chambers. Isolated axons at 9-10 days in vitro were treated with Aβ conditioned media (Aβ-CM) for 24 h. Aβ-CM, collected from Aβ oligomer-challenged microglia, contains neuroinflammatory factors that induce neuritic tau beading with exposure to non-compartmentalized neurons. Restricted exposure of Aβ-CM to axons within compartmentalized

chips for 24 h caused a redistribution of tau to the somatodendritic compartment in the absence of neuritic beading. In addition to tau mislocalization, we found that exposure of axons to Aβ-CM for 24 h was sufficient to cause a significant increase in synaptic vesicle release rate. We quantified synaptic vesicle release rate by using a FM dye based optical method in conjunction with electrical stimulation. Further we found that application of a local activity blockade (tetrodotoxin and low calcium) at the time of treatment largely inhibited the mislocalization of tau puncta and normalized the synaptic vesicle release rate. To confirm that tau mislocalization causes the change in presynaptic vesicle release, we cultured tau knock-out (KO) and wildtype (WT) neurons within compartmentalized microfluidic chambers and treated their axons with Aβ-CM for 24 h. We found that exposure of tau KO axons to Aβ-CM did not affect the proportion of responsive FM puncta in the somatodendritic compartments in contrast to WT neurons treated with Aβ-CM. These results indicate that tau mislocalization causes synaptic defects and these defects are ameliorated by pharmacological activity blockade. Together, our results provide confirmation that tau redistribution can be quantified in our *in vitro* model in advance of cell death, mirroring AD phenotype *in vivo* and providing a unique platform to identify therapeutic targets that may reduce the spread of AD pathology in the brain.

Title: Role of Nogo-A as a plasticity suppressor in APP/PS1 mice model of Alzheimer’s Disease

Authors: *M. VAZQUEZ[1], S. NAVAKKODE[2], S. SREEDHARAN[1];
[1]Natl. Univ. of Singapore, Singapore, Singapore; [2]Nanyang Technological Univ., Singapore, Singapore

Abstract: Nogo-A, a myelin associated protein, is long known as a neurite growth inhibitor. However, in recent years, the role of Nogo-A as a plasticity suppressor has gained more importance. Nogo-A has been shown to inhibit protein synthesis dependent long-term potentiation (late-LTP), a cellular correlate of learning and memory. Interestingly, Nogo-A has been found to be overexpressed in the hippocampus of Alzheimer’s disease (AD) patients, however its role in AD remains elusive. Alzheimer’s disease, a progressive neurodegenerative disease, is the most common type of dementia in the world. Although much research has been done, the molecular cause of the disease remains unknown and thus, till date, there are no effective treatments. Therefore, further research on the molecular basis of the disease is

needed. In our study we have focused on the role of Nogo-A as a plasticity suppressor in the hippocampus of APP/PS1 mice which is an AD mice model. Loss of synaptic plasticity has been reported in AD mice at 3 months of age, a timepoint that is earlier than the widespread neuron death observed at a later stage of the disease, which signifies that loss of synaptic plasticity is one of the first events to occur in the progression of the disease. Considering these aspects, we hypothesized that the early loss of synaptic plasticity could be reversed by inhibiting the Nogo-A protein in APP/PS1 mice. Our results showed that inhibiting the Nogo-A pathway via Nogo receptor antibody (Nogo-R ab) led to the rescue of late-LTP in APP/PS1 mice. Next, we tested whether the rescue of synaptic plasticity can be achieved in aged APP/PS1 mice, in which the pathology is more advanced. We found that inhibiting the Nogo-A pathway also led to the rescue of late-LTP in aged APP/PS1 mice. Additionally, we tested whether inhibition of the Nogo-A pathway would also rescue Synaptic Tagging and Capture (STC), a cellular model for associative plasticity and memory, which has also been found to be impaired in APP/PS1 mice. Inhibition of the Nogo-A pathway via Nogo-R ab led to the rescue of STC in APP/PS1 mice. Overall, our results revealed the beneficial role of inhibiting Nogo-A to rescue plasticity in neurodegeneration.

Title: Beta Amyloid-Induced Dysregulation of the Exocyst Complex Impedes Postsynaptic Receptor Trafficking and Alters Dendritic Spines

Authors: *K. M. ORMSBEE, B. FOGELGREN, R. A. NICHOLS;
Cell and Mol. Biol., Univ. of Hawaii, Honolulu, HI

Abstract: Synaptic dysfunction and loss are hallmarks of the early pathogenesis of Alzheimer’s disease (AD), leading to impaired cognitive function, including disruption of memory processing. Accumulation of neurotoxic oligomeric beta amyloid (Aβ) in the prodromic period leading up to AD is thought to contribute to dendrite atrophy, altered dendritic spine dynamics resulting in synaptic dysfunction and spine loss, but the molecular mechanisms for these Aβ-associated changes are still unclear. The exocyst has been studied extensively in yeast and other mammalian cell types, but little is known of role of the exocyst at the synapse. The exocyst complex is an eight-subunit complex implicated in vesicle tethering and trafficking preceding fusion facilitated by SNARE proteins. Preliminary work in our lab has found evidence of exocyst involvement in APP trafficking in murine primary neurons. This insight prompted us to investigate exocyst involvement in trafficking of certain key synaptic receptors when challenged by Aβ. Aβ oligomers may disrupt synaptic plasticity through dysregulation of postsynaptic glutamate receptor trafficking. Disruption of this balance has been found to modulate dendritic spine size, and may

prompt dendritic spine elimination. Aβ oligomers have been shown to promote AMPAR endocytosis, but the impact of Aβ on dysregulation of exocyst-dependent AMPAR exocytosis onto the postsynaptic membrane has not been explored. This study is assessing a novel role for the exocyst in Aβ-induced dysregulation of AMPAR GluA1 delivery, culminating in a decrease in dendritic spine density. Mouse primary hippocampal neurons were treated with Aβ and changes in dendritic spines were quantified via immunocytochemistry. Preliminary results show an increase in Exoc1 staining following Aβ treatment, correlating to decreased postsynaptic AMPAR GluA1 presence, diminished spine size and overall increased dendrite simplification. Live imaging will be conducted to visualize the Aβ induced modulation of the exocyst complex to further elucidate the potential consequences of these changes in exocyst function on dendritic spines.
Understanding how Aβ modulates postsynaptic receptor trafficking may reveal key events in disease pathogenesis, allowing for targeted intervention.

Title: Rescue of the pathological effect of amyloid precursor protein intracellular domain on synaptic plasticity in hippocampal CA1 pyramidal neuron in early Alzheimer's disease: a computational modeling study

Authors: *J. DAINAUSKAS[1], M. MIGLIORE[2], H. MARIE[3], A. SAUDARGIENE[4];
[1]Lithuanian Univ. of Hlth. Sci., Kaunas, Lithuania; [2]Natl. Res. Council, Palermo, Italy; [3]Inst. de Pharmacologie Moleculaire et Celluaire (IPMC), Valbonne, France; [4]Dept. of Informatics, Vytautas Magnus Univ., Kaunas, Lithuania

Abstract: Alzheimer’s disease (AD) is a progressive memory loss and cognitive dysfunction brain disorder brought on by the dysfunctional amyloid precursor protein (APP) processing and clearance of APP peptides. Increased APP levels lead to the production of AD related peptides such as amyloid beta and the amyloid APP intracellular domain (AICD), and consequently modify the intrinsic excitability of the hippocampal CA1 pyramidal neuron and impair synaptic plasticity of Schaffer collateral synapses

(Pousinha et al., Cell Reports 2019).This study explores the extent of AICD effect on synaptic plasticity at Schaffer collateral synapses in early AD and the possible treatment targets. We used a detailed compartmental computational model of CA1 pyramidal neuron (Migliore et al., PLOS Comp Biology 2018) and a modified NMDA receptor-dependent voltage-based model of synaptic plasticity (Clopath et al., Front. Synaptic Neurosci., 2010) to analyse alteration in synaptic plasticity at the clustered Shaffer collateral synapses under the effect of AICD. The neuron was stimulated at 2 bursts of 100 Hz for 1 s each to induce long-term potentiation (LTP). We included the influence of the pathological AICD levels by increasing the maximal conductances of SK channels and L-type calcium channels by the factors of 4.5 and 1.3, respectively, and strenghthening the contribution of the GluN2B-containing NMDA receptor (NR2B) at a synaptic level by a factor of 4 (Pousinha et al., Elife 2017). Our simulation reproduced experimental results shutting down synaptic plasticity during LTP induction protocol (Pausinha et al., Cell Reports 2019). The possible rescue of the AICD effects on impaired synaptic plasticity was modeled by blocking the SK channel and NMDA NR2B conductances. The results show that the strength of synaptic plasticity is gradually restored as the SK channel and NMDA NR2B conductances are decreased. When both SK channel and NMDA NR2B conductances are downscaled by a factor of 0.6 or lower if compared to the pathological AICD level conditions, synaptic plasticity is restored due to the absence of the overactivation of SK channels by NMDA NR2B-mediated calcium influx. The computational model provides us with the insights into the complex interactions of intrinsic neuronal excitability and synaptic plasticity mechanisms in AD pathophysiology, and allows suggesting the conditions under which the pathological effects of AICD increase can be negated and normal function can be restored.

Title: Synaptic density in atypical and non-Alzheimer’s dementia

Authors: *A. DIFILIPPO[1], Y. XIN[2], T. BARNHART[1], T. BETTHAUSER[1], J. ENGLE[1], M.-E. PASQUESI[1], S. C. JOHNSON[1], B. B. BENDLIN[1], B. T. CHRISTIAN[2];
[1]Dept. of Med. and Publ. Hlth., [2]Waisman Ctr., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Objectives: [^{11}C]UCB-J is a PET radioligand which specifically binds to synaptic vesicle glycoprotein SV2A and is designed to reflect synaptic density. The accumulation of beta amyloid plaques and neurofibrillary tau tangles distinguishes Alzheimer’s from other dementia-causing diseases. While

people with Alzheimer's disease typically present with cognitive impairment, there have been cases where no clinical presentation of disease is present despite a significant accumulation of plaques and tangles. In this analysis we are looking to analyze hippocampus UCB-J uptake in these participants when compared to a control group.
Methods: Thirty-one participants (67.5±6.7 years old, 18F/11M) recruited from the Wisconsin ADRC and the Wisconsin Registry for Alzheimer's Prevention study underwent [^{11}C]UCB-J dynamic PET imaging to assess synaptic density, T1w-MR imaging, and the Rey Auditory Verbal Learning Test (RAVLT). Of this group twenty are cognitively unimpaired. [^{11}C]PiB dynamic imaging was performed to assess amyloid-β plaque accumulation and [^{18}F]MK-6240 dynamic imaging to assess neurofibrillary tangle accumulation. Subject-specific hippocampus ROIs for [^{11}C]UCB-J analysis were defined using FreeSurfer (v7) segmentation of the participant's MR image. [^{11}C]UCB-J uptake was quantified by calculating the distribution volume ratio (DVR) using SRTM2. **Results**: Twenty participants were cognitively unimpaired, eighteen with no significant plaque accumulation (CU A-) with a hippocampus UCB-J distribution volume ratio DVR of 0.99±0.07. Despite their cognitively unimpaired status two participants had significant plaque and tangle accumulation (CU A+T+) and a hippocampus UCB-J DVR of 0.99±0.02. Two participants were found to have dementia but are low accumulators of plaques and tangles (Dementia A-T-) with a hippocampus UCB-J DVR of 0.77±0.11. **Conclusions:** This preliminary data suggests that [^{11}C]UCB-J uptake in the hippocampus is unchanged in participants with a significant amount of plaques and tangles in the absence of cognitive impairment. It was also observed that participants with a lack of significant plaques and tangles with dementia-level cognitive impairment show decreased uptake in the hippocampus compared to the CU A-T- control group. This shows that [^{11}C]UCB-J may be helpful in determining changes in cognition as well as determining why participants with significant amounts of plaques and tangles seem to have a resilience to clinical presentation of the disease.

Title: Adult hippocampal neurogenesis in a preclinical model of sporadic a Alzheimer's disease

Authors: *G. CERVANTES[1], C. CARRILLO PRADO[1], S. DIAZ-CINTRA[2], P. C. BELLO-MEDINA[2]; [1]Escuela Nacional de Estudios Superiores, Unidad León, Univ. Nacional Autónoma de México, León, Mexico; [2]Dept. de Neurobiología del Desarrollo y Neurofisiología, Inst. de Neurobiología Campus Juriquilla, Univ. Nacional Autónoma de México, Querétaro, Mexico

Abstract: Most of the cases of Alzheimer's disease in patients (95%) are sporadic (ADs). So the ADs mice model has been implemented by the administration of intracerebroventricular streptozotocin (STZ-icv), which produces a decrease in glucose in the brain, neuroinflammation, cholinergic deficit, oxidative stress, and impairment in learning and memory. It is now recognized that adult neurogenesis (AN) plays an important role in learning and declarative long-term memory. On the other hand, the overtraining (increase in training sessions number) of a spatial task produces structural changes that modify the functioning of the hippocampus network and facilitate learning and memory. The objective of this study is to evaluate the effect of overtraining in the Morris water maze (MWM) on adult neurogenesis on the dentate gyrus (DG) in an STZ-icv induced model of AD. CD1 mice were administered vehicle (VEH) or STZ-icv (3.0 mg/Kg). Body weight was recorded for 30 days, subsequently, they were subjected to the MWM task. The mice were randomly assigned in four groups: 1) STZ-Naïve, 2) STZ-swimming control without training, 3) STZ-MWM1 who were trained in one session (8 trials each), or 4) STZ-MWM3 who were trained in three sessions (8 trials each), all groups count their respective controls (VEH). The doublecortin protein (DCX) detection was realized with immunohistochemistry in the ginu, upper blade, and lower blade of DG of the dorsal hippocampus. A decrease in body weight was observed in all groups during the administration of the STZ-icv and on day 5, the weight was increased in the VEH compared to STZ groups, who presented a significant decrease from day 2 to 17. In the MWM has been observed a decrease in escape latency in the MWM1-VEH and MWM3-VEH groups. The MWM1-STZ group did not show any significant decrease, however, the MWM3-STZ decreased its latency on the third day of training similar to the MWM1-VEH group. Histological analysis of the DCX protein (AN marker) in the dorsal hippocampus GD is in progress. We thank A. Aguilar Vázquez and N. Hernández Ríos for their excellent technical support. The present work was supported by PAPIIT IN204519.

Title: Multiscale and multimodal imaging of AD pathology reveals amyloid plaque-associated neuronal and mitochondrial abnormalities

Authors: V. SAMPATHKUMAR[1], S. FOXLEY[2], H. B. DODIYA[4], **H. GAN**[6], A. J. GARCIA, III[5], S. SISODIA[3], *N. KASTHURI[7];

Abstract: Diseases of the brain typically exhibit pathology in various cell types and at multiple scales. Alzheimer's disease (AD), for example, involves dysfunctions of neurons, glia and vessels, with abnormalities ranging from changes at individual synapses to the dysregulated metabolism in various brain regions. Thus, understanding AD requires information about pathological changes at both macro and nano scales, preferably, in the same brain. No current technology is suitable or practical for such a purpose. We address this gap by adapting our recently reported pipeline for multiscale multimodal imaging of entire brains using MRI, micron scale synchrotron source X-ray microscopy, and automated serial electron microscopy (EM). With this pipeline, we are able to image brain pathology over six orders of magnitude in resolution in the same AD transgenic mouse. Synchrotron source X-ray microscopy clearly reveals the composition of individual plaques in various brain regions corresponding to MRI imaging. The speed of X-ray microscopy allows rapid evaluation of amyloid plaque accumulation over multiple experimental conditions including developmental ages, across different transgenic lines, and in mouse models of sleep apnea. Large volume EM reconstructions of the same brains reveal deficits of neuronal networks and mitochondrial abnormalities associated with amyloid plaque deposition. We envision that this multiscale multimodal imaging pipeline will greatly facilitate the investigation of pathogenic processes in human AD brains as well as in mouse models of AD.

Abstract: Beta-amyloid (Aβ) deposition is the earliest pathology associated with Alzheimer's Disease (AD). However, the relationship between Aβ and cognitive decline, be it in healthy aging or preclinical AD, (i.e., in mild cognitive impairment, MCI), is not completely understood. While summary measures of total cortical Aβ deposition may be correlated with cognitive performance, few studies have identified relationships between regional Aβ and specific cognitive deficits. In-vivo imaging studies are vital to advancing our understanding of the role of Aβ in preclinical AD. In this study, we used data driven analyses of Aβ-PET to investigate the relationship between the spatial distribution of Aβ deposition and domain-specific cognitive impairment. Forty-seven participants with multi-domain amnestic MCI (md-aMCI) and thirty-seven healthy, cognitively normal comparison subjects underwent clinical and neuropsychological assessments and high-resolution positron emission tomography (PET) to measure Aβ deposition. Voxel-wise and partial least squares correlation (PLSC) analyses were conducted to identify spatial patterns of Aβ deposition that best correlated with performance on the California Verbal Learning Test (CVLT), the Brief Visual Memory Test (BVMT) and the Delis-Kaplan Executive Function System (DKEFS) measures of semantic and phonemic fluency. Statistical significance of the identified spatial patterns of amyloid was assessed using permutation testing and confidence intervals were estimated via bootstrapping. Significant clusters were defined to exceed 50 contiguous voxels correlated at a significance level of $p < 0.001$. We found that md-aMCI was associated with greater Aβ burden relative to comparison subjects. Within the md-aMCI cohort, but not comparison subjects, distinct regional patterns of Aβ correlated with impaired performance in immediate verbal recall ($R = -0.48 \pm 0.06$, $p < 0.001$), delayed verbal recall ($R = -0.39 \pm 0.08$, $p < 0.001$), immediate visual-spatial recall ($R = -0.48 \pm 0.06$, $p < 0.001$), delayed visual-spatial recall ($R = -0.54 \pm 0.06$, $p < 0.001$) and semantic fluency ($R = -0.41 \pm 0.06$, $p < 0.001$) but not in phonemic fluency. These results suggest that among those with mild cognitive impairment, regional deposition of Aβ may be correlated with the nature and degree of cognitive deficits.

Title: NMDA receptor GluN3A subunit as a pathogenic regulator of sporadic Alzheimer's disease

Authors: *S. P. YU[1], W. ZHONG[1], K. BERGLUND[1], X. GU[1], M. Q. JIANG[1], L. WEI[2];
[1]Emory Univ., Atlanta, GA; [2]Emory Univ., Decatur, GA

Abstract: Abstract: Alzheimer's disease (AD) is a common neurodegenerative disease, evolving amyloidosis and tau protein hyperphosphorylation, synapse dysfunction, neuron degeneration, and cognitive deficits. Extensive investigations based on the Aβ/tau hypothesis have been performed in transgenic animal models expression familial/mutated AD genes. However, treatments based on this hypothesis, including the recent amyloid antibody Aduhelm, have not provided effective clinical therapies. Hyperactivity of the glutamatergic NMDA receptor (NMDAR) is a common pathophysiology of AD and has been viewed as a consequence of Aβ pathology. Among NMDAR subunits GluN1, 2, 3 (NR1, 2, 3), GluN3A is an inhibitory subunit that suppresses NMDA currents and Ca^{2+} influx. Recent evidence from rodent and human studies shows that GluN3A is widely expressed and plays important functional roles in neonatal and adult brains. Cellular Ca^{2+} overload is a trigger of excitotoxicity, while GluN3A may play a regulatory role in Ca^{2+} homeostasis. The role of GluN3A regulation in AD is unknown. We tested the novel hypothesis that chronic neuronal hyperactivity and Ca^{2+} dysregulation caused by GluN3A deficiency could lead to slowly advanced "neurodegenerative excitotoxicity", dementia and AD pathology in an age-dependent manner. Ca^{2+} imaging and MultiElectrode Array recordings in GluN3A KO brain slices revealed moderate but sustained elevation of cytosolic Ca^{2+} levels, neuronal hyperactivity, and impaired synaptic plasticity compared to age-matched controls. Aging GluN3A KO mice showed increased Ca^{2+}-dependent signals, chronic inflammation, neuronal loss and recapitulated the disease symptoms including early onset of olfactory dysfunction followed by cognitive deficits. The AD hallmarks, including β-amyloid deposition and tau protein hyperphosphorylation, were identified as a late pathology in the cortex and hippocampus. In the "gain of function" experiment, expression of GluN3A in the GluN3A KO brain prevented AD progression. Early treatment at the pre-clinical stage using the NMDAR antagonist memantine (MEM; 10 mg/kg/day, 3 months) prevented/attenuated symptoms in GluN3A KO mice. Western blot analysis of AD patient's brains showed lower levels of GluN3A in the cortex compared to normal aging subjects. Our results support the "Ca^{2+} hypothesis" of AD with the novel amyloid-independent mechanism that the deficiency of GluN3A alone causes a slight lifelong Ca^{2+} dyshomeostasis that can lead to AD pathophysiology and amyloid pathology. The long-term GluN3A modulation of NMDARs signifies new therapeutic targets and possible preventive interventions for a sporadic type of AD.

Title: Upregulation of endothelial Picalm with a drug identified from an FDA-approved drug screen ameliorates amyloid pathology in mice

Authors: *K. KISLER, A. P. SAGARE, D. LAZIC, S. A. BAZZI, E. J. LAWSON, C.-J. HSU, E. ZUNIGA, A. R. NELSON, Z. ZHAO, B. V. ZLOKOVIC;

Abstract: *PICALM*, phosphatidylinositol binding clathrin assembly protein, is a known genetic risk factor in Alzheimer's disease (AD). In healthy mice and humans, PICALM is highly expressed in brain endothelial cells, and involved in clathrin-mediated endocytosis, trafficking, and clearance of amyloid-β (Aβ) from the brain across the blood-brain barrier. PICALM brain endothelial levels are reduced in AD. PICALM reduction leads to reduced Aβ clearance from brain and exacerbation of Aβ pathology, which could be reversed by increasing *Picalm* endothelial expression. This suggests that therapeutic strategies that upregulate *Picalm* expression in the vasculature could alleviate brain Aβ pathology. To identify a drug to increase *Picalm* levels, we developed a luciferase reporter assay and screened a library of 2007 FDA-approved drugs. Secondary mRNA screening revealed a lead hit compound, T-65, elevating *Picalm* mRNA and protein levels by 2-3 fold *in vitro* in a human endothelial cell line and *in vivo* in mouse brain endothelium. Treatment of *Picalm*-hemizygous 5XFAD mice with T-65 increased endothelial *Picalm* levels, reduced brain Aβ load, and improved behavior. Endothelial-specific genetic deletion of *Picalm*, however, abolished the beneficial effects of T-65, suggesting that the drug targets endothelial PICALM. Together this confirms the importance of endothelial PICALM and indicates that PICALM upregulation could be a promising new therapeutic strategy for AD.

Title: Memory impairments and synaptic deficits in Tg19959 and APP/PS1 AD model mice are alleviated by eEF2K inhibitor A-484954

Authors: *N. KASICA, X. ZHOU, W. YANG, X. WANG, T. MA;
Wake Forest Univ., Winston Salem, NC

Abstract: Mounting evidence indicates synaptic failure as an early and key event in Alzheimer's Disease (AD) pathophysiology. Maintenance of long-term memory and synaptic plasticity requires *de novo* protein synthesis. Phosphorylation of mRNA translation factor eukaryotic elongation factor 2 (eEF2) by its kinase eEF2K results in inhibition of general protein synthesis. Previous studies have shown elevated levels of eEF2 phosphorylation in post mortem AD human brain tissue and in AD mouse models. Here, we investigated whether suppression of eEF2 phosphorylation via eEF2K inhibitor A-484954 can alleviate AD-associated synaptic failure and memory impairments. Aged Tg19959 mice (6-9 months), APP/PS1 (12-16 months) and age-matched controls were treated with a subcutaneous pellet containing A-484954 or vehicle. The pellet continuously releases treatment over 30 days. Starting two weeks after pellet placement, the mice underwent cognitive assessment via the Novel Object Recognition (NOR) and Morris Water Maze (MWM) tasks. Golgi-Cox Stain, Amyloid Beta immunohistochemistry, Western blots, SUnSET Assays, mass spectrometry (MS) proteomic analysis, and transmission electron microscopy (TEM) were also performed. We found that cognitive impairments displayed in aged Tg19959 and APP/PS1 mice were alleviated with treatment of A-484954. Brain tissue from these mice also underwent high performance liquid chromatography (HPLC) to assess drug concentration in the brain. In addition, Golgi-Cox stain was done to assess dendritic spine density and morphology. Spine analysis indicates a rescue in levels of mature spines in the CA1 region of the hippocampus in APP/PS1 mice treated with A-484954. TEM analysis indicated a rescue in dendritic polyribosome assembly, post-synaptic density (PSD) formation, and PSD length. Additionally, SUnSET assays revealed a rescue in translational capacity in the hippocampi of AD mice treated with A-484954. Taken together, our results suggest that treatment with a eEF2K inhibitor, A-484954, alleviates cognitive impairments, restores synaptic morphology, and rescues translational capacity in mouse models of AD.

Title: Chronic Pharmacological Inhibition of Glymphatic Function Exacerbates Propagation of Tau Pathology in an Animal Model

Authors: *D. M. LOPES[1], J. A. WELLS[1], Z. AHMED[2], M. F. LYTHGOE[1], I. F. HARRISON[1]; [1]Univ. Col. London, London, United Kingdom; [2]Neurosci. Next Generation Therapeut. (NGTx), Eli Lilly and Co., Cambridge, MA

Abstract: The glymphatic system describes the exchange of peri-arterial cerebrospinal fluid (CSF) with interstitial fluid in the parenchymal extracellular space, and peri-venous clearance out of the brain. Facilitated by astrocytic aquaporin-4 channels, this pathway has been shown to effectively clear proteins prone to aggregation in neurodegenerative diseases, such as amyloid-β, tau, and α-synuclein. Many of these proteins have been the focus of intense research efforts in recent years following the discovery of their 'prion-like' mechanism of propagation throughout the brain. The extracellular space, that which is cleared by the glymphatic system, defines the major conduit for cell-to-cell propagation of such proteins in the brain, positioning the glymphatic system as a candidate for therapeutic enhancement for neurodegenerative disease. Here, we tested proof-of-principle, that modulation of glymphatic function affects propagation of tau pathology in an animal model of such pathological aetiology. Tau propagation was initiated in young (2 m.o.) Thy1-hTau.P301S mice (P301S mice), by injection of aged P301S mouse brain homogenate (or wildtype control), into the hippocampus and overlying cortex. Following recovery, animals received chronic treatment with the pharmacological aquaporin-4 inhibitor, TGN-020 (50mg/kg, i.p., 3 times/week) or vehicle for 10 weeks. Behavioural performance was accessed at baseline, 2, 4 and 10 weeks post-injection. At the end of the study, in vivo structural brain MRI scans were acquired for quantification of regional volumetric changes, and CSF and brains were collected for quantification of the extent of tau propagation, aggregation and resultant neurodegeneration following chronic impairment of glymphatic function. Mice chronically treated with TGN-020 exhibited exacerbated outcomes in hippocampal dependent cognitive memory tasks compared to vehicle treated controls. This was accompanied by intensified atrophy in treated brains, and a greater extent of tau aggregation and neurodegeneration following chronic drug treatment.These data suggest that modulation of the function of the water channel aquaporin-4, and by extension the function of the glymphatic system, is capable of altering the extent to which tau is able to propagate throughout the brain. These findings provide hope for therapeutic development against neurodegenerative disorders defined by 'prion-like' propagation, and rationale for further study of the involvement of the glymphatic system in neurodegenerative proteinopathies.

Title: Trametinib restores memory deficits by activating endogenous neurogenesis in mouse model of Alzheimer's disease

Authors: *M.-Y. KIM[1], M. KIM[1], H. KIM[1], K.-J. YOON[2], S. HAN[1];
[1]Genuv Inc., Seoul, Korea, Republic of; [2]Korea Advanced Inst. of Sci. and Technol. (KAIST), Daejeon, Korea, Republic of

Abstract: Alzheimer's Disease (AD) is a neurodegenerative disorder characterized by dementia due to synaptic loss and neuronal death, among many other causes. Proposed treatments based on neurotoxic protein elimination, however, have brought disappointing results until recent controversial approval of Aduhelm™, suggesting that new approaches should be explored. Here, we suggest that encouraging adult neurogenesis from endogenous neural stem cells (NSCs) in patient's brain can be a potential therapeutic for Alzheimer's disease. To develop regenerative CNS drug discovery, we established a phenotype-based drug discovery platform, ATRIVIEW®, aiming to identify agents that induce neuronal differentiation of adult NSCs of AD model mice. Using a FDA-approved drug library, we identified the most potent hit, SNR1611 (Trametinib), a selective MEK1/2 inhibitor. Trametinib induced neuronal differentiation of adult NSCs dose-dependently. MEK1/2 knock-down by shRNA, as trametinib did, induced neuronal differentiation and reduced apoptosis of NSCs derived even from the brain of AD model mouse, 5XFAD. When administered orally, trametinib recuperated neurogenesis in hippocampal dentate gyrus (DG) and subventricular zone (SVZ). Especially, we found evidence of NSCs' existence in the brain cortex and trametinib enhanced neurogenesis from these cortical NSCs. Trametinib administration also rescued cognitive deficits in 5XFAD mice. Altogether, these observations provide evidence that MEK inhibition by trametinib induces endogenous neurogenesis in the brain cortex as well as in the DG/SVZ and is a potential therapeutic approach for the recovery from neurodegeneration. Therefore, we are suggesting that trametinib is a new therapeutic candidate for AD.

Title: Inhibition of G9a ameliorates reactive gliosis in Alzheimer's Disease

Authors: *R. N. SHEEHY[1], L. XIE[2], Y. LI[1], L. J. QUINTANILLA[1], X. CHEN[2], J. SONG[1];

Abstract: Alzheimer's Disease (AD) is a neurodegenerative disease that characterized by progressive cognitive failure. A prominent feature of AD pathology is the extracellular accumulation of amyloid-beta (Aβ) peptides that aberrantly activates astrocytes and microglia, inducing neuroinflammation. The histone/lysine methyltransferase G9a (EHMT2) has recently been implicated in AD. A recent study

showed that enzymatic inhibition of G9a with a partially brain penetrant inhibitor rescued synaptic and cognitive functions in AD mice, implicating constitutively active G9a and G9a-associated pathways in AD etiology. Despite the established role of G9a in synaptic functions, it remains unknown whether G9a regulates glial-mediated neuroinflammation and the transition to reactive gliosis in AD pathology. Our recent data demonstrated that Aβ induces G9a hyperactivity. We hypothesized that a brain penetrant G9a inhibitor would significantly ameliorate reactive gliosis in AD. To test this hypothesis, we treated an Aβ AD mouse model, 5xFAD mice, with a brain penetrant G9a inhibitor. After 3 days of treatment, the hippocampi of treated and control mice were isolated for proteomic analysis. G9a inhibitor treated mice showed a significant decrease in protein abundance of many hallmark AD risk genes, including amyloid precursor protein (APP), Presenilin 1 (Psen1), and Apolipoprotein E (Apoe), as well as a significant reduction in glial fibrillary acidic protein (GFAP), a characteristic marker of astrocytes. Furthermore, immunofluorescence analysis in G9a inhibitor treated detected decreased reactive astrocytes, increased association of microglia with Aβ plaques, and a trending decrease in Aβ plaque abundance. These results suggest that G9a inhibition ameliorates reactive gliosis and may decrease Aβ plaque formation by improving microglia clearance. Overall, our data suggest that G9a is a novel therapeutic target in the treatment of AD and possibly other neuroinflammatory disorders.

Title: Kir6.2-containing KATP channels are necessary for hyperglycemic dependent increases in amyloid-β

Authors: *J. GRIZZANTI[1], M. PAIT[1], L. DEITZELWEIG[1], W. MORITZ[2], M. STANLEY[4], C. M. CARROLL[1], J. A. SNIPES[1], D. M. HOLTZMAN[3], C. NICHOLS[2], S. L. MACAULEY[1]; [1]Gerontology, Wake Forest Sch. of Med., Winston Salem, NC; [2]Dept Neurol., Washington Univ., St. Louis, MO; [3]Dept Neurol., Washington Univ., Saint Louis, MO; [4]Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Aberrant excitability contributes to the production and deposition of Aβ in the Alzheimer's disease brain. Previous work from our lab demonstrated that hyperglycemia, or elevated blood glucose levels, increased brain excitability and Aβ levels potentially through inward rectifying, ATP-sensitive potassium (K_{ATP}) channels. K_{ATP} channels are present on several different cell types and help to maintain excitatory thresholds throughout the brain. K_{ATP} channels are sensitive to changes in the metabolic environment, which are coupled to changes in cellular excitability. Therefore, we hypothesize that neuronal K_{ATP} channels are necessary for the hyperglycemic-dependent increases in extracellular Aβ and knocking out these channels will uncouple the relationship between metabolism, excitability, and Aβ pathology. Kir6.2, the pore forming subunit, and SUR1, the sulfonylurea receptor, heterodimerize to form

K_{ATP} channels preferentially expressed on neurons. To determine the relationship between these channels, Aβ, and hyperglycemia, we crossed APP/PS1 mice with mice lacking neuronal K_{ATP} channels, the Kir6.2 -/- mice. Acutely, we utilized in vivo microdialysis under normal and hyperglycemic conditions to monitor Aβ release into the hippocampal interstitial fluid (ISF) in APP/PS1 mice, with or without K_{ATP} channels. Chronically, we exposed Kir6.2-/-, APP/PS1 mice to high sugar water for 3 months to determine the effects of chronic hyperglycemia on amyloid plaque burden in these mice. We found no difference in steady state ISF Aβ levels in APP/PS1 mice with or without Kir6.2-containing K_{ATP} channels. However, in the presence of a hyperglycemic clamp, Kir6.2+/+, APP/PS1 mice showed a significant increase in ISF Aβ levels compared to Kir6.2-/- mice. This was accompanied by increases in ISF lactate, a marker of neuronal activity. Chronically, Aβ plaque load was comparable between APP/PS1 mice with or without Kir6.2-K_{ATP} channels. When APP/PS1 mice with or without K_{ATP} channels were given a chronic hyperglycemic challenge, Kir6.2+/+, APP/PS1 mice showed a significant increase in cortical and hippocampal plaque deposition, while no increase in plaque load was observed in Kir6.2-/-, APP/PS1 mice. This demonstrates that Kir6.2-containing K_{ATP} channels are necessary for hyperglycemia dependent increases in Aβ levels and amyloid plaque formation and, under hyperglycemic conditions, the absence of Kir6.2 affords protection against further increases in Aβ production and deposition. These data suggest that pharmacological antagonism of Kir6.2-K_{ATP} channels holds therapeutic benefit in reducing Aβ pathology for diabetic and prediabetic patients.

Title: Alzheimer's disease preclinical efficacy database: improving the scientific rigor, reproducibility, and predictive value of preclinical research for alzheimer’s disease

Authors: *S. CHAKROBORTY, A. SHARMA, Z. MARTIN, J. YUAN, S. PETANCESKA, L. REFOLO;
Natl. Inst. on Aging, Bethesda, MD

Abstract: The Alzheimer’s Disease Preclinical Efficacy Database (AlzPED) is a publicly available data repository created by the National Institute on Aging (NIA) to address the poor scientific rigor, predictive value, and translatability of preclinical efficacy studies in Alzheimer’s disease (AD) animal models. The database is designed to house published and unpublished preclinical therapeutic studies incorporating experimental details of both positive and negative data. AlzPED specifically incentivizes the submission of unpublished negative data by providing a platform to create citable reports of these data. Studies are submitted to AlzPED through a curator and obtained from multiple sources. Prior to publication in the database, each study is carefully curated by two experts for data on authors, AD animal models,

therapeutic targets and agents, outcomes and most importantly evaluated for rigor in study design and methodology with a Rigor Report Card consisting of a standardized set of expert-recommended study design elements. AlzPED currently hosts curated summaries for nearly 1200 published therapeutic studies in AD animal models. The database provides easy access to information on study design, 195 animal models, 1019 therapeutic agents, 225 therapeutic targets, more than 2000 AD-related outcomes, principal findings, funding sources, patents, and related clinical trials. Evaluation of Rigor Report Cards from each study demonstrates significant under-reporting of critical elements of methodology such as power/sample size calculation, blinding for treatment, blinding for outcomes, randomization, balancing for sex, animal genetic background, and inclusion/exclusion criteria, these being reported by fewer than 30% of the nearly 1200 curated studies. Our analysis of curated studies demonstrates serious deficiencies in reporting critical elements of methodology. These deficiencies diminish the scientific rigor, reproducibility, and translational value of the preclinical studies. Adopting a standardized set of best practices like those proposed by AlzPED can improve the predictive power of preclinical studies in AD animal models and promote the effective translation of preclinical drug testing data to the clinic.

Title: Low-dose radiotherapy and HDAC inhibition in the 3xTg-AD model of Alzheimer's disease

Authors: *N. RICCIARDI[1], F. MODARRESI[2], I. LOHSE[3], I. NEWMAN[2], M. BROWN[2], C.-H. VOLMAR[2], C. WAHLESTEDT[2], B. MARPLES[4];
[1]Dept. Biochem. and Mol. Biol., [2]Dept. of Psychiatry & Behavioral Sci., [3]Univ. of Miami Miller Sch. of Medicine, Ctr. For Therapeut. Innovation, Miami, FL; [4]Dept. of Radiation Oncology, Univ. of Rochester, Rochester, NY

Abstract: Rationale: Single-target therapeutic approaches for Alzheimer’s disease (AD) have yielded suboptimal results over the last 2 decades in efforts to slow or reverse cognitive decline. Previous work has shown that the epigenetic histone deacetylase 3 (HDAC3) inhibitor RGFP966 can improve memory and hold disease modifying potential. Additionally, our collaborators have shown that cranial radiotherapy is a plausible, noninvasive therapy in pre-clinical AD models. These two multifactorial treatments act by independent mechanisms that complement each other however their historically known side effects at high doses have kept them from clinical exploration. **Objective:** Explore the synergistic potential of low-dose RGFP966 and radiation therapy on AD hallmarks and memory *in vitro* and *in vivo.* **Methods:** *In vitro* studies of innate immune modulation and amyloid precursor protein (APP) processing were performed in cell lines (SIM-A9 and HEKAPP$_{Swe}$) and primary microglia cells via ELISA, Western

blotting, confocal imaging, and RT-qPCR. *In vivo* experiments were performed in 3xTg-AD mice (male and female, n= 6-9/group). Vehicle (V), 3 mg/kg RGFP966 (RGFP), 2 Gy/wk radiotherapy (RT), and low-dose combination therapy (LDCT) animals were treated for 2 months and then behavioral assessment of spatial memory (Y-maze, Barnes maze) and recognition memory (novel object recognition) was performed. Molecular analysis included hippocampal gene expression evaluation by NanoString neuropathology panel, confirmatory RT-qPCR, Western blotting, ELISA assessment of amyloid and tau processing, and blood and hippocampal Luminex panel for cytokine production. All *in vitro* studies were replicated 2-3 times. **Results:** LDCT elicits a tolerant microglial response evidenced by downregulation of master regulator genes (*Spi.1, Iba1*, and *Trem2*) and cytokine gene expression (*Il6* and *Il10*). These genes remain downregulated after stimulation with oligomeric $A\beta_{42}$ compared to control treated cells or individual treatments. LDCT also increases $A\beta_{42}$ uptake in primary microglia and promotes non-amyloidogenic APP processing and neurotrophic gene expression in $HEKAPP_{Swe}$ cells. *In vivo* studies supported the immune down regulation (*Csfr1*) and neurotrophic gene (*Npas4, Bdnf, Fos*) upregulation of LDCT. We also observed modest improvements in memory in the Barnes maze in both RT and LDCT treated animals compared to V treated mice. **Conclusions:** LDCT elicits a unique anti-AD gene expression profile *in vitro* and *in vivo* that does not occur in single-treatment animals. The synergistic potential of LDCT was further supported by modest spatial memory improvements and decreased cytokine production

Title: Near-infrared light stimulation confers neuroprotection against α-synuclein toxicity by activating PGC-1α mediated mitochondrial biogenesis

Authors: *A. S. C. FOO[1,4,5], G. G. Y. LIM[5], H.-J. KIM[2], W. TANG[5], H. C. CHOONG[6], H. Y. CHAN[3], J. S. Y. HO[2], T. W. SOONG[1], K. L. LIM[7,5];

Abstract: There is presently no treatment capable of preventing neuronal death in Parkinson's Disease (PD), a progressive neurodegenerative disorder characterized by the presence of intracellular aggregates containing misfolded α-synuclein. In this study, we examine the neuroprotective and mitochondrial modulatory effects of near-infrared (NIR) light stimulation in in-vitro Parkinsonian models. Using monochromatic light of 680nm wavelength, we treated α-synuclein preformed fibril (α-synPFF) seeded cortical neuronal cultures derived from E16-17 mice embryos and determined the extent of intraneuronal phosphoserine-129 α-synuclein (pS129 α-syn) propagation. Concurrently, we also assessed treated neurons for apoptotic marker expression levels and changes in mitochondrial morphology. To assess the effects of NIR on mitochondrial status, we stimulated monolayer HeLa cell cultures with 680nm monochromatic light and 1) measured cellular adenosine triphosphate (ATP) levels using a bioluminescence assay, 2) quantified mitochondrial membrane potential changes and 3) examined expression levels of fission/fusion and mitobiogenesis-inducing proteins. We observe in cultured cortical neurons that chronic NIR stimulation mitigates intracellular accumulation of pS129 α-syn and reduces expression of the apoptosis driver cleaved caspase-3. Concomitantly, NIR stimulation also reverses mitochondrial elongation induced by α-synPFF seeding in cultured neurons. In HeLa cell cultures, NIR stimulation upregulates the expression of peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1α), a transcriptional co-activator with a central role in the regulation of mitochondrial biogenesis. This is observed in conjunction with increases in cellular ATP levels as well as transcription factor A mitochondria (TFAM) expression; TFAM being a downstream effector molecule of PGC-1α essential for mitochondrial DNA transcription. In addition, we also observe that an upstream promoter of PGC-1α transcription, phosphoserine133-cAMP response element binding protein, is increased in HeLa cells with NIR stimulation. Collectively, these results suggest that PGC-1α mediated mitochondrial biogenesis, triggered by exposure to NIR light, may confer cytoprotection against α-synuclein induced toxicity.

Title: Mitochondrial targeted triphenyl phosphonium ethyl ferulate improved rotenone-induced behavioral deficits, oxidative changes, and mitochondrial dysfunction in rotenone induced rat model of parkinson's disease.

Authors: *A. S. PATIL, M. K.I, S. SATHAYE, M. DEGANI;
Dept. of Pharmaceut. Sci. and Technol., Inst. of Chem. Technol., Matunga, India

Abstract: Parkinson's disease (PD) is one of the most common neurodegenerative disorders. Pathological changes in PD leads to degeneration of dopaminergic neurons in the Substantia nigra area of the brain responsible for controlled movement of the muscles. Ethyl ferulate (ethyl 4-hydroxy-3-methoxycinnamate, EF), an alkyl ester derivative of ferulic acid, has been shown to possess various biological activities like anti-cancer, anti-oxidant, protecting mitochondrial dysfunction, neuroprotective activity etc. In this exploratory work, based on above data suggestive of neuroprotective potential of EF; we decided to explore EF for its anti-Parkinson's potential. Mitochondrial dysfunction is implicated in PD. To address this, we decided to synthesize mitochondrial targeted ethyl ferulate (M-EF) to increase its efficacy. This was done by substituting hydroxyl groups of EF and with a propyl linker and TPP+ moiety. The coupling to TPP+ results in targeting the mitochondrial matrix. The objective of the present study was to evaluate the comparative neuroprotective effect of EF and M-EF against pathological alterations induced by rotenone in rat brain. Rotenone is a known mitochondrial toxicant leading to its dysfunction. In the present study rats were injected bilaterally with rotenone (12 μg) in Substantia nigra and further treated orally with EF (10, 20 and 50mg/kg) and M-EF (1,5 and 10 mg/kg) for 30 days. During the study behavioural tests such as the Rota-rod, open field, and Barnes maze test were performed. At the conclusion of the study, antioxidant (reduced glutathione, superoxide dismutase, catalase, and lipid peroxidation) and proinflammatory (TNF-α) as well as mitochondrial (complex I) characteristics were assessed in mid-brain homogenates. EF and M-EF significantly improved the locomotor activity and the muscle strength as compared to the negative control group. A significant attenuation in the cognitive dysfunction by EF and M-EF was observed in barnes maze test. The effects of EF and M-EF treatment on oxidative stress and inflammation produced by rotenone poisoning were dramatically reduced. Rotenone inhibition of mitochondrial complex I was likewise significantly reduced by EF and M-EF. The preliminary findings show that EF and M-EF have neuroprotective properties against rotenone-induced neurotoxicity in rats. A tenfold higher activity was seen with M-EF as compared to EF. Further confirmation of the activity will be assessed using immunohistochemistry for dopaminergic activity along with mitochondrial function and health.

Title: Profiling MCC-950 as a potent and selective Nod-like receptor family pyrin domain containing 3 (NLRP3) inhibitor for Parkinson's Disease (PD)

Authors: *M. PAPAKOSTA, H. SUN, N. ENGLISH, P. ROLZIN, J. BLIESATH, Y. CHEN, U. BANERJEE, D.-A. HARRIS, C. WRIGHT, A. GREEN, J. MCLAUGHLIN, A. HOLLAND, N. BROADBENT, H. ZOU, M. BAKSH, J. SCHACHTER, T. WOLINSKY, H. ESTRELLA, M. VILKHOVOY, C. ROTTER, T. NISHI, E. CHANG, H. MONENSCHEIN, R. HODGSON;
Takeda Develop. Ctr. Americas, Inc., San Diego, CA

Abstract: PD patients show chronic neuroinflammation, α-synuclein inclusions in the form of Lewy bodies in neurons and substantial loss of dopaminergic neurons projecting from the substantia nigra pars compacta (SNc) to the corpus striatum (Jiang and Dickson 2018). Despite huge advances in understanding PD, safe, effective treatments elude patients. The central nervous system (CNS) inflammatory component in PD is mainly due to chronically activated microglial cells, sensed by the NLRP3 inflammasome, an important component of the innate immune system expressed in the cytosol (Sawada et al 2006; Poewe et al 2017). NLRP3, upon activation by pathogen-associated molecular patterns (PAMPs) or danger-associated molecular patterns (DAMPs) such as misfolded proteins, ATP, nigericin, assembles and oligomerizes with adaptor apoptosis-associated speck-like protein (ASC) and pro-caspase-1 to form multiprotein intracellular complexes, which activate the caspase-1 cascade. Proinflammatory cytokines (interleukin (IL)-1β and IL-18) are released, inducing a lytic cell death (pyroptosis), which induces inflammation leading to dopaminergic neuronal death (Guo et al. 2015). Postmortem brains from PD patients show elevated levels of NLRP3, ASC and caspase-1 and PBMCs and serum from PD patients show increased NLRP3 activation and higher levels of IL-1β, that correlate with severity and progression of PD (Gordon et al 2018; Chaterjee et al. 2020; Fan et al 2020; Anderson et al 2021). Thus, the NLRP3 inflammasome may be an effective therapeutic target for PD. We have conducted *in vitro* and *in vivo* studies to characterize the NLRP3 small molecule inhibitor, MCC-950 (Perregaux et al., 2001; Collet al., 2015) and assess its utility in PD preclinical *in vivo* studies. In agreement with the literature, we show that MCC-950 directly and selectively binds NLRP3 with high affinity and potently inhibits cytokine release in activated microglia/macrophages *in vitro* across a variety of assays. MCC-950 inhibits NLRP3 *in vivo* in a pharmacokinetic/pharmacodynamic (PK/PD) model in the periphery with high potency (IC_{50} = ~17 nM free plasma) and efficacy. However, MCC-950 has no significant efficacy in brain PK/PD assays, possibly due to poor pharmacokinetic characteristics exemplified by a very low unbound relative, Kp,uu value (0.07; mouse) which is a measure of the extent of the distribution equilibrium of a compound between the unbound fractions in brain and in blood plasma. Therefore, MCC950 is not a suitable tool compound for investigating the role of NLRP3 in central neurodegenerative activity in vivo.

Title: Myelination in a nonhuman primate model of Parkinson's disease cardiac sympathetic neurodegeneration

Authors: *J. M. METZGER[1], H. N. MATSOFF[1,2], D. VU[1], A. D. ZINNEN[1], K. M. JONES[1], V. BONDARENKO[1], H. A. SIMMONS[1], C. F. MOORE[3], M. E. EMBORG[1,4];

Abstract: Minimal myelination is proposed to be a contributing factor to the preferential nigral neuronal loss in Parkinson's disease (PD). Similar to nigral dopaminergic neurons, sympathetic neurons innervating the heart have long, thin axons which are unmyelinated or minimally myelinated. Interestingly, cardiac sympathetic loss in PD is heterogeneous across the heart, yet the spatial relationship between myelination and neurodegeneration is unknown. Here we report the mapping of myelin basic protein (MBP) expression across the left ventricle of normal rhesus macaques (n=5) and animals intoxicated with systemic 6-OHDA (50 mg/kg iv) to model parkinsonian cardiac neurodegeneration (n=10). A subset of 6-OHDA-treated rhesus received daily dosing of pioglitazone (5 mg/kg po; n=5), a PPARγ agonist with neuroprotective properties. In normal animals, MBP-immunoreactivity (-ir) was identified surrounding approximately 14% of axonal fibers within nerve bundles of the left ventricle, with more myelinated nerve fibers at the base level of the left ventricle than the apex ($p < 0.014$). Greater MBP-ir at the base was related to greater number of nerve bundles at that level relative to the apex ($p<0.05$), as the percent of myelinated nerve fibers in bundles was not significantly different between levels of the heart. Cardiac sympathetic loss following 6-OHDA was associated with decreased MBP-ir in cardiac nerve bundles, with the percent decrease of MBP-ir greater in the apex (84.5%) than the base (52.0%). Interestingly, cardiac regions and levels with more MBP-ir in normal animals showed attenuated sympathetic loss relative to areas with less MBP-ir in 6-OHDA + placebo ($r = -0.7$, $p < 0.014$), but not in 6-OHDA + pioglitazone ($r = -0.1$) subjects. Our results demonstrate that myelination is present around a minority of left ventricle nerve bundle fibers, is heterogeneously distributed in the heart of rhesus macaques, and has a complex relationship with cardiac sympathetic neurodegeneration and neuroprotection.

Title: Glial cell line-derived neurotrophic factor signaling: a new mechanistic perspective in exercise-mediated recovery of motor impairment in a rat hemi-parkinson's model

Authors: *E. A. KASANGA[1], M. K. SHIFFLET[1], V. A. NEJTEK[1], M. F. SALVATORE[2];
[1]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX; [2]Inst. for Healthy Aging, Univ. of North Texas Hlth. Sci. Ctr., Ft Worth, TX

Abstract: Identifying the CNS mechanisms driving beneficial motor effects of exercise in Parkinson's disease (PD) can yield viable molecular targets for genetic or pharmacological approaches. By targeting these exercise-responsive mechanisms, the likelihood of mitigating disease progression is increased, given the yet unknown CNS mechanisms that are driving the motor benefits already established in PD patients. Rodent PD models can yield insight into exercise-driven CNS mechanisms, but arguably studies must be tethered in practicable limits of exercise intensity for a PD patient for optimal translation to the patient. In our study, we used this guideline to investigate exercise-responsivity of glial cell line-derived neurotrophic factor (GDNF) signaling in a treadmill exercise paradigm initiated after establishing motor impairment in the 6-hydroxydopamine (6-OHDA) hemi-Parkinson's rat model. Rats that were later assigned to the exercise (EX) or non-exercise (NE) groups were first acclimated to our established treadmill exercise protocol. Seven days after nigrostriatal lesion induction by 6-OHDA, motor impairment was verified by at least 25% reduction in the use of the forepaw associated with lesion and rats were assigned into the EX or NE groups with similar forepaw use deficits. Rats exercised three times per week at a final treadmill speed of 10 m per min for 40 min. Forepaw use was evaluated on a weekly basis on the day following the third exercise session each week for three weeks. Our treadmill regimen was associated with a highly significant recovery (~50% increase) of forepaw use by the third week of exercise. However, we did not observe any difference in striatal GDNF protein expression between the lesioned NE or EX groups. In contrast, we observed significant increases in the GDNF family receptor, GFR-alpha1, and receptor tyrosine kinase, RET protein expression in the lesioned hemisphere of the striatum of the EX group. These results shed new light on the plausibility that increased GDNF signaling plays a role in recovery of motor function following loss of nigrostriatal neurons, as seen in PD. As such, it is plausible that these receptors may be targeted to maintain exercise benefits, given the progressive nature of PD and the known barriers faced by PD patients to exercise.

Title: A proteomic survey of sex- and age-differences in the striatum and substantia nigra of non-human primate brain to identify novel treatment targets in Parkinson's disease

Authors: *J. K. BLACKBURN, R. WILSON, A. WONG, T. LAM, J. D. ELSWORTH;
Yale Univ., New Haven, CT

Abstract: Oxidative stress is a major contributor to the damage and death of dopamine neurons in Parkinson's disease (PD). Current PD treatments only temporally alleviate symptoms, thus there is a dire need for new, effective therapies that target underlying causes. So we have conducted a high-throughput proteomic survey in non-human primate (NHP) brain to identify novel neuroprotective targets. We based this exploratory study on two phenomena: (1) dopamine neurons in the infant NHP brain are resilient against oxidative stress (Morrow et al. 2012) and (2) the male sex is a significant risk factor for PD (Pinares-Garcia et al. 2018). Thus, we sought to identify age- and sex-dependent proteins in substantia nigra and striatum of NHPs with neuroprotective potential. We exploited label-free quantitative tandem mass-spectrometry to perform deep proteomic profiling of substantia nigra (SN) and striatum (STR) in St Kitts green monkeys. Whole tissue samples were dissected from 20 monkeys (5 male and 5 female of two ages: infant (11-28 days) and adult (4.5-6 KG) We detected a total of 3824 proteins, with 992 and 1263 showing age-dependent expression in SN and STR, respectively. Just over half (59%) were down regulated in adults compared to infants, and about half of down-and up-regulated proteins were shared between SN and STR, thus a substantial number of differentially expressed proteins are region specific. Functional analysis revealed that differentially expressed proteins are involved in mechanisms associated with PD, such as glutathione metabolism and intracellular transport in SN, and mitochondria function, protein catalysis, and vitamin B6 in STR. Principal component analysis revealed that only adult SN proteomes have an overall sex difference. 36 proteins in SN and 2 proteins in STR had sex-dependent expression. Several proteins that had higher expression in females were associated with neuroprotective mechanism, such as SLC6A3 and PGAM5, whereas proteins that were expressed higher in males included GPR37 and EIF4G1, which are associated with PD. Together these results indicate that some sex-dependent proteins align with sex-dependent risk of PD and they warrant further investigation. In summary, this exploration of age- and sex-differences in NHP brain provides an unprecedented opportunity for identifying new therapeutic targets in PD. Title: A dopamine-derived biomarker produced via neurotoxicants

Authors: *R. CRAWFORD[1], E. GILARDONI[2], K. BOWMAN[1], J. DOORN[1];
[1]Univ. of Iowa, Iowa City, IA; [2]Univ. of Milan, Milan, Italy

Abstract: Background. Parkinson's disease is a neurodegenerative disorder characterized by disruption of dopamine homeostasis and oxidative stress. The aldehyde metabolite of dopamine, 3,4-dihydroxyphenylacetaldehyde (DOPAL), is implicated in dopaminergic cell death due to its ability to modify proteins and cause oxidative stress. Aberrant DOPAL production may be caused by exposure to certain pesticides that disrupt the dopamine homeostatic pathway. This research has identified a DOPAL conjugate that is produced in SH-SY5Y neurons after supplementation with dopamine and exposure to the pesticide rotenone. Specifically, the amino acid L-cysteine scavenges DOPAL to form a putative thiazolidine ring that is identifiable and quantifiable via mass spectrometric methods. This has implications in neuroprotection as well as the potential for a novel biomarker for dopamine dyshomeostasis. **Methods.** SH-SY5Y neurons were supplemented with dopamine and exposed to 1μM of the PD-correlated pesticide rotenone. Both intracellular and extracellular components were evaluated at intermittent time points from 0 to 24 hours. Controls included cells that were also supplemented with N-acetyl cysteine (i.e., the precursor to L-cysteine) and cells that were treated with only dopamine. L-cysteine was also evaluated for its protective abilities by observing modification of proteins (i.e., glutathione S-transferase or bovine serum albumin) by DOPAL in the presence of absence of this scavenger. Mass spectrometric methods were employed to assess the mechanism of action of protection by L-cysteine and elucidate the formation of an L-cysteine-DOPAL conjugate. **Results.** L-cysteine fully protected glutathione S-transferase activity from modification by dopamine and DOPAL. L-cysteine was also found to form a putative thiazolidine conjugate with DOPAL via LC-MS. This conjugate was also found to form in SH-SY5Y neurons after treatment with dopamine and n-acetyl cysteine, or when cells were treated with dopamine and exposed to rotenone. The DOPAL-L-cysteine conjugate is exported to the extracellular matrix. **Conclusions.** Because aberrant DOPAL production is a hallmark of the etiopathology of Parkinson's disease, an identifiable DOPAL derivative may help diagnose disease earlier. We propose that the observed DOPAL-L-cysteine production is a novel pathway of neuroprotection and that it is relevant to diseases that are marked by dopamine disruption, such as Parkinson's disease.

Title: High-intensity, short-term exercise protects against 6-OHDA in an animal model of Parkinson's Disease

Authors: *M. HANNA, A. PEREZ, J. ROSALES;
Vanguard Univ., Costa Mesa, CA

Abstract: Parkinson's disease (PD) is a neurodegenerative movement disorder characterized by the degeneration of the dopaminergic neurons of the nigrostriatal pathway. Patients with PD typically experience motor symptoms, including tremors, rigidity, slowness of movement, and postural instability. Lewy Body pathology from misfolded α-synuclein aggregates is another major hallmark of the disease. In animal models of PD, increased oxidative stress, reactive oxygen species, inflammatory cytokines, and microglial activation have been reported to play a significant role in mediating PD pathology. In this study, we tested if five weeks of high-intensity treadwheel exercise before administering the dopaminergic neurotoxin 6-hydroxydopamine exerts a neuroprotective effect in an animal model of Parkinson's disease. After injection of 6-OHDA, behavioral tests were assessed within one week of the injection through examining apomorphine-induced rotation, methamphetamine-induced rotation, and sensory neglect. Apomorphine and methamphetamine-induced rotation are used to assess the extent of impairment caused by 6-OHDA and directly correlate to the degree of dopaminergic loss. Results showed that in 6-OHDA injected rats, prior exercise training reduced apomorphine-induced contralateral rotation and methamphetamine-induced ipsilateral rotation compared to the non-exercised 6-OHDA group. Exercised and non-exercised rats in the 6-OHDA groups showed reduced sensory neglect on the contralateral side of the body compared to saline groups; however, prior exercise training did not significantly improve sensory neglect compared to the non-exercise 6-OHDA group. The data suggest that high-intensity, short-term exercise can act as a neuroprotectant factor by reducing the extent of dopaminergic neurodegeneration. 5-weeks of prior exercise training was not sufficient to improve sensory neglect.

Title: Analysis of neuroprotective and anti-inflammatory activity of sub-anesthetic ketamine-treatment in the progressive unilateral 6-OHDA-lesion rat model

Authors: *C. J. STOPERA[1], M. J. BARTLETT[3], M. R. SEXAUER[1], K. BERNARD[1], J. A. STANCATI[5], S. J. SHERMAN[1], K. STEECE-COLLIER[6], H. W. MORRISON[2], T. FALK[4];
[2]Col. of Nursing, [1]The Univ. of Arizona, Tucson, AZ; [3]Dept. of Pharmacol., [4]Dept. Of Neurol., Univ. of Arizona Col. of Med., Tucson, AZ; [5]Dept. of Translational Neurosci., [6]Michigan State Univ., Grand Rapids, MI

Abstract: Low-dose, sub-anesthetic ketamine has been shown to be neuroprotective in rodent models of cerebral ischemia and traumatic brain injury, with anti-inflammatory effects contributing to ketamine's neuroprotective actions. Our lab has shown prior that sub-anesthetic ketamine reduces L-DOPA-induced dyskinesia in a rat 6-hydroxydopamine (6-OHDA) Parkinson's disease (PD) model, is acutely anti-parkinsonian, and ketamine's long-term anti-dyskinetic effects were identified as brain-derived neurotrophic factor (BDNF)-dependent. We have also shown sub-anesthetic ketamine may exhibit neuroprotective effects in a progressive 6-OHDA rat model of PD. Here, male Sprague-Dawley rats were treated with either ketamine or vehicle via the following protocol (6-hr treatment; 3 x 20 mg/kg; *i.p.*; 2-hrs apart) beginning 6-hrs prior to a unilateral intrastriatal 6-OHDA lesion. Rats were then treated daily with the 6-hr protocol for 7 days post-lesion. Using the amphetamine-induced rotation test, as an estimate of lesion severity, rats were injected with D-amphetamine (5 mg/kg; *i.p.*) and rotational asymmetry was assessed by counting the net ipsilateral rotations (mean ± SEM) over 90-minutes. On Day 28 post-lesion, rats treated with ketamine (211 ± 116) showed a significantly decreased number of net ipsilateral rotations compared to the vehicle (666 ± 187) group (Two-tailed t-test; $p < 0.05$; n=15), suggesting a neuroprotective effect of ketamine. To investigate anti-inflammatory action via activation of microglia, we have stained the substantia nigra (SN) and striatum (STR) with the microglia marker, IBA1, and analyzed branch length/cell and end points/cell. We found no effects in the SN, but there was a significant reduction of branch length/cell by 6-OHDA, compared to the intact STR (Two-way ANOVA; $p < 0.001$; n=8). Ketamine further significantly reduced branch length/cell in the intact STR ($p < 0.05$). The number of end points/cell was also significantly reduced by 6-OHDA in vehicle treated rats ($p < 0.001$), but not in those treated by ketamine. These data provide the first indicator of ketamine's effects on microglial morphology. Additional morphological analyses and assessment of a functional marker of microglia (CD68) are ongoing. We are also currently analyzing astrocyte activity using GFAP as a marker of activation. Unbiased stereology of dopaminergic neurons in the SN is ongoing and we are investigating the role of BDNF in ketamine's neuroprotective effects via *in situ* hybridization for RNA of both BDNF and its receptor, TrkB. In conclusion, an acute neuroprotective activity of ketamine is further supporting the ongoing clinical evaluation in individuals with PD.

Abstract: The fetal origin of adult disease's hypothesis predicts that adult neurodegenerative diseases may arise as a result of gestational insults. Parkinson's disease (PD) is now recognized to be induced by exposure to environmental neurotoxins that impair mitochondrial oxidative metabolism. Hence, mothers exposed to such neurotoxins during gestation and/or lactation might give rise to adult offspring offended by PD. In this work we tested this prediction by first exposing pregnant and/or lactating mother rats to daily subcutaneous injections of rotenone during gestation and/or lactation. As expected, their adult offspring displayed motor behavior disturbances, nigral dopaminergic neurodegeneration, and reduced dopamine and increased lipid peroxidation, α-synuclein availability and senescent cell number in the substantia *nigra*. All these disturbances were prevented or greatly attenuated in adult offspring by supplementing the diet of ROT exposed pregnant and/or lactating rats with a daily oral dose of Nano-PSO. Hence, our results show that adult Parkinsonism can indeed be acquired after being exposed to environmental neurotoxins during the prenatal and early postnatal life. The condition may be fully or partly avoided by facilitating the access and promoting the consumption of potent antioxidant agents such as Nano-PSO during gestation and lactation. This work was funded by the yearly stipend provided GGO by the Instituto de Investigaciones Biomédicas, UNAM.

Title: Developmental cell death in the hippocampus and related cognitive behaviors are altered by perinatal exposure to phthalates

Authors: *E. P. SELLINGER[1], H. FENTON[2], A. BRINKS[1], J. M. JURASKA[3];
[1]Neurosci. Program, [2]Vet. Med., [3]Psychology, Univ. of Illinois, Champaign, IL

Abstract: The plasticity of the perinatal period leads to increased susceptibility to environmental insult from endocrine-disrupting chemicals such as the plasticizers known as phthalates. There is an association between developmental phthalate exposure and impaired cognitive and emotional processing outcomes in children (Radke et al., 2020), however their mechanism of action remains unclear. Using a rat model, our lab has demonstrated exposure to an environmentally relevant mixture and dose of phthalates during the perinatal period results in fewer neurons in the adult medial prefrontal cortex that correlates with impaired cognitive flexibility (Kougias et al. 2018). More recently, we have shown this reduction in neurons is due, at least in part, to elevated cell death both pre- and postnatally (unpublished observations). The mPFC forms connections with the hippocampus, a brain region that also undergoes protracted development. The present study aims to investigate how phthalates alter the normal course of cell death in the dorsal and ventral hippocampus and to assess whether early exposure results in immediate cognitive behavioral changes.To expose developing pups to the phthalate mixture, dams were fed 0, 0.2, or 1 mg/kg/day on a cookie from gestational day 2 through 25 days post-partum. One male and one female pair per litter were sacrificed on P5 and another on P10 for analysis of cell death using a TUNEL label. A third male/female pair from each litter was tested on the elevated plus maze (EPM) on P27 followed by the Morris Water Maze (MWM) beginning on P29. A preliminary analysis (n=4-6/group) reveals a significant increase in cell death in dorsal CA1 ($p=0.045$) in both sexes on P5 after phthalate exposure and a similar, though non-significant, increase in the dentate. A significant effect of phthalate exposure is also seen in males only (n=5-6/group) on the percent of open arm entries measured on the EPM ($p = 0.04$). Males exposed to 1mg/kg also show a decreased latency to enter the open arm compared to controls ($p = 0.02$). Finally, no apparent effects of phthalate exposure were seen in preliminary analyses (n=5-6/group) of the MWM. Increased N and more sampled days for apoptosis and behavior will be added.

Title: Effects of corn grown on dredge-amended soil on hippocampal development and behavior

Authors: *K. A. S. FLANIGAN[1], A. N. JULIAN[2], V. R. RIESGO[1], M. A. RÚA[2], J. WILLING[1];
[1]Bowling Green State Univ., Bowling Green, OH; [2]Wright State Univ., Dayton, OH

Abstract: Agricultural practices designed to improve environmental health may be exposing developing mammals to compounds that can alter fundamental facets of neurodevelopment. In an effort to mitigate soil degradation, natural and synthetic amendments are administered to avoid yield losses, including the use of dredged sediment removed from local waterways (‘dredged sediment’). This sediment contains

nutrients necessary for crop production but also contains contaminants of concern (COC) including heavy metals, bisphenol-A, and polyaromatic hydrocarbons. These compounds can negatively impact neurodevelopment and behavior in mammals, particularly following perinatal exposure. Because COC can bioaccumulate in crops grown on amended soils, mammals consuming these crops, including both livestock and humans, may be impacted. The current study investigates the neurodevelopmental and behavioral impact of corn grown on dredged sediment amended fields in Long Evans rats. Female rats were exposed to corn grown on dredged sediment (or a non-dredge amended source of corn) during pregnancy and lactation. Progeny of control and exposed females were behaviorally tested in the elevated plus maze, open field, and novel object recognition tasks in young adulthood. Perinatal exposure to dredge-grown corn resulted in mild increases in anxiety-like behavior on the elevated plus maze and open field tests. In addition, we assessed the long-term effects of corn grown with dredged sediment on body weight, brain weight and hippocampal volume. These results suggest caution and further study to determine the safety of specific agricultural practices on mammalian brain development.

Title: The Impact of Perinatal Exposure to a Flame Retardant Mixture on Microglial Density, Reactivity, and Morphology in Adult Prairie Vole Brain

Authors: *W. P. MARINELLO, S. A. GILLERA, B. M. HORMAN, H. B. PATISAUL;
Biol. Sci., North Carolina State Univ., Raleigh, NC

Abstract: Microglia are known to shape brain sex differences critical for social behaviors. Chemicals, including flame retardants, can disrupt brain sexual differentiation but there is limited data regarding how they impact microglia distribution and function. We focused on the prevalent flame retardant mixture Firemaster 550 (FM550) which is used in foam-based furniture and infant products including strollers and nursing pillows. We hypothesized FM550 exposure would disrupt microglial density and reactivity in brain regions known to be highly sexually dimorphic or associated with social disorders in humans. We used prairie voles (*Microtus ochrogaster*) because they display spontaneous prosocial behaviors not seen in rats or mice, and thus are a useful model for studying chemical exposure-related impacts on social behavior and the underlying neurobiological systems. We have previously demonstrated that perinatal FM 550 exposure sex-specifically impacts socioemotional behaviors in prairie voles. Vole dams were exposed to FM550 (0, 500, 1000, 2000 µg/day) via subcutaneous injections through gestation, and pups were

directly exposed beginning the day after birth until postnatal day 21. Adult offspring's brains were assessed for ionized calcium-binding adapter molecule 1 (Iba-1)-positive microglia using unbiased stereology in the medial prefrontal cortex (mPFC) and the cerebellum (lobules VI-VII) and thresholding method in the amygdala. For stereology, microglia were classified based on reactivity (ramified, intermediate, ameboid). To further quantify the differences in microglia morphology after FM550 exposure, Sholl and skeleton analysis was carried out on individual microglia. Effects were sex- and dose-specific in the regions of interest. Our studies demonstrate the utility of the prairie vole for investigating the impact of chemical exposures on the developing brain, particularly regions essential for pro-social behavior.

Title: Correlations between neuronal damage and epileptic EEG discharges from diisopropylfluorophosphate in the rat

Authors: K.-C. HSIEH[1,2], K.-T. CHEW[1], S. RAI[1], S. KUMAR[1,4], *D. G. FUJIKAWA[1,3];

Abstract: Introduction: Organophosphate nerve agents cause irreversible inhibition of acetylcholinesterase, which leads to prolonged seizures and neuronal damage. It is unclear if the damage resulted from seizures. In the current study, we analyzed the relationship between the severity of neuronal damage and the intensity/duration of EEG seizure discharges in the rat model of acute diisopropylfluorophosphate (DFP) exposure. Methods: Male Sprague-Dawley rats weighing 240-300g were used for experiments after being implanted with EEG electrodes on the skull and a telemetric temperature sensor intraperitoneally. The DFP was administered at 3-4 mg/kg s.c., 30 min after pyridostigmine and shortly after methylatropine and pralidoxime injections i.m., which were given to enhance the survival rate of the animals. Standard treatment for organophosphate poisoning in humans, or Chempack (the triple antidotes of diazepam, atropine sulfate, and pralidoxime), was administered 60 min after the onset of status epilepticus. The animals were monitored for 24 h and sacrificed for histological evaluation with hematoxylin and eosin (H&E) staining (n=12). The severity of brain damage was rated visually on a 7-point scale by the approximate percentage of damaged neurons in the total neuronal population in 23 brain regions. Seizure discharges were quantified by variables derived from spectral power analysis in the frequency band of 20-70Hz. Results: All animals exposed to the DFP displayed stereotypical epileptic behavioral signs and hours of continuous EEG spike discharges to varying degrees. The Chempack treatment tended to reduce the seizures temporarily but was ineffective in stopping them.

A wide range of neuronal damage was found with H&E histology, most consistently in the piriform cortex and entorhinal cortex. Correlations between the severity of neuronal damage and variables in EEG seizure discharges were found mainly in the ventral hippocampus, especially CA2 (24-h total discharge duration, $R=0.939$, $p<0.001$), and in the cerebral cortex (total spectral power of 20-70Hz in the first hour after DFP injection, $R=0.757$, $p<0.005$). Damage in other brain regions with more severe neuronal loss was not correlated with the intensity or duration of the seizure discharges. Conclusion: These results suggest that neuronal damage after DFP exposure may be induced by a more complex mechanism than excitotoxicity alone.

Title: Phenotypic alteration of macrophages contributing to regeneration or degeneration in PNS and CNS

Authors: *Y. SEO[1], M. J. KWON[2], B. G. KIM[1,3];
[1]Neurosci. Grad. Program, Dept. of Biomed. Sci., Ajou Univ. Grad. Sch. of Med., Suwon-Si, Korea, Republic of; [2]Dept. of Brain Sci., Ajou Univ. Grad. Sch. of Med., Suwon, Korea, Republic of; [3]Dept. of Neurol., Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Macrophages dynamically change their molecular characteristics following injuries and their distinct phenotypes can have consequential effects on the outcome of neural injuries. Therefore, it would be important to understand the spectrum of phenotypic diversity of post-injury macrophages and how to regulate their phenotypes to drive regeneration while curbing secondary degeneration concurrently. The present study sought to replicate the phenotypic diversity in cultured macrophages and to examine functional influence of different macrophage phenotypes on regeneration or degeneration of PNS and CNS neurons. Cultured bone marrow-derived macrophages (BMDMs) were treated with factors that are known to induce regeneration or degeneration phenotype: lipopolysaccharide (LPS)/IFN-γ (M1), IL-4 (M2), zymosan, CCL2, and curdlan, a dectin-1 receptor agonist. Zymosan treatment induced both M1 and M2 genotypes, whereas CCL2 imparted strong and curdlan weak M2 genotype. When conditioned medium (CM) from the polarized BMDMs were treated to cultured dorsal root ganglion (DRG) neurons, M2 and CCL2-treated CMs increased DRG neurite outgrowth, and zymosan-treated CM exhibited the strongest neurite-outgrowth activity. CMs collected from all the conditions did not show evidence of toxicity to DRG neurons. When BMDM CMs were treated to cultured cortical neurons, CNS neurites

showed degeneration regardless of treatments, indicating macrophage-derived CM is inherently toxic to CNS neurons. We previously reported that neuron-macrophage interaction can drive pro-regenerative macrophage activation. When BMDMs were co-cultured with neurons and treated with cAMP, which mimics injury signals, collected CM exhibited robust neurite-outgrowth activity without any sign of toxicity for DRG neurons. Surprisingly, the CNS neurotoxicity by macrophage-derived CMs were sharply reduced by the CM from BMDM + neuron cocultures. Chemokine array revealed a significant decrease in CCL5 in the coculture CM and blocking CCL5 significantly reduced the toxicity of macrophage-derived CM for CNS neurites. Our study showed that diverse macrophage phenotypes can influence regeneration or degeneration in PNS and CNS. Blood-derived macrophages may be prone to cause degeneration for CNS neurons, and the interaction with neurons could reduce the toxicity via a CCL5-dependent mechanism.

Title: Hippocampal neuroinflammatory and neurogenesis perturbations in diabetic male rats treated with combined antiretroviral therapy (cART)

Authors: *J. E. ASOUZU JOHNSON[1], R. NDOU[2], F. E. MBAJIORGU[1];
[1]Univ. of the Witwatersrand, johannesburg, South Africa; [2]Sefako Makgatho Hlth. Sci. Univ., Pretoria, South Africa

Abstract: Diabetes is associated with inducing hippocampal atrophy by disrupting hippocampal cytokines and neurogenesis. The diabetic condition is further burdened in Sub-Saharan Africa by the scourge of HIV and prevalent management with Combined antiretroviral therapy(cART). While cART is an efficient treatment, its potential to induce metabolic syndrome and type 2 diabetes may compound the neuropathological effects of diabetes. Therefore, this study aims to investigate the effects of cART within the type 2 diabetes model on body weight, pro-inflammatory cytokines, histomorphology, and neurogenesis in the hippocampus. MaleSprague Dawley rats were divided into 4 groups of six rats each including, NC (untreated group), AV (normal rats treated with cART composed of efavirenz, emtricitabine, and tenofovir disoproxil fumarate), DB (diabetic rats), and DAV (diabetic rats treated with cART). After ninety days of treatment, the rats were terminated, the brains were excised for immunoassay (IL-1α, IL-6, and TNFα), immunohistochemical (Ki67 and DCX), and Nissl stain histomorphology analysis in the brain homogenate and brain sections, respectively. All animal handling protocols were performed according to the standard protocol set forth by the University of the Witwatersrand Animal Research Ethics Committee approval number AREC 2018/011/58/C. Our results show that cART insignificantly increased body weight and cytokines but significantly reduced the number of neurons in

the dentate gyrus only (Bonferroni post hoc test $p = 0.001$). Diabetes significantly reduces body weight, pro-inflammatory cytokines, neuronal density (CA1 and dentate gyrus), expression of Ki67 and DCX, and significantly increased neuronal nuclei area (all hippocampal regions) at $p \leq 0.034$ Bonferroni post hoc test. However, the concurrent presence of cART in the diabetic condition significantly reduces body weight, IL-6, neuronal density (all hippocampal regions), Ki67, and DCXexpression in the hippocampus compared to the control only (Bonferroni post hoc test $p \leq 0.002$). These findings indicate that cART in diabetes can reduce neuronal density and neurogenesis in the hippocampus even in the absence of TNFα and IL-1α response.

Title: Estradiol and 3βdiol protect cortical astrocytes from oxidative stress by regulating connexin 43-containing Gap Junctions

Authors: *S. KIM[1], N. K. KUBELKA[2], V. KRISHNAMOORTHY[1], H. LAPORTE[1], M. SINGH[1]; [1]Loyola Univ. Chicago Stritch Sch. of Medici, Maywood, IL; [2]Ctr. for Neurosci. Discovery, Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Cx43 is a transmembrane protein, expressed highly in astrocytes, that can comprise either hemichannels or gap junctions. Cx43 plays an important role in regulating inter-cellular communication influencing cell viability and has also been implicated in the regulation of oxidative load within a cell. Since gonadal androgens and estrogens are known to protect against oxidative stress, we wanted to determine if Cx43 expression and/or function (either as hemichannels or gap junctions) are a downstream target/mediator of the cytoprotective effects of either estrogens (estradiol, E2 and 3β-diol) or androgens (dihydrotestosterone, DHT). To validate this hypothesis, we assessed changes in Cx43 mRNA expression, Cx43 permeability in response to 100 nM E2, DHT, or the DHT metabolite, 5-α-androstane-3,17-β-diol (3βdiol), and correlated it with cell protection (against iodoacetic acid-induced metabolic/oxidative insult) afforded by these same hormones. We conducted these studies in cortical astrocytes derived from neonatal female C57/Bl6 mice. MTT viability assays were conducted to assess cell viability/health, and determining the contribution of Cx43 hemichannels versus gap junctions in hormone-induced protection against the oxidative stress was facilitated using the pharmacological agents, Gap19 (hemichannel blocker) and Gap26 (gap junction blocker). We also used 10Panx (Pannexin 1 blocker) to discern the possible involvement of the Pannexin 1 channel. Moreover, we complemented these studies with an analysis of Cx43 hemichannel and gap junction permeability, using ethidium bromide (EtBr) and lucifer yellow dye uptake assays, respectively. While all three steroids transiently increased astrocyte Gap26 mRNA expression, Cx43 mRNA expression was unaltered. Either opening or closing Cx43 hemichannels or Pannexin 1 channels exacerbated IAA induced cell death, an effect not prevented by any hormone, indicating altered Cx43 hemichannel and Pannexin 1 channel permeability may not play a significant role

in hormone protection against oxidative stress. However, E2 and 3βdiol-mediated inhibition of Cx43 gap junction permeability (as determined by dye uptake studies) were correlated with E2 and 3βdiol induced cytoprotection. Taken together, these data are the first to suggest Cx43-containing gap junctions as a mediator of E2 or 3βdiol induced protection of cortical astrocytes

Title: Multiplexed structure-function assay for neurotoxicity and disease modeling

Authors: *D. MILLARD, D. SULLIVAN, H. HAYES;
Axion Biosystems, Atlanta, GA

Abstract: The flexibility and accessibility of induced pluripotent stem cell technology has allowed complex human biology to be reproduced in vitro at high throughput scales. Indeed, rapid advances in stem cell technology have led to widespread adoption for the development of in vitro models of neuron electrophysiology to be used in screening applications in drug discovery and safety. Furthermore, advanced cells preparations, such as spheroids or organoids, are under intense investigation with aims towards establishing mature human phenotypes in vitro. For the development and validation of in vitro neuronal models, it is critical to evaluate the structure and function of neurons, synapses, and networks. The objective of this work is to develop and validate a multiplexed structure-function assay as an efficient approach for evaluating neuronal models in vitro. A planar grid of microelectrodes embedded in the substrate of each well interfaces with cultured cellular networks to continuously monitor both the electrophysiological function and structural viability of cells. The electrodes detect the raw electrical activity from the cells to identify changes in function, while structural effects, such as morphological changes and cell viability, are detected as changes in impedance at the cell-electrode interface. Here, we characterized and validated this multiplexed assay using known control compounds that differentially affected the cell structure and function. All compounds tested (GABA, glutamate, tributyltin, and Triton X-100) altered functional spiking activity relative to a vehicle control (DMSO). Tributyltin, glutamate, and Triton X-100 also affected neuronal viability, as measured through the microelectrode-based impedance, with Triton X-100 serving as the positive control for complete loss of membrane integrity. These results support the continued development and use of human iPSC-derived neural assays on the Maestro Pro for high throughput drug discovery and safety assessment.

Title: Chronic chemogenetic stimulation of the superior colliculus as a neuroprotective strategy in glaucoma: comparative transcriptome analysis of isolated retinal ganglion cells and collicular lysates

Authors: M. CLAES, C. VAN DEN HAUTE, V. BAEKELANDT, L. H. ARCKENS, L. DE GROEF, *L. MOONS;
KU Leuven, Leuven, Belgium

Abstract: Abstract Glaucoma is a neurodegenerative eye disease characterized by a progressive loss of retinal ganglion cells (RGCs), whose axons shape the direct linkage between the retina and visual processing centers in the brain. RGCs might be prone to die due to a deficiency of target-derived neurotrophic factors after perturbed axonal transport, one of the major glaucoma hallmarks. Based on the established linkage between neuronal activation and the release of neurotropic factors, we hypothesize that chemogenetic stimulation of neurons in the superior colliculus might increase the production and secretion of target-derived neurotropic factors and, upon retrograde transport of those factors to the retina, might aid the RGCs in their struggle for survival in an experimental glaucoma model. To explore this hypothesis, a bulk RNA sequencing experiment was performed on FACS sorted RGCs and collicular lysates from mice subjected to sham, glaucoma, chemogenetic stimulation and glaucoma + chemogenetic stimulation. Chemogenetic activation of the neurons in the superior colliculus was achieved via injection of an adeno-associated viral vector (AAV2/7-CaMKIIα) coding for the hM3Dq receptor. Starting one day before glaucoma induction (the microbead occlusion model), mice received a systemic injection of 3 mg/kg body weight clozapine-N-oxide (CNO). During the following 5 weeks, mice received three CNO injections per week. We evaluated the differentially expressed genes in the RGCs of all aforementioned goups; and studied how these retinal transcriptomic changes related to the altered transcriptome in the superior colliculus. These results provided interesting insights on how retinal neurons rely on their target connections in the brain for vitality, together with novel cues to fuel future treatment routes in glaucoma and other optic neuropathies.

Title: TRPM3 agonists activate AMPK and enhance mitochondrial function to augment neurite outgrowth in adult sensory neurons

Authors: *S. CHAUHAN, P. FERNYHOUGH;
Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Peripheral neuropathy affects approximately 50% of the population with diabetes mellitus depending on age and disease severity. It is associated with substantial morbidity and is characterized by induction of pain and loss of sensory function beginning distally in the lower extremities. Recent studies suggest that molecular cascades maintaining mitochondrial function and calcium homeostasis are effective therapeutic targets for diabetic peripheral neuropathy. Interestingly, our lab has recently reported that muscarinic acetylcholine type 1 receptor (M1R) antagonists stimulated neurite outgrowth, in part, by activating Ca^{2+}/calmodulin-dependent protein kinase kinase II (CaMKKII) and mobilization of AMP-activated protein kinase (AMPK). This further augmented mitochondrial function in sensory neurons imparting protection against small and large fiber neuropathy in various rodent models of peripheral neuropathy (including diabetes). Transient receptor potential melastatin receptor 3 (TRPM3) is a TRP type cation channel that triggers Ca^{2+} influx. TRPM3 is quite unique in that it binds calmodulin and is open under high phosphoinositide levels (the latter would be predicted during blockade of the M1R). We hypothesized that opening of TRPM3 could activate CaMKKII and induce neurite outgrowth and may mimic antimuscarinic drug effects. Dorsal root ganglion (DRG) neurons were isolated from adult control and streptozotocin-induced type 1 diabetic male Sprague–Dawley rats. Assessment of neurite outgrowth was performed in response to pregnenolone sulphate (PS) or CIM0216 (selective and specific TRPM3 agonists, respectively). A significant dose-dependent elevation of neurite outgrowth was observed. These TRPM3 agonists also increased AMPK activation and extracellular signal-regulated kinases (ERK) signaling in control and diabetic DRG neuron cultures. There was also a significant augmentation of mitochondrial activity. Specifically, TRPM3 agonists elevated maximal respiration in diabetic DRG neuronal cultures. Our investigations towards understanding of TRPM3 activation and its downstream molecular cascade will hopefully lead to potential therapeutic targets for impeding detrimental effects of peripheral neuropathy.

Title: Neuroprotective Effects of σ2R/TMEM97 Modulators in Neuronal Model of Huntington's Disease

Authors: *J. JIN[1], N. ARBEZ[1,3], J. J. SAHN[4], Y. LU[4], K. T. LINKENS[4], T. R. HODGES[4], A. TANG[1], R. WISEMAN[1], S. F. MARTIN[4], C. A. ROSS[1,2];
[1]Div. of Neurobiology, Dept. of Psychiatry, [2]Departments of Neurology, Neurosci. and Pharmacol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Cell. Sci. Dept., IdRS, Croissy-sur-Seine, France; [4]Dept. of Chem., The Univ. of Texas at Austin, Austin, TX

Abstract: Huntington's disease (HD) is a genetic neurodegenerative disease caused by an expanded CAG repeat in the human Huntingtin gene (*HTT*), yielding and expanded polyglutamine (polyQ) repeat in the exon-1 of the human mutant huntingtin (mHTT) protein, which results in neuronal degeneration with no cure nor treatment that modifies disease progression. Small molecules that bind selectively to the recently-cloned sigma 2 receptor (σ_2R), which is identical to TMEM97, have been shown to have neuroprotective effects in Alzheimer's disease, traumatic brain injury and other neurological disorders. To assess whether modulating pathways involving σ_2R/TMEM97 can provide protection in HD, we used an HD cell model to evaluate the effects of σ_2R/TMEM97 ligands on mHTT induced neuronal toxicity. We first synthesized a set of compounds designed to bind to σ_2R/TMEM97, and binding profiles (K_i) of these ligands were determined. Modulators with high selectivity for σ_2R/TMEM97 relative to σ_1R were then tested in our HD cell models. Primary cortical neurons were cultured in vitro for 7 days and then co-transfected with either normal HTT construct (Htt N-586-22Q/GFP) or mHTT construct (Htt-N586-82Q/GFP). Transfected neurons were treated with σ_2R/TMEM97 or σ_1R modulators for 48 hours. After treatment, neurons were fixed and stained with Hoechst. Condensed nuclei were quantified to assess cell death in transfected neurons. Significantly, σ_2R/TMEM97 modulators reduced the neuronal toxicity induced by mHTT, and their neuroprotective effects were not blocked by NE-100, a selective σ_1R antagonist. These results indicate for the first time that σ_2R/TMEM97 modulators can protect neurons from mHTT induced neuronal toxicity, suggesting that targeting σ_2R/TMEM97 may provide a novel therapeutic approach to treat HD patients.

Imaging and Bioengineering, NIH, Bethesda, MD

Abstract: Background: Neurodevelopmental impairment is one the most important current challenges for survivors after neonatal cardiac surgery. Cardiopulmonary bypass (CPB) can cause substantial oxidative/inflammatory stress and microglial activation. Bone marrow-derived mesenchymal stromal cells (BM-MSCs) have significant immunomodulatory properties and regulate microglial activation. We hypothesize that BM-MSC delivery to the neonatal brain at the time of cardiac surgery limits inflammation and microglial activation caused by CPB.**Methods:** Two-week old piglets were randomly assigned to one of three groups: (1) Control, (2) CPB, (3) CPB followed by BM-MSC administration. BM-MSCs ($10x10^6$/kg) were delivered through CPB during the rewarming period.**Results:** In the developing cortex, caspase-3 was activated at 3hrs post CPB-induced insult and normalized by postoperative day 1. During this time window, we identified a significant link between oxidative/inflammatory stress and the activation of JAK-STAT3 pathway, suggesting JAK-STAT3 signaling as a potential therapeutic target. Positron emission tomography indicated that intra-arterial BM-MSC delivery through CPB uniformly distributed the cells to most of the organs analyzed. *T2**-weighted brain imaging and immunohistochemistry showed an even distribution of BM-MSCs between right and left hemispheres and within the cortex and white matter. At 3hrs post surgery, 46 and 44% of BM-MSCs were localized to the cortical and white matter parenchyma, respectively. No evidence of micro-embolic events or detrimental effects was observed. CPB caused acute microglial expansion and activation. BM-MSC treatment suppressed CPB-induced STAT3 activation and inhibited microglial STAT3-phosphorylation, thereby switching the microglial phenotype to a less pro-inflammatory state. In addition to an increase in circulating anti-inflammatory cytokines, genome-wide RNA profiling identified inhibition of pro-apoptotic transcriptional signatures, likely resulting due to the reduction of reactive-oxygen species following BM-MSC treatment. BM-MSC delivery through CPB inhibited acute caspase-3 activation in cortical neurons and limited the induction of apoptotic signals caused by cardiac surgery. Neuronal capase-3 activation was correlated with microglia activation, indicating BM-MSC-involvement in suppression of microglia-mediated neurotoxicity.**Conclusions:** BM-MSC delivery through CPB has a significant translational potential for minimizing oxidative/inflammation stress during CPB and subsequent inhibition of microglia-mediated neurotoxicity in children undergoing cardiac surgery.

Title: Vegf-c confers neuroprotection and ameliorates ischemic stroke outcomes

Authors: L. S. BRAGA BOISSERAND[1], J. BOUCHART[3], H. BENVENISTE[2], F. HYDER[4], L. H. SANSING[1], A. C. EICHMANN[5], J. L. THOMAS[6];
[1]Neurol., [2]Anesthesiol., Yale Sch. of Med., New Haven, CT; [3]Neurol., [4]Radiology & Biomed. Imaging, [5]Cardiovasc. Res. Ctr. and the Dept. of Cell. and Mol. Physiol., [6]Yale Univ. Sch. of Med., New Haven, CT

Abstract: Meningeal lymphatic vessels promote tissue clearance and immune surveillance in the central nervous system (CNS). Vascular Endothelium Growth Factor-C (VEGF-C) regulates meningeal lymphatic growth and has therapeutic potential for neurological disorders such as cognitive aging and brain tumors, and might be beneficial in stroke injury repair. Here, we investigated effects of VEGF-C overexpression on brain fluid drainage, gene expression and stroke outcome. Intra-cerebrospinal administration of an adeno-associated virus expressing VEGF-C (AAV-VEGF-C) and post-contrast T1 mapping of the head and neck showed that VEGF-C increased the size of collecting lymph nodes and their drainage by CNS-derived fluids. Single nuclei RNA sequencing of forebrain cells isolated from VEGF-C pretreated and control mice revealed that VEGF-C inhibited microglia proliferation and increased the DNA damage response in subsets of neural cells. Using a mouse model of ischemic stroke induced by transient middle cerebral artery occlusion, we found that AAV-VEGF-C pretreatment, but not post-injury treatment with recombinant VEGF-C, reduced ischemic stroke injury, ameliorated motor performances in the subacute stage and increased expression of BDNF and NGF in the forebrain. VEGF-C pretreatment thus promotes CNS-derived fluid and solute drainage, confers neuroprotection to brain tissues and protects against ischemic stroke damages.

Title: The rap guanine exchange factor 4, EPAC2, may have a neuroprotective effect on degenerating photoreceptors

Authors: M. RASMUSSEN[1], J. ZHOU[1], F. SCHWEDE[2], *P. EKSTRÖM[1];
[1]Ophthalmology, Dept. Clin. Sci., Lund, Lund Univ., Lund, Sweden; [2]BIOLOG Life Sci. Inst. GmbH & Co, Bremen, Germany

Abstract: The eye disease Retinitis Pigmentosa (RP) leads to severe vision loss due to neuroretinal degeneration with photoreceptor death, but the mechanisms are still unknown. Therefore, to develop therapies to prevent disease progression in RP, there is a dire need to reveal the underlying pathology. During RP in mice (i.e., *rd* models) detrimental high cyclic GMP (cGMP) levels are observed in photoreceptors. cGMP is a common second messenger, which interacts with various proteins and a recent study showed that the protein rap guanine exchange factor 4 (EPAC2) is a cGMP interactor in the neuroretina. EPAC2 is activated by cAMP and is an accepted cGMP-interacting protein, albeit cGMP has almost no activatory effect *in vitro*. However, whether EPAC2 may be affected by cGMP and thus play a role in RP remains unclear.
To decipher this, we collected retinas from RP mouse models at different ages (postnatal day = PN); *rd1* (PN11-19), *rd10* (PN17-22), *rd2* (PN19-22), and corresponding wild-type (wt, controls) and quantified the EPAC2 expression using immunofluorescence. Proximity Ligation Assay (PLA) was applied to verify if cGMP or cAMP and EPAC2 were in proximity in the photoreceptor layer (outer nuclear layer = ONL). Lastly, *rd10* and wt (PN12-PN24) retinal explant cultures were used to pharmacologically manipulate retinal EPAC2 activity. The results were analyzed using 2-way ANOVA.
Our results show significantly increased EPAC2 expression in the ONL during degeneration in *rd1* and *rd10* retinas, but not in the *rd2* model, as compared to wt. Moreover, the PLA indicated that the number of cGMP:EPAC2 interactions increased significantly over time in *rd1* and to some extent in *rd10*, but not in the *rd2* model. In comparison to cGMP:EPAC2, the cAMP:EPAC2 interactions were fewer in *rd10* and *rd2* and again increasing over time in *rd1*. Manipulation of EPAC2 activity in the *rd10* retina revealed that EPAC2 inhibition reduced ONL thickness and significantly elevated EPAC2 expression compared to *rd10* retinas treated with an EPAC2 activator. The decreasing ONL did not correspond with an increased number of TUNEL positive cells, probably because the *rd10* photoreceptor death peaked before PN24.
In summary, we showed that EPAC2 expression and the number of cGMP:EPAC2 interactions in the ONL increased during retinal degeneration in the *rd1* and *rd10* models, although not in *rd2*. This is compatible with that high cGMP levels may negatively affect EPAC2's yet undefined, but perhaps neuroprotective, role in the RP photoreceptors, and that the retina tries to compensate for this by increasing the EPAC2 expression. This is as such supported by that EPAC2 inhibition decreased the ONL thickness and increased the EPAC2 level.

Title: Beneficial effects of a plasma fraction on processes induced in a mouse model of inflammaging

Authors: *C. THADANI, J. TORRES, R. ALCANTARA-LEE, E. CZIRR, I. GALLAGER; Alkahest, Inc., a subsidiary of Grifols, San Carlos, CA

Abstract: We previously identified that a plasma fraction (PF), derived from human plasma donations (average age 32-years-old), contains beneficial factors which have been shown to ameliorate multiple age-related deficits across varied organ systems, including the brain, in aged mice. We are now characterizing high-fat diet (HFD) fed mice as a model of inflammaging in younger mice to test the effects of PF. Providing HFD chow in mice from 6 weeks of age until the time of tissue collection at 7.5 or 13.5 months results in CNS changes including decreased cell proliferation and neurogenesis, increased inflammation, increased anxiety and depressive phenotypes, and decreased synaptic connectivity within the hippocampal region in the CNS when compared to normal diet (NC) controls. Importantly, all these are characteristics observed to be exacerbated in aged brains. We evaluated intravenous administration of PF daily for 7 days for alleviation of neurological and histopathological phenotypes observed in 7.5-month-old and 13.5-month-old male C57/Bl6 mice on HFD. Through these studies, we confirmed that PF ameliorated HFD-induced anxiety and depression and improved neural progenitor cell survival. In addition, we observed a decrease in circulating inflammatory plasma cytokines and an increase in anti-inflammatory plasma cytokines without impacting the underlying metabolic changes induced by HFD. In summary, we demonstrate that PF is a multifactorial and multimodal intervention for changes induced through inflammaging.

Title: Nano PSO administration attenuates cognitive and neuronal deficits before and after a traumatic brain injury

Authors: *D. QUBTY[1], K. FRID[2,3], V. RUBOVITCH[1], M. HAR-EVEN[1], R. GABIZON[2], C. G. PICK[1]; [1]Dept. of Anat. and Anthropology, Sackler school of medicine, Tel Aviv Univ., Tel aviv, Israel; [2]Dept. of Neurology, The Agnes Ginges center for Human Neurogenetics, [3]Med. school, The Hebrew university, Jeruslalem, Israel

Abstract: Traumatic Brain Injury (TBI), one of the most common causes of neurological damage in young populations, is widely considered as a risk factor for neurodegenerative diseases, such as Alzheimer's disease (AD) and Parkinson's (PD) disease. These diseases are characterized in part by the accumulation of disease-specific misfolded proteins, and share common pathological features, such as neuronal death, as well as inflammatory and oxidative damage. We have recently shown that a novel Nano formulation of Pomegranate seed oil (Nano-PSO) can target its active ingredient to the brain and thereafter inhibit memory decline and neuronal death in mice models of AD and genetic Creutzfeldt Jacob disease (gCJD).PSO is comprised of large levels of Punicic Acid (Omega 5), one of the strongest natural lipid antioxidants, which is metabolized *in-vivo* into CLA (conjugated linoleic acid), both an antioxidant and a calpain inhibitor. In this study, we show that administration of Nano-PSO to normal mice whether before or post TBI application prevents cognitive and behavioral decline, as measured by behavioral tests, such as novel object recognition, Y maze, elevated plus maze, open field, and staircase. In addition, immuno-histochemical staining of brain slices at the end of the experiments indicate that the preventive Nano-PSO treatment significantly decreased neuronal death and reduced gliosis. As shown for other models of neurological disease, Nano-PSO administration prevented mitochondrial damage in the affected cells, demonstrated by COXIV1 immunostaining in the brains. Finally, to clarify the effect of our TBI model and different treatment approaches of Nano-PSO on the expression of neuroprotective proteins. We examined levels of Sirtuin1 (SIRT1) and Synaptophysin (SYP) in the cortex using western blotting. SYP, a major integral transmembrane protein of synaptic vesicles, provides a molecular marker for the synapse and serves as a functional marker of the brain. Nano-PSO consumption showed a higher level of SYP protein post-injury. Several studies have shown that SIRT1 plays a significant role in inducing neuroprotection following dietary restriction. We found a significant reduction of SIRT1 levels in the cortex, using a mouse model of TBI. This reduction was prevented in mice that consumed Nano PSO after TBI. Taken together, our results indicate that Nano PSO, as a natural brain targeted antioxidant, can prevent at least part of TBI-induced damage.

Title: Progranulin preserves autophagy function in neurons under high-glucose stress through modulation of glia

Authors: *C. DEDERT, F. XU, V. MISHRA;
Dept. of Biol., St. Louis Univ. Dept. of Biol., Saint Louis, MO

Abstract: Hyperglycemia, or elevated blood glucose, is prevalent in type II diabetes and causes neural pathology through impaired autophagy and accumulation of protein aggregates in brain tissue. Progranulin is an endogenous neurotrophic factor whose mutation is implicated in the neurodegenerative disease frontotemporal dementia (FTLD), characterized by aggregation of the protein TAR DNA-binding protein 43 (TDP43). However, while progranulin is known to function in the lysosome, its mechanism of neuroprotection is not known. In this study, we investigated whether progranulin restores autophagic function in neurons under hyperglycemic stress. Primary cell cultures from E18 rat cortex were incubated in high glucose medium and treated with recombinant progranulin for 72 hours, and cellular health and function were assessed. We found that while high glucose treatment decreased macroautophagy and chaperone-mediated autophagy (CMA) activity, pre-treatment with progranulin significantly attenuated downregulation. Specifically, we assessed autophagy flux as an increase in LC3B lipidation in western blot and puncta formation in immunofluorescent imaging; we found that autophagy flux was significantly decreased in high glucose conditions and progranulin pre-treatment prevented this decrease. To assess the CMA function, we measured LAMP2A expression and perinuclear puncta formation in immunocytochemistry imaging. Our results showed that although total LAMP2A levels were unaffected, localization to the perinuclear region was decreased in high glucose-treated cells, but preserved with progranulin treatment. Intriguingly, immunofluorescence images indicated that modulation of autophagy occurred largely in the glia as opposed to neurons, indicating a role of this cell type in regulating neuronal well-being through autophagy. These novel findings implicate glial involvement both in the neuronal autophagy process and in progranulin's mechanism of effect. Our findings showcase a potential for progranulin as a promoter of autophagy under harmful stress conditions through glial activation.

Abstract: Hypoxic-ischemic encephalopathy (HIE) is one of the main causes of neonatal death, and in survivors it generates long-term neurological sequelae that include learning and memory deficits, motor damage and cerebral palsy. Among the mechanisms that contribute to neurological dysfunction are excitotoxicity, apoptosis, necrosis and inflammatory process; all associated with epigenetic modifications that maintain control of gene expression during HIE. Histone deacetylases (HDAC) are enzymes that catalyze the deacetylation of histone lysine residues and their activity is related to gene repression. Furthermore, changes in HDAC gene expression have been described after hypoxia-ischemia injury. Previous studies in our laboratory have shown that Cerebrolysin administration in rats with HIE improves motor skills, learning and memory. This study aimed to evaluate the effect of Cerebrolysin administration on the HDAC gene family expression in neonatal rat model of HIE. We analyzed cerebral cortex and hippocampal samples obtained from HIE rats, 24 hours and 21 days after cerebral injury. Total RNA extraction and reverse transcription were performed; subsequently, the expression of the HDAC family genes were evaluated by q-PCR. The expression of HDAC genes family after 24 hours of hypoxia-ischemia injury, did not show statistical differences between experimental groups. Whereas, at 21 days after the brain injury, we found an increase in expression of HDAC2 and HDAC3 genes in the cortex compared to HIE (0.75±0.05 and 0.79±0.03 fold change, respectively; $p < 0.01$); and increase in expression of HDAC2, HDAC3 and HDAC7 genes in the ipsilateral hippocampus of HIE animals treated with Cerebrolysin compared to HIE (1.6±0.14, 2.37±0.21 and 5.35±0.13 fold change, respectively; $p < 0.01$). Gene expression of HDAC4, HDAC5, HDAC6, HDAC8, HDAC10 and HDAC11 were not modified. Our findings demonstrate that Cerebrolysin administration in neonatal rats with HIE exerts its epigenetic effect on learning, memory and motor system by up-regulation of HDAC2, HDAC3 and HDAC7 genes.

Title: Effect of intestinal microbiota composition on neuroinflammatory response after neonatal hypoxia-ischemia

Authors: *A. DROBYSHEVSKY, I. GOUSSAKOV, S. SYNOWIEC;
NorthShore Univ. HealthSystem, Evanston, IL

Abstract: Premature infants are often lacking normal microbial community in their intestines that naturally should have come from mothers. Premature infants are also often at risk of perinatal hypoxic-ischemic (HI) brain injury, considered as one of the major factors leading to motor, sensory and cognitive deficits. We hypothesize that neonatal gut microbiota composition can modulate immune reaction of the neonatal brain to hypoxic brain injury. C57BL/6 mouse pups were exposed to HI protocol at P10 (Vanucci model) consisting of permanent left carotid artery ligation and 8% oxygen exposure for 60 min at 37C. Microbial manipulation groups consisted of 1) naïve pups, 2) triple-antibiotic treated from E18 (maternal) to P5, 3) antibiotic treatment E18-P5 + *E.coli* gavage, 4) antibiotic treatment E18-P5 + *B. infantis* gavage. Extent of initial injury (edema) and recovery was measured on T2 weighted MRI at 24 and 72 hours after HI. Brain and gut tissue was collected for cytokine expression RT-PCR measurements. Mean extent of initial (24h) and delayed (72h) edematous HI injury was not different between microbiota groups. Injury volume decreased by 72h, with the smallest decrease in antibiotic+E.coli group. Proportion of pups with no decrease or increase of injury at 72h was largest in naïve + HI group. Significantly elevated expression of pro- (IL1b, IL6, IL2, TNF-a) and anti-inflammatory cytokines (TGF-b, IL10) was found on HI group relative to naïve and sham controls. This increase was less pronounced in HI + antibiotic group and H-I + gavage groups. Pro-inflammatory cytokines expression increased with the extent of HI injury but the slopes were not different between microbiota groups. We conclude that neuroinflammatory response after neonatal hypoxia-ischemia is affected by intestinal microbial composition, providing opportunities for therapeutic intervention through targeted nutritional supplementation.

Title: Role of estrogen receptor alpha in mediating normal fear response following perinatal hypoxic ischemic encephalopathy

Authors: M. HACKETT[1], B. OZAYDIN[1], N. AYCAN[1], S. YAPICI[1], N. KARAHAN KELES[2], E. BICKI[1], O. TAPARLI[1], K. CORCORAN[1], C. LAGOA-MIGUEL[1], T. Z. SHEIKH[1], P. FERRAZZANO[1],

J. E. LEVINE[1], *P. CENGIZ[1];
[1]Pediatrics, [2]Univ. of Wisconsin, Madison, WI

Abstract: Background: Perinatal hypoxic ischemic (HI) encephalopathy is one of the major causes of learning disabilities and memory deficits in children. The learning disabilities and memory deficits might be related to the increased fear or hyperactivity behavior following perinatal HI. We have previously showed that estrogen receptor (ER) alpha is upregulated in the female neonatal mice hippocampi following HI, leading to tyrosine kinase B (TrkB) mediated neuroprotection. To test the role of ER alpha on fear response and anxiety behavior in neonatal mice following HI, we performed elevated plus maze (EPM) and MRI 3 months post HI with and without TrkB agonist (7,8-dihydroxyflavone) in ER alpha wild type (WT) and complete knock-out (ERKO) mice.**Methods:** HI was induced in postnatal (P) day 9 C57BL/6J mice by using Vannucci's HI model in WT and ERKO mice. Mice were treated with 7,8 DHF (5mg/kg, i.p.) or vehicle control starting at 10 min post-HI for 7 days. At P 90+, mice underwent elevated plus maze (EPM) testing for 15 minutes. Video recordings of the EPM were analyzed using AnyMaze software. Percent (%) time spent in open arm is reported in mean ± SEM. ANOVA was used to analyze the EPM data. MRI was performed under anesthesia following EPM testing using 4.7-tesla small animal MRI. Masks of ipsilateral and contralateral hemispheres were created using ImageJ. Hemispheric areas were calculated from 8-11 slices/brain and averaged. The data is presented as the difference in CL area versus IL area for each brain as (CL−IL)/CL×100 and reported as IL hemispheric area loss. Percent time in open arm (EPM) and IL hemispheric area loss is fitted with linear regression. **Results:** Significant differences in % time spent in open arm of the EPM test indicated differing fear response between treatment groups (p= 0.013). HI mice exhibited abnormal fear response and TrkB agonist treatment rescued abnormal fear response only in female mice (%19±1) versus the male mice (%25±3) (p=0.034) in an ER alpha dependent manner. Hemispheric area loss positively correlated with % time spent in open arm (p=0.002). % open arm time for sham ER alpha KO mice was 50% less than sham WT mice. **Conclusion:** HI mice preferred the open arms of the testing apparatus indicating an abnormal fear response compared to sham mice. 7,8-DHF recovered the fear response in female mice to the sham levels but not in male mice 90 days post-HI in an ER alpha dependent way. This data suggests that TrkB agonist therapy restores the normal fear response and decreases hyperactivity in female mice in an ER alpha dependent way. Lack of ER alpha predisposes both male and female mice to have exaggerated fear response with possibly through different mechanisms.

Title: Chronic real-time calcium imaging of seizures and neuronal death tracking after perinatal oxygen-glucose deprivation

Authors: *M. A. MCNALLY[1], K. P. LILLIS[1], T. BALENA[2], L. A. LAU[5], V. I. DZHALA[3], K. J. STALEY[4];
[1]Neurol., [3]Dept. of Neurol., [2]Massachusetts Gen. Hosp., Charlestown, MA; [4]Massachusetts Gen. Hosp., Boston, MA; [5]Neurol. Res., MGH, Boston, MA

Abstract: Rationale: Neonatal seizures after hypoxia-ischemia (HI) are common in newborns and associated with significant mortality and chronic morbidity. However, definitive data indicating whether they are independently harmful or not after HI is a critical gap in the field. Our central hypothesis is that neonatal seizures independently worsen brain injury after HI. To address this question, we developed a system to track neuronal survival and seizures after oxygen-glucose deprivation (OGD). We used sustained emission of transgenically-expressed fluorescent proteins as a robust biomarker of neuronal viability (Arrasate *et al.* Nature 2004) and genetically encoded calcium indicators to follow seizure activity for 2 weeks post-OGD. **Methods:** Organotypic hippocampal slices prepared from neonatal mice expressing a neuronal red fluorescent protein and green calcium indicator (GCaMP6s) underwent 20 min of OGD. Chronic high resolution two-photon imaging of the pyramidal cell layer was performed. Neuronal death was quantified using the fluorophore quenching assay (Balena *et al. in prep*). To assess for caspase activation, slices were incubated with Biotracker NucView 405 Blue Caspase-3 Dye (Sigma-Aldrich). All analyses were performed in ImageJ. **Results**: 1) After OGD, calcium imaging demonstrated recurrent seizures (duration 23±1 sec (mean±SE)). 2) OGD induced an excess of acute (<24 hours) and chronic (1-14 days) neuronal death compared to controls (n=5 slices per group). 3) Neurons that died after OGD participated in seizure activity, did not activate caspase acutely post-injury, and exhibited robust fluorescence emission up to the time of death. 4) Neurons that died after OGD had lower ictal calcium burdens immediately post-OGD compared to neurons that survived. 1-3 days post-OGD, the ictal calcium activity was indistinguishable between groups. 5) No differences in interictal calcium activity were seen between neurons that died early or late versus those that survived. **Conclusions:** This is the first study to longitudinally measure neuronal death and seizures in real-time after perinatal acute injury. We found that neurons died with time courses consistent with both early necrotic and later apoptotic deaths. Neurons that eventually underwent apoptosis participated in seizure activity after OGD, albeit to a lesser degree than neurons that survived. This demonstrates, for the first time, a calcium activity signature immediately post-OGD that predicts which neurons will die and which neurons will survive. Critically, these data also support the hypothesis that acute post-injury seizures are a potentially treatable cause of late neuronal death after OGD.

Sch. of Nanjing Univ., Baltimore, MD

Abstract: Abstract Chronic stroke is a disease of immense public health importance with serious economic andsocial consequences. By integrating multidisciplinary expertise unique to the researchenvironment at Johns Hopkins Medicine, we are focusing on chronic ischemic stroke becausethere is no treatment for the large and growing stroke survivors living with the long-termconsequences of stroke.We propose combinational reparative approaches to promote neural repair following chronicstroke: using the biodegradable hydrogel guided and supported (1) endogenous stem cellstimulation and (2) exogenous stem cell transplantation to promote the functional integrationand recovery of chronic stroke. We specifically proposed these streams together because thedevastation of stroke is phenomenal and previous clinical trials have demonstrated that thereis no silver bullet: multiple parallel strategies are required for success.First, to take advantage of our resident stem cells to restore function, we will implore abioengineering-driven idea to develop tissue-like viscoelastic biomaterials to activate theseendogenous stem cells to promote repair. We have now developed neural tissue-likebiomaterial with brain tissue compatible properties. We will use these materials to boost theendogenous stem cell repairing.Second, with this neural tissue-like biomaterial, we will achieve safe delivery of authentichuman brain cells to the stroke-injured area in a minimally-invasive way. Using human ES/iPS,we have developed a high-efficiency rosette-type neural stem cell-derived aggregates(RONA)-method for generating authentic human cortical neural cells that containrepresentative excitatory and inhibitory precursors as well as oligodendrocytes. We are able totransplant every CNS cell type thought important for recovery post-stroke. Using this strategy,we will employ dynamic observation of survival, proliferation, migration, differentiation, andfunctional integration of grafted cells to optimize cell delivery interventions to providebehaviorally measurable recovery after stroke. The long-term goal is to responsibly translatecell-based therapies into novel therapies for stroke.Building on the combined expertise in neural stem cell biology and regenerative medicine,bioengineering, and neurosurgery and stroke, we will create and test a novel combinatorialstem cell strategy for chronic stroke treatment that will pave the way for clinical trials andstrengthen our position as an international leader in the stem cell field.

Basal ganglia-related neurodegenerative and psychiatric disorders are debilitating and lack disease-modifying therapy. In the last decade, stem cell therapies have come to the forefront of research as a promising therapy. The lack of ethical considerations, pluripotency, availability in nearly unlimited supply, and low immunogenicity and tumorgenicity make human Placental derived Stem Cells (hPSCs) a "New Hope" for clinical application. Major obstacles include the limited capability to differentiate stem cells into neurons, poor tracking/ control over transplant cell differentiation and survival, and poor evaluation of preclinical efficacy in animal models. We have tested different serotypes and transgene promoters that achieved more than 80% transduction efficiency with long-term stable transgene expression. We have performed transplantation of hPSCs into the striatum and substantia nigra of mice. We identified engrafted hPSCs with fully differentiated neurons in multiple brain regions, suggesting functional connections. In order to achieve a higher cell survival rate, multilineage neurodifferentiation, and robust vascularization, we grew cerebral organoids from the hPSCs using a modified protocol, yielding organoids with validated morphology and composition. The hPSCs derived brain organoids are transplanted into the striatum of a murine middle cerebral artery occlusion (MCAO) model. Efficacy is evaluated using a single-neuron genetic labeling method together with volume imaging to gain unprecedented temporal and spatial profiling of neurodegeneration and neuroinflammation after stroke. A series of neurological, motor, cognitive, and psychiatric behavioral are used across various time points to examine the efficacy of transplantation. Our study provides crucial insights for clinical translation of human brain organoid-based stem cell therapy for stroke, neurodegenerative, and psychiatric disorders.

Title: Glial response to paracrine factors secreted by transplanted stem cells in a rodent model of stroke

Authors: S. S. TIGCHELAAR, *C. DONG, R. L. AZEVEDO-PEREIRA, X. LIANG, T. M. BLISS, G. K. STEINBERG;
Stanford Univ., Palo Alto, CA

Abstract: Background: Human neural stem cell (hNSC) transplantation shows great potential as a therapy for ischemic stroke. A paracrine signaling mechanism of action is favored with stem cell-secreted factors signaling to the host brain. However, what stem cell-secreted factors are important for recovery is not known, and how the brain responds to these factors remains to be investigated. We recently made a major step towards answering these critical questions by identifying paracrine factors expressed by transplanted human neural stem cells (hNSCs) in the stroke-injured brain. The expression of several of these factors positively correlated with functional recovery. In this study, we focus on one of these paracrine factors that correlated best with stroke recovery, matrilin-2, and investigate how the brain responds to this paracrine factor with particular emphasis on the glial cell response as they are major players in brain recovery.
Method: Adult male nude rats underwent stroke using the distal middle cerebral artery occlusion (dMCAo) model. One week later, recombinant matrilin-2 was infused into the peri-infarct region, using ALZET® osmotic pumps, for 5 days. Animals were assessed for functional recovery for 5 weeks using both the Montoya staircase test and the whisker-paw reflex test. Four weeks post-treatment, brains were stained for GFAP and IBA1 to visualize astrocytes and microglia/macrophages, respectively. Images were taken and glial morphology analyzed using the Bitplane Imaris image analysis software. Output measurements of the number of cells/mm^2, cell volume, cell branching, and process length and thickness were obtained to characterize the changes in astrocytic and microglial response to injury and paracrine factor treatment.
Results: Matrilin-2 treatment significantly enhanced functional recovery compared to the vehicle group. Preliminary analyses revealed that astrocytes in the cortex of stroke rats receiving matrilin had significantly greater volume and surface area in both the ipsi- and contra-lesional hemispheres, compared to animals that received vehicle. Analysis of microglia is ongoing.
Conclusion: Matrilin-2 infusion promotes stroke recovery and modulates the glia response in the ischemic brain. Identifying paracrine factors involved in recovery following implantation of hNSCs in stroke brain, and understanding how the brain responds to these factors, is an important step in elucidating molecular pathways important for brain recovery and may ultimately identify novel therapeutic targets for stroke.

Abstract: Translational controls permeate pain. One class of sensory neurons, nociceptors, plays an integral role in the detection and propagation of pain signals. Nociceptors can undergo persistent changes in their intrinsic excitability. Pharmacologic disruption of nascent protein synthesis diminishes acute and chronic forms of pain-associated behaviors. Yet, the targets of translational controls that facilitate plasticity in nociceptors are unclear. Here, we used ribosome profiling to probe the translational landscape in DRG neurons after treatment of the inflammatory mediators, NGF and IL-6. We found that the transcription factor, c-Fos, is preferentially translated after treatment of inflammatory mediators. We demonstrate that c-Fos is expressed in sensory neurons. We also confirmed that inflammatory mediators that promote pain in both humans and rodents increase the accumulation of c-Fos protein. Given that inflammation is known to stimulate mTOR signaling, we reasoned that downstream factors might control c-Fos levels. We found that the ribosomal protein S6 kinase 1 (S6K1) is essential for c-Fos biosynthesis. We next asked if c-Fos or S6K1 play a role in inflammatory pain using the hyperalgesic priming model. We found that inhibition of S6K1s or c-Fos with small molecules diminish mechanical and thermal hypersensitivity in response to inflammatory cues. Additionally, both inhibitors reduce evoked nociceptor activity *in vitro*. Collectively, our data reveal a novel role of S6K1 in modulating rapid response to inflammatory mediators, with c-Fos being one key downstream target.

Title: Rapgef Family Members Expressed In Mouse Dorsal Root Ganglion Neurons Contribute To Erk Phosphorylation Downstream Of G_s-coupled Receptors

Authors: *Z. AL-ABBASI[1,2], R. GEGUCHADZE[1], D. C. MOLLIVER[1];
[1]Biomed. Sci., UNIVERSITY OF NEW ENGLAND, BIDDEFORD, ME; [2]Grad. Sch. of Biomed. Sci. and Engin., Univ. of Maine, Orono, ME

Abstract: Members of the Rap guanine nucleotide exchange factor (Rapgef) family activate Rap/Ras signaling pathways by exchanging GTP for GDP. Four of the 6 Rapgefs have been identified as effectors of cAMP signaling: Rapgef2, Rapgef3/Epac1, Rapgef4/Epac2, and Rapgef6. Rapgef1(C3G) does not bind cAMP, but has been implicated in Protein Kinase A (PKA)-dependent ERK activation. ERK signaling is required for some components of nociceptor sensitization, therefore cAMP signaling to ERK may represent an important pathway in the induction of inflammatory hyperalgesia by G_s-coupled receptors (G_sPCRs). We recently identified a role for Epac2 in nociceptor sensitization and behavioral hyperalgesia evoked by prostaglandin E2 (PGE2). Epac signaling has been reported to be mediated by both Protein Kinase C (PKC) and ERK1/2. However, studies in heterologous systems suggest that activation of ERK downstream of G_sPCRs is mediated by Rapgef2, either alone or in combination with PKA. To examine these divergent signaling pathways downstream of G_sPCRs, we first tested the distribution of Rapgef family members in dorsal root ganglia (DRG) of male mice by qPCR. We found that all 6 Rapgefs are expressed in DRG, to varying degrees. Next, we examined the relative contributions of PKA and Rapgef2 in the activation (phosphorylation) of ERK (pERK) downstream of cAMP. Application of the cAMP analog 8-Br-cAMP to dissociated DRG neurons induced pERK. The Rapgef2-selective cAMP analog N^6-Phe-cAMP also showed a dose-dependent (150-1000 micromolar) induction of pERK. Co-application of 1mM SQ22356 (an inhibitor of Rapgef2) reversed the effect of N^6-Phe-cAMP, supporting the activation of ERK by Rapgef2. Next, we examined whether activation of endogenous receptors was capable of inducing pERK. To identify G_sPCRs highly expressed in DRG, we examined published RNA-seq data and then confirmed expression of beta-adrenergic receptors Adrb1-3 and dopamine receptors Drd1, 5 by quantitative PCR. Of these receptors, Adrb2 and Drd1 were the most highly expressed. Application of 10 micromolar isoproterenol (Adrb2) or 1 micromolar SKF38393 (Drd1/5), induced pERK by 360% or 160% above baseline, respectively. While PKA inhibitor peptide PKI reduced the effect of isoproterenol by ~50%, it only slightly reduced the effect of SKF38393. These results suggest that different G_sPCRs may be differentially coupled to Rapgef2. In conclusion, Rapgef1, 2, and 6 are expressed in DRG and may contribute to cAMP signaling to ERK downstream of G_sPCRs.

Title: Mir-544-3p mediates arthritis pain through regulation of fcγri

Authors: *Y. LIU, S.-M. JEON, M. J. CATERINA, L. QU;
Neurosurg., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Chronic or episodic joint pain is a major symptom in rheumatoid arthritis (RA) and its adequate treatment represents an unmet medical need. However, the cellular and molecular mechanisms underlying RA pain remain elusive. Non-coding microRNAs (miRNAs) have been implicated in the pathogenesis of RA as negative regulators of the stability or translation of specific target mRNAs. Yet, their significance in RA pain is still not well defined. We and other groups recently identified neuronally expressed FcγRI as a key driver of arthritis pain in mouse RA models. Thus, we tested the hypothesis that miRNAs that target and regulate neuronal FcγRI attenuate RA pain. Here, qPCR analysis revealed that miR-544-3p was robustly downregulated whereas FcγRI was significantly upregulated in the dorsal root ganglion (DRG) in two mouse RA models, namely collagen II-induced arthritis (CIA) and antigen-induced arthritis (AIA). In situ hybridization showed a downregulation of miR-544-3p expression in joint-innervating DRG of mice with CIA. Rescuing miR-544-3p downregulation by intrathecal injection of miR-544-3p mimic (3 µg; 10 µl) significantly attenuated established arthritis pain in the CIA model. Moreover, this effect was likely mediated, at least in part, by FcγRI since miR-544-3p mimic downregulated FcγRI in the DRG under arthritis conditions and genetic deletion of FcγRI produced similar antihyperalgesic effects in the CIA model. Using the dual-luciferase assay, we found that miR-544-3p mimic reduced luciferase reporter activity in HEK293 cells transfected with a construct containing the full length of 3'UTR sequence of Fcgr1 but not one containing a mutant Fcgr1-3'UTR. These findings further confirmed that miR-544-3p directly targets the 3'UTR of Fcgr1 to downregulate Fcgr1 mRNA expression. In addition, Fcgr1 mRNA expression in dissociated DRG neurons in vitro was downregulated by miR-544-3p mimic and upregulated by miR-544-3p inhibitor. In naïve mice, in vivo transfection of either miR-544-3p mimic or miR-544-3p inhibitor had no effects on basal mechanical and thermal sensitivity. Yet, miR-544-3p mimic alleviated acute joint pain hypersensitivity induced by IgG immune complex (IgG-IC), whereas miR-544-3p inhibitor potentiated the pro-nociceptive behavioral effect of IgG-IC. These findings suggest that miR-544-3p causally participates in the maintenance of arthritis pain by targeting neuronal FcγRI, and thus define miR-544-3p as a new potential therapeutic target for treating RA pain.

Title: Role of Cathepsin K in Chronic Inflammatory Pain

Authors: *A. THAKAR[1], M. PARACHA[2], R. A. DARLING[2], T. E. BROWN[1];
[1]IPN, Washington State Univ., Pullman, WA; [2]Univ. of Wyoming, Laramie, WY

Abstract: Chronic inflammatory pain involves various underlying pathophysiological mechanisms and is far more complex than acute pain. Current therapeutics for chronic inflammatory pain are often not effective because the etiology responsible for the pain is not addressed by traditional pharmacological treatments. There is a need to find novel targets that not only alleviate the symptomology associated with chronic pain but address the underlying mechanisms responsible for pain. Cathepsin K is a cysteine protease that has traditionally been studied in the context of bone and joint disorders. Previous work by others has shown that inhibition of cathepsin K activity reduces osteoarthritis-associated nociception in joints. However, the role of cathepsin K in models of cutaneous inflammation is understudied. We assessed the effectiveness of genetic deletion or pharmacological inhibition of cathepsin K activity in male mice on the expression of nocifensive behaviors after formalin injection or mechanical and thermal hypersensitivity after injection of complete Freund's adjuvant (CFA) into the mouse hind paw. Our data demonstrates that cathepsin K knockout mice (*Ctsk*$^{-/-}$) have an attenuation in the longer-lasting, more persistent phase of the formalin test (WT=48.1s ± 7.3s, n=8; *Ctsk*$^{-/-}$=7.1 s± 2.9s, n=8). In addition, *Ctsk*$^{-/-}$ mice do not develop mechanical or thermal hypersensitivity after CFA injection for up to 7 days. Specifically, paw withdrawal threshold (PWT) was measured with von Frey filaments, which showed a significant attenuation in CFA-induced mechanical hypersensitivity in *Ctsk*$^{-/-}$ mice (day 1=1.5 g and day 7=1.7 g, n=8) compared to WT mice (day 1=0.75 g and day 7= 1.2 g, n=8). Moreover, inhibition of cathepsin K activity was effective at reducing the expression of mechanical hypersensitivity (day 1-DMSO=0.63 g ± 0.10 g, n=12; cKi=1.23 g ± 0.15 g, n=13; and day 7- DMSO=0.52 g ± 0.08 g, n=13; cKi=1.04 g ± 0.13 g, n=13) and thermal hypersensitivity (day 1-DMSO=5.74 s ± 0.39 s, n=11; cKi=7.87 s ± 0.76 s, n=12; and day 7- DMSO=4.88 ± 0.41 s, n=11; cKi=6.58 ± 0.55 s, n=12] after CFA injection. In addition, 1 day after CFA injection the mRNA levels (3.77 fold, n=8) and cathepsin K activity levels (2.6 fold, n=8) were elevated and persisted for 7 days (mRNA- 5.24 fold, n=8 and activity- 2.96 fold, n=7). Based upon our data we demonstrate that cathepsin K plays a key role in the expression of chemically induced cutaneous hypersensitivity as Ctsk$^{-/-}$ mice and pharmacological reduction of cathepsin K activity in WT mice attenuated nocifensive behaviors.

Title: The role of Transient Receptor Potential ankyrin 1 in the Knee osteoarthritis of rat

Authors: *H. TAMAI[1], M. YAMANAKA[1], W. TANIGUCHI[1], N. NISHIO[1], D. FUKUI[1], M. SONEKATSU[1], R. TAIJI[1], Y. MATSUYAMA[1], T. UENO[1], R. MIYAKE[1], T. NAKATSUKA[2], H. YAMADA[1];
[1]Wakayama Med. Univ., Wakayama, Japan; [2]Pain Res. Ctr., Kansai Univ. of Hlth. Sci., Kumatori, Japan

Abstract: Knee osteoarthritis (knee OA) is a leading cause of impaired mobility in the elderly, and is one of the most common diseases that are often treated in clinical practice. It is thought that the pain due to knee OA is caused by the bones hitting each other due to the worn cartilage, but X-ray changes and pain do not necessarily correlate. Despite its widespread prevalence, pathogenesis of pain due to knee OA is unknown and various studies are being conducted. The Transient Receptor Potential (TRP) channels that have been attracting attention in recent years are ion channels that are expressed in various tissues throughout the body, and among them, TRP ankyrin receptor subtype 1 (TRPA1) and TRP vanilloid receptor subtype1 (TRPV1) have been reported to be associated with intraspinal pain previously. However, the little is known about the role of TRPA1 involved in chronic pain such as knee OA. Therefore, we investigated the effect of intra-articular TRPA1 on glutamatergic excitatory synaptic transmission in substantia gelatinosa (SG) neurons of knee OA model rats by using *in vivo* patch-clamp technique. We also assessed gait parameters and pain threshold with CatWalk and Pressure application measurement (PAM). In the knee OA models, excitatory postsynaptic current in SG neurons significantly increased by intra-articular administration of allyl isothiocyanate, a TRPA1 agonist. On the other hand, application of HC-030031, a TRPA1 antagonist, induced significant decrease of that. Next, we found that pain-related gait and pain threshold improved with CatWalk and PAM test by intra-articular administration of HC-030031. These results indicate that TRPA1 is expressed in the knee OA model rat, and the activation enhances the pain due to knee OA. In this study, we demonstrated that TRPA1 was critical channel for the pain caused by Knee OA.

Title: Long-lasting pain and profound changes in the transcriptome are caused by the disruption of mitochondrial pyruvate oxidation in dorsal root ganglia

Authors: *O. MELEMEDJIAN, T. LUDMAN;
Univ. of Maryland Dent. Sch., Baltimore, MD

Abstract: Metabolism is inextricably linked to every aspect of cellular function and defects in metabolic pathways are associated with a variety of neoplastic, cardiovascular, and neurodegenerative diseases. Additionally, polymorphisms and inborn errors in metabolic genes are associated with a multitude of chronic pain conditions. Similarly, nerve growth factor (NGF) is associated with a multitude of chronic pain conditions, but its potential role in regulating the metabolism of sensory neurons is largely unknown.

Hence, we explored whether intraplantar NGF injection in mice alters the metabolism of sensory neurons. We determined that intraplantar NGF injection disrupts mitochondrial pyruvate oxidation leading to an increased extrusion of lactate and protons. These changes were driven by the enhanced expression of pyruvate dehydrogenase kinase 1 (PDHK1) and lactate dehydrogenase A (LDHA). Moreover, pharmacological and genetic blockade of PDHK1 and LDHA attenuated NGF-induced tactile allodynia. Direct disruption of mitochondrial pyruvate oxidation in dorsal root ganglia was sufficient to cause tactile allodynia that lasted at least 3 months - unlike NGF-induced allodynia which resolves within 72 hours. Full-length transcript analysis revealed that the disruption of mitochondrial pyruvate oxidation significantly altered the transcription of over 400 genes, reduced the poly-A tail length of mRNAs, and modified the alternative splicing of hundreds of transcripts. These findings demonstrate that aberrant mitochondrial pyruvate oxidation is a crucial mechanism for the development and maintenance of chronic pain.

Title: Sex-specific patterns of spinal cord neuroinflammation in a mouse model of complex regional pain syndrome.

Authors: *G. P. B. MUWANGA, H. SHEN, N. A. HUCK, C. E. JORDAN, T. E. FORMAN, S. A. CORDONNIER, E. S. HAIGHT, F. DALE-HUANG, Y. TAKEMURA, V. L. TAWFIK;
Stanford Univ., Stanford, CA

Abstract: Chronic pain is a major physical, emotional, and financial burden affecting 100 million Americans. Understanding the molecular mechanisms underlying pain is essential for developing safe and effective therapies. Microglial activation mediates chronic pain, according to numerous preclinical studies. However, translational efforts using known glial modulators have largely failed, possibly due to poor specificity of the compounds studied or an incomplete understanding of microglial reactivity. To better understand the contributions of microglia to chronic pain, we used a clinically relevant mouse model of complex regional pain syndrome (CRPS) and monitored microglial activation throughout disease progression in both males and females. We found that while both sexes exhibit spinal cord microglial activation evidenced by increases in Iba1, this activation was attenuated and delayed in

females. We also sought to evaluate the expression of the newly identified microglia-specific marker, TMEM119. We found two distinct populations of myeloid cells in the spinal cord based on the relative expression of TMEM119 and morphology: TMEM119+ microglia and TMEM119- infiltrating myeloid lineage cells, which comprised of Ly6G+ neutrophils and Ly6G- macrophages. Further studies to uncover glial-targeted therapies need to consider sex, timing after injury, and exact target population to achieve the specificity needed for translation. This is especially important because mixed myeloid populations infiltrate the spinal cord after peripheral injury and may have varying functions in pain progression or resolution.

Title: Inhibition of acute inflammation leads to chronification of inflammatory pain

Authors: *L. V. LIMA[1], M. PARISIEN[2], G. G. DUTRA[1], J. RAYMONDI SILVA[3], N. GHASEMLOU[3], L. DIATCHENKO[2], J. MOGIL[1];
[1]Psychology, [2]McGill Univ., Montreal, QC, Canada; [3]Queen's Univ., Kingston, ON, Canada

Abstract: Introduction: Recent data from a human genetics study suggests that pain resolution is coordinated by inflammatory cells during the acute phase of an inflammatory response. Thus, we hypothesized that inhibition of inflammatory response might lead to pain chronification. **Methods**: CD-1 male and female mice were treated with dexamethasone (a corticosteroid) or vehicle for seven consecutive days (0.5 mg/kg/day). On the second day of treatment, mice received either a unilateral nerve injury (chronic constriction injury; CCI) or inflammatory injury (complete Freund's adjuvant; CFA). Mechanical paw-withdrawal threshold (PWT) was measured prior to treatment (baseline) and at regular intervals until average PWTs returned to baseline values. To assess whether the phenomena is due to anti-inflammatory effects rather than analgesic action, the NSAID, diclofenac, and two analgesics with no known anti-inflammatory action (systemically administered gabapentin and peripherally administered lidocaine) were tested in the CFA model. The involvement of neutrophils was examined by depletion using anti-Ly6G or direct injection of isolated neutrophils into the hind paw. Finally, we tested whether cryotherapy (application of ice) would have similar effects after CFA injury.**Results**: Dexamethasone produced an acute anti-allodynic effect in the CFA but not CCI injured mice, but significantly delayed PWT recovery to baseline in both groups. CFA allodynia in mice receiving dexamethasone took twice as long to recover to baseline compared to vehicle. Diclofenac, gabapentin, lidocaine, and cryotherapy all reduced allodynia during the treatment period, but only diclofenac and cryotherapy prolonged the

duration of CFA-induced allodynia, suggesting that the delay in recovery is, in fact, due to the reduction of inflammation. Finally, treatment with anti-Ly6G antibody reduced acute allodynia but prologued its duration whereas neutrophil injection entirely prevented the allodynia-prolonging effect of dexamethasone, suggesting that neutrophils are involved in the resolution of pain after injury and that dexamethasone delays allodynia recovery by directly affecting neutrophils.**Conclusions**: Our observations suggest that interfering with the inflammatory response taking place immediately after injury with a corticosteroid (dexamethasone), NSAID (diclofenac) or cryotherapy, although producing the acute relief of pain, might simultaneously lead to pain chronification. If this phenomenon is also seen in humans, it could have dramatic implications for the treatment of acute pain.

Abstract: Expression of ectopic heat shock protein 90 (eHsp90) in male and female primary afferent nociceptors regulates inflammatory pain

Yaomin Wang[1], Scott Scarneo[1, 2], Shin Hyung Kim[1,3], Xin Zhang[1], Kelly W. Yang[2], PhilipHughes[2], Timothy Haystead[2], and Andrea G. Nackley[1,2]
Affiliations:[1]Center for Translational Pain Medicine, Department of Anesthesiology, Duke University Schoolof Medicine, Durham NC 27705[2]Department of Pharmacology and Cancer Biology, Duke University School of Medicine,Durham NC 27705[3]Department of Anesthesiology and Pain Medicine, Yonsei University College of Medicine,Seoul, Korea.

Heat shock protein 90 (Hsp90) is a ubiquitously expressed integral cellular protein essential toregulating proteomic stress. Previous research has shown that Hsp90 regulates critical signalingpathways underlying chronic pain and inflammation. Recent discovery of membrane bound ectopic Hsp90 (eHsp90) on tumor cells has shown that Hsp90 induction to the plasma membrane can stabilize disease-relevant proteins. Here, we characterize eHsp90 expression in a mouse model of inflammation and demonstrate its role in nociception and pain. We found that intraplantar complete Freund's adjuvant (CFA) induced robust

expression of eHsp90 on the cell membranes of primary afferent nociceptors located in the L3-L5 dorsal root ganglia (DRG), bilaterally, with minimal to no expression in other tissues. CFA-induced increases in eHsp90 expression on lumbar DRG were significantly greater in females compared to males. Furthermore, exogenous Hsp90 applied to primary Pirt-GCaMP3 nociceptors induced increases in calcium responses. Responses were estrogen-dependent such that greater activity was observed in female or estrogen-primed male nociceptors compared to unprimed male nociceptors. Treatment of mice with the selective eHsp90 inhibitor HS-131 (10 nmol) significantly reversed CFA-induced mechanical pain, thermal heat pain, and hindpaw edema. Notably, a higher dose (20 nmol) of HS-131 was required to achieve analgesic and anti-inflammatory effects in females. Here, we provide the first demonstration that inflammation leads to an upregulation of eHsp90 on DRG nociceptors in a sex-dependent manner, and that inhibition of eHsp90 reduces nociceptor activity, pain, and inflammation. Thus, eHsp90 represents a novel therapeutic axis for the development of gender-tailored treatments for inflammatory pain. Title: Estrogen and serotonin synergistically enhance the release of interleukin-6 and fractalkine from murine macrophages: a potential mechanism underlying sex differences in pain

Authors: *T. M. HICKMAN, S. KAUR, E. H. SIMMONS, L. K. HANSON, D. L. AVERITT; Texas Woman's Univ., Denton, TX

Abstract: Sex differences in the immune system could contribute to pain conditions more prevalent in women. In the peripheral nervous system, serotonin (5HT) can be released by immune cells, including macrophages. Peripheral 5HT can bind to excitatory 5HT receptors, including $5HT_{2A}$, expressed on nociceptors to initiate and sensitize pain signaling. Macrophages reportedly express estrogen receptors and may be sensitive to the gonadal hormone levels in females. We previously reported 5HT content in the rat vibrissal pad to be higher in female rats compared to males and that 5HT evokes significantly greater pain sensitivity when gonadal hormone levels are in flux. Further, 17β-estradiol (E2) enhances 5HT's nociceptive effects on sensory neurons. While it is clear that E2 modulates 5HT-evoked pain signaling in sensory neurons, it remains unclear if E2 can modulate the release of 5HT or other peripheral proinflammatory mediators from immune cells to contribute to pain. Here we hypothesized that E2 triggers the release of 5HT and/or proinflammatory cytokines and chemokines from cultured male and

female murine macrophages. Supernatant from IC-21 (male C57BL/6) or J774A.1 (female BALB/cN) cultures was collected before and after 1-hour treatment with 150 pM, 1 nM, or 50 nM E2 or vehicle and 5HT release was quantified by ELISA. These concentrations were used to mimic the high and low E2 levels observed during diestrus and proestrus of the rat estrous cycle. In separate cultures, supernatant was collected before and after 1-hour treatment with 100 μM 5HT, 50 nM E2, 5HT + E2, or vehicle and the release of cytokines and chemokines were quantified using a Proteome Profiler Cytokine Array. Macrophages were then fixed in 10% formalin and ERα, ERβ, and $5HT_{2A}$ receptor expression was detected by immunocytochemistry. A separate group of macrophage cultures were treated with 50 nM capsaicin (nociceptive stimulus), 10 μM 5HT + 50 nM capsaicin, 50 nM E2 + capsaicin, or 5HT + E2 + capsaicin and cell lysates were analyzed by Phospho-Kinase Array. We report that proestrus-level E2 triggers release of 5HT from macrophages which co-express ERα and $5HT_{2A}$. While E2 triggered the release of many cytokines and chemokines, E2 + 5HT synergistically increased the release of IL-6 and fractalkine, which are known to trigger allodynia. Further, we report that E2 + 5HT increased phosphorylation of p38, JNK, and Src kinases, while reducing RSK phosphorylation, implicating an intracellular interaction between ERα and $5HT_{2A}$. Together, our data suggest that E2 modulates release of proinflammatory mediators from macrophages which is exacerbated by 5HT, providing a novel mechanism underlying sex differences in pain.

Title: Exclusive blockade of extrasynaptic NMDA receptors ameliorates chronic pain

Authors: *N. VOITENKO[1,2], A. HONCHAROVA[2], I. LAZORENKO[2], A. SAVTCHENKO[3], E. MOLOKANOVA[4];
[1]Bogomoletz Insitute of Physiol., Kyiv, Ukraine; [2]Biophysics and Mol. Physiol., Kyiv Academic Univ., Kyiv, Ukraine; [3]Bioengineering, Nanotools Biosci., Encinitas, CA; [4]Nanotools Biosci., LA Jolla, CA

Abstract: Chronic pain is associated with glutamatergic excitotoxicity due to tonic overactivation of NMDA receptors at extrasynaptic sites (eNMDAR). Therefore, chronic pain can be treated by blocking eNMDARs. To test this hypothesis, we developed AuM, a first-in-class exclusive antagonist of eNMDARs, by attaching memantine (M) to a gold (Au) nanoparticle, so that the resulting nanotherapeutic

is too large to gain access to the synaptic cleft. We studied the effect of eNMDAR blockade on pain sensitivity in two experimental models: right-side spared nerve injury (SNI, mice) or left-paw chronic inflammation inducted with CFA (Complete Freund's Adjuvant, 0,1 ml emulsion, subcutaneously, rats). We stereotaxically injected 0.5 µl of 25 nM AuM or saline into the right spinal dorsal horn (mice) or epidurally injected 20 µl of 25 nM AuM or saline into the spinal canal under the foramen between L5-L6 vertebrae (rats). In the SNI model, mice were subjected to mechanical sensitivity testing by von Fray filaments starting from 3 to 25 day after injury. Our data revealed that SNI mice treated with AuM right after the injury show significant slowing down of allodynia compared to saline-injected SNI mice. Post-SNI (5 days) treatment display significant reduction of hypersensitivity. In the CFA model, rats were subjected to mechanical sensitivity testing and thermal sensitivity testing by Hargreaves starting from 1 hour to 14 days after CFA administration. CFA-inflamed animals treated with AuM right after the injury shows significant slowing down of allodynia progressing compared to saline-injected animals. In summary, our findings indicate the involvement of eNMDAR at different stages of chronic pain development and offer the opportunity to develop novel therapeutics to ameliorate the impact of nerve injury.

Title: Parietal contributions to illusory tactile pulling sensations

Authors: *J. DE HAVAS[1], S. ITO[1], S. BESTMANN[2,3], H. GOMI[1];
[1]NTT Communication Sci. Labs., Atsugi, Japan; [2]Inst. of Neurol., London, United Kingdom; [3]Wellcome Ctr. for Human Neuroimaging, UCL, London, United Kingdom

Abstract: The sensation of directional forces and their associated sensorimotor commands are inextricably intertwined, complicating the identification of brain circuits responsible for tactile pulling sensations. One hypothesis is that, like tactile frequency discrimination, pulling sensations are generated by early sensory-frontal activity. Alternatively, they may be generated later in the somatosensory association cortex. To dissociate these accounts and uncouple the pulling sensation from unrelated but correlated sensory and motor processing, we combined high-density EEG with an oddball paradigm and asymmetric vibration at the fingertips in 15 human participants (5 females, mean age = 33.33yrs). Asymmetric vibration reliably created an illusory sensation of the hand being directionally pulled either leftwards or rightwards (left/right discrimination accuracy = 94%). Oddballs that created a pulling sensation in the opposite direction to common stimuli were compared to the same oddballs in the context of neutral common stimuli (symmetric vibration) and to neutral oddballs. Brain responses to having

directional pulling expectations violated by directional stimuli were therefore isolated. Contrary to the sensory-frontal account, sensory P50 amplitude did not differ across conditions and frontal N140 brain activity was actually larger for neutral than pulling oddballs. Instead, puling sensations were associated with amplitude and latency modulations of midline P200 and P3b potentials, and specifically, to contralateral parietal lobe activity 264-320ms post-stimulus. Source localization showed this latter activity to be from the postcentral sulcus, superior parietal lobule and intraparietal sulcus, supporting the somatosensory association cortex account of the pulling sensation. Our results show that illusory tactile pulling sensations can uniquely disambiguate the role of complex tactile sensations from their associated low-level sensorimotor processing. Pure pulling sensations depend on activity in somatosensory association cortex responsible for processing body position, tactile orientation and peripersonal space. This first step towards a spatiotemporally precise account of the pulling sensation elucidates parietal lobe function during tactile processing.

Title: Slow binding of paired stimulus features in tactile perception

Authors: *S. KUROKI[1], S. NISHIDA[1,2];
[1]NTT Communication Sci. Labs., Atsugi, Japan; [2]Kyoto Univ., Kyoto, Japan

Abstract: When we touch an object, we can extract its features such as texture, shape, and direction. Previous studies have shown remarkable human's abilities to detect and discriminate individual features. For correct perception of the object by touch, not only detection of specific features, but also that of the correct combination of features is necessary. To better understand how and at what stage of information processing in the brain the tactile feature binding takes place, we psychophysically measured temporal limit of feature binding. In the experiment, the observer touched a tactile stimulator (Latero, Tactile Lab) with a single finger. The stimulator has an array of 64 pins that constructs a 10 x 10 mm contact surface, and each pin can independently produce lateral movements of the contacted surface of the skin. In the experiment, we combined pin-vibration frequency (temporal texture) and orientation as a feature pair. In a trial, two patterns were alternatively presented for four seconds. In half of the trials, the patterns were a 45-deg (right-upward) diagonal line produced by a low-frequency (20 Hz) vibration, and a -45-deg (right-downward) diagonal line produced by a higher-frequency (30, 40, 80 or 160Hz) vibration. In the other half, the two patterns were the reversed combinations of frequency and orientation. We changed the duration of each pattern presentation, and asked observers to report whether the low-frequency vibration was paired with the 45-deg or -45-deg tilt. The performance dropped with decreasing the duration of each pattern (increasing the alternation rate) or with reducing the difference in vibration frequency between the

two pairs. Critically, observers could not report the correct paring of vibration frequency with orientation unless slowing down the presentation rate (< 4 Hz, corresponded to > 125 ms for each feature pair). This poor performance cannot be explained solely by the short duration of each pattern, since the performance was greatly improved when the two patterns were presented with more-than-one-second temporal gaps. We observed same trend when the vibration frequency and motion direction were combined as a pair. Observed temporal limit was as slow as that of multimodal binding (visuo-tactile, audio-tactile), and much slower than that of visual feature pairings of color or luminance with orientation. Since fast pairing rates suggest the processing of feature binding at early stages, no evidence was observed for early binding of tactile basic features.

Title: The neural dynamics of tool-extended sensing

Authors: *C. FABIO[1,2], R. SALEMME[1,3], A. FARNÈ[1,2,3,4], L. MILLER[1,2,3,5];
[1]Ctr. for Res. in Neurosci., Bron, France; [2]Claude Bernard Univ., Lyon, France; [3]Neuro-Immersion, Hospices Civils de Lyon, Lyon, France; [4]Ctr. for Mind/Brain Sci., Univ. of Trento, Rovereto, Italy; [5]Donders Inst., Radboud Univ., Nijmegen, France

Abstract: Tool use is one of the defining traits of humankind. Tools allow us to explore our environment and expand our sensorimotor abilities. For this reason, the topic of tool use has been extensively studied, though mostly from a motor control perspective. We recently demonstrated that humans can accurately localize tactile information (e.g. impacts) along the entire tool surface, raising questions about the neural mechanism underlying this ability. Previous EEG studies have found that the alpha (7-14 Hz) and beta (15-30 Hz) frequency bands are involved in the spatial processing of touch on the body. Activity in the alpha band contributes mainly to the mapping of touch in external spatial coordinate systems, whereas activity in the beta band seems to be modulated mainly when mapping touch in skin-centered coordinates. To date, whether these frequency bands also relate to spatial processing of touch on hand-held tools remains unknown. Our goal here was therefore to fill this gap. In a first study, participants had to judge the relative location of two successive contacts on a hand-held rod. Using analyses based on repetition effects, we found evidence that alpha oscillations may code for spatial aspects of touch on a tool (Fabio, et al., in prep). In a second study, we aimed at pinpointing the role of alpha oscillations during tool-

extended sensing. Participants performed a tactile detection task where contact was applied to either hands, or the tips of hand-held rods. The posture of the hands/tool-tips was uncrossed or crossed at participants' body midline. Notably, when tool-tips were crossed the hands remained uncrossed, thus allowing us to disentangle brain responses related to different coordinate systems. That is, whether brain response reflected the coding of contact on the tool in external or tool-centered spatial coordinates. Similar external-related signals in alpha were found for tools and hands, suggesting that the brain uses similar oscillatory mechanisms for mapping touch on a rod and on the body. Ongoing analyses are further exploring this effect.

Title: Single unit and population coding of bimanual interactions in human sensory cortex

Authors: J. VERGARA[1], R. W. NICKL[2], G. L. CANTARERO[3], M. S. FIFER[5], F. TENORE[6], P. A. CELNIK[4], *J. YAU[1];

Abstract: Mundane tasks like fastening a button or tying shoelaces are possible because of specialized neural circuits for coordinating our use of two hands. Although bimanual movement control has received great attention, the coordination of sensory processing over the hands remains poorly understood. Tactile cues experienced on one hand exert systematic influences on the perception of cues experienced on the other hand revealing robust bimanual interactions. These interactions may be mediated by higher-order somatosensory cortical neurons which frequently have bilateral receptive fields that span both hands. Alternatively, bimanual touch may reflect integration in primary somatosensory cortex, where neural activity that is predominantly associated with touch on contralateral body sites can sometimes be modulated by ipsilateral cues.
Here, we recorded neural activity in microelectrode arrays implanted in the postcentral gyri of a patient with incomplete spinal cord injury (C5-C6 ASIA B). Exploiting his residual sensibilities, we required the participant to perform a simple oddball detection task that ensured attentional engagement with vibration cues delivered to his fingers. We characterized single unit responses to cues delivered only to the contralateral or ipsilateral hands, and compared these activity patterns to bimanual cue responses. We also determined how spiking activity related to variations in vibration frequency or amplitude. In addition to

single unit characterizations, we explored population coding of the unimanual cues and bimanual interactions using neural dimensionality reduction. These preliminary analyses establish how vibrotactile cues are signaled by individual neurons in human sensory cortex and how neural populations can dynamically represent cue interactions over the hands.

Title: Somatosensory and auditory systems support tactile frequency discrimination

Authors: *A. GRENIER, A. SHARP, P. ALBOUY;
Ctr. De Recherche CERVO, Québec, QC, Canada

Abstract: Somatosensory and auditory systems support tactile frequency discriminationAuditory scene analysis is essential to many daily activities: understanding speech in noise, localization of sounds, musical perception, etc. Most of the time, several senses are involved in these activities. For example, when a violinist plays a note, sounds and vibrations are produced by the instrument. Hearing and tactile systems are activated. Understanding how the brain recruits each of these senses and how they interact with each other remains a matter of study. To better understand tactile perception, the study of neuroanatomical correlates is necessary via low-level perceptual tasks. Therefore, the main goal of this study was to investigate neural correlates of tactile perception during a simple frequency (pitch) discrimination task via the tactile modality only (no auditory perception). We hypothesized that both somatosensory and auditory cortices will be recruited during the frequency (pitch) discrimination task even if no sounds were presented to the auditory system. During the EEG recordings, using an oddball paradigm, tactile stimulation was delivered to 20 healthy participants through a left hand vibrotactile stimulation glove. The paradigm includes five deviant stimuli (225Hz, 250Hz, 500Hz, 800Hz, 1000Hz) differing in frequencies and presented randomly between the standard stimuli (200Hz). To control for auditory perception, participants were asked to listen to a continuous white noise while wearing earplugs during the entire experiment. Source reconstruction of vibro-tactile event related potentials showed right lateralized evoked response in both somatosensory and auditory regions for the average of all standard stimuli. The somatosensory response was earlier than the auditory response. For the detection of deviant sounds (as compared to standard sounds) two ERPs were observed. The first component was an early negative wave with a peak around 300ms, with generators in the auditory and somatosensory cortices. This wave was observable only in response to the 500Hz and the 800Hz deviant stimuli but not for the 225Hz, 250Hz and 1000Hz stimuli. A second positive wave was observed at around 450ms with generators in the dorsal stream and was observable only for deviants 500Hz, 800Hz and 1000Hz. These findings suggest that pitch discrimination without auditory perception is performed by an interplay between tactile and auditory systems but are limited by the frequency discrimination capacities of the

tactile system. These results provide a better understanding of multisensory interaction during tactile uni-sensory perception.

Title: Neural Specialization for Social and Interactive Touch in rTPJ

Authors: *T. BUCK[1], C. DICOCCO[1], J. L. CUZZOCREO[1], J. A. NOAH[1], X. ZHANG[1], J. HIRSCH[1,2,3,4,5];
[1]Psychiatry, Yale Univ., New Haven, CT; [2]Neurosci., [3]Comparative Med., Yale Sch. of Med., New Haven, CT; [4]Med. Physics and Biomed. Engin., Univ. Col. London, London, United Kingdom; [5]Haskins Labs., New Haven, CT

Abstract: Physical touch is a natural form of social and interactive communication. Although the neural representations of the sensory systems are well understood, the social and communicative functions associated with sensorimotor touch remain understudied. In one model the social/affective function would be processed by sensory pathways. However, the nexus model of social processing proposes that the right temporal parietal junction (rTPJ) serves as a neural hub for social functions and predicts that social touch would also be represented in the rTPJ[1]. We test these alternative models with real vs. simulated hand clasps using the right and left hands. The design of this study takes advantage of the anatomically crossed sensory and motor pathways where expected responses for sensory touch include contralateral regions in sensorimotor hand areas (Figure 1A. & 1B.) and test the hypothesis that social responses (real vs simulated hand clasps) are expected in right parietal regions. 15 dyads (n=30) performed right and left-hand clasps with their partners' hand (social) or a simulated hand (non-social condition). Neuroimaging findings for right- and left-hand handclasps with real vs. simulated hands were consistent with social properties of rTPJ and extend the nexus model to social touch (Figure 1C., $p < .001$, $t = 3.19$).

Title: Create your own sensations: from custom built intracortical microsimulation to tactile feedback for prosthetic control

Authors: *C. VERBAARSCHOT[1,4], V. KARAPETYAN[1,2], M. BONINGER[1,2,3], B. SORGER[4], R. A. GAUNT[1,2,3];
[1]Rehab Neural Engin. Labs, [2]Bioengineering, [3]Physical Med. and Rehabil., Univ. of Pittsburgh, Pittsburgh, PA; [4]Psychology and Neurosci., Maastricht Univ., Maastricht, Netherlands

Abstract: An ideal prosthetic arm should both act and feel like a healthy human arm to enable a user to interact naturally with individuals and objects around them. To do so, the prosthesis needs to convey physical object characteristics, such as how soft or rough something feels. Intracortical microstimulation (ICMS) may be a way to achieve such tactile feedback. To date, the effects of ICMS have been primarily explored using experimenter-driven parameter manipulations. In this study, we use a participant-driven

approach to test whether (1) specific ICMS settings can create distinguishable tactile sensations and (2) whether these artificially created sensations can convey object characteristics.
Two people with tetraplegia participated in this study and have microelectrode arrays implanted in their somatosensory cortex that can generate localized sensations in their right hand. The participants have limited arm control and used their left hand to interact with a tablet interface. The interface visually presented one of several objects to the participant and evoked ICMS stimulation when touched by the user. By moving a cursor around in two virtual rectangles with parameters randomly assigned to their axes, participants could manipulate four ICMS parameters: amplitude, frequency, transient shape and drag. Participants repeatedly defined specific ICMS parameter settings in the rectangles for each object, attempting to get their tactile perception as close to the pictured object as possible. To assess what the created sensations feel like and determine whether they are distinguishable, previously defined ICMS settings were replayed to the participants and they were asked to (1) describe the experienced tactile characteristics and (2) select the object that best matches this sensation.
Preliminary results indicate that participants can create distinct tactile experiences that represent object characteristics; participants verbally report experiences of compliance, temperature and texture. For example, ICMS-evoked sensations that were created for an 'apple' are repeatedly reported as feeling 'smooth' and 'cool'. Moreover, both participants report the ability to create intended object-specific sensations to a satisfactory degree.
In contrast to previous research, this study puts participants in control of their own brain stimulation. This increases experimental efficacy as participants can interactively review and update ICMS parameter settings according to their tactile experience. Moreover, the experimental design allows for the identification of ICMS parameters that significantly influence tactile sensation in an engaging way.

Title: Somatosensory Duration Mismatch Negativity in Young Adults

Authors: *E. ISENSTEIN[1], A. XU[2], I. DEANDREA-LAZARUS[3], E. G. FREEDMAN[4], J. J. FOXE[5]; [1]Dept. of Brain and Cognitive Sci., [3]Translational Biomed. Sci., [2]Univ. of Rochester, Rochester, NY; [4]Del Monte Inst. for Neurosci., Univ. of Rochester - Neurosci., Rochester, NY; [5]Neurosci., Univ. of Rochester Sch. of Med., Rochester, NY

Abstract: Compared to other sensory domains, few studies exist that examine the neurophysiology of tactile perception. There are many disorders that involve dysregulated somatosensory processing, such as autism spectrum disorder and sensory processing disorder, yet little is known about the neurological underpinnings of atypical tactile sensitivity. In this experiment we aim to clarify the role of predictability in how the brain responds to tactile stimulation in neurotypical young adults. This study used a

somatosensory duration mismatch negativity (MMN) paradigm to assess vibrotactile novelty detection in 17 neurotypical young adults. The MMN is a specific event-related potential that occurs when a repeated sequence of identical, predictable 'standard' stimuli is interrupted by a novel, unpredictable 'deviant' stimulus that differs from the standard majority. By maintaining one stimulus as the majority of the input (80%), any perceived deviation from the anticipated stimulus results in a distinct, measurable electrophysiological response. In this study, vibrations of standard (100 ms) and deviant (115, 130, 145, and 160 ms) durations were presented while an electroencephalogram (EEG) measured cortical activity. Difference waves were calculated by subtracting the standard waveform from each respective deviant waveform. Peak amplitude of the difference wave was extracted from fronto-central electrodes between 150 and 210 ms after stimulus presentation to represent the MMN. The average peak difference wave amplitudes and standard deviations were as follows: 115 ms: -.54 (.60) μV, 130 ms: -1.15 (.66) μV, 145 ms: -.85 (.65) μV, 160 ms: -1.05 (.69) μV. A one-way ANOVA revealed a statistically significant difference in MMN amplitude between at least two groups ($F(3,64) = 2.88$, $p = .04$); this effect was driven by a significant difference between the 115ms and the 130ms amplitudes $t(16) = 3.58$, $p = .003$). This paradigm effectively captures cortical discrimination between predictable and unpredictable tactile stimulation. The differentiation of amplitudes in response to the deviant conditions indicates that this measure is sensitive not only to the presence of novelty, but also the degree of the novelty. We plan to expand this experiment to be used as a biomarker for tactile sensitivity in clinical populations.

Abstract: Sensorimotor attenuation (SMA) is a phenomenon where a self-generated touch feels weaker than an externally generated touch of the same intensity. Because the brain can predict the sensory consequences of our own actions, it uses that prediction to attenuate afferent sensory feedback of our own movements, thereby increasing the saliency of external signals. Previous studies suggest that SMA is mediated by premotor cortical inputs to somatosensory cortex (Voss M et al., 2006). Although, some theories argue that SMA is based on efference copies of motor commands from primary motor cortex (M1) to other areas such as the cerebellum and primary somatosensory cortex (S1), our knowledge of the neural correlates of SMA in S1 and how it is related to the perception of SMA is lacking. To better understand the role of S1 in SMA, we performed, to our knowledge, the first study of SMA in the

sensorimotor domain in a human using intracortical recordings. The participant was a tetraplegic male with preserved cutaneous sensation (age 50 y.o., C5/C6 ASIA B), who was implanted with 3 microelectrode arrays in S1 (Blackrock Microsystems). We recorded the perceptual and multi-unit activity (MUA) and event-related potentials (ERPs) as the participant performed a bimanual, force comparison, self-touch paradigm with two taps per trial. The first tap of 2N, was either self-generated by the participant or externally generated by a motor. The second tap was externally generated by a motor and consisted of a range of force values. The participant was asked to identify whether the second tap was felt to be perceptual equal to the first tap. As a control, we repeated the paradigm on a sample of healthy adults without sensorimotor injuries (n=18, Average Age: 30.68+/- 12.42). We tested two hypotheses; (1) SMA would be retained given that sensation was preserved in the patient. (2) Neural activity in S1 would differ between the self and externally generated conditions; that is, MUA firing rates and ERPs would be lower in the self-generated condition than the externally generated condition, consistent with attenuation. Our healthy control results showed a perceptual attenuation of self-generated forces compared to externally generated forces. However, the patient showed no perceptual SMA of self-generated force compared to an externally generated force. Importantly, neural activity matched perception; there was no difference in S1 event-related activity and MUA between the two experimental conditions. Our results suggest that perceptual SMA is not observed in our tetraplegic participant and that the S1 MUA and ERP activity is closely related to the behavioral perception of force intensity.

Title: Imaging dynamic sub-surface skin strain patterns during object interaction using Optical Coherence Tomography

Authors: *G. CORNIANI[1], Z. S. LEE[2], M. J. CARRÉ[2], R. LEWIS[2], B. P. DELHAYE[3], H. P. SAAL[1]; [1]Dept. of Psychology, [2]Dept. of Mechanical Engin., Univ. of Sheffield, Sheffield, United Kingdom; [3]Inst. of Neurosci., Univ. catholique de Louvain, Woluwe-saint-Lambert, Belgium

Abstract: The fingertip acts as an efficient tactile sensing organ with high acuity and sensibility. It is populated by thousands of mechanoreceptors responsible for translating the various aspects of the skin deformations into spike trains. However, receptors are located within the skin and separated from the surface, where object contact happens, by several layers of skin tissue. Little is known about the biomechanics of the skin below its immediate surface, even though sub-surface skin strains are ultimately

transduced by mechanoreceptors to form the first stage of sensory encoding in the tactile system.
In this study, we employ Optical Coherence Tomography (OCT), a non-invasive imaging technique appropriate for biological tissue, to capture the skin's internal morphology. The recorded data consists of images acquired with OCT at a rate of 20 frames per second and presents a sliced side view along the proximal-distal axis of the fingerpad with high spatial resolution (7.5 μm lateral and 5μm axial resolution). The images capture the finger pad while various surfaces slide against it along the imaging direction. The skin surface, the epidermal ridges, the stratum corneum, and the dermis-epidermis ridges can be identified in the acquired images.
To study the biomechanics of the captured tissues, we first tracked features of the movement of the skin in different layers. Then we reconstruct time-varying strain patterns to derive the local skin strain changes at different depths. In particular, a Delaunay triangulation was computed over the tracked features, and for each triangle, displacement field gradients were derived within adjacent frames and used to calculate Green-Lagrange strains. This technique allows us to reconstruct the skin mechanics at the location where mechanoreceptors are typically located.We found stereotypical spatiotemporal patterns of mechanical strain that depend on the mechanical, elastic, and geometrical features of both the sliding object and the skin. Interestingly, we observed differences in the strain propagation between and within different skin layers.
This study provides valuable insight into the mechanical transduction process at different skin layers. The data will help understand how surface strains propagate into deep layers of the skin tissues towards mechanoreceptor locations and shed light on the nature and function of skin morphology in encoding tactile stimuli.

Title: Age-related changes of Merkel cell distribution in the human cheek and visualization of touch force propagation to activate Merkel cells

Authors: *S. SAKAGUCHI[1], M. TSUTSUMI[1], K. TAKAGAKI[1], N. ARAKAWA[1], K. KAJIYA[1], M. KONYO[2];
[1]MIRAI Technol. Institute, Shiseido Co., Ltd., Yokohama, Japan; [2]Grad. Sch. of Information Sciences, Tohoku Univ., Sendai, Japan

Abstract: The face and fingers have high tactile sensitivity relative to other body parts and can be used for communication. As we get older, tactile sensation decreases in most body parts. One of the causes of tactile deterioration is thought to be a decrease of mechanoreceptors, such as Merkel cells (MCs), which transmit gentle touch sensations to nerve fibers. Surprisingly, recent studies have shown a new role for MC activation to reduce age-related itching.

Despite the importance of MC activation, the actual state of age-related changes in MCs in the face has not been investigated. Our aim was to clarify how the density and distribution of MCs—and connected nerve fibers in the cheek skin—change with age to propose a touch method that efficiently transmits tactile sensation even if there are fewer MCs.
Since only a few MCs were observable in vertical cross-sections of skin, we prepared epithelial sheets to acquire the distribution of MCs in horizontal sections of skin. Human cheek samples were obtained from 7 donors (60.9±23.0y). Those samples were stained by antibodies against K8 and K20 and observed using confocal laser scanning microscopy. PGP9.5 and NF200 immunostaining was also performed in the cross-sections from the same subjects and quantified. Cluster analysis was applied to evaluate the distribution of the MCs. Finally, a finite element method (FEM) was used to find an effective touch method when transmitting tactile sensation in consideration of the mechanical behavior of skin when pushing the cheek with a rigid object imitating a finger.
As a result, MCs were found around the hairs, glands, and ridged parts of the skin in accordance with previous reports. Surprisingly, MCs were basically scattered in cheek skin, but not clustered like a touch dome. MC density showed a dramatic reduction of roughly 75% when comparing a 27-year-old ($26.4 MCs/mm^2$) to a 91-year-old ($6.7 MCs/mm^2$). A comparison of A-fiber and MC densities in the same donor showed a positive correlation. Cluster analysis showed that MCs decreased in each small group, when the cutoff value was 50um in the complete linkage method. Taken together, these results suggest that they decrease as part of a MC-neurite complex rather than independently as single MCs.
In addition, we found that increasing the boundary of the contact surface between the finger and cheek is effective for transmitting strain energy to the surface layer of the skin where MCs are present.In conclusion, we observed a scattered distribution of MCs in the human cheek and a decrease in MC and A-fiber density due to aging. FEM analysis showed that the possibility of maintaining tactile sensation and alleviating itch regardless of fewer MCs.

Title: Cortical projection neurons differentially contribute to the acquisition and expression of an auditory categorization task

Authors: *R. F. KRALL, M. P. ARNOLD, C. N. CHAMBERS, M. K. FRUM, R. S. WILLIAMSON; Otolaryngology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Sensory-guided behavior is ubiquitous in everyday life, whenever sensory information is used to guide the decisions we make and the actions we take. During sensory-guided behavior, distinct populations of neurons work to encode relevant sensory information and to transform it into an appropriate behavioral response. A fundamental open problem is identifying which neural circuits contribute to such behaviors. In the auditory system, information is first propagated through a feed-forward hierarchy that runs from the cochlea to the primary auditory cortex (ACtx). Corticofugal neurons in the ACtx send extensive projections to multiple nodes of this ascending auditory pathway as well as targeting distinct downstream regions associated with decision making, action, and reward. Through these diverse projections, corticofugal neurons are positioned to widely broadcast behaviorally-relevant information and shape auditory representations across brain-wide networks. We hypothesized that distinct classes of ACtx projection neurons critically and differentially mediate auditory-guided behaviors. To test this hypothesis, we developed a head-fixed behavioral task, where water-restricted mice are trained to categorize auditory stimuli into two groups to receive a water reward. Mice are tasked with categorizing amplitude-modulated noise bursts by licking one of two spouts yoked to the modulation frequency. To determine the role of ACtx in this behavior, we optogenetically silenced excitatory neurons during stimulus presentations using soma-targeted *Guillardia theta* anion-conducting channelrhodopsins (GtACRs). We found that sparse inactivation (20% of trials per session) of ACtx excitatory neurons did not disrupt task learning across days, allowing us to assess the contribution of ACtx neural populations longitudinally across task acquisition and expression. We found that inhibition of excitatory neurons in the ACtx altered task performance in a manner dependent on the extent of learning and task difficulty. Our ongoing research seeks to characterize the specific contributions of distinct ACtx projection neuron class using selective expression of GtACRs to inhibit activity across task acquisition and expression.

Title: Noise exposure in postnatal critical period accelerates development of perineuronal nets in the rat auditory cortex

Authors: *J. SVOBODOVA BURIANOVA[1], J. W. FAWCETT[2], J. C. KWOK[3], J. SYKA[1]; [1]Inst. of Exptl. Med. CAS, Prague, Czech Republic; [2]John Van Geest Ctr. for Brain Repair, Univ. of

Cambridge, Cambridge, United Kingdom; [3]Sch. of Biomed. Sciences, Fac. of Biol. Sci., Univ. of Leeds, Leeds, United Kingdom

Abstract: In the rat auditory system, a period of increased vulnerability to external stimuli (known as the critical period, CP) starts with the onset of hearing (PD 12) and ends around three weeks later. It is expected that the closing of the critical period is paralleled with maturation of perineuronal nets (PNNs), lattice-like extracellular matrix structures that appear around the soma and proximal dendrites of mainly parvalbumin (PV) expressing inhibitory neurons. The exposure to loud sound during the CP can significantly affect morphology and electrophysiology of neurons in the rat auditory cortex. Whether the exposure can also change the pattern of PNN maturation remains unknown. Long-Evans rats were exposed at PD14 to a 125 dB SPL broad-band noise for 8 min. The content of PNNs was evaluated in auditory cortex sections stained for *Wisteria floribunda* agglutinin in exposed rats aging from PD14 to PD106, and compared with non-exposed controls. We did not observe visible PNNs at PD14, neither in the exposed animals nor in the controls. PNN appeared in both groups, however, in a significantly greater number in exposed than control animals. The number of PNNs further increased at PD28, but the difference between groups remained to be present. The development of PNNs of both groups had aligned since PD35. Interestingly, despite the different onset of PNNs development, no morphological differences in PNNs between the groups were found in PD106 when PNNs are considered mature. To summarize, the early development of PNNs appeared to be more accelerated in the noise-exposed animals than in the non-exposed controls. These results suggest that noise exposure may lead to a premature closing of the CP window, thus limiting the plasticity of early postnatal development in the auditory cortex. In ongoing part of the experiment, using fluorescence staining, we plan to determine to what extent the accelerated development of PNN occurs in PV neurons by evaluating colocalization PNN with PV and PNN with GAD (glutamate dehydrogenase) that labels all GABAergic inhibitory neurons.

Title: Distinct populations of cortical projection neurons are differentially modulated by arousal

Authors: *K. J. KAUFMAN[1], R. F. KRALL[2], M. P. ARNOLD[2], R. S. WILLIAMSON[2];
[1]Ctr. for Neurosci., [2]Otolaryngology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Fluctuations in behavioral state, such as attention and arousal, persist during wakefulness and influence both task performance and sensory information processing. Many studies have now reported

strong correlations between pupil diameter, a biomarker of arousal state, and evoked neural activity in multiple sensory cortices. Lin et al (2019) found that arousal modulates both the frequency tuning and response magnitude of L2/3 pyramidal neurons in the primary auditory cortex (ACtx). ACtx pyramidal neurons massively innervate a variety of downstream targets, both within and outside of the central auditory pathway. These corticofugal neurons comprise a diverse set of projection neurons with unique anatomy, morphology, and intrinsic and synaptic properties. Corticofugal neurons broadly fall into three classes: intratelencephalic (IT), extratelencephalic (ET), and corticothalamic (CT). The distinct anatomy and connectivity profiles of these cells lead us to hypothesize that arousal states may differentially modulate their sensory tuning properties. To investigate this, we recorded neural activity from ACtx with two-photon calcium imaging in awake mice while simultaneously capturing facial movements and pupil dilations using high-speed videography. We drove GCaMP expression in IT/ET/CT populations through Cre-dependent viral transfection of GCaMP8s. Similar to Lin et al. (2019), we found arousal-dependent changes in the tuning properties of L2/3 IT cells, evidenced by an increase in bandwidth and response magnitude coinciding with higher arousal states. Our preliminary data suggests that the effect of arousal differs in other projection classes, with response magnitudes peaking at intermediate levels of arousal, following the classic inverted-U dependence (Yerkes-Dodson curve). The characterization of these state-dependent effects on distinct excitatory populations offers a key-first step towards understanding how sensory information is shared brain-wide to guide perception and action.

Title: Auditory Long-range Parvalbumin Cortico-Striatal Neurons

Authors: *A. BERTERO, H. ZURITA, M. NORMANDIN, A. J. APICELLA;
Biol. Department, Neurosci. Inst., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: For over 30 years the assumption has been that cortical auditory input to the striatum is exclusively excitatory. Only recently our lab showed a direct inhibitory projection from the cortex to the striatum via somatostatin-expressing neurons. Here we have characterized the nature and physiological impact of a previously unknown long-range GABAergic projection from the auditory cortex to the striatum via parvalbumin-expressing neurons. Particularly, we tested the hypothesis that the auditory cortex, via cortico-striatal parvalbumin-expressing neurons (CS-Parv), has a direct inhibitory projection to the dorsal striatum. We addressed this fundamental question by taking advantage of in vitro viral and non-viral anatomical, and electrophysiology approaches, demonstrating that the dorsal striatum not only receives glutamatergic excitatory inputs from the cortex but also inhibitory inputs. Our results establish a

previously unknown cortico-striatal long-range inhibitory circuit (**CS-Parv inhibitory projections → striatum**). We also demonstrated that the CS-Parv neurons have higher concentrations in infragranular layer (layer 5 and 6 of the auditory cortex). This is not reflecting the overall Parv neurons distribution, which generally show higher abundancy in layer 4, paralleling the distribution of excitatory auditory cortico-striatal projections. Moreover, we analyzed their characteristic voltage-dependent membrane potential gamma oscillation, generated by intrinsic membrane mechanisms and able to trigger intermittent and irregular bursts (stuttering) of action potential in response to steps of depolarizing current pulses. In fact, the first action potential of layer 5 CS-Parv neurons burst is triggered by an oscillation, whose frequency is in the gamma range (30-100 Hz), while the second action potential was maintained by a different membrane mechanism. These findings are very important for understanding how the transformation of auditory signals to an appropriate behavioral output is achieved by the dynamic interaction of specific neuronal circuits that process information through different cell-types. A direct inhibitory input to the dorsal striatum may suggest that the timing and ratio of excitation and inhibition, two opposing forces in the mammalian cerebral cortex, can dynamically affect the output of the striatum, providing a general mechanism for reward-learning, and action-selection behavior driven by auditory stimuli.

Title: Spatiotemporal dynamics of auditory responses of cholinergic projections to the auditory cortex

Authors: *F. ZHU[1], S. E. ELNOZAHY[1], J. LAWLOR BLONDEL[1], K. KUCHIBHOTLA[1,2];
[1]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: The cholinergic basal forebrain (CBF) projects extensively to the cortical mantle, including to the auditory cortex (ACx). Multiple studies have shown that pairing external phasic stimulation of the CBF with a sensory stimulus drives long-lasting sensory cortical plasticity. For this to be a plausible mechanism of cortical plasticity during learning (i.e. without external stimulation), we hypothesize that the CBF should also exhibit a stimulus-evoked response. This phasic, sensory signal from the CBF potentially allows neutrally-valenced sensory stimuli to drive cortical plasticity. To date, however, little is known about the intrinsic sensory-evoked dynamics of the CBF.
Here, we use simultaneous two-color, two-photon imaging of CBF axon projections and cortical neurons in the ACx to examine stimulus-evoked responses in head-fixed mice passively-listening to a suite of auditory stimuli. We observed a striking, non-habituating, phasic response of CBF axons to neutral

auditory stimuli that depends on the level of tonic cholinergic activity, a known neural correlate of brain state. We then tested whether CBF axons exhibit 'tuning' in the frequency-dimension and whether that tuning correlates with the surrounding cortical network at a mesoscopic (tonotopy) or microscopic (nearby neurons) level. We observed no evidence of tonotopy in CBF axons; there is a coarse population tuning to low-to-mid frequencies that was consistent across the ACx. Interestingly, individual axon segments exhibited heterogenous tuning within imaging sites, allowing the CBF to respond to all the frequencies presented. Despite this microscopic heterogeneity, the tuning of axon segments and nearby cortical neurons was un-coupled. Finally, we investigated the sources of auditory information to the CBF. Using chemogenetic inactivation of the ACx and auditory thalamus while imaging CBF axons in the ACx, we demonstrate that inactivation of the auditory thalamus, but not the ACx, abolishes the frequency tuning of CBF axons and significantly dampens their responsiveness.
Our work proposes a novel, non-canonical function for the CBF in which it receives auditory input from the auditory thalamus, modulates these signals based on brain state, and then projects the multiplexed signal to the ACx. These signals are temporally-synchronous with cortical responses but differ in their underlying tuning, providing a potential mechanism to influence cortical sensory representations during learning and task engagement.

Title: Different excitation-inhibition correlations between tone-evoked and spontaneous activity in primary auditory cortex neurons

Authors: K. C. M. CHEW, V. KUMAR, ***A. Y. Y. TAN**;
Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Tone-evoked synaptic excitation and inhibition are highly correlated in many primary auditory cortex neurons of pentobarbital-anesthetized rats. In contrast, there is less correlation between spontaneous excitation and inhibition in visual cortex neurons under the same anesthetic conditions. The corresponding correlation between spontaneous excitation and inhibition in the primary auditory cortex has not been measured. Here we report whole-cell voltage-clamp measurements of excitation and inhibition in primary auditory cortex neurons of pentobarbital-anesthetized rats. Spontaneous excitatory and inhibitory currents each appeared to consist of distinct events. The event rate was lower for inhibition than for excitation in many neurons. The spontaneous inhibitory event rate was sufficiently lower than the spontaneous excitatory event rate to suggest a lower excitatory-inhibitory correlation for spontaneous

activity than for tone-evoked responses in a subset of neurons with highly correlated tone-evoked excitation and inhibition.

Title: Auditory cortical projection neurons exhibit distinct organizational motifs

Authors: *M. P. ARNOLD[1], R. F. KRALL[1], S. LAM[2], R. S. WILLIAMSON[1];
[1]Otolaryngology, [2]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The auditory pathway is a beautifully complex series of brain stations that are dedicated to the processing and interpretation of our sense of sound. Incoming sensory signals traverse an ascending hierarchy from the cochlea to the primary auditory cortex (ACtx), before being propagated brain-wide through networks of excitatory projection neurons to inform emotion, attention, decision-making, and action. These neurons fall into three broad classes: intratelencephalic (IT), extratelencephalic (ET), and corticothalamic (CT). Of these classes, ET cells are unique as they form the only direct connection between the ACtx and myriad sub-cortical targets. Their distinct morphology, with prominent apical dendrites and diverse axonal targets, has led to their portrayal as canonical “broadcast” neurons that pool inputs and transmit signals throughout the brain. ET cells typically exhibit “one-to-many” connectivity motifs, placing them in a privileged position to broadcast sensory signals to multiple downstream targets simultaneously. However, the extent of their axonal collateralization, the spatial organization of their projections in downstream brain regions, and whether or not these distinct organizational motifs receive differential synaptic input remains unknown. To address these questions, we characterized the input/output circuitry of ACtx ET cells and compared their anatomical organization to that of IT and CT populations. Using an intersectional strategy utilizing both Cre- and Flp-recombinase, we drove selective expression of adeno-associated viruses in distinct sub-populations of ET cells, allowing us to both quantify downstream projection densities with high spatial resolution and identify local and long-range synaptic input through monosynaptic rabies tracing. Our preliminary results indicate that the majority of ET neurons collateralize to the non-lemniscal regions of the inferior colliculus and thalamus, confirming previous reports (Chen et al, 2019). Monosynaptic rabies tracing demonstrated widespread synaptic inputs to both ET and CT cells from many cortical and subcortical areas, including the thalamus, contralateral ACtx, as well as ipsilateral visual, somatosensory, and retrosplenial cortices. Our ongoing experiments are focused on extending these findings to distinct ET organizational motifs. This work will provide a foundation for understanding how brain-wide interactions between distinct areas cooperate to orchestrate sensory perception and guide behavior.

Title: Layer-specific branching patterns of mouse auditory cortico-collicular neurons

Authors: L. K. ISSA, ***D. A. LLANO**;
Mol. and Integrative Physiol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Multiple studies have shown that the auditory cortex exerts a powerful, yet heterogeneous, effect on the inferior colliculus. Similar to the corticothalamic system, cortico-collicular projections emanate from two distinct bands in the auditory cortex: one from layer 5 and the other from layer 6. These projections have distinct physiological and anatomic properties and likely have different roles in modulating their subcortical targets. In addition, while several studies have suggested that corticofugal projections from layer 5 branch widely to subcortical structures, other studies have suggested that there are multiple, mostly independent sets of layer 5 corticofugal projections. Even less is known about layer 6; no studies have examined whether layer 6 corticothalamic and cortico-collicular projections are independent. Therefore, we examined this issue using an intersectional anatomical approach employing viral tracers. A flippase-inducing, Cre-dependent retrograde transported Canine adenovirus virus 2 (Cav-flx-flp) was injected into the inferior colliculus of RBP4 (Layer 5)-Cre or FOXP2 (Layer 6)-Cre mice, followed by a flippase-dependent AAV9-mCherry virus into the auditory cortex. We found that this approach strongly labels layer 5 or layer 6 cortico-collicular neurons, respectively, and their branches. As expected from previous work (Asokan et al. 2018), layer 5 cortico-collicular branches heavily innervated the auditory thalamus. Layer 5 cortico-collicular branches were also seen across a spectrum of other subcortical targets, including striatum and amygdala, but not in the contralateral auditory cortex. Layer 6 cortico-collicular neurons also showed unexpectedly wide branching, with terminals throughout the thalamus and other subcortical forebrain and midbrain targets. These data suggest that both layer 5 and layer 6 cortico-collicular widely branch to subcortical targets, supporting the notion that one mode of action of corticofugal pathways to broadcast signals widely throughout the subcortical auditory system.

Title: Synaptic zinc release at specific cortical synapses shapes intracortical synaptic transmission in mouse auditory cortex

Authors: *P. T. R. BENDER, C. T. ANDERSON;
Neurosci., West Virginia Univ. Sch. of Med., Morgantown, WV

Abstract: The primary auditory cortex is crucial for the perception of sounds. It contains highly organized networks of neurons that form precise synaptic microcircuits and process auditory information. Despite the importance of synaptic microcircuit organization of the cortex and the different functional properties of these synapses for auditory function, synaptic mechanisms that support the diversity and specificity of these connections are less-well understood.
This cortical area is highly enriched in synaptically released zinc which acts as a potent modulator of cortical function and sound processing. Zinc (as Zn2+) is loaded into synaptic vesicles by the zinc transporter protein ZnT3 where it is coreleased with glutamate during synaptic transmission. Synaptically released zinc shapes multiple aspects of synaptic signaling and can inhibit AMPA and NMDA glutamate receptor function. Mounting evidence strongly suggests that synaptic zinc is only released from a subset of glutamatergic cortical neurons and in a cortical layer-specific manner. Since the principals governing cortical microcircuit organization relate to both cortical layer and neuronal type, this suggests that synaptic zinc may contribute to the specificity and diversity of intracortical synaptic microcircuits.
Here, to understand the role of synaptic zinc signaling at specific cortical synapses, we optogenetically stimulated different presynaptic neuronal populations and recorded the synaptic inputs they provide to the same class of postsynaptic cortical neuron. In acute brain slices of the auditory cortex, we performed whole-cell patch-clamp recordings from identified layer 5 corticocollicular neurons while optogenetically stimulating inputs from specific presynaptic neuronal populations of cortical Cre-expressing neurons in layer 2/3 and layer 5. Our results reveal that the effects of synaptic zinc release are cell-type specific and we also find a novel role for synaptic zinc in potentiating AMPA receptor function at specific intracortical synapses. Together, these results reveal a novel role of synaptic zinc within the cortex and suggest that synaptic zinc signaling contributes to the diversity and specificity of intracortical synaptic connections that support normal cortical function and auditory processing.

Title: Differential Effects of Synaptic Zinc on Sound-Evoked Responses of Long-Range Cortical Projection Neurons in the Mouse Auditory Cortex

Authors: *M. MCCOLLUM[1], C. T. ANDERSON[2];
[1]West Virginia Univ. - PhD In Neuros Neurosci. Grad. Program, Morgantown, WV; [2]WVU Sch. of Med., Morgantown, WV

Abstract: The primary auditory cortex is crucial for the perception of sound. This structure integrates ascending auditory information with a variety of corticocortical and thalamocortical input and sends descending long-range axonal projections to subcortical auditory processing areas such as the striatum, thalamus, inferior colliculus, and brainstem. As a monosynaptic connection from the auditory cortex, these long-range axonal projections allow cortical input to directly influence the activity of neurons in subcortical auditory structures. In layer 5 of the auditory cortex, there are two major classes of long-range projection neurons: pyramidal tract (PT)-type neurons and intratelencephalic (IT)-type neurons. Although it is known that these long-range projection neurons are important for dynamic tuning, auditory learning, and auditory plasticity, much less is understood about the intracortical synaptic mechanisms that shape their activity. The auditory cortex is highly enriched with synaptic zinc. Zinc (as Zn^{2+}) is loaded into presynaptic vesicles by the membrane zinc transporter protein ZnT3 and is coreleased with glutamate during synaptic transmission. Synaptic zinc is a potent modulator of synaptic signaling and refines the sound-encoding properties of layer 2/3 auditory cortical neurons in a cell-type specific manner. Since long-range projection neurons integrate information from a variety of local sources (including layer 2/3 neurons) and convey these computations to multiple targets, they are the key link between cortical processing and subcortical signaling. However, the effect of synaptic zinc signaling on the sound-evoked activity of these long-range projection neurons remains unknown.Here, we performed widefield and 2-photon calcium imaging from PT and IT-type neurons in layer 5 of the auditory cortex in awake mice. We find that synaptic zinc signaling differentially shapes the sound-evoked properties of these layer 5 long-range projection neurons. Synaptic zinc increases the sound frequency tuning bandwidth and suppresses the response gain of PT-type neurons while it has the opposite effects on layer 5 IT-type neurons. By differentially supporting the sound frequency tuning and the response gain of these neurons, synaptic zinc serves to support the diverse sound-evoked properties of these neuronal populations. Our experiments reveal a novel role for synaptic zinc in shaping the output of long-range projection neurons in the auditory cortex and suggest a novel intracortical mechanism capable of modulating auditory processing.

Title: Decoding selective attention from EEG during simultaneous presentation of two melodies

Authors: *K. MIZOKUCHI[1], T. TANAKA[1], T. G. SATO[2], Y. SHIRAKI[2];
[1]Dept. of Electrical and Electronic Engin., Tokyo Univ. of Agr. and Technol., Koganei-shi, Japan; [2]NTT Communication Sci. Labs., Nippon Telegraph and Telephone Corp., Atsugi-shi, Japan

Abstract: Introduction: People can pay selective attention to music or speech from various sounds. It has been reported that while speeches are presented, the attentional task not only enhances neural entrainment [1] but also affects the spatial distribution of electroencephalogram (EEG) [2]. However, the attentional effect on EEG is still unclear when listening to multiple pieces of music at the same time. In this study, we hypothesized that attention under multiple music presentations would enhance neural entrainment to the attended music and that the spatial distribution of EEG is different depending on the attentional task. Methods: Fifteen healthy young adults (eight males, mean age 21.7 ± 1.16; range 20–23 years old) participated in the experiment. All participants had normal hearing. They gave their written informed consent, and the research ethics committee approved the study in the institution. In this experiment, we measured EEGs while two melodies with different tempos were presented simultaneously from spatially different directions. The participants were instructed to pay attention to one of the melodies. In the analysis, the cross-correlation function calculated between the filtered EEG (0.4–40 Hz) and the envelope of the melodies was used as a feature to classify the direction of attention using a support vector machine (SVM). Next, to search the effect of attention on the spatial distribution, we extracted features by the common spatial pattern (CSP) method from both EEG and cross-correlation function, respectively. For each feature, we estimated the direction of attention using the SVM. Results: As a result of task classification using the cross-correlation function as a feature, three participants achieved a classification accuracy of over 90%. Therefore, as well as speeches, attention affects neural entrainment when listening to melodies. Furthermore, in the classification results using CSP as a feature, nine participants achieved a classification accuracy of over 90%. Hence, we found that attention affected neural entrainment and the spatial distribution under the presentation of multiple pieces of music.References:[1] Horton et al., *J. Title: Auditory discomfort in migraine and the visually sensitive

Authors: *S. M. HAIGH, L. R. MENDOZA, M. MONTERO;
Psychology and Integrative Neurosci., Univ. of Nevada Reno, Reno, NV

Abstract: Sensory sensitivity is commonly reported in a range of clinical conditions, including migraine. While stimuli that evoke visual discomfort are well-defined, little is known about auditory discomfort. Here, we manipulated pitch and the manner in which it was varied in three separate experiments to begin to map the parameters of auditory stimuli that make them uncomfortable to hear. We then compared the discomfort reported from individuals with migraine (total N=65) and headache-free controls (total N=60). In Experiments 2 and 3, we also measured number of illusions seen in the Pattern Glare (PG) Test to examine whether those individuals who experience visual sensitivity (>=2 illusions) exhibited greater discomfort to the sounds compared to those with low PG (<2 illusions). In Experiment 1 (N=58; 46F/12M/1 declined; age 18-32 years), we measured discomfort to amplitude-modulated (AM) tones that differed in their pitch (250-8000Hz) and modulation frequency (0-32Hz). Discomfort significantly increased with pitch (p<.001). Discomfort also increased with modulation frequency (p=.027) but higher modulation frequencies reduced the effect of pitch on discomfort (p<.001). Specifically, 3000Hz and 4000Hz tones were significantly more comfortable when modulated by a 32Hz carrier than a 2Hz or 0Hz carrier. To further examine the effects of temporal presentation frequency, in Experiment 2 (N=70; 51F/18M/1 declined; age 18-27 years), we manipulated the number of frequency-modulated (FM) sweeps presented per second (5-50Hz). As with the AM tones, the greater the number of sweeps, the greater the discomfort (p<.001). In Experiment 3 (N=63; 34F/28M/1 declined; age 18-23 years), we manipulated the central frequency (625-1875Hz) and the range of frequencies (250-1500Hz) contained within FM sweeps. There was no linear effect of range on discomfort. However, the higher the central frequency, the greater the discomfort (p<.001; similar to the pitch of the AM tones). For all experiments, we found that individuals with migraine experienced slightly but non-significantly greater discomfort compared to those who were headache-free (ps>.05; Cohen's d~0.33). However, those with high PG reported more auditory discomfort than those with low PG (ps<.05; Cohen's d>0.5). This suggests that sensitivity in one sensory modality might generalize to another, and that those with migraine do not necessarily experience greater auditory discomfort. In addition, while temporal presentation (AM modulation and FM sweep frequency) impacted discomfort, pitch had stronger effects on discomfort.

Title: The interplay between uncertainty and relevance in sound categorization

Authors: *J. SHETH, J. COLLINA, K. P. KORDING, Y. E. COHEN, M. N. GEFFEN;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Everyday hearing and communication require that we categorize sounds encountered under different levels of uncertainty or relevance. For example, background noise can reduce both the certainty about the sound we hear, as well as introduce irrelevant sound components. However, little is understood about how sound uncertainty and relevance affect perception. Bayesian theory postulates that both relevance and uncertainty affect human auditory categorization, while accounting for multiple strategies for their interplay. In the first experiment, to understand which strategy humans use in categorizing sounds with varying uncertainty and relevance, we asked subjects to categorize sequences of three tones into a high or low frequency category. The three tones were drawn from a complex probability distribution, such that the tones were 70% likely to be drawn from a "signal" Gaussian distribution with the mean of 354.8 Hz (low) or 707.9 Hz (high), and a standard deviation of 0.5 Octaves; or 30% from a uniform distribution over the 90-3000 Hz range. Subjects incorporated relevance in decision making using three different strategies - 1. Categorization based on the average of all three tones, 2. Categorization by averaging over the "signal" tones only, 3. Categorization using a voting strategy wherein each tone is individually classified as "high" or "low" and then a cumulative decision is made. We modeled this variability in strategies using an optimal Bayesian model that is built on uncertainty, formalizes relevance and estimates priors. We also analyzed the subject data using a generalized linear model (GLM) which captured the weight assigned to each experimental tone for categorization. Using parameters obtained from the Bayesian model and the GLM fits, we characterize the diversity in subjects' decision making. We found that while some subjects can be clearly found to follow one of the three strategies, others will combine them. In the second experiment, we asked how long-term statistics of sounds affects categorization by imposing a bias on the prior category probabilities. A subset of subjects detected the prior, which affected their categorization, while others did not. Subjects exhibiting behavioral long-term bias performed less accurately than unbiased subjects. Those exhibiting long-term bias used a combination of the voting and categorization based on mean of all tones strategies, whereas the others recognized irrelevant tones and classified trials according to the mean of the signal tones. Combined, our results provide for an elegant quantification for the interplay between estimating stimulus uncertainty and relevance in auditory categorization.

Title: Relationships between transducer placements and peripheral propagation of the cartilage-conduction assessed by hearing threshold with water injection into the ear canal

Authors: *Y. SUGAWARA, S. OTSUKA, S. NAKAGAWA;
Chiba Univ., Chiba, Japan

Abstract: In bone-conduction (BC), a sound transducer is attached to the mastoid process of the temporal bone and the sound is transmitted as 4 components: (1) the osseotympanic component, (2) the inertial BC component, (3) the compressional BC component, and (4) the air-conducted (AC) component. BC has been applied to devices such as hearing aids for the conductive hearing loss. However, BC also has some disadvantage in wearability of a sound transducer. Therefore, cartilage conduction (CC) has been proposed and applied to devices such as hearing aids and smartphones. In CC, a sound transducer is placed on the cartilage portion of the pinna, and AC and the osseotympanic components are said to be dominantly transmitted. On the other hand, even in CC, the transducer often contacts not only with the aural cartilage but also with the osseous parts of/around the pinna and generate change of sound sensation. In this study, relationships between the transducer placements and the hearing thresholds were investigated. Contributions of AC and the osseotympanic components to CC perception were evaluated by blocking each of them using water injection into the auditory canal.5 normal-hearing participants took part in the experiment. The transducer was placed on (1) the pinna, (2) the mastoid process, and (3) the ear-front point (middle of between the tragus and the mandibular condyle). The hearing thresholds measurements were conducted under condition that participants' auditory canal was filled water. The amount of the injected water was varied 0, 20, 40, 60, 80 and 100% of the volume of the auditory canal. Under the water injection conditions, the increase of hearing thresholds in the pinna and ear-front point was generally larger than that in the mastoid. Since the increase of the hearing thresholds arise from AC and the osseotympanic components blocked by the injected water, it is thought that the contribution of AC and the osseotympanic components are larger for the pinna and ear-front point. However, in the low frequency range (250 and 500 Hz) for the pinna and ear-front point, the hearing thresholds decreased as the amount of the injected water increased. It is thought that as the injected water increases, the osseotympanic component which is dominant in the low frequency range is transmitted through the water. On the other hand, the effect of the amount of the injected water was not observed at the mastoid, indicating that contribution of the osseotympanic component is less than other locations.These results suggest that the proportion of the inertial and compressional BC components within the entire perception increases when the transducer is presented to the osseous parts.

Title: Acute impact of anterior temporal lobe disconnection on fronto-temporal neural signals

Authors: *Z. KOCSIS[1,4], R. L. JENISON[5], T. E. COPE[6], P. N. TAYLOR[4,7], B. MCMURRAY[2], A. E. RHONE[1], M. E. SARRETT[8], Y. KIKUCHI[4], P. E. GANDER[1], C. K. KOVACH[1], F. BALEZEAU[4], I. Abstract: Understanding the impact and compensatory mechanisms of surgical disconnection on neural responses in the human brain could advance models of normal neurophysiology and its disruption by pathology. We present rare data from two patients (one woman and one man; 63 and 32 years of age, respectively) who underwent surgical disconnection of the anterior temporal lobe (ATL) as part of their clinical procedure to treat intractable epilepsy. During the surgery, we obtained both pre- and post-resection intraoperative electrocorticographic (ECoG) recordings while the patients were lightly sedated, but awake and responsive during a speech-sound perceptual prediction task. We also obtained pre- and post-operative magnetic resonance imaging (MRI) including T1 and T2 structural and diffusion-weighted scans. Diffusion MRI tractography from ATL seed regions confirmed disconnection of the temporal pole from other cortical areas. Post-disconnection neurophysiological responses to the speech sounds showed a striking dissociation from the pre-disconnection signal in the form of, 1) magnified responses in auditory cortex (Heschl's gyrus) across oscillatory frequency bands (3-150 Hz); and, 2) disrupted oscillatory responses in prefrontal cortex (Inferior Frontal Gyrus, IFG). Moreover, after the disconnection auditory cortical mismatch responses and theta-gamma coupling to the speech sounds were disrupted, while neural responses to different speech sounds became less segregable (i.e., more similar). State-space conditional Granger Causality analyses revealed substantial change in neural information flow between auditory cortex and IFG post disconnection. The results with these rare datasets demonstrate an immediate and incomplete compensation by intact frontal and auditory cortical areas responding to speech sounds after the loss of ATL neural signals.

Title: Functional geometry of human auditory cortical resting state networks derived from intracranial electrophysiology

Authors: *M. I. BANKS[1], B. M. KRAUSE[1], D. G. BERGER[1], D. I. CAMPBELL[1], H. KAWASAKI[2], M. STEINSCHNEIDER[3], K. V. NOURSKI[2];
[1]Anesthesiol., Univ. of Wisconsin Sch. of Med. and Publ. Hlth., Madison, WI; [2]Neurosurg., The Univ. of Iowa, Iowa City, IA; [3]Neurol., Albert Einstein Col. of Med., Bronx, NY

Abstract: Introduction: Critical organizational features of human auditory cortex (AC) remain unclear, including the definition of information streams (e.g., dorsal, ventral) and the relationship of AC to non-auditory regions of interest (ROI). We investigated these features using diffusion map embedding (DME) applied to functional connectivity derived from intracranial electroencephalographic (iEEG) recordings in neurosurgical patients. DME maps data into a space in which distance represents similarity in connectivity to the rest of the sampled network, and has been applied previously to resting state functional connectivity data to elucidate the hierarchical structure of neocortex and structural changes across treatments, disorders, and aging. **Methods:** Resting state iEEG data were obtained from 41 adult neurosurgical patients (18 female). Data were analyzed from 5836 recording sites, including AC, temporo-parietal auditory, prefrontal (PFC), sensorimotor and limbic/paralimbic cortex. Data were denoised and segmented into 1-minute epochs, and functional connectivity was measured via gamma band power envelope correlations. Connectivity was averaged within ROI, then across subjects, thresholded (top 33%) and normalized to yield the transition probability matrix **P**, which was analyzed using DME. **Results:** The eigenvalue spectrum $|\lambda_i|$ of **P** showed a clear inflection for $i>3$, indicating that a 3-D representation is a reasonable approximation. The data in embedding space roughly formed a tetrahedron, with clusters of functionally-related ROIs at each of four corners: (1) AC; (2) temporal and parietal auditory-related; (3) limbic and paralimbic cortex; and (4) PFC. Some regions scattered along the edges (e.g. lower bank of the superior temporal sulcus [STS], planum polare [PP], insula, sensorimotor and anterior cingulate cortex) and in the interior of the data cloud (e.g., anterior portions of superior and middle temporal gyrus, and cingulate gyrus). Clustering in embedding space segregated data into hierarchically-related functional groups, including portions of dorsal and ventral auditory streams. **Conclusions:** Distances between the two banks of the STS, and between PP and the rest of AC, are consistent with previously reported functional segregation of these regions. ROIs in the interior of the data cloud may correspond to global hubs. The relative positions of (a) AC, (b) posterior vs anterior insula, PP, and anterior superior temporal gyrus, and (c) limbic ROIs suggest a distinct auditory limbic stream that may carry memory- and emotion-related auditory information.

Title: Comparison of functional geometry of cortical networks derived from functional magnetic resonance imaging (fMRI) versus intracranial electroencephalography (iEEG)

Authors: *D. G. BERGER[1], B. M. KRAUSE[2], D. I. CAMPBELL[3], A. D. BOES[4], J. E. BRUSS[5], H. KAWASAKI[6], K. V. NOURSKI[7], M. I. BANKS[8];
[2]Dept. of Anesthesiol., [1]Univ. of Wisconsin-Madison, Madison, WI; [3]Dept. of Anesthesiolog, Univ. of Wisconsin Madison, Madison, WI; [4]Pediatrics, Neurol. & Psychiatry, Univ. of Iowa, Iowa City, IA; [5]UIHC, Iowa City, IA; [6]Dept Neurosurg., Univ. Iowa Hosp Clin., Iowa City, IA; [7]The Univ. of Iowa, Iowa City, IA; [8]Dept. of Anesthesiol., Univ. of Wisconsin, Madison, WI

Abstract: Introduction: Resting state networks (RSNs) are typically derived from fMRI, but iEEG offers superior spatiotemporal resolution. However, iEEG samples from only a subset of brain regions of interest (ROIs), with non-uniform electrode coverage of each ROI. Sparse, non-uniform sampling may distort RSNs derived from iEEG. We studied this issue by comparing cortical networks derived from iEEG vs fMRI data using diffusion map embedding (DME), which maps data into a space where distance represents similarity in connectivity to the rest of the network.
Methods: Resting state functional connectivity was obtained in 10 neurosurgical patients via iEEG [θ 3-8 Hz;α 8-12 Hz;β 12-30 Hz;γ 30-80 Hz; γH80-150 Hz power envelope correlations, n = 84 -220 recording sites/patient in temporal, parietal, and frontal cortex] and pre-surgical fMRI(BOLD time series Pearson correlations). MRI voxels corresponding only to electrode locations (er-fMRI) or to the full scan (f-fMRI) were used. DME analysis was applied to thresholded, normalized connectivity matrices for iEEG and fMRI data, which was compared via correlations between inter-node distances in DME space. Nodes are averaged across electrodes in an ROI (avgEl; iEEG, er-fMRI), or averaged across entire ROIs (avgROI; er-fMRI, f-fMRI). Three sets of comparisons are made: (1) iEEG_avgEl vs er-fMRI_avgEl, to inform the relevance of fMRI for evaluating iEEG; (2) er-fMRI_avgEl vs er-fMRI_avgROI, to evaluate non-uniform within-ROI sampling; (3) er-fMRI_avgROI vs f-fMRI_avgROI, to evaluate limited brain sampling.
Results: iEEG vs fMRI correlations (r =0.41 -0.64) were RSN and frequency band-dependent(Ctrl: α>β>θ>γH>γ, DMN: α>β>θ>γH>γ, dAttn: θ>β>α>γ>γH, Limbic: γ>β>α>γH>θ, Sal/vAttn: α>γ>θ>β>γH, SomMot: θ>α>γ>β>γH, Vis: θ>γ>γH>α>β). Correlations restricted to auditory cortex were 0.68 -0.87 (γH>γ>β>α>θ). Correlation across all sampled ROIs were 0.24 -0.54 (γ>γH>β>α>θ). Correlations for er-fMRI_avgEl vs er-fMRI_avgROI and f-fMRI_avgROI vs er-fMRI_avgROI were 0.49±0.13 and 0.88±0.031 (mn±SD across subject), respectively.
Conclusions: Correlations between iEEG and fMRI data are consistent with previous results, which motivates using fMRI data to evaluate the effects of limited, non-random sampling. Within RSNs, frequency dependence is variable, while in auditory cortex and across all ROIs fMRI matches iEEG best at higher frequencies. Correlations between f-fMRI_avgROI vs er-fMRI_avgROI show that network structure is retained when using a non-random sub-sample of ROIs. However, weaker er-fMRI_avgElec vs er-fMRI_avgROI correlations suggest that sparse sampling within a given ROI is more consequential.

Title: Listening to music modulates the theta-gamma cross-frequency coupling of human cortical and subcortical neurons

Authors: H.-J. LEE[1,2], *W.-J. KUO[3,4], H.-Y. YU[5,4], C.-C. CHOU[5], C.-C. LEE[6,4], *F.-H. LIN[1,2]; [1]Physical Sci., Sunnybrook Res. Inst., Toronto, ON, Canada; [2]Dept. of Med. Biophysics, Univ. of Toronto, Toronto, ON, Canada; [3]Inst. of Neurosci., [4]Brain Res. Ctr., Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan; [5]Neurol. Dept., [6]Dept. of Neurosurg., Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Neuronal oscillations interact at different frequencies. Such cross-frequency coupling at the hippocampus is particularly active between the theta (5-10 Hz) and gamma (30-100 Hz) bands. In particular, the amplitude of gamma-band oscillation correlates with the phases of the theta-band oscillation. Phase-amplitude coupling (PAC) has also been reported for cortical neuronal oscillations in humans.

Here, we used stereo-electroencephalography (SEEG) data collected from epilepsy patients (n = 4) to study the PAC at both cortical and subcortical regions. Specifically, we examined the PAC at the hippocampus and the temporal lobe in both the resting state and during music listening. SEEG was recorded with 2,048 Hz. Electrode contacts were localized by magnetic resonance imaging.

Significant neuronal oscillation coupling was found between phases at theta-alpha (4-16 Hz) bands and amplitudes at beta-gamma (20-60 Hz) bands during the resting state at the hippocampus. This PAC was significant and reproducible during music listening. Strong PAC was found at the resting state at the auditory cortex between phases at theta-alpha (4-16 Hz) bands and amplitudes at beta-gamma (20-200 Hz) bands. PAC was strongly suppressed during music listening, showing significant PAC only between phases for 10-Hz oscillations and amplitudes around 40-Hz oscillations.

In summary, SEEG provided a spatiotemporally accurate recording of neuronal oscillations. The revealed task-dependent PAC in humans in both cortical and subcortical regions suggests the neural mechanism supporting the information processing and integration under naturalistic stimuli.

Title: Neurocomputational transformations of sequences into mental structures: Relational codes and fronto-temporal information flow

Authors: *R. M. CALMUS[1], B. WILSON[1,2,3], Y. KIKUCHI[1], Z. KOCSIS[4,1], H. KAWASAKI[4], T. D. GRIFFITHS[1], M. A. HOWARD, III[4], C. I. PETKOV[1];

Abstract: Understanding how the brain represents and binds complex information distributed over time is a challenging problem, requiring computationally and neurobiologically informed approaches to solve. The combinatorial binding problem is highly relevant to language, where human syntactic knowledge facilitates 'movement' and hierarchical restructuring of words/phrases for perception and cognition. Yet the problem is also broadly relevant for cognitive neuroscience. For instance, structured-sequence-learning tasks engage fronto-temporal regions including inferior frontal areas 44/45 ("Broca's area") and the frontal operculum. However, how neural representations emerge as these and other areas interact - and by which binding mechanisms - remains unknown. We recently proposed a vector-symbolic computational model, VS-BIND, which triangulates reported findings across a broad fronto-temporal network, specifying mechanistic roles for regions including areas 44/45 and motor/premotor cortex during interactions with temporal cortex (Calmus et al., 2019). We test this model here using human behavioural and intracranial recordings obtained under an Artificial Grammar Learning (AGL) task in neurosurgery patients being monitored for epilepsy treatment. Under the AGL task, 12 patients listened to auditory speech sequences containing adjacent and non-adjacent dependencies, and were then tested on their ability to distinguish novel "grammatical" and "ungrammatical" sequences. We analysed intracranial data using traditional methods, demonstrating engagement of the fronto-temporal network, and additionally undertook a battery of established and novel multivariate analyses to reveal: 1) the representational geometry of regional speech encodings; 2) time-resolved representational patterns; and 3) causal representational information flow between fronto-temporal regions. The results reveal that certain prefrontal areas integrate relational information, including the ordinal position of items in a sequence, in concordance with site-specific predictions of the VS-BIND model. Furthermore, we observed net causal information flow consistent with feed-forward and feedback predictive signalling, suggesting that expectation-driven predictions are fed back to primary auditory cortex from areas including 44/45. These results indicate a critical role for fronto-temporal areas in transforming the sensory world into mental structures and, more specifically, provide evidence for the integration of key stimulus features using relational codes.

Title: Rhythmic visual stimulation at the subject specific intrinsic alpha frequencies causes increased connectivity within the occipito-parietal cortex

Authors: C. JAEGER, R. NUTALL, C. SORG, ***A. WOHLSCHLAEGER**;
Klinikum rechts der Isar, TUM, Munich, Germany

Abstract: The “communication through coherence” hypothesis poses that processing of the bottom-up information flow in the visual cortex is controlled by top-down processes in the alpha-beta band (Fries 2015 Neuron) which are inhibitory in nature. Posterior alpha range processes are a prominent feature in electrophysiological measurements. Individual subject exhibit different peak frequencies. Spontaneous power increases within the alpha frequency band during rest are associated with reduced fMRI functional connectivity (FC) within the occipital cortex (Scheeringa 2012 brain conn). Active stimulation via visual flicker leads to a reduced fMRI response (Parkes 2004 Neuroimage) conforming with the notion of inhibition. However, it remains unclear how decidedly targeting the subjects’ specific individual alpha frequencies (IAF) by a bottom-up process affects the intrinsic communication within the occipito-parietal cortex. We addressed this question by contrasting FC during sustained rhythmic flicker stimulation at the IAF to arhythmic stimulation as well as to stimulations at other frequencies of the alpha range. The preprocessed fMRI time series from the occipito-parietal cortex were parcellated into regions of the Glasser atlas (Glasser 2016 Nature) and cross-correlated for each flicker condition separately. The resulting FC measures were tested for connectivity differences between conditions (Zalesky 2010 Neuroimage). Rhythmic stimulation at the IAF induced significantly more connected networks that ranged across occipital and parietal regions and across hemispheres as compared to rhythmic stimulation at all other frequencies. This suggests that rhythmic stimulation at the IAF frequency results in entrainment and a higher degree of synchronization across occipital and parietal regions. Our results show that modulatory changes to the intrinsic alpha rhythm influences the degree of synchronicity of neural activity across the visual cortex and may thus help regulate visual information processing and communication during visual processing.

Title: Visual Thalamocortical Mechanisms of Movement/Arousal-Related Activity and Alpha Oscillations

Authors: *D. NESTVOGEL, D. MCCORMICK;
Univ. of Oregon, Eugene, OR

Abstract: The brain exhibits highly variable patterns of spontaneous, ongoing activity that are commonly referred to as brain states. Brain states are strongly related to animal behaviors, such as the levels of motor movements and arousal, and are known to profoundly shape sensory responses and behavioral performance. The neural mechanisms underlying the generation and modulation of brain states are incompletely understood, but results from several studies suggest that the thalamus plays a central role in this process. Here, we studied the role of thalamocortical interactions in regulating two prominent brain

states in the primary visual cortex (V1) of awake mice - 1) a state-dependent 3-5 Hz oscillation that is thought to be an evolutionary precursor of the primate alpha oscillation and 2) rapid membrane potential depolarizations that occur during movement / high arousal. To this end, we employed intra- and extracellular electrophysiology techniques in awake behaving mice together with pharmacological and optogenetic manipulations. Our results indicate that the alpha-like oscillation in mice reflects a thalamocortical rhythm that involves low threshold Ca^{2+} spike (LTS) mediated action potential bursting in thalamic neurons, depends upon thalamocortical interactions and predominantly occurs following a reduction in movement and/or arousal. We further found that visual thalamic activity correlates strongly with the rapid arousal/movement-related membrane potential depolarizations in V1 and strongly shapes these signals in V1. Taken together, our results indicate that thalamocortical interactions together with cell-intrinsic properties of thalamocortical cells play an essential role in regulating the 3-5 Hz alpha-like oscillation and rapid membrane potential depolarizations of V1 cells during movements / high arousal. These two prominent brain states, in turn, are known to shape sensory responses and to impact behavioral performance.

Title: Joseph Emerson

Authors: *J. H. EMERSON[1], C. A. OLMAN[2];
[1]Neurosci., Univ. of Minnesota Grad. Program In Neurosci., Minneapolis, MN; [2]Psychology, Univ. of Minnesota, Minneapolis, MN

Abstract: Perception of visual features is influenced by context. The influence of context on low-level visual perception is observed in the orientation tilt illusion in which the perceived orientation of a grating stimulus is influenced by the orientation of a surrounding grating stimulus. This phenomenon can be explained by interactions between the classical receptive field (CRF) and the extra-classical receptive field (eCRF). Recent theoretical work suggests that a specific recurrent circuit motif implemented in primary visual cortex (V1) can account for the tilt illusion. This circuit motif posits that two subpopulations within the eCRF, an excitatory near surround and an inhibitory far surround, exert complementary influence on the CRF. While this work has shown that the steady-state activation of neural populations observed during the orientation tilt illusion can be recapitulated using this circuit motif, it has not yet been shown whether neural dynamics are similarly accounted for, which would provide important insights into the function of the underlying circuits. We hypothesized that by incorporating this circuit motif into a model based on recurrent amplification, the tilt illusion could be recapitulated, while providing more biologically plausible dynamics. We found that the model was

capable of reliably reproducing steady-state behavior expected in the tilt illusion, while also generating gamma oscillations (30-100 Hz), a proposed biomarker for normalization. This model provides testable predictions for future studies examining neural dynamics with EEG and MEG and identifies a plausible neural circuit mechanism for context integration in primary visual cortex.

Title: The influence of expectation on neural population activity during natural scene discrimination

Authors: *P. L. STAN[1], M. A. SMITH[2];
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Biomed. Engin., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Expectation heavily influences our visual perception, allowing us to identify relevant information from the vast amount of visual input found in the natural world. Behaviorally, expectation biases visual perception and improves stimulus detection. However, most studies showing a clear behavioral effect of expectation do not assess the neural underpinnings of these effects. Studies that do assess the effects of expectation on brain activity have primarily used fMRI, with few looking at the neuronal level. Although a handful of studies have focused on single neuron activity, little work has sought to understand how populations of sensory cortical neurons change their responses with expectation. Additionally, the majority of studies manipulate expectation in a way that is dissociated from behavioral performance (i.e. subjects passively view expected or unexpected images). The lack of neuronal level data paired with a task where expectation is decision-relevant greatly limits our ability to understand how expectation influences neural activity and shapes our perceptual abilities. To probe the effects of expectation on visual perception and neural activity, we recorded from populations of V4 neurons using implanted 100-electrode arrays in alert macaques engaged in a natural scene change detection task. We modulated the expectation of which image the subject will need to detect a change in on the following trial. During high expectation blocks, the same image (e.g. image A) was used on every trial. During low expectation blocks, a random image (from 10 possible images, including image A) was chosen for each trial, thereby reducing the expectation that image A would be selected for the following trial. We then compared both neural activity and behavior for image A during high expectation blocks with image A during low expectation blocks. Data from 3 monkeys showed a robust improvement in the ability to detect a change in an image when the image was expected. Our recordings from 2 monkeys showed that, in contrast to the typical enhancement seen for attention, expectation decreased neural activity. For the same image, firing rates were lessened when the image was expected. Additionally, we saw changes in the magnitude and distribution of pairwise correlations as well as in population-level

metrics such as shared variability and dimensionality. Our data offers a novel view into the neural changes in sensory areas that underpin expectation, and our results suggest that shifts in individual neuron activity and interactions between neurons underlie perceptual improvements due to expectation.

Title: Representation of Uncertainty by Macaque V1 Populations

Authors: *Z. M. BOUNDY-SINGER, C. M. ZIEMBA, R. L. T. GORIS;
Univ. of Texas At Austin, Austin, TX

Abstract: Perception is fundamentally uncertain. As a consequence, probabilistic inference as formalized by Bayesian theory is the "right" way to solve perceptual tasks. This in turn implies that the neural circuits which process sensory information must also survey the uncertainty of this information and put this estimate to use for perceptual inference. How this works is unknown. A prominent general hypothesis is that the same sensory neurons that encode a given stimulus feature also encode the uncertainty about this feature. Here, we investigate this notion in macaque V1, where neural populations encode local image orientation. We recorded V1 population activity from awake, fixating macaques using linear electrode arrays while presenting stimuli with varying orientation and uncertainty. We manipulated uncertainty in two distinct ways. First, by lowering stimulus contrast, thereby exposing noise internal to the system. And second, by increasing spread in the orientation domain, thereby adding noise external to the system. To investigate how V1 populations encode stimulus orientation and orientation uncertainty, we first fit each neuron's responses with a stimulus-response model built from operations of linear filtering, nonlinear transduction, gain control, and a doubly stochastic noise process. This model captured the effects of orientation, contrast, and spread on the neurons' response mean and variance. We then used this model to derive the maximum likelihood estimator of stimulus orientation on the basis of V1 population activity. Stimulus orientation estimates were on average unbiased, even in the presence of nuisance variation (contrast and spread). On individual trials, orientation estimation error tended to be small for high contrast, small spread stimuli, but could be substantial when contrast was low or spread was high. Thus, as expected, stimulus orientation estimates decoded from V1 population activity are less precise when either internal or external noise corrupts neural activity. We then asked which aspect of neural activity distinguishes uncertain from certain trials. We identified two candidate representations of uncertainty. First, the overall level of activity (the higher the population firing rate, the better the quality of the

orientation estimate). And second, a model-based estimate of cross-neural variability in response gain (the higher this variability, the lower the quality of the orientation estimate). These findings clarify how sensory circuits jointly encode stimulus features and their uncertainty.

Abstract: It is widely assumed that trial-by-trial variability in visual detection performance is explained by the fidelity of visual responses in visual cortical areas influenced by fluctuations of internal states, such as vigilance and behavioral history. However, it is not clear which neuronal ensembles represent such different internal states. Here, we utilized a visual detection task, which distinguishes internal states in response to identical stimuli, while recording neurons simultaneously from the primary visual cortex (V1) and the posterior parietal cortex (PPC). We found that rats sometimes withheld their responses to visual stimuli despite the robust presence of visual responses in V1. Our unsupervised analysis revealed distinct population dynamics segregating hit responses from misses, orthogonally embedded to visual response dynamics in both V1 and PPC. Heterogeneous non-sensory neurons in V1 and PPC significantly contributed to population-level encoding accompanied with the modulation of noise correlation only in V1. These results highlight the non-trivial contributions of non-sensory neurons in V1 and PPC for population-level computations that reflect the animals' internal states to drive behavioral responses to visual stimuli.

Title: Interpreting sensory and cognitive signals in the cortical reading network

Authors: *G. LERMA-USABIAGA[1], R. LE[2], C. GAFNI[4], M. BEN-SHACHAR[5], B. A. WANDELL[3]; [1]BCBL. Basque Ctr. On Cognition, Brain and Langua, Donostia-San Sebastian, Spain; [3]Psychology, [2]Stanford Univ., Stanford, CA; [4]Univ. of Haifa, Haifa, Israel; [5]Bar Ilan Univ., Ramat Gan, Israel

Abstract: Many important tasks, such as reading, require the coordination of sensory and cognitive processing. Regions of ventral occipito-temporal (VOT) cortex, close to the visual field maps, are part of the neural circuitry that is engaged by reading: we refer to the regions of the VOT that are more responsive to words than to other stimulus categories as the VOT reading circuitry (VOTRC). In previous work, we used fMRI and the population receptive field (pRF) analysis to characterize the visual responses in the VOTRC. The FOV of a region of interest (ROI) defines the portion of the visual field that reliably evokes a response in any of the ROI voxels. We showed that the FOV of the VOTRC is largely confined to the central portion of the visual fields and that the position of the FOV is stimulus-dependent, differing when contrast patterns comprised words versus checkers. This finding can be explained by at least two types of neural models. The first model is that responses in the VOTRC voxels are dominated by sensory input: changing the stimulus from checkers to words shifts the sensory input so that the VOTRC receives signals from different regions of visual space. A second model is that the signals reaching the VOTRC include a large contribution from non-visual, cognitive regions. In this case, using the pRF model to analyze the VOTRC responses incorrectly assigns differences in the BOLD response to changes in receptive field center locations and sizes. To understand the origin of this stimulus dependency in the VOTRC, here we expand on the prior reports: we quantify the stimulus-dependency in the ventral visual field maps (V1, V2, V3, hV4, VO-1) whose signals are delivered to the VOTRC. A small stimulus-dependent effect is measured as early as V1 and becomes more pronounced in every subsequent map. The stimulus-dependent differences in pRF center location are systematic: the word stimuli generally produce estimates that are as much as 3-4 deg closer to the fovea and fall along radial visual field lines. We further observe stimulus-dependent differences in pRF center positions using false-fonts and Hebrew script stimuli. Specifically, VO-1 responds similarly to words and false fonts, whereas the VOTRC responses differ between false fonts and words. We suggest that VOTRC responses are a combination of sensory and cognitive terms: interpreting the VOTRC responses with purely sensory pRF model, and thus as shifts in visual field position and extent, may miss an important aspect of the signal. We propose an extension of the pRF model to account for this cognitive signal.

Title: A mechanism for inter-areal coherence through communication based on connectivity and oscillatory power

Authors: M. SCHNEIDER[1], A. S. BROGGINI[2], B. DANN[3], A. TZANOU[1], C. URAN[1], S. SHESHADRI[3], H. SCHERBERGER[3], ***M. VINCK**[1];
[1]Ernst Struengmann Inst. for Neurosci. in Cooperation with Max Planck Society, Frankfurt Am Main, Germany; [2]Ernst Strüngmann Inst., Frankfurt am Main, Germany; [3]German Primate Ctr., Goettingen, Germany

Abstract: Inter-areal coherence between cortical field potentials is a widespread phenomenon and depends on numerous behavioral and cognitive factors. It has been hypothesized that inter-areal coherence reflects phase-synchronization between local oscillations and can flexibly gate communication. Here, we reveal an alternative mechanism, in which coherence is a consequence and not the cause of communication, and naturally emerges as a consequence of the fact that spiking activity in a sending area causes post-synaptic inputs both in the same area and in other target areas. Consequently, coherence depends in a lawful manner on the oscillatory power and phase-locking in a sending area and connectivity between a sender and receiver. We show that local changes in oscillatory power explain prominent changes in long-range beta-coherence during a visually guided reach task, and LGN-V1 gamma-coherence with arousal and visual stimulation. Optogenetic silencing of spiking in area V1 and simulations of E/I networks demonstrate that afferent synaptic inputs rather than spiking entrainment are the main determinant of inter-areal coherence. These findings suggest that the unique spectral profiles of different brain areas automatically give rise to large-scale inter-areal coherence and Granger-causality patterns that follow anatomical connectivity and continuously reconfigure as a function of behavior and cognition. In a second study, we show that feedforward gamma (LGN to V1, V1 to V2) results in phase-locked responses of fast-spiking interneurons in the granular layer of the receiving area, however with much weaker phase-locked responses of excitatory neurons in the receiver, compatible with the low-pass filtering properties of excitatory neurons. The latter findings suggest that gamma is not a mechanism to promote feedforward communication, but that gamma may recruit inhibition in downstream areas and thereby contribute to normalization mechanisms.

Amsterdam, Amsterdam, Netherlands; [8]Helmholtz Inst., Utrecht Univ., Utrecht, Netherlands

Abstract: Neurons in visual cortex are sensitive to the image elements in their receptive field (RF) but also to the context determining if the elements are part of an object or not. These contextual modulations of neural activity have been extensively studied with artificial stimuli but not in natural vision. Here we determined the effect of object perception (object boundaries and interiors) on neural activity in early visual cortex elicited by natural images. We recorded the response of several visual regions in humans using fMRI and the activity of neurons in V1 and in V4 using electrophysiology in macaques. We presented images from the BSD, a library of natural images in which human observers marked object boundaries (Fig. 1A). We report that the early visual cortex (V1, V2 and V3 in humans and V1 and V4 in monkeys: Fig. 1B) responded stronger to marked boundaries than to non-marked boundaries with similar contrast. We also observed that the interiors of objects elicited stronger responses than the background (in V1 and V2 in humans and V1 and V4 in monkeys: Fig. 1B). Our experiments revealed that boundary effects occur remarkably early in V1, ~50ms after stimulus onset. The latency of the response enhancement elicited by object interiors is later (~80ms) if the monkey sees the image for the first time, and earlier (~60ms) if a previous saccade shifted the object into the RF, indicating that the enhancement of object interiors builds up across eye movements (Fig. 1C). The boundary modulation in V1 is earlier than the latency of ~95ms observed in studies with synthetic images, suggesting that visual cortical neurons are tuned to features characterizing object boundaries in natural scenes. We tested this hypothesis in two further experiments in V1 in monkeys and observed that the boundary modulation is explained by RF tuning and is delayed (to ~80ms) by a change in context while keeping the content in the RF the same. Our results reveal how object perception shapes the representation of natural images in early visual cortex in both humans and monkeys, by enhancing the representation of object boundaries and interiors.

Title: Pulses of gamma activity in mouse V1 predict visually guided behavior

Authors: *Q. PERRENOUD, A. H. O. FONSECA, A. AIRHART, J. BONANNO, R. MAO, J. A. CARDIN;
Dept. of Neurosci., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Neocortical gamma band activity (30-80Hz) is a hallmark of active wakefulness and cognition in rodents and humans, and its disruption is associated with several neurodevelopmental disorders including schizophrenia and autism. Gamma activity is easily detectable in the frequency spectrum using Fourier analysis or its derivatives. However, the local network events underlying this broad gamma range activity are difficult to track in the temporal domain. Furthermore, cortical gamma oscillations largely occur in short bouts, rather than sustained oscillatory periods, presenting a challenge for precise detection. As a result, the mechanisms and function of gamma oscillations remain poorly understood. Here we studied gamma activity in the visual cortex (V1) of awake behaving mice using laminar probe and whole cell patch clamp recordings. Gamma activity typically increases in mouse V1 during running, providing a template for detection. Taking advantage of this, we developed an analytical method combining spectral analysis and unsupervised clustering called Clustering of Activity Motifs by State (CLAMS) for high-fidelity tracking of gamma bouts in the temporal domain. Using CLAMS, we find that gamma events in the cortical local field potential (LFP) correspond to transient pulses synchronizing the membrane potential dynamics of neurons in cortical layers 2 to 5. Gamma pulses coincide with a stereotypical propagation of activity from layer 4 into layer 2-3 and then into layer 5, suggesting that they may arise via feedforward thalamocortical processing. Though gamma pulses were more frequent during running, they occurred several times per second regardless of behavioral state. Using CLAMS, we examined state-dependent bouts of gamma activity in mouse V1 during learning and performance of a visual contrast detection task. We found that V1 gamma pulses increased in frequency preceding responses, but not miss, in mice trained to perform the task. The rate of gamma pulses was thus highly predictive of behavioral outcome on a trial-by-trial basis. This enhancement of gamma was not present in naïve mice prior to the formation of an association between the visual stimulus and reward but emerged following learning. In addition, increased gamma activity was modality-specific, as we observed no enhancement in gamma bouts in V1 during successful performance of an auditory task. Based on these findings, gamma in V1 may correspond to pulses of synchronized cortical activity that facilitate sensory integration during visually guided behavior.

Title: Sub-regions of the SCN receive a heterogeneous synaptic input from the retina

Abstract: The suprachiasmatic nucleus (SCN) of the hypothalamus is the central pacemaker regulating the circadian rhythmicity of tissues throughout the body. The SCN is receiving photic information through melanopsin-expressing ganglion cells of the retina (mRGCs) to synchronize the body with the environmental light cycles. The SCN is a complex nucleus composed of several subtypes of neurons receiving information from the retina as well as other brain regions. Understanding how these different inputs affect the SCN network is crucial to understand the regulation by light of the circadian clock. This level of detail is not accessible using common light microscopy techniques, we thus used a Cre-dependant electron microscopy reporter, APEX2, to specifically label mitochondria of mRGCs axons, and serial blockface electron microscopy to access the fine structures of the SCN that cannot be done in light microscopy. We thus obtained the first in deep study of the connectome organization of SCN in two specific regions, the core and the shell, known to be composed of different neuronal subtypes, and their mRGCs inputs. Our results indicate that a network of neurons forming dendro-dendritic synapses is present in both sub-regions of the SCN and receives denser mRGCs synaptic input in the shell compared to the core. This challenges the idea that photic information coming directly from the retina is mainly integrated by the core region of the SCN.

Abstract: Sensing is an active process. Humans use saccadic eye movements to relocate the fovea and sample different bits of information multiple times per second. Saccades modulate neuronal oscillations across the visual system shifting neuron ensembles to a common momentary state just after fixation. Whether these effects extend outside of the visual system is unknown. Here, we combined intracranial electroencephalography (iEEG) with eye tracking during natural free viewing in lieu of auditory stimulation to evaluate the possibility that saccades modulate neural activity in classical auditory and speech processing cortical areas. Studying fixation-locked field potentials, we discovered two anatomically separate mechanisms operating in synchrony with the eye movements: one operating in low level auditory areas and another in higher order speech processing areas. We also found dynamical multiplexed connectivity between the auditory system and regions involved in generation of saccades. Our results support an active vision model in which saccades are tied to dynamic modulation of neural excitability across a network that extends into the auditory system.

Title: Learning-induced changes in the dorsal regions of auditory and motor striatum support associative learning through sensorimotor integration.

Authors: J. GAY[1], N. PARAOUTY[2], ***T. MOWERY**[1];
[1]Rutgers Univ., Piscataway, NJ; [2]Dept. d'études cognitives-DEC IEC, Ecole Normale Superieure Paris, Paris, France

Abstract: Background: Prior to behavioral output, information from the sensory and motor systems are integrated in a region of the basal ganglia, known as the striatum. There, sensory information about the environment (e.g., stimuli) is utilized to shape a motor output (e.g., behavior). For naïve animals, a sensory input will not reliably evoke a specific behavioral response (absence of stimulus response association). In contrast, in animals that have mastered an associative learning task, a particular sensory input will reliably produce a desired behavioral response. In this study, we asked how neuronal response properties in the motor and auditory regions of the dorsal striatum change as a function of associative learning of a Go-Nogo task.
Methods: Adult Mongolian gerbils (n=5) were implanted with wireless 64-channel electrode array that spanned the dorsal striatum from the anterior motor regions to the posterior auditory/visual regions. Each animal was trained on an amplitude-modulation (AM) rate discrimination task using an appetitive reinforcement operant conditioning procedure. The freely-moving animals were trained to initiate each trial by a nose poke, and a 12-Hz AM stimulus indicated the availability of a food pellet (Go stimulus), versus a 4-Hz AM stimulus which signaled the absence of a reward (Nogo stimulus). A sensitivity measure, dprime (d' = z(hit rate) - z(false alarm rate), was computed for each animal across training days.
Results: Single-unit recordings (N=815; Motor MSNs (418), Aud MSNs (397)) were carried out for each day of training and compared as a function of task trial type response (Go-hit, Nogo-false alarm, Nogo-correct reject), learning state (naïve, acquisition, mastery), and striatal region (motor, auditory). Response latency was also calculated and compared within animals across learning states. As animals learned the task (d' improve), the neuronal responses to the Go and Nogo stimuli were significantly altered. The changes seen in neuronal responses accurately predicted task trial type response, learning states and response latencies. In addition, significant differences to stimulus evoked motor and auditory responses emerged as animals moved from the naïve learning state to the mastery phase (e.g., response magnitude, latency to peak, temporal coding precision).
Conclusions: Together, these results demonstrate how neuronal response properties in striatal circuits are altered by associative auditory learning. Those changes in striatal circuitry may be pivotal for additional learning of more complex associations.

Title: Investigating the entopeduncular nucleus contribution to ipsi/contralateral movements and decisions

Authors: *A. VERMA RODRIGUEZ, J. O. RAMIREZ-JARQUIN, F. TECUAPETLA;
Univ. Nacional Autónoma de México, Ciudad de Mexico, Mexico

Abstract: The entopeduncular nucleus (EPN, rodent analog of the Globus Pallidus internal segment, GPi) is one of the main outputs of the basal ganglia. It has been implicated in action evaluation via reward-related signals. As well, movement correlated activity under certain memory-dependent contexts has been suggested. Furthermore, the basal ganglia have been shown to differentially contribute to ipsilateral and contralateral decisions and movement-related variables (such as speed) in freely moving rodents. Given that studies focusing on the GPi have mostly been done in head-fixed tasks, this study intends to analyze the contribution of this nucleus to movement and decision in a freely behaving animal. Preliminary results:

- We trained mice in an auditory two-alternative forced-choice task that involved turning right or left and moving towards the reward port.
- The auditory stimuli were graded in difficulty such that a psychophysical curve could be obtained. The increased uncertainty in the decision increased the reaction time and decreased the speed of their movement.
- Preliminary analyses of recordings from the entopeduncular nucleus show activity correlated with the decision. Some units show anticipatory activity that distinguishes whether the turn will be ipsi- or contralateral.
- Reward-related signals are modulated according to the difficulty of the auditory stimulus.
- However, movement-related activity, especially involving speed, has not been conclusively established. Further analysis is needed to ascertain how the activity is related to movement parameters.

Title: Longitudinal in vivo calcium imaging of striatal neurons during associative learning and chronic haloperidol administration

Authors: *S. S. BASKAR, T. J. VAJTAY, D. J. MARGOLIS;
Rutgers, The State Univ. of New Brunswick, Piscataway, NJ

Abstract: The integration of sensory and motor signals is a key role of the dorsal subdivision of the dorsal striatum (DStr), the main input nucleus of the basal ganglia. This process is mediated by diverse microcircuitry that includes two spiny projection neuron (SPNs) and multiple interneuron populations. The interplay between these populations is critical for the coordination of sensory-guided behavior and sensorimotor learning. Our goal was to measure the activity dynamics of D1- and D2-SPNs (the major populations of dopamine receptor-expressing projection neurons) during learning of a cue-reward behavioral task, and how activity changed after chronic haloperidol administration, a D2-SPN antagonist that is used clinically as an antipsychotic. We injected double transgenic adult D1-tdTomato mice (100-150d; n=2) with a viral vector expressing the genetically encoded calcium indicator GCaMP6m, and implanted a gradient index (GRIN) lens above the DStr. Post-recovery (4-6wks), mice were water restricted and trained in a simple sensory paired conditioning task that paired air-puff whisker stimulation with water reward, and in vivo calcium signals of DStr neurons were recorded using a two-photon microscope. One week of baseline recordings was followed by 2 weeks of chronic intraperitoneal injections of Haloperidol (Hal; 1mg/kg; once daily). Analysis of the baseline week showed overall trends of cue-driven calcium signals in the majority of DStr neurons, suggesting that DStr neurons encode responses to sensory cues rather than general movement or reward. Interestingly, by the end of the week the same highly responsive cells had reduced their overall responding significantly, potentially suggesting a role in cue-associated sensory learning. Preliminary analysis of average cell activity of the Hal trials showed both an increase in overall spontaneous activity from the previous baseline day and distinct time-locked activation around the sensory cue on the first Hal session, which became less temporally stereotyped by the end of the week. These data suggest that chronic haloperidol administration may disrupt previously encoded learning cues, however it remains to be determined to what extent changes in behavioral state (e.g., catatonia) also contribute. Further analysis will elucidate the specific roles of D1 and D2-SPNs in the maintenance and recuperation of sensorimotor learning in the DStr.

Title: Motor skill learning and execution in a distributed brain network

Authors: *S. B. E. WOLFF[1,2], A. K. DHAWALE[2], R. KO[2], B. P. OLVECZKY[2];

Abstract: The remarkable capacity of the brain to acquire and execute motor skills depends on a distributed motor network. While many components have been identified, less is known about their specific roles and how they interact during skill learning and execution. Here we probe this network through the lens of complex, spatiotemporally precise motor sequences we train in rats. We focus on the basal ganglia and the contributions made by their main inputs, from motor cortex and thalamus, respectively. Using electrophysiological recordings, we find that the dorsolateral striatum (DLS), the main motor-related input nucleus of the basal ganglia, encodes the detailed kinematic structure of the learned motor sequences. We further show that the DLS is necessary for their execution and that animals revert to simple innate behaviors after loss of the DLS. Moreover, we find that not only the DLS, but also the inputs it receives from motor cortex are necessary for learning the skills we train. This very same pathway, however, becomes dispensable after the behaviors are acquired. In contrast, thalamic inputs to the DLS remain crucial for the generation of the learned skills and loss of these inputs disrupts performance akin to DLS lesions. Taken together, our results identify the DLS as a central hub in the motor network and suggest that motor cortex 'tutors' sub-cortical motor circuits during learning, potentially by guiding plasticity at thalamostriatal synapses. Such adaptive reprogramming of lower-level motor circuits may broaden their flexibility and allow them to store and generate complex learned motor skills.

Title: Action learning process mediated by dopaminergic reinforcement

Authors: *J. TANG[1], V. PAIXAO[3], F. CARVALHO[3], A. SILVA[3], R. M. COSTA[2];
[2]Neurosci., [1]Columbia Univ., New York, NY; [3]Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: Animals have the remarkable ability to explore a novel environment in a self-paced manner and hone in on actions and action sequences that promote rewarding consequences. Dopamine is a reward signal involved in reward-prediction and motivated behavior. Emerging evidence suggests that dopamine acts at striatal synapses to mediate behavioral reinforcement, but it is unclear how dopamine

reinforcement transforms freely moving behavior such that animals can hone in on reward-causing actions. It remains even more elusive how dopamine mediates the learning of temporally distal actions that trigger rewards with variable delays. Here, we applied a novel closed-loop system to show that VTA dopaminergic self-stimulation not only reinforces the reward-causing target action, but also similar actions in naïve and experienced animals. Actions of the repertoire undergo differential dynamics as animals hone in on single targets, and specific dynamics can be predicted by an action's similarity and natural, temporal proximity to target. Notably, behavior performed within a 1-1.2 second window leading up to and during self-stimulation was reinforced. This critical window mediates learning of two-action sequences, which for target action pairs that are naturally performed with long time gaps, is characterized by preferential refinement for the proximal target early on in learning, and subsequently refinement of the distal target upon truncation of the proximal-to-distal action time interval below a critical level. These findings reveal the behavioral process by which the dopamine backpropagating critical window promotes learning and honing in on specific reward-causing action and action sequences in a spatiotemporal manner in freely moving animals.

Title: Basal ganglia-spinal cord pathway that mediates locomotor asymmetries

Authors: *J. CREGG[1], R. LEIRAS[1], O. KIEHN[1,2];
[1]Dept. of Neurosci., Univ. of Copenhagen, Copenhagen, Denmark; [2]Dept. of Neurosci., Karolinska Inst., Solna, Sweden

Abstract: The basal ganglia are critical for voluntary motor control, and dysregulation of basal ganglia circuitry contributes to locomotor impairments in Parkinson's disease. The basal ganglia are thought to initiate motor actions via disinhibitory control over a number of brainstem nuclei, whose detailed function and connectivity are under active investigation. One hallmark feature of hemi-Parkinsonism in mice and humans is the manifestation of locomotor asymmetries, e.g. turning, where locomotion exhibits a dominant directional tendency. The brainstem motor program which mediates hemi-Parkinsonian asymmetries is not known. Based on our recent finding that excitatory *Chx10* gigantocellular (Gi) neurons are required for locomotor asymmetries in mammals (Cregg et al. 2020), we hypothesized that basal

ganglia asymmetries act via this spinal projection pathway. Using deep brainstem calcium imaging in mice, we examined *Chx10* Gi Ca^{2+} responses to optogenetic stimulation of striatal D1 medium spiny neurons. D1 stimulation evoked contralateral turning accompanied by a time-locked increase in Ca^{2+} activity of *Chx10* Gi neurons on the contralateral side, suggesting a discrete pathway from basal ganglia output (i.e. substantia nigra pars reticulata, SNr) to *Chx10* Gi neurons. We used a viral screening strategy to identify brain regions that interface between SNr and Gi. This screen uncovered only one brainstem nucleus which links SNr to Gi. Excitatory neurons of this brainstem nucleus receive inhibitory input from the ipsilateral SNr and project to contralateral *Chx10* Gi neurons. Optical stimulation of this small cluster of brainstem neurons evoked contralateral turning, whereas photoinhibition evoked ipsilateral turning. Our results identify a dominant crossed pathway for locomotor asymmetries, from action selection in the basal ganglia to spinal motor output: D1 medium spiny neurons -> SNr -> brainstem nucleus -> contralateral *Chx10* Gi neurons -> spinal locomotor networks. These data indicate that selection of locomotor direction by basal ganglia circuits works via disinhibitory control over a small brainstem target that directs *Chx10* reticulospinal neurons to execute the movement.

Title: Cell type/class specific inputs to the caudoputamen from visual cortical areas in the mouse

Authors: *Q. WANG, L. NG, M. NAEEMI, S. YAO, S. SORENSEN, H. ZENG;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The caudoputamen (CP, or dorsal striatum) is a major input component of the basal ganglia that is associated with motor control, cognition, emotion and learning. As in primate and cat, the CP in mouse receives topographic inputs from various cortical areas. In the previous studies, we have shown that mouse visual areas are organized in a hierarchical fashion and form ventral and dorsal streams (Harris et al., 2019; Wang et al., 2012). Cortical areas from both streams show differential projections to subcortical structures such as amygdala and superior colliculus. However, it remains unclear whether the dorsal and ventral stream areas project to the same territory in the CP or not. Furthermore, cell type/class specific inputs from visual cortical areas to CP have not been systemically investigated. Our recent study delineated ten visual cortical areas in a 3D mouse brain atlas - the Allen Mouse Brain Common Coordinate Framework version 3 (CCFv3) (Wang et al., 2020). Pan-neuronal and Cre-dependent anterograde AAV tracing data in the Allen Mouse Brain Connectivity Atlas, including these visual cortical areas (Harris et al., 2019; Oh et al., 2014), were remapped to the CCFv3. In this new 3D framework, we systemically studied pan-neuronal and layer/subclass-specific visual cortical inputs to CP. We found that the dorsal and ventral visual areas project to the visual zone of the CP but are partially overlapping. Specifically, the dorsal stream areas (VISal, VISrl, VISam, VISpm and VISa) send widely spread projections in the dorsal CP and shift the projections gradually away from the primary visual

cortex (VISp) zone toward the dorsolateral somatomotor zone. The ventral stream areas (VISl, VISpl, VISli and VISpor) send denser projections to posterior CP than to anterior CP. The higher visual areas send stronger projections to CP than the VISp. Projections of VISp were labeled from the dorsoposterior to anterior dorsomedial CP in a restricted longitudinal strip lining the lateral ventricle. We found that different cell types in each layer of visual areas send projections to the CP with different strengths. In general, across visual areas, layer (L) 2/3 IT neurons send sparse projections to the ipsilateral visual zone of CP. L4 IT and L6b IT neurons send extremely sparse projections to the ipsilateral visual zone of CP. L5 IT and a mixture type of L5 IT and PT neurons send strong projections to the visual zone of bilateral CP with an ipsilateral dominance. A subset of L5 PT and L6 CT neurons project sparsely to the ipsilateral visual zone of CP. Our results reveal cell type specific inputs to the CP from mouse visual cortical areas.

Title: Rhythm parameters were encoded by striatal neurons of mice running in complex stepping.

Authors: *K. HIROKANE[1,2], T. NAKAMURA[1], T. TERASHITA[1], T. YAGI[1], Y. KUBOTA[3], D. HU[3], A. M. GRAYBIEL[3], T. KITSUKAWA[1,2];

Abstract: Our behavior encompasses many continuous movements such as running and playing musical instruments. Such behaviors consist of many individual actions of multiple body parts. When we play the piano, multiple fingers move simultaneously, or alternately, sequentially. The movement of fingers is often repetitive and rhythmic. In addition, each rhythm of the fingers is coordinated temporally as if all of the finger rhythms were connected each other. However, it is not clear how such coordination of movements is shaped in the brain. In our previous study, we developed a complex stepping task for mice, the step-wheel. The step-wheel is a motor-driven wheel in which mice run for water reward and can control the speed and their step-patterns. But the step-patterns can be experimenter-controlled by the arrangements of the of pegs that serve as footholds for the mice. The steps of mice can be detected by voltage sensors attached to each peg. Here, we recorded spike activity from the dorsal striatum as mice performed step-wheel tasks. We found neurons responding to events including the start or stop of drinking, licking of the spout, and touches of forelimb paws to pegs. Among them, we focused on neurons with phasic responses to touches. Even with complex peg-patterns, in which the arrangements of pegs

were irregular, the touch- responding neurons showed phasic responses correlated with the touches of forelimb paws to pegs. However, the responses were not uniform to every touch; responses were high for some touches but low for others. By aligning the spikes to right or left touches, we found that the responses to touch-to-touch intervals and/or left-right timing of limbs were different neuron by neuron. To confirm such responsiveness of the neurons, we used two peg-patterns: the peg-pattern I for Interval and peg-pattern P for left-right difference. In peg-pattern I, the space between two consecutive pegs were gradually changed from narrow to wide . In peg-pattern P, the relative positions of left and right pegs (phase) were gradually changed. We found that considerable number of touch-responsive neurons showed the modulation of firing rate by the interval and/or phase. In addition, we analyzed the relationship between stepping and spiking over several continuous steps to see whether the touch-responsive neuron activities were associated with repetition, another parameter of rhythm. We found that the firing rates of those neurons were increased in response to repeated touches with a particular touch interval. These findings indicate that the striatal neurons may coordinate body parts in repetitive movements using the parameters of rhythm, the phase, interval and repetition.

Abstract: Maternal care is profoundly important for mammalian survival, and non-biological parents can also express maternal behavior after experience with infants. One critical maternal molecular signal is oxytocin, a hormone centrally released by hypothalamic paraventricular nucleus (PVN). In mice, oxytocin enables neuroplasticity in the auditory cortex, and these neural changes are required for maternal behavior in biological and non-biological mothers. However, it is unclear when hypothalamic signaling promotes cortical plasticity and onset of maternal care during initial parental experience. Here we determined what episodes activate PVN in non-biological parents, by continuously monitoring homecage behavior of female virgin mice co-housed with an experienced mother and litter. This documentary approach was synchronized with neural recordings from virgin PVN, including from oxytocin neurons. These cells were activated as virgins were enlisted in maternal care by experienced mothers, who shepherded virgins into the nest and demonstrated retrieval of isolated pups. Shepherding activated 19% of oxytocin and 9.2% of PVN neurons in virgins, nest entry activated 28.5% of oxytocin and 26.1% of PVN neurons, and maternal retrieval activated 29.4% of oxytocin and 14.4% of PVN neurons in virgins. Virgins visually observed maternal pup retrieval, which promoted their own retrieval behavior. When the observation was unhindered, 11/15 virgins learned to retrieve. When virgins observed mothers across a transparent barrier, 12/19 learned to retrieve. However, only 2/18 virgins retrieved after exposure to maternal pup retrievals across an opaque barrier. We find that monosynaptic projections from visual layers of the superior colliculus could engage oxytocin neurons during observation of maternal retrievals. Optogenetic stimulation of these projections induced retrieval in 4/5 virgins undergoing opaque barrier exposure. Thus rodents can acquire maternal behavior by social transmission, providing a mechanism for adapting brains of adult caregivers to infant needs via endogenous oxytocin.

Title: Medial preoptic area projections to the infralimbic cortex and ventral tegmental area modulate caregiving behaviors attuned to the needs of offspring

Authors: *K. COPELAS, N. CELESTIN, M. PEREIRA;
Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: The medial preoptic area (mPOA) is critical to the facilitation of maternal caregiving behavior, where hormonal signals and offspring-related sensory information converge. Prior research in the lab suggests that the mPOA orchestrates flexible caregiving behaviors to resolve the constantly changing needs of the young. The objective of this study was to determine whether varying need signals from the offspring are represented in maternal mPOA neurons projecting to two critical downstream areas: the infralimbic cortex (IL) and ventral tegmental area (VTA). To this aim, we used red and green Retrobeads retrograde tracers and cFos immunohistochemistry to identify the subregional origins of cFos-expressing mPOA->IL and mPOA->VTA neurons in the maternal mPOA during interactions with offspring of varying needs (normal needs (NDEM) versus increased needs (DEM)). Consistent with our prior work, Sprague-Dawley (SD) mother rats interacting with DEM pups adjusted their caregiving, resulting in significant behavioral differences between groups. Ongoing cFos analysis, using a supervised automated counting protocol, thus far indicates that the observed behavioral change in mothers interacting with DEM pups was accompanied by a significant upregulation of cFos expression in the mPOA, including neurons projecting to the IL and VTA. In addition, Retrobeads labeling analysis suggests that no mPOA neurons extend axons to both the IL and the VTA. Together, results further support our hypothesis that the mPOA participates in aspects of maternal sensitivity. Follow-up studies are being conducted to understand the specific role of the mPOA in this crucial maternal ability.

Abstract: Oxytocin is a neuropeptide important for maternal physiology and social behaviors (Jurek & Neumann Physiol Rev 2018). One behavior influenced by central oxytocin signaling in rodents is pup retrieval (Marlin et al. Nature 2015; Scott et al. Nature 2015; Schiavo et al. Nature 2020). When pups are out of the nest, they emit vocalizations that prompt dams to fetch the pup back to the nest. Virgin females do not initially retrieve pups, but can learn to retrieve after several days of co-housing with an experienced mother and pups. In our lab we have filmed days-long videos of co-housing, allowing us to identify interactions that may serve as training for naïve virgins to learn maternal behaviors. We noticed mothers often spontaneously dragged pups out of the nest, generating retrieval episodes that co-housed virgins could potentially observe (Carcea et al. Nature 2021). To examine how maternal behavior might be socially transmitted through the visual system, we had non-co-housed virgins observe the mother retrieve through a transparent wall. We found that virgins learned to retrieve after four days of exposure and failed to acquire retrieval behavior when the barrier is opaque, impeding visual input. A population of neurons in the mouse superior colliculus seemed to provide this visual signal to hypothalamic oxytocin neurons (Carcea et al. Nature 2021). To explore what aspects of maternal behavior are socially transmitted, we showed audio-visual movies to head-fixed awake virgin female mice that initially did not retrieve pups. We found that head-fixed virgins exposed to audio-visual movies of maternal retrievals (N=18) expressed alloparenting earlier than virgins presented with dark backgrounds (N=21; p=0.0349) and more reliably by day two (p=0.0360). Conversely, virgins presented with videos of maternal mistakes (out of the nest retrievals; N=4) rarely expressed alloparenting behavior. Surprisingly, videos of other sole adult mice without pups (conspecifics, N=15; dam without pups, N=11) also accelerated pup retrieval learning. To further assess the role of oxytocin in this type of learning, we optogenetically suppressed oxytocin neuron activity during exposure to movies of dams retrieving pups, which prevented the enhancement of alloparenting by maternal video playback (N=4). These results demonstrate that maternal behavior in mice can be socially transmitted through a virtual experience and that the mouse visual system provides input to the oxytocin neurons for enhancement of alloparenting.

Title: Effect of ERα polymorphisms in maternal behavior of mouse

Authors: *L. DEVI[1,2], A. TANAVE[3], Y. IMAI[1], K. TAKANAMI[1,2], T. KOIDE[1,2];
[1]Natl. Inst. of Genet., Mishima, Japan; [2]Dept. of Genet., The Grad. Univ. for Advanced Studies, SOKENDAI, Mishima, Japan; [3]Lab. for Mouse Genet. Engin., RIKEN Quantitative Biol. Ctr., Osaka, Japan

Abstract: Induction of maternal behavior in mammals relies on changes at the level of the genome. However, the ability to characterize a specific behavioral phenotype to a naturally occurring genetic change i.e. polymorphism is considered to be a rare phenomenon. Maternal responsiveness is thought to be mediated by several hormonal and neuronal changes, yet the effect of underlying polymorphisms on the extent of bonding cannot be foreseen. One of the well-studied protein for its role in determining maternal- infant bonding is Estrogen receptor α (ERα), encoded by gene estrogen receptor 1 (*Esr1*). The expression of ERα in hypothalamic medial preoptic area (MPOA) and the adjacent ventral bed nucleus of stria terminalis (vBNST) plays an essential role in controlling maternal behavior. Mice are extensively used model animals to study regulation and function of ERα *in-vivo*. In our study we identified that mice from different genetic background, laboratory strain C57BL/6J (B6) and wild derived mouse strain MSM/Ms (MSM) differs in *Esr1* gene structure. We found an insertion polymorphism, (insertion "A") in exonic region of B6 genome when compared to MSM. To analyse the role of the insertion "A", we developed an $Esr1^{\Delta A}$ mice in which the "A" sequence was deleted in B6 mice through CRISPR/Cas9-mediated genome editing. We report here that (i); $Esr1^{\Delta A}$ heterozygous mice showed reduced pup survival in the breeding. (ii); Maternal behavior analysis showed that $Esr1^{\Delta A}$ heterozygous mice were reluctant to retrieve pups (took more time) when compared to the wild type control. (iii); $Esr1^{\Delta A}$ heterozygous mice showed higher mRNA and lower protein expression, indicating the effect of polymorphism on regulation of translation. (iv); Reduced ERα and cFOS (immediate early gene) expression in the MPOA of $Esr1^{\Delta A}$ heterozygous mice after maternal behavior. Altogether, our study provides a glance of how a *Esr1* genetic polymorphism has affected the brain and maternal behavior within mice species. In future studies, we would like to understand how the abnormal maternal behavior was occurred in the $Esr1^{\Delta A}$ heterozygous mice using molecular and neural approaches.

Title: Disrupting serotonin system development via early life antidepressant exposure leads to impaired maternal care and increased serotonin receptor expression in adult female offspring

Authors: *K. A. UNROE[1], J. MALTMAN[1], E. A. SHUPE[2], S. CLINTON[2];
[2]Sch. of Neurosci., [1]Virginia Tech., Blacksburg, VA

Abstract: Experiments in rodents show that manipulating serotonin (5-HT) levels in the developing brain (via early-life SSRI treatment or genetic manipulation of 5-HT levels) has lifelong negative impact on emotional behavior. Neonatal SSRI exposure produces a variety of behavioral disturbances in adulthood. Neonatal SSRI treatment also triggers several neurobiological changes in the adult brain, including diminished expression of tryptophan hydroxylase and the serotonin transporter in the raphe and altered

monoamine levels in several brain regions. The role of 5-HT in maternal behavior has not well characterized up to this point, as most of the work has looked at more stereotypical neuropeptides (e.g., oxytocin). The current study has extended this work to determine whether early life SSRI exposure alters female offspring behavior once they become mothers themselves. To test this idea, we treated adult female Sprague Dawley rats with the SSRI citalopram in drinking water throughout pregnancy and the postpartum period. Female perinatal SSRI-exposed and control offspring were raised to adulthood and subsequently mated with male rats with no history of SSRI exposure. After the females gave birth, we observed maternal care in the SSRI-exposed and control mothers during both the light and dark phase of the day. Our results indicate that maternal care is impacted due to early-life exposure to SSRIs. Specifically, we found that perinatally SSRI-exposed mothers spend less time in contact with their pups, show less arched-back nursing, and decreased maternal behavior consistency in the light phase. In the dark phase, we found that SSRI-exposed mothers lick and groom their pups less, spend more time on non-care behaviors, and show decreased maternal behavior consistency. Next, since previous work demonstrated that early life exposure to SSRI exposure perturbs expression of 5HT-related molecules in the developing as well as adult brain, we sought to determine whether this included alterations within brain structures that play important roles in regulating maternal behavior. Thus, we used qRT-PCR to measure expression of multiple 5-HT receptor subtypes (e.g., 5-HTR1A, 1B, 2A, and 2C) in the basolateral amygdala, bed nucleus of the stria terminalis, medial preoptic area (mPOA), and the prefrontal cortex (PFC) of adult perinatal SSRI-exposed and control females. In the mPOA, we found increased expression of 5-HTR1A in perinatally SSRI-exposed mothers. In the PFC, we found increased expression of 5-HT1B, 5-HT2A, and 5-HT2C in perinatally SSRI-exposed mothers. Taken together, these results show the importance to 5-HT in the regulation of maternal care in rodents.

Title: Individual variation in human infant microbiomes has minimal or no effect on rodent maternal behaviors in a small, pilot study

Authors: *A. WHITE[1], S. LIU[1], H. DUBEY, SR[2], J. S. LONSTEIN[3], R. KNICKMEYER[2];
[1]Michgan State Univ., East Lansing, MI; [3]Neurosci Program, [2]Michigan State Univ., East Lansing, MI

Abstract: Background: Maternal behaviors such as feeding, thermoregulation, and protection are essential to offspring survival. In both rodents and humans, reduced quality of maternal care is associated with reduced cognitive performance, impaired social affiliation, and increased anxiety in offspring**.** Given the lifelong impact of quality of maternal care on offspring neurodevelopment and mental health, it is essential to understand the factors that produce variations in the quality of maternal care. Multiple rodent

studies show that manipulating gut microbiota influences non-maternal social behaviors and alter cellular and molecular features in brain regions that also play a role in maternal behavior. Furthermore, a particular E. coli strain was recently shown to disrupt the maturation of maternal behavior in mice. However, no study has examined how normal variation in human gut microbiomes might influence maternal behavior.**Method**: Human infant gut microbiota dominated by Bacteroides (BAC), human infant gut microbiota dominated by Bifidobacterium (BIF), and murine specific pathogen-free gut microbiota (SPF) were transplanted into pregnant germ-free Swiss Webster mice (BAC n=2, BIF n=3, SPF n=2). Maternal behaviors were observed in a minimal/stress-free environment three days a week, from day five until day nineteen postpartum. During observation, dam behaviors were marked at every minute for twenty-five minutes.**Results**: Initial results suggest that maternal behavior is not affected by transplant with these particular human microbiomes.**Implications/Future Directions**: We will be studying offspring behavior, neuroanatomy, and neurochemistry. Current results suggest that any differences observed in offspring are not mediated by differences in maternal behavior.

Title: The amygdalohippocampal area neurons projecting to the hypothalamus and bed nucleus of the stria terminalis mediates infanticide, aggression, and mating

Authors: *K. SATO, M. MINAMI, T. AMANO;
Dept. of Pharmacol., Grad. Sch. of Pharmaceut. Sciences, Hokkaido University., Hokkaido, Japan

Abstract: In rodents, the medial preoptic area (MPOA) is thought to be the most important region for parental behavior. Although tracing studies reveal that the MPOA receives input from multiple regions, the functional input to the MPOA remains unclear. Here, we focused on the amygdalohippocampal area (AHi), which projects to the MPOA and expresses oxytocin receptor (OXTR). c-Fos immunostaining experiments revealed that MPOA-projecting AHi neurons were activated by both parenting and aggression toward pups. Pharmacogenetic activation disrupted the expression of parental behavior in both paternal mice and partially paternal mice (father in gestation experience; FGE mice) which showed either parental or aggressive behaviors. Interestingly, in paternal mice, but not FGE mice we observed a decrease in the proportion of individuals exhibiting aggressive behavior from day to day. Next, to assess how OXT affects these neurons, we recorded inhibitory response of MPOA-projecting AHi neurons using whole-cell patch-clamp recording. Bath application of oxytocin increased the frequency of spontaneous inhibitory postsynaptic currents in both virgin and paternal mice, which a greater increase in paternal

mice, suggesting plasticity in sensitivity to oxytocin. Recent studies report that the AHi mediate other social behaviors such as aggression and mating via projecting to several brain regions. However, it is still unclear whether subpopulation in the AHi innervate downstream brain regions singly or collaterally. We found that MPOA-projecting AHi neurons send axons to multiple targets collaterally. Among them, the ventromedial nucleus of the hypothalamus (VMH) and bed nucleus of the stria terminalis (BNST) which were thought to be important regions for aggression and mating connected to MPOA-projecting AHi neurons via excitatory synapse. Retrograde tracing using cholera toxin subunit B (CTB) revealed that approximately half of projector in the AHi innervated two or three regions. Immunostaining against c-Fos, a marker of neuronal activity, combined with retrograde tracers showed that several subpopulations of the AHi were activated by specific social behaviors based on their projection patterns. In conclusion, our study suggested the presence of distinct inputs from the AHi to the MPOA, VMH, and BNST that biases male's behavior choice. The AHi is a neural locus that can expand the neural circuits underlying social behavior in response to the counterpart through direct excitatory control of MPOA, VMH, and BNST.

Title: A circuit from the locus coeruleus to the anterior cingulate cortex displays sex-dependent activity in offspring-directed behavior

Authors: *A. CORONA, P. OSTEN, S. D. SHEA;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: How sexually divergent behaviors arise from sex differences in the underlying neural networks for social behavior remains elusive. Interestingly, mice display pronounced sex differences in offspring directed behaviors. Parental behaviors are fundamental for survival of offspring, and while the maternal brain has been studied extensively in rodents, the neural networks underlying paternal care are less well understood. In order to compare the networks that underlie parenting behavior in males and females, we used *c-fos* as a marker for neuronal activation after pup interactions, and an automated pipeline to map whole-brain activity at cellular resolution. We identified candidate brain regions that responded to pup-directed behaviors including the anterior cingulate area (ACA). We chose to focus on ACA because it has been implicated in sensitivity to social distress and it is interconnected with the noradrenergic locus coeruleus (LC), an important regulator of maternal behavior. We used fiber photometry to observe activity in ACA and LC during free interactions with pups. We found that excitatory neurons in the ACA are differentially activated in males and females during pup retrieval behavior and that inhibitory neurons show reciprocal activity patterns. We also observed that pup retrieval behavior evokes strong sex-

dependent neuronal responses in LC. Moreover, using neuroanatomical tracing, we confirmed that ACA receives robust inputs from LC, and using a noradrenaline sensor, we observe that pup retrieval behavior evokes noradrenaline release in ACA. Finally, we showed that chemogenetic inactivation of excitatory neurons in ACA disrupts pup retrieval behavior in early postnatal days and decreases motivation to interact with pups in distress. Based on these findings, we hypothesize that the ACA signals social distress from the pups and guides decision making in parenting behavior. Moreover, sexually divergent activation of this circuit may contribute to behavioral differences between males and females.

Title: The role of the amygdalohippocampal transition area in cognition and parenting

Authors: *V. M. SEDWICK[1], K. OLUYEMI[1], *M. DAYE[3], A. E. AUTRY[1,2];
[1]Dominick P. Purpura Dept. of Neurosci., [2]Dept. of Psychiatry and Behavioral Sci., Albert Einstein Col. of Med., Bronx, NY; [3]Mercy Col., Bronx, NY

Abstract: Postpartum depression has a prevalence of 15-20% in new mothers and 10% in new fathers. While the condition is predominantly characterized by impairments in parental care and mood, diagnosed individuals also display cognitive impairments and metabolic disruptions such as memory loss and weight gain. In many species, particularly mammals, parenting behavior is highly conserved. The full spectrum of parental expression can be seen in laboratory mice. We have identified a nucleus in the amygdala, the amygdalohippocampal transition area (AHi), to be a key brain area in the parental behavior circuit. Several groups have shown that activation of AHi subpopulations promotes infant-directed aggression in virgin males and fathers as well as intermale aggression. We believe that the AHi plays a role in both sociosexual behaviors as well as cognitive functions such as memory. To test this hypothesis, we lesioned the AHi using NMDA in males and female (n=5/group), and saline for the controls. Through lesion studies, we find that total loss of function of the AHi results in increased infant-directed aggression and social dominance in females suggesting that the nucleus can promote both negative and positive parental expression. Additionally, we observed sexually dimorphic metabolic disruptions such as increase weight gain in females, and hyperphagia in males compared to non-lesioned controls. We also aim to identify whether AHi related deficits in parenting are also correlated with memory impairments. The goal for this study is to improve our understanding of the AHi's role in sociosexual behaviors such as parenting. We believe this study may offer better insights to the amygdala's role in pathologies related to parental behavior such as postpartum depression.

Title: Observation of foster and biological mother offspring relationships and the development of orphaned Sumatran orangutans in captivity

Authors: A. KOCOSKI[1], E. E. ALPERS[1], V. S. QUINN[1], *C. M. RAGAN[2];
[1]Purdue Univ. Northwest, Hammond, IN; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Sumatran orangutans (*Pongo abelii*) are a critically endangered subspecies of Great Apes found in Sumatra, Indonesia. Due to deforestation perpetrated through multiple sources, the Sumatran orangutan population is projected to further decrease throughout the next decade. Deforestation displaces offspring from their mothers which is devastating due to their heavy reliance on their mothers to learn essential survival skills. While studies have gauged the extent of deforestation and its impact on species survival, little research or public awareness efforts have been undertaken that explore effective primate conservation programs that can immediately help affected species or alert the public of this dire situation. Our study attempts to fill this gap by examining video observations among foster and biological Sumatran orangutan mother-offspring interactions from existing online footage and video recordings we collected at Zoo Atlanta. These observations allow us to explore comparisons between foster and biological family group interactions while highlighting current conservation efforts. We hypothesized that successful foster mother-offspring relationships should imitate biological mother-offspring relationships as foster conservation programs intend to simulate biological mother-offspring bonds while providing offspring with the same nurturing opportunities throughout development. Although publicly-available foster pair video observations are limited, we have begun to accumulate live footage throughout our study. Subjects include Sumatran orangutans at Zoo Atlanta and fourteen biological mother-offspring pairs obtained from online video resources. Preliminary findings from previously-recorded videos suggest both biological and foster mother-offspring pairs engage in similar levels of trademark behaviors. Both mother groups engaged in similar levels of movement-oriented behaviors like climbing and traveling. In addition, offspring groups engaged in similar levels of carried behavior, where offspring cling to their mothers' fur, which is an indicator of healthy orangutan development. These data, alongside existing foster studies in other primates, suggest foster programs are a feasible form of primate conservation. Upon completion of coding behavior from orangutans at Zoo Atlanta, we will analyze foster and biological mother-offspring interactions, such as: being carried, traveling, climbing, etc. Our foster pair analyses compared with biological mother-offspring interactions allow us to understand the benefits primate foster programs provide.

Title: Inactivation of basolateral amygdala by hM4D(Gi) inhibits the expression of amphetamine-induced conditioned place preference

Authors: H. RIM[1], J. HAN[1], W. CAI[2], W. KIM[2], *J.-H. KIM[1];
[1]Dept. of Med. Sci., [2]Dept. of Physiol., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: The environment repeatedly paired with drugs of abuse can be preferably chosen by animals. Such phenomenon called conditioned place preference (CPP) basically consists of 2 phases; acquisition and expression. Although basolateral amygdala (BLA) has been shown to be important in emotional and reward processing, it is not clearly determined yet what role it has in each phase of CPP. In this study, we examined whether amphetamine (AMPH)-induced CPP is influenced by activation of designer receptors exclusively activated by designer drugs (DREADDs) in the BLA. Male Sprague-Dawley rats received AAV encoding an inhibitory hM4D(Gi) bilaterally into the BLA. In experiment 1, rats received systemic injections of deschloroclozapine (DCZ) (0.02 or 0.1mg/kg, IP), a selective muscarinic DREADD actuator, or saline 15 minutes before the start of each AMPH (2.5 mg/kg) conditioning (acquisition phase) and they were tested for conditioning with no drugs. In experiment 2, rats received repeated AMPH with no DCZ but they were tested for conditioning with injection of DCZ (0.02 or 0.1mg/kg, IP) (expression phase).

Interestingly, we found that chemo-genetic inactivation of BLA neurons inhibited the expression of AMPH-induced CPP, while it has no effect on the acquisition. These results indicate that activation of the BLA is critical for the expression of cue-induced drug-associated memory and implicate its role in reward-seeking behavior.

Title: Effects of methamphetamine on within and between network connectivity in healthy adults

Authors: M. MALINA[1], *S. KEEDY[1], J. WEAFER[2], K. VAN HEDGER[3], H. DEWIT[1];
[1]Univ. of Chicago, Chicago, IL; [2]Univ. of Kentucky, Lexington, KY; [3]Univ. of Western Onatario, London, ON, Canada

Abstract: Methamphetamine (MA) abuse remains an urgent public health problem. Understanding how the drug affects brain function will help to identify how it leads to abuse and dependence. Previous studies indicate that MA and other stimulants have complex effects on resting state functional connectivity. Here, we used a hypothesis-free approach to examine the acute effects of MA (20mg oral) vs placebo on neural connectivity in healthy adults aged 18 to 35 (n=22, 12 women). Using networks identified by an independent component analysis (ICA) using placebo data, we examined the effects of MA on within and between resting state networks, expanding the search for drug effects beyond conventional drug-reward circuitry. The placebo ICA scan yielded 28 networks, and MA reduced connectivity in 9 of these, including in the visual and sensorimotor cortex, and subcortical structures. MA had mixed effects on connectivity between networks. It increased connectivity between frontal, fronto-parietal and temporal networks, and between subcortical and cortical networks, but decreased connectivity across other networks, including basal ganglia and thalamus. MA produced its expected subjective effects, but these were not significantly related to connectivity. The findings extend our knowledge of how MA affects connectivity by delineating its effects both within and between networks. Future studies with other behavioral measures may reveal relationships between the neural and behavioral actions of the drug.

Title: The Role of Syntaxin 1 Phosphorylation in the Reverse Transport of Dopamine

Authors: *S. MABRY[1], A. SHEKAR[2], M. H. CHENG[3], D. ZANELLA[1], J. I. AGUILAR[2], S. M. PATEL[1], A. M. CARTER[1], I. BAHAR[3], H. MATTHIES[1], A. GALLI[1];
[1]Surgery, Univ. of Alabama Birmingham, Birmingham, AL; [2]Pharmacol., Vanderbilt Univ., Nashville, TN; [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The dopamine (DA) transporter (DAT) is an *SLC6* family presynaptic membrane protein that maintains DA homeostasis in the brain via active reuptake of DA. Although the conventional role of this transporter, DA reuptake, is well-characterized, less is known about its less prevalent and unconventional role, reverse transport of DA (DA efflux). In this study, we defined the context and mechanisms underlying DA efflux *via* the DAT and its regulation by the soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) protein syntaxin 1 (Stx1). We uncovered that N-terminal phosphorylation of DAT is required to promote both amphetamine (AMPH)-induced and constitutive DA efflux. We also determined that Stx1 interacts with the DAT N-terminus and this interaction enhances DA efflux. Furthermore, blocking of AMPH-induced Stx1 phosphorylation *via* pharmacological inhibition of casein kinase 2 (CK2) or by genetic manipulation prevents DA efflux. Insights from molecular dynamic simulations demonstrated that AMPH-induced phosphorylation of DAT and Stx1 leads to the breaking of multiple salt bridges in DAT, most notably between K66 and D345. The disruption of these salt bridges alters the dynamics of the intracellular gate in favor of an inward open conformation of DAT that binds DA on the intracellular face, a conformation we hypothesize promotes DA efflux. We translated these findings to *Drosophila melanogaster* where we found that AMPH-induced DA efflux and its behavioral consequences (increased locomotion, courtship behaviors, and preference) are inhibited by the pharmacological blockade of Stx1 phosphorylation. In conclusion, these studies have uncovered new mechanisms underlying DA efflux and identified key proteins in the reverse transport pathway. These proteins are potential therapeutic targets for patients that harbor DAT disease variants that exhibit constitutive DA efflux as well as patients that suffer from substance use disorders involving psychostimulant drugs like AMPH.

Title: Parkin Regulates Drug-Taking Behavior In Rat Model of Methamphetamine Use Disorder

Authors: A. SHARMA[1], B. L. SCHNEIDER[2], R. GARCIA-MILIAN[3], T. LAM[3], ***A. MOSZCZYNSKA**[1];
[1]Wayne State Univ., Detroit, MI; [2]Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland; [3]Yale Univ., New Haven, CT

Abstract: There is no FDA-approved medication for methamphetamine (METH) use disorder. New therapeutic approaches are needed, especially for people who use METH heavily and are at high risk for overdose. This study used genetically engineered rats to evaluate PARKIN as a potential target for METH use disorder. PARKIN knockout, PARKIN-overexpressing and wild type young adult male Long Evans rats were trained to self-administer high doses of METH using an extended-access METH self-administration paradigm. Reinforcing/rewarding properties of METH were assessed by quantifying drug-taking behavior and time spent in a METH-paired environment. PARKIN knockout rats self-administered more METH and spent more time in the METH-paired environment than wild type rats. Wild type rats overexpressing PARKIN self-administered less METH and spent less time in the METH-paired environment. PARKIN knockout rats overexpressing PARKIN self-administered less METH during the first half of drug self-administration days than PARKIN-deficient rats. Proteomic data suggests that different pathways mediate predisposition and resilience to METH addiction in these two genotypes. The results indicate that rats with PARKIN excess or PARKIN deficit are useful models for studying neural substrates underlying “resilience” or vulnerability to METH use disorder, and identify PARKIN as a novel potential drug target to treat heavy use of METH.

Title: Prenatal methamphetamine exposure affects gene expression and cognitive development in a mouse model

Authors: ***T. T. ADEYELU**[1], P. A. ADENIYI[2,1], A. SHRESTHA[2,1], C. C. LEE[1];
[1]Louisiana State Univ., Baton Rouge, LA; [2]Oregon Hlth. and State Univ., Portland Oregon, OR

Abstract: Methamphetamine is a highly addictive drug, an adrenergic agonist, that activates reward circuitry. Prenatal exposure to methamphetamine is implicated in cardiac defects, neurological disorders, and cognitive decline, but these have not been well characterized. In this study, we employed behavioral approaches, biochemical assays, as well as RNA-based differential gene expression analysis, to assess the impact of prenatal exposure to methamphetamine on cognitive development. RNA samples from mice prenatally exposed to methamphetamine and saline control were analyzed by Novogene lab in which RNA-FASTQ transcripts were mapped to the reference genes. The gene expression levels were measured and the differentially expressed genes were obtained by comparing between groups. Bioinformatic analysis using GO annotations, KEGG pathways, and protein interaction networks revealed differentially expressed genes such as ADCY1, Camk2α, and Akt3 that are implicated in methamphetamine neurotoxicity. Furthermore, the behavioral analysis revealed a statistically significant ($p<0.05$) decline in cognitive behaviors of the methamphetamine exposed animals compared to controls. These data reveal links between methamphetamine neurotoxicity and alteration of several genes which might be implicated in altering pathways that are also implicated in memory formation and reward-seeking behaviors.

Title: Evaluation of the chronic oral administration of clobenzorex or amphetamine on motor behaviors, the glia, and the dopaminergic system.

Authors: *A. PATRICIO-MARTÍNEZ[1,2], G. D. APÓSTOL DEL ROSAL[1], I. MARTÍNEZ[3], I. D. LIMÓN[1];
[1]Lab. de Neurofarmacología-FCQ-Benemérita Univ. Autónoma de Puebla, Puebla, Mexico; [2]Facultad de Ciencias Biológicas-Benemérita Univ. Autónoma de Puebla, Puebla, Mexico; [3]Lab. de Neuroquímica-FCQ-Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: Clobenzorex hydrochlorate, trade name Asenlix, is an N-substituted compound of S (+) - amphetamine. In Mexico, it is one of the five main anorectic drugs used to treat obesity. A controlled drug sold only by prescription, clobenzorex is available on the illicit market, where it is sold as a recreational drug. Some studies have shown that the consumption of clobenzorex produces hepatotoxicity and cardiovascular side effects such as heart failure, arterial hypertension, and pulmonary artery hypertension. However, its toxic effects on the central nervous system are unknown. Various studies have shown that amphetamines induce dopaminergic neurotoxicity and neuroinflammation in the striatum, symptoms which are associated with motor damage. For this reason, the aim of this study was to evaluate the effect of chronic clobenzorex administration on motor behaviors, TH immunoreactivity, gliosis, and the neurodegenerative process in the striatum and substantia nigra pars compacta (SNpc). The present

research was conducted on three experimental groups of male Wistar rats: the vehicle group; the amphetamine group (2 mg / kg); and, the clobenzorex group (30 mg / kg). All groups were subject to oral administration every 24 hours for 31 days. Motor activity and motor coordination were evaluated every 10 days in the open field test and the beam walking test, respectively. Thirty-two days post-administration the animals were euthanized to enable the extraction of their brains for the evaluation of tyrosine hydroxylase (TH) levels, the immunoreactivity of the glial cells (GFAP and Iba-1), and the neurodegeneration of both the striatum and SNpc. The results obtained show that amphetamine and clobenzorex administration decrease motor activity (distance traveled, average speed and number of rearings) and motor coordination (number of errors) in the beam walking test and cause increased gliosis in the striatum, while no significant changes were observed in terms of immunoreactivity to TH and neurodegeneration in both the striatum and SNpc. These results suggest that the chronic administration of clobenzorex may decrease motor function in a manner similar to amphetamine, via the neuroadaptive and non-neurotoxic changes caused to the striatum under this administration scheme.

Title: Reactive oxygen species modulate amphetamine induced effects

Authors: *C. BLANLOT, J. ZEGERS, J. NOVOA, F. CALDERON, H. YARUR, C. BASTIAS, K. GYSLING;
Dept. of Cell. and Mol. Biol., Pontificia Univ. Catolica De Chile, Santiago, Chile

Abstract: The increase of dopamine (DA) in the reward system is related to the reinforcing effects of drugs of abuse and hyper locomotion induced by psychostimulants. The increase of DA induced by drugs of abuse generates oxidative stress, a cellular condition produced by high amount of reactive oxygen species (ROS). Interestingly, it has been showed that ROS could modulate psychomotor response and reinforcing effects induced by drugs of abuse such as cocaine and methamphetamine (METH). Nevertheless, the relation of ROS and amphetamine (AMPH) has not been evaluated. Here, we show that administration of the ROS scavenger 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPOL) results in the attenuation of AMPH enhancement of locomotor activity in rats. Furthermore, TEMPOL also attenuates the oxidative stress and the increase of DA induced by AMPH in nucleus accumbens (Nac). Finally, TEMPOL reduce DAT phosphorylation when is co-infused with AMPH in Nac synaptosomes. Taking together, our results suggest that ROS modulate locomotor and reward effects induced by AMPH in rats. Funded by FONDECYT grant N° 1191274.

Title: Amphetamine induced toxicity in PC12 cells is due to the production of oxidative stress

Authors: *C. BASTIAS[1], J. A. ZEGERS[2], K. GYSLING[1];
[1]Dept. of Cell. and Mol. Biol., [2]Fac. of Biol. Sci. Dept of Cell. and Mol. Biol., Pontificia Univ. Catolica De Chile, Santiago, Chile

Abstract: Amphetamine has been reported to cause toxicity in PC12 cells but the mechanism by which it occurs is unknown. Treatment with 2.5 mM amphetamine reduces cell number up to 4 times while treatment with 3mM amphetamine entirely eliminates PC12 cells. We used the oxidative stress marker 8-hydroxy-2′-deoxyguanosine (8-OHdG) to further study the effects of incubation of PC12 cells with amphetamine. A significant increase in the fluorescence of 8-OhdG in the cells was observed when PC12 cells were incubated with 1.5 and 2.5mM amphetamine, in addition to a morphological loss of cells. We propose that the effect of amphetamine may be generated by changes in the dopamine transporter (DAT). Thus, we are analyzing the levels of DAT and P-DAT in PC12 extracts. We expect that the effect of amphetamine will be attenuated or rescued with the co-incubation of amphetamine with antioxidants such as alpha-lipoic acid and Tempol.Funded by FONDECYT grant N° 1191274

Title: Mechanistic Insight into Microbial Regulation of Psychostimulant Abuse

Authors: S. J. MABRY[1], X. CAO[3], S. M. PATEL[1], A. M. ELAM[2], Y. ZHU[1], D. P. SALEEBY[1,3], H. WU[3], *A. GALLI[1], **A. M. CARTER**[1];

Abstract: Amphetamines (AMPHs) are highly effective psychostimulants commonly used for the treatment of neuropsychiatric disorders and are abused with devastating outcomes. The abuse potential and psychomotor stimulant properties of AMPHs have been associated with their ability to increase extracellular dopamine (DA) levels. This increase is mediated, at least in part, by the reversal of DA transporter (DAT) function, which causes non-vesicular DA release, here defined as DA efflux. Recent studies suggest that imbalances in the gut microbiome (dysbiosis) participate in the pathogenesis of substance use disorders. Microbial products such as short-chain fatty acids (SCFAs), are suspected to play a fundamental role in this process. Among SCFAs, butyrate is known to cross the blood-brain barrier and directly act on neurons and glial cells. *Fusobacterium nucleatum* (*F. nucleatum*) is a bacterial species that secretes butyrate and whose abundance is increased by AMPH abuse in both rodents and humans. It is important to note that butyrate is a potent inhibitor of histone deacetylases (HDACs) and that inhibition of HDACs robustly increases expression of both DAT mRNA and protein levels in cultured cells. Changes in DAT expression regulates both AMPH-induced DA efflux and psychomotor actions. Here, we report that colonization of the intestinal tract of gnotobiotic *Drosophila* with *F. nucleatum* significantly enhances AMPH-induced DA efflux and associated behaviors such as locomotion, courting, and preference. This potentiation of AMPH actions by *F. nucleatum* was paralleled by oral administration of butyrate. In contrast, acetate, another SCFA secreted by *F. nucleatum*, failed to enhance both AMPH-induced DA efflux and locomotion. Further, inhibition of HDACs using Trichostatin A, as well as genetic knockdown of HDAC1 in DA neurons *via* RNAi, both increased AMPH-induced DA efflux and locomotion. Importantly, both pharmacological inhibition, as well as genetic knockdown of HDAC1, also lead to a significant increase in DAT expression. These data demonstrate that *F. nucleatum* modulates AMPH-induced behaviors through secretion of butyrate, inhibition of HDACs, elevation of DAT expression, and increased DA efflux. These findings suggest modulation of the gut microbiome as a therapeutic approach for the treatment of substance use disorders.

Title: Sigma-1 ligands modulate methamphetamine sensitization and reward circuitry

Authors: *A. R. ALLEYNE[1], L. L. WILSON[1], S. W. HARDEN[1], C. R. MCCURDY[2], C. J. FRAZIER[1], J. P. MCLAUGHLIN[1];
[1]Pharmacodynamics, [2]Medicinal Chem., Univ. of Florida, Gainesville, FL

Abstract: Sigma-1 receptors (σ1Rs) are ubiquitously expressed chaperone proteins implicated in neuroplasticity, neuroprotection, and cardiovascular function. While basally located within the mitochondria-associated membrane, cellular stress promotes σ1R translocation to the plasma membrane where they modulate the function of other receptors and ion channels to alter cellular physiology. Evaluating this state-dependent localization of σ1R activation has proven challenging. As σ1R antagonism within pain and reward circuitry has demonstrated therapeutic relevance in both preclinical and clinical studies, a better understanding of mechanisms regulating σ1R translocation and interaction with other proteins is needed. Using both *in vivo* and *ex vivo* techniques, we examined the role of σ1Rs in methamphetamine (METH)-induced locomotor sensitization, hypothesizing that σ1Rs modulate sensitization by promoting excitation in reward/locomotor circuitry which is attenuated with σ1R antagonism. Using mice treated twice daily for 7d with saline (0.9%, i.p.), METH (2 mg/kg, i.p.), the σ1R antagonist, CM304 (30 mg/kg, i.p.), or both METH & CM304, we recorded locomotor behavior resulting from a 1 mg/kg, i.p. treatment of METH. Following a 1 week washout without treatment, mice that had been treated with both METH & CM304 demonstrated a significant reduction in METH-induced hyperlocomotion compared to METH-treated positive controls, suggesting σ1R antagonism may prevent psychostimulant sensitization. To characterize potential cellular mechanisms driving this behavior, we used electrophysiological tools to evaluate the effect of σ1R ligands on medium spiny neurons (MSNs) within the nucleus accumbens (NAc), a key region within the reward pathway. We found that while acute application (10 min) of the σ1R agonist SA4503 (cutamesine; 10 μM) excites NAc MSNs, prolonged exposure (30-90 min) significantly reduces their ability to fire action potentials continuously during a maintained depolarization, interestingly without altering instantaneous firing frequency. In contrast, prolonged exposure to the σ1R antagonist S1RA increased the ability of MSNs to fire continuously in response to moderate current injections, also without altering instantaneous firing frequency. Together these findings suggest that σ1Rs may modulate the psychostimulant effects of drugs of abuse such as METH by altering neuronal excitability in reward circuitry sensitive to σ1R antagonist treatment, providing a novel target for the treatment of substance abuse disorder.

Title: Neural substrates of sex-specific modulation of motivation by value

Authors: *J. COX, W. T. FLEMING, C. HAYES, S. ORNELAS, A. BANDI, C. A. ZIMMERMAN, N. F. PARKER, I. B. WITTEN;
Princeton Univ., Princeton, NJ

Abstract: While there is emerging evidence of sex differences in decision-making behavior, the neural substrates that underlie such differences are largely unknown. To examine the neural basis of sex differences in value-based decision making, we trained mice to perform a self-initiated, probabilistic reversal learning task in which they regulated both their trial-by-trial choices as well as their motivation to engage in the task, based on recent experiences. We found that while choices were similar between the sexes, motivation to engage in the task was modulated by chosen value in females more strongly than in males. Both the prefrontal cortex (PFC) and the dorsomedial striatum (DMS) are thought to be important for making value-based choices and regulating motivation. Therefore, we performed single-photon calcium imaging and optogenetic inhibition of neurons in the anterior cingulate cortex that project to the DMS (ACC-DMS neurons) to determine whether there were sex differences in the representation of task-specific information in these neurons. Consistent with the behavioral differences, in females, ACC-DMS neurons had stronger representations of negative outcomes, and more neurons were active when the value of the chosen option was low, compared to males. In contrast to these differences in the representation of outcomes and the value of the chosen option, the representation of each choice was similar between the sexes. Finally, optogenetic inhibition of activity in ACC-DMS neurons disrupted the relationship between chosen value and motivation specifically in females, without affecting motivation in males. Additionally, this inhibition did not affect choice in either sex. Thus, we show that the projection from ACC to DMS has a sex-specific role in the modulation of motivation by value.

Title: Gabaergic interneurons driven by dorsal raphe-projecting pyramidal neurons of medial prefrontal cortex regulate feeding of adolescent female mice undergoing activity-based anorexia

Authors: *M. DU[1,2], A. N. SANTIAGO[2], C. J. AOKI[2];
[1]New York Univ. Shanghai, Shanghai, China; [2]New York Univ., New York, NY

Abstract: Anorexia Nervosa (AN) is a mental illness, characterized by voluntary food restriction and excessive exercise and with a mortality rate that surpasses that of major depression. An animal model, activity-based anorexia (ABA), captures the characteristics of AN and has been used to understand the neurobiological mechanisms underlying individual differences in vulnerability to AN. Previous studies have uncovered the role of dorsal raphe (DR) in regulating feeding behaviors of mice. Interestingly, DR does not receive any direct input from the primary sensory or motor cortices but does receive substantial input from layer 5 pyramidal cells of the medial prefrontal cortex (mPFC), suggestive of higher-order cognitive control. In this study, we used Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to activate layer 5 pyramidal cells of mPFC projecting to DR (mPFC-DR) to explore the role of mPFC in an animal's decision to eat within the context of ABA. Contrary to expectations, although intraperitoneal Compound 21 (C21) could activate ~44% of the mPFC-DR cells, this did not reveal significant group mean difference in the amount of food intake of ABA mice undergoing food restriction (N=7, female), compared to the control ABA mice without mPFC-DR cell activation (N=11, female). However, further analysis through triple immunofluorescence (IF) of individual animals' responses to C21 during ABA revealed a significant and positive correlation between DREADD-expressing cells that co-express the immediate early gene, cFos, and the food intake ($r=0.78$, $p=0.0384$). Furthermore, triple IF used to label mCherry (for mPFC-DR pyramidal neurons), GABA cells and cFos within mPFC revealed that ~8.6% of GABA cells also expressed cFos, a level that was significantly greater than that in the control group ($p=0.043$), suggesting that mPFC-DR pyramidal cells recruit GABA cells. Besides, electron microscopic immunohistochemistry showed that GABAergic innervation is 60% stronger for the mPFC-DR cells than that of the non-DR-projecting pyramidal cells in layer 5 ($p=0.0312$) and correlates negatively with the food intake specifically on the day of C21 administration ($r=-0.9181$, $p=0.0035$). Thus, C21 is likely to have resulted in minimal change of food intake due to activation of two antagonistic pathways in the mPFC: (1) mPFC-DR pyramidal cells that promote food intake, and (2) GABA cells in mPFC that dampen food intake through feed-forward inhibition of mPFC-DR pyramidal cells. These results indicate that GABA cells driven by mPFC-DR cells may participate in regulating feeding of adolescent female mice undergoing ABA, and may be a potential target for treating AN.

Title: To eat or to run. A chemogenetic investigation of the role of PV/GABA cells in the prefrontal cortex of food restriction-stressed adolescent mice in an animal model for anorexia nervosa

Authors: *C. AKIZ[1], A. N. SANTIAGO[2], C. J. AOKI[3];
[1]New York Univ. Ctr. For Neural Sci., New York, NY; [3]Ctr. Neural Sci., [2]New York Univ., New York, NY

Abstract: Anorexia Nervosa (AN) is a mental illness characterized by severe self-imposed starvation and intense anxiety manifested as fear of gaining weight. With no accepted pharmacological treatments available and high mortality and relapse rates, better understanding of the neurobiological basis of AN is needed. Activity-based anorexia (ABA) is an animal model of AN that captures the core features of AN: voluntary food restriction (FR), excessive exercise heightened anxiety. The FR-evoked excessive running can become lethal if energy expenditure exceeds caloric availability. Chemogenetic modulation of the medial prefrontal cortex (mPFC) pyramidal cells can bi-directionally alter running during hours preceding limited food availability, but not during days with ad libitum food access in the ABA model (Santiago, Makowicz et al., 2020). The same study yielded a new hypothesis - that axo-somatic inhibition by parvalbumin-containing GABAergic interneurons (PV) of the mPFC is the site of plasticity, yielding individual differences in resilience to FR-evoked stress, such as ABA. We tested this hypothesis by chemogenetically modulating PV cells in the mPFC during the FR phase of ABA using excitatory and inhibitory DREADDs transfected by the cre-dependent AAV in PV-Cre knockin mice. The active cells in the mPFC were identified by cFos immunoreactivity (ir). cFos+/GAD+ ir was identified as activated GABA cells while cFos+/GAD- was identified as activated pyramidal cells. mCherry ir identified PV cells expressing Gq-DREADDs and driven by Compound 21 (C21). We report on three results supporting the hypothesis: (1) The calories an animal consumed on the FR days that PV cells were chemogenetically modulated correlated negatively with the percent of all cells encountered (immunolabeled for GAD and/or cFos and/or mCherry) that were activated GABA cells (r=-0.8; p=0.055, N=6, FR4) and were positively identified to be PV cells (r=-0.95, p=0.012, N=5, FR2) This result supports the idea that PV/GABAergic suppression of the excitatory outflow from mPFC suppresses food consumption. (2) The percentage of activated GABA cells and calories the animal consumed on FR4, relative to their average food consumption prior to FR correlated positively (r=0.94; p=0.04, N=6) as did the cells positively identified to be PV (r=0.98 , p=0.004, N=5, FR4). The reversal in the correlation direction is explained largely by (3) the positive correlation between the GABA cell firing and food consumption prior to FR (r=0.83; p=0.04, N=6). These results suggest that individual differences in ABA resilience is strongly dictated by the GABAergic inhibitory tone in mPFC that precedes the onset of FR stress.

Title: A hierarchy of distributed representations in the anterior cingulate cortex

Authors: *T. R. COLIN, I. IKINK, C. B. HOLROYD;
Ghent university, Ghent, Belgium

Abstract: The function of the anterior cingulate cortex (ACC) remains mysterious. Univariate functional magnetic resonance imaging (fMRI) analyses fail to discriminate between dominant theories, which predict similar univariate responses: the ACC is sensitive to errors, conflict, difficulty, rewards and punishments, and shows activation during many sequential decision-making tasks. We used multivariate fMRI and computational modeling to investigate the hypothesis that ACC implements distributed representations of hierarchically-organized task sequences. First, we developed a family of artificial recurrent neural network (RNN) models of the ACC and trained those models on a hierarchical sequence task (i.e., making coffee or tea according to a pre-specified set of rules). Second, we conducted a representational similarity analysis using a searchlight procedure to compare the activity patterns of these RNN models to multivoxel patterns of fMRI activity of participants performing the same task. Comparisons were obtained using three successively more complex models: (1) an Elman RNN (2) an Elman RNN with "goal" units and (3) a goal model that incorporated an "abstraction gradient" in the hidden layer of the network. We find that all three models produce representations that match caudal areas of the ACC, but models (2) and (3) also match more rostral areas, confirming the hypothesis. Finally, we evaluate the goal model behaviourally by scaling up the task and stressing the model; consistent with previous observations, we find that the model degrades in a manner that resembles a distracted human's action slips.

Title: Temporal neural ensemble decoding of approach-avoidance behavior in prelimbic and infralimbic cortex in rats

Authors: J. JEONG, *J.-S. CHOI;
Sch. of Psychology, Korea Univ., Seoul, Korea, Republic of

Abstract: The medial prefrontal cortex (mPFC) has been implicated in various cognitive processes including threat evaluation and defensive behaviors in both humans and animals. In the current study, food-deprived rats, approaching for sucrose solution, were faced with a robot predator. The robot was programmed to evoke a fast attack motion 3- or 6-s after the first lick which produces an immediate withdrawal response in rats. The rats have to decide when to stop consuming sucrose solution to avoid the attack. Several responses were identified: head entry to the lick port (ENT), avoidance before the attack

(AVO), and escape after the attack (ESC). In-vivo ensemble recordings using tetrodes revealed different encoding patterns in the prelimbic (PL) and infralimbic cortex (IL). Specifically, machine learning analysis using a support vector machine (SVM) showed that ensemble activity in PL was strongly correlated with ENT but could not distinguish between AVO and ESC. In contrast, an SVM trained from IL ensemble activity was able to discriminate all three responses. Furthermore, we performed classification accuracy analysis along the time axis to determine the critical time window for predicting the impending behavior. The IL ensemble data 3~5 seconds before the event were sufficient to reach accuracy asymptote, but PL showed linearly increasing performance peaked at the onset of the behavior. Taken together, these results suggest that two sub-regions in the mPFC encode distinctive aspects of approach-avoidance behavior, notably, IL may contribute to threat evaluation before the execution of the behavior in the conflict situation.

Title: A role for prefrontal cortex dopamine in regulating cognitive control

Authors: *Y. YANG, H. J. RICE, M. A. TRONOLONE, H. CHANG, I. T. ELLWOOD;
Cornell Univ., Ithaca, NY

Abstract: A critical role of the prefrontal cortex (PFC) in behavior is to allow for the context-dependent selection of appropriate actions, while inhibiting unwanted behaviors. The dopamine system in the PFC is believed to regulate this process by increasing or decreasing cognitive flexibility. Despite this, recent recordings of PFC dopamine in rodents have found release primarily following aversive stimuli. Using fluorescent dopamine sensors, we recorded dopamine concentrations in the PFC while mice performed two reward-seeking tasks that required behavioral inhibition. In our first task, mice had to cross over a metal grating where they had previously received a shock to obtain a reward. We found that dopamine levels increased prior to them crossing and decreased as they crossed. In our second task, mice had to decide whether to stay at a reward port for a chance at a reward or leave and reset the trial and we found that PFC dopamine increased when mice decided to leave. Together, our findings suggest that higher levels of PFC dopamine correlate with increased cognitive control, suppressing either aversive associations or reward associations that are not currently valid.

Title: Ramping activity in the medial prefrontal cortex integrates time and rewards in opposing directions during patch foraging

Authors: *M. BUKWICH[1], M. G. CAMPBELL[1], J. I. STERN[1], M. TOMOV[1], H. R. KIM[1,2], J. DRUGOWITSCH[3], N. UCHIDA[1];
[1]Harvard Univ., Cambridge, MA; [2]Sunkyunkwan Univ., Suwon, Korea, Republic of; [3]Harvard Med. Sch., Boston, MA

Abstract: As animals forage for food and water, a key decision they need to make is when to abandon a depleting resource to search elsewhere in the environment. The Marginal Value Theorem (MVT) provides a normative framework for this behavior: Animals should leave a depleting 'patch' of resources once the instantaneous reward rate in the patch drops below the average value of the environment. Computing the exact patch leaving time in this manner requires comprehensive knowledge of one's environment — knowledge that animals do not have under naturalistic conditions. Despite this epistemic limitation, many species appear to well-approximate the MVT. How they do, however, remains largely unknown. To address this question, we designed a patch foraging task wherein head-fixed mice run along a 1-dimensional virtual track in search of patches containing water rewards. To mimic naturalistic conditions, rewards were delivered with varying probabilities, with probability decaying over time within patches to simulate a depleting resource. We confirmed a key prediction of the theory: Mice had greater patch residence times when rewards were larger or more frequent ($p<0.0001$ for both reward size and frequency, generalized linear mixed effects model, n = 18 mice). To investigate the neural basis of patch leave decisions, we recorded activity of neurons in the medial prefrontal cortex (mPFC) using high-density probes (Neuropixels) during the foraging task (3,683 neurons, 5 mice). We observed task-relevant dynamics throughout mPFC, most prominently in a neural population whose activity, in the absence of reward, ramped up over time as a patch leave decision became more imminent. When rewards were delivered, this same ramping population's activity dipped, suggesting an evidence accumulation process that approximates the normative strategy by integrating time and rewards in opposing directions relative to a leave decision. To quantify coding properties of the recorded neurons, we fit a generalized linear model (GLM) of spiking activity as a function of task-relevant variables carrying information about rewards and time, as well as motor activity such as running and licking. Of the 1,664 neurons that met a minimum firing rate criterion for inclusion in the GLM analysis, ~50% carried information about key foraging variables. Of these, ~40% were identified as ramping units based on unsupervised clustering using a Gaussian mixture model. Taken together, our results suggest an evidence accumulation process occurs during foraging decisions, and that it is widely represented as ramping activity throughout mPFC.

Title: Change and maintenance of neural representations across different behavioral context in primate medial frontal cortex

Authors: *M. AWAN[1], H. MUSHIAKE[1], Y. MATSUZAKA[2];
[1]Sch. of Med., Tohoku Univ., Sendai, Japan; [2]Neurosci., Tohoku Med. and Pharmaceut. Univ., Sendai, Japan

Abstract: Flexible, context dependent behavior necessitates the selection of diverse protocols to convert sensory information into valid action (i.e. behavioral tactics).The central nervous system of higher mammals can perform diverse cognitive tasks but little is known about how such flexible switching of function is implemented at cellular level. Specifically, does a neuron encoding a particular aspect of behavior (e.g. action) preserve that representation across different tasks, or that neural representation of behavioral factors changes dynamically under different behavioral context? To answer this question we designed a behavioral task that required monkeys to remember the tactics cues (pro-reach or anti-reach) and the position cue(left or right) separately by presenting first tactics and then position cues (tactics-precued) and vice versa(position-precued). Then monkeys were required to integrate two pieces of information to determine appropriate action. Under the first condition (tactics-precued), a trial started as the monkeys pressed the home button attached to a primate chair. Then a color cue briefly appeared (0.5s) to instruct the tactics (cyan/green color instructed pro- and blue/red for anti-reach) but not action, then disappeared. After a variable length of delay period, a position cue (illuminated either the left or the right button) prompted the monkeys to perform an action to reach either left or right button based on tactics. Under the second condition (position-precued), the order of presentation of tactics cue and position cue was reversed. While the monkeys were performing this task, neuronal activity was recorded from the posterior medial prefrontal cortex (pmPFC), the presupplementary motor area (preSMA) and the supplementary motor area (SMA) and their relation to the cued tactics, cue position and the monkeys' action was done by epoch-based analysis.
We found that tactics, cue position, and action were represented in medial frontal areas. We compared neuronal activities under the tactics- and position-precued condition. Our results indicate that the three cortical areas play distinct roles in representing and integrating position and tactics information into action under two behavioral paradigms.

Adaptive decision making in dynamic environments requires the activation of multiple neural circuits including prefrontal networks that have not been extensively investigated. Our previous work has demonstrated that orbitofrontal-subcortical circuits control distinct reinforcement-learning computations, including updating of action values for positive and negative outcomes and maintaining value representations of unchosen options. The circuit responsible for maintaining value representations of the chosen option, however, is not known. Value representations may be stored in regions that are known to be involved in working memory, such as the medial prefrontal cortex (mPFC). We hypothesized that mPFC projections to the orbitofrontal cortex (OFC), but not OFC projections to the mPFC, would control the degree to which action values for chosen options would be maintained across subsequent trials. To test this, we trained and tested adult, male Long Evans rats (N=40) in a three-choice, probabilistic reversal-learning (PRL) task. Using a dual viral approach, we selectively expressed diphtheria toxin receptors in either mPFC projections to the OFC (N=20) or OFC projections to the mPFC (N=20). Rats were retrained on the PRL task and then received either saline (control; N=20) or diphtheria toxin (DT; N=20) to ablate individual circuits in a directionally selective manner. 72 h after the injections, the performance of rats on the PRL task was reassessed. Trial-by-trial choice data collected before and after saline/DT injections was fit with a differential forgetting reinforcement-learning algorithm and examined between circuit (mPFC◊OFC vs. OFC◊mPFC) and injection (saline vs. DT) groups. We found evidence suggesting dissociable roles of mPFC-OFC circuits in value representations that are consistent with our initial hypothesis and suggest a key role of working memory circuits in reinforcement learning. Our ongoing work is combining this circuit based viral approach with intravenous drug self-administration to determine how these reinforcement-learning circuits may be involved in addiction pathophysiology.

Title: The influence of cognitive fatigue on physical effort-based decision-making

Authors: *M. H. DRYZER, V. S. CHIB;
Biomed. Engin., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Fatigue is a lack of energy or motivation that can be caused by both physically and cognitively demanding tasks. It is often perceived that fatigue in one effort domain (e.g., cognition) can impact judgements of effort in another domain (e.g., physical). Despite these ubiquitous feelings of cross-talk between domains of fatigue, little is known about how fatigue in one domain influences decisions in another domain. In this experiment, we characterized individuals' subjective preferences for physical effort and examined how these preferences, and associated brain activity, changed when they were in a state of cognitive fatigue. To accomplish this, we scanned subjects with functional magnetic resonance imaging while they made decisions about exertion of physical effort (i.e., grip exertion), before and after they performed bouts of cognitively fatiguing exertion (i.e., working memory). Participants first learned an association between physical force produced and a numerical scale ranging from zero to one hundred relative to participants' maximum physical exertion. They then performed a series of risky binary gambles involving varying levels of physical exertion. During each choice, participants made a decision to risk equal probability of high physical exertion or rest, or forgo any risk and select a guaranteed lower level of exertion. After participants performed a baseline session of choices for physical effort, they performed a series of cognitively fatiguing n-back working memory trials. Following these cognitive fatigue bouts, they repeated the same physical exertion choices as in the baseline state. In a baseline state, we found that the majority of participants exhibited convex subjective effort value functions, indicating that the marginal subjective values of physical effort increased as more effort was required. When participants were in a cognitively fatigued state, the marginal subjective value of physical effort became more pronounced as indicated by an increased convexity in the subjective effort value function. Subsequent analyses of the neuroimaging data will examine brain regions with activity associated with participants' subjective preferences for physical effort, and shifts in physical effort value as a result of cognitive fatigue.

Title: The neural representation of people and relationships in social network

Authors: *D. KWON[1,3], W. SHIM[1,3,2];
[1]Biomed. Engin., [2]Intelligent Precision Healthcare Convergence, Sungkyunkwan Univ., Suwon, Kyunggi-Do, Korea, Republic of; [3]Ctr. for Neurosci. Imaging Res., Inst. of Basic Sci., Suwon, Kyunggi-Do, Korea, Republic of

Abstract: Understanding the personal characteristics of individuals and their social relationships plays a crucial role in navigating the social world, such as knowing with whom to form a social group and how to interact with each individual. Previous studies have shown that the ventromedial prefrontal cortex (vmPFC) and hippocampus represent a cognitive map that contains relational information about non-spatial and even social knowledge, such as representations of social agents (Park et al., 2020). However, it remains unclear how social relationship structures that reflect a multidimensional bidirectional distance metric for individual relationships are represented. In this study, we investigated how neural representations of a small-sized social network that consists of node and edge information, which corresponds to each individual and their relationships respectively, are constructed using behavioral and fMRI data. During fMRI scanning, subjects watched a Web drama with rich and dynamically varying social interactions and rated the traits of each of six fictional characters (node) and pairwise directional social relationships between characters (edge) in multiple dimensions. From each subject's ratings, we constructed a behavioral representational dissimilarity matrix (RDM) for individual characters and a distance matrix (DM) for their pairwise relationships and calculated a rank correlation between behavioral RDMs and neural RDMs in 50 brain regions based on Neurosynth whole-brain parcellation. A neural RDM in vmPFC and hippocampus showed significant correlations with subjects' behavioral ratings for each character and the perceived distance of social relations among characters. These results suggest that the structured knowledge of a social network, which comprises multifaceted information on individuals and their directional relationships, is represented in the hippocampus and vmPFC.

Title: Elasticity in the brain: dynamic reconfigurations underlying cognition, vulnerabilities, and resilience

Authors: *J. O. GARCIA[1], I. L. D. PINTO[2], K. BANSAL[3];
[1]Human Res. and Engin. Directorate, US DEVCOM Army Res. Lab., San Francisco, CA; [2]Human Res. and Engin. Directorate, US DEVCOM Army Res. Lab., SAN FRANCISCO, CA; [3]Biomed. Engin., Columbia Univ., New York, NY

Abstract: The human brain is a complex dynamical network composed of a collection of heterogeneous modules that adaptively reorganize, much like an elastic system, for seamless interactions within a complex and dynamically changing environment. This particular architecture makes the brain sensitive to a wide range of stimuli and efficiently respond to situations with different cognitive demands. Advancements in network neuroscience approaches equipped us with ways to quantify the elasticity of the brain by computing how 'flexibly' the network modules of the brain reconfigure and have shown its importance in many cognitive phenomena, including learning and memory. Four of our recent and independent studies provide support for the hypothesis that the flexibility in the brain provides a necessary mechanism for behavioral resilience. First, we found that the flexibility of a group of brain regions increased following low sleep episodes during working memory task performance. Second, we found that the higher flexibility of the nodes within the frontal cortex relate negatively with the likelihood of opinion change (on various social issues, quantified through questionnaires before and after the interaction with a simulated social media platform with real and fake news). Third, we find significant differences in the flexibility of the awakening brain as compared to the fully awake brain during a psychomotor vigilance task. Typically, the brain experiences a decrease in cognitive performance during waking up from sleep, so-called sleep inertia. Across these studies, involving different cognitive experiments, flexibility of brain regions seems to be playing an important role in maintaining/ achieving optimal performance. Finally, with transcranial magnetic stimulation, we have shown that this flexibility may be triggered by non-invasive magnetic stimulation, further suggesting that elastic features may be not only cognitively relevant, but may be initiated to adapt and respond to in a rapidly changing environment, and perhaps even harnessed in future efforts in human-technology hybrid systems.

Title: Learning What Others Think of Us: Encoding and Consolidation of Social Feedback During Rest

Authors: *S. BRIETZKE[1], K. BARBAROSSA[2], *M. MEYER[3];
[1]Psychological and Brain Sci., [2]Dartmouth Col., Hanover, NH; [3]Psychological and Brain Sci., Dartmouth Col., Hartford, VT

Abstract: Learning what other people think about us is critical for social function, yet we know relatively little about how we encode and remember what people think about us. To help close this gap, we assessed two possibilities that come from the learning and memory literature: 1) that we consolidate what other

people think of us during rest periods that follow the feedback ('post-feedback rest') and 2) that the extent to which feedback violates our self-concept will impact memory. We ran an fMRI study (n=42) in which participants received feedback about which characters from the TV sitcom The Office they reminded a set of raters based on a video and photograph participants submitted prior to their scan session. Further, subjects viewed another person receiving feedback from other people. Interleaved between conditions were resting state scans to assess whether feedback is consolidated during post-feedback rest. Following the scan, subjects completed a surprise memory test. We found no difference in memory retention between self and other for consistent feedback. However, we found that for inconsistent feedback, memory for others' feedback degrades while the memory performance for self inconsistent feedback is preserved. We found that the interaction between consistency and target yielded significant activity in DMPFC and vMPFC. Larger degrees of discrepancy in self-inconsistent feedback were associated with greater activity in DMPFC, whereas larger degrees of discrepancy in self-consistent feedback were associated with greater activity in MPFC. Further, we will analyze resting state functional connectivity (rsFC) of default mode network (DMN) during rest. We predict there will be greater rsFC in core sub-system of DMN following feedback for the self and greater rsFC in the dorsomedial sub-system of DMN following feedback for the other. We hypothesize that greater DMN connectivity during post-feedback rest will correlate with better memory performance.

Title: Cortical network properties of social personality traits and their disorder

Authors: *Y. KFIR, M. MUSTROPH, P. R. NG, M. JAMALI, Z. WILLIAMS;
Massachusetts Gen. Hospital, Harvard Med. Sc, Boston, MA

Abstract: Humans display an astonishingly wide array of social personality traits that powerfully influence our interactions with others. The cortical network properties that precisely underlie these traits or that underpin their dysfunction in conditions such as Autism spectrum disorder (ASD), however, remain largely unknown. Current research in humans is based mainly on non-invasive methods which have limited spatial and\or temporal resolution. Here, using a rare opportunity to perform intracranial recordings in large cohorts of participants and by employing a comprehensive battery of tests, we identify multidimensional social traits unique to each individual, their interrelation with other cognitive abilities, and overlap with ASD related psychopathology. By further examining local- and network-activities across individuals, we describe preliminary patterns that underlie specific traits. We also identify patterns that appear to be uniquely related to ASD. Together, these findings set the groundwork for building a

more comprehensive network-based understanding of social behavior and its disruption through disorders such as ASD.

Abstract: Teaching is a profession associated with high stress and burnout. The perceived effort due to cognitive and emotional workload reduces teachers well-being perception and increases disease prevalence. Teacher self-reported distress and burnout also affect students well-being, impacting on education. Uruguayan female pre-primary and primary public-school teachers exhibit the highest levels of stress and burnout in Latin America. Positive school environments and teacher well-being depend on their emotional regulation and stress-coping strategies, and the implementation of well-being-focused training programs as meditation in the education field is growing worldwide. Teachers training in Mindfulness or Self-Compassion skills reduce self-reported stress and improve social and emotional indexes, but the conjunction of both methodologies has not been assessed. We studied the effects of virtual training in Mindful Self-Compassion (MSC) on psychological and neurobiological signs of stress, empathy and emotional regulation in a sample of Uruguayan primary-school teachers. We used a quasi-experimental longitudinal pre-test post-test with an active control group (Kundalini yoga) experimental design. Teachers filled online questionnaires before and after MSC or Yoga training, to assess their global and work-related stress, empathy and emotion regulation. Teachers neural response to others perceived pain

was studied by EEC and ECG recordings during the visualization of a series of digital colour pictures showing right hands or feet of people in painful and non-painful situations involving nociceptive stimuli. ECG data are being analyzed in time and frequency domains to study several parameters of heart rate variability (HRV). EEG data are being analyzed in the frequency domain as well as the heart evoked potentials. Parametric and non-parametric statistical analysis of the psychological tests revealed a significant increase in the levels of mindfulness, self-kindness, common humanity, self-judgment, perspective taking and overall well-being, and a decrease in levels of personal distress, emotional exhaustion, global stress and emotional suppression in the MSC group. In the Yoga group, levels of mindfulness, self-kindness, self-judgment, over-identification and overall well-being significantly increased, and only the levels of global stress significantly decreased. Non-parametric statistical analysis of HRV evidenced a significant difference between MSC and Yoga in the change between post- and pre-training of the difference between pain and no pain situations, indicating greater parasympathetic tone after MSC than Yoga training.

Title: Neural systems for gaze-cueing are modulated by visual dwell time

Authors: *T. PARKER[1], X. ZHANG[2], J. A. NOAH[2], M. KELLEY[1], J. HIRSCH[2,3,4,5,6];
[1]Interdepartmental Neurosci. Program, [2]Psychiatry, [3]Neurosci., [4]Comparative Med., Yale Sch. of Med., New Haven, CT; [5]Med. Physics and Biomed. Engin., Univ. Col. London, London, United Kingdom; [6]Haskins Labs., New Haven, CT

Abstract: Eye gaze plays a salient role in social interactions by providing cues that assist in directing attention to another person or object. However, the underlying mechanisms for the relationship between visual sensing and face processing are not known. We compare a social robot with a simplified humanoid face and eye features, Maki[1], with a human partner to test the hypothesis that face processing mechanisms for real faces are modulated by visual sensing using functional near-infrared spectroscopy (fNIRS) and eye-tracking. Participants engaged in a gaze cueing task in which an initiator (robot or human) used eye gaze to direct the participant's eyes to one of two circular targets on a glass partition. During the gaze

cueing task, the initiator looked at the participant's eyes for 2-seconds and then averted gaze to a dot (left or right) for 2-seconds. The paradigm consisted of 3 gaze cueing events, followed by 15-seconds of rest, for a total of 3 minutes per run (two runs per condition). Eye following accuracy was 100% in both robot and human gaze cueing conditions. Visual dwell time during the first 2-seconds of the gaze cueing event decreased during human face viewing relative to robot face viewing [$t = 7.46$, $p < 0.0005$] for 21 neurotypical adult participants. To test whether dwell time modulated social processing of real faces, dwell time was used as a regressor for neural activity during face viewing and gaze cueing. The human gaze cueing condition showed greater activity in right supramarginal gyrus (56, -60, 42), right primary somatosensory cortex (20, -48, 74), right pre-motor and supplementary motor cortex, and right dorsolateral prefrontal cortex (46, 46, 14) than the robot gaze cueing. Additionally, activity in the visual cortices increased during the human gaze cueing condition relative to the robot gaze cueing condition. Regression with individual dwell time showed enhancement in the right inferior parietal lobule and dorsal lateral prefrontal cortex. These results are consistent with the hypothesis that visual sensing mechanisms as represented by dwell time play an important behavioral role in live face processing and visual attention.

Title: Real-time human-human and human-agent chitchats: An fMRI study

Authors: *J.-T. CHENG[1,2], T.-R. HUANG[1,2];
[1]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan; [2]MOST AI Biomed. Res. Ctr., Tainan, Taiwan

Abstract: Recent advancements in artificial intelligence have led to a variety of impressive results and applications, such as human-like chatbots for companion or therapy purposes. While all of the deep-learning-based chatbots have been computationally evaluated and optimized during development based on some performance metrics, only some chatbots have been thoroughly tested with humans. The human-centered approach evaluates the quality of a chatbot by assessing the feelings of its users about the chatbot. Because of the loud scanning noises during scans of functional magnetic resonance imaging (fMRI), past fMRI studies on human-agent interaction often used simple games as their experimental paradigms, and human-centered evaluations of conversational agents primarily relied on surveys. By leveraging real-time denoising techniques, the present study explored the possibility of using fMRI to evaluate the quality of a conversational agent *during* rather than *after* human-agent conversations.

Compared to behavioral assessments, such neural assessments arguably surfer less from various response biases. Our results showed that 28 healthy participants engaged the right TemporoParietal Junction in the brains while conversing with a person or a chatbot (Mitsuku or XiaoIce), presumably exercising Theory of Mind. However, the participants showed greater brain activities in the Dorsal Attention Network during chitchats with chatbots than with a person, suggesting a higher cognitive load during human-agent than human-human conversations. Taken together, these results demonstrate the feasibility of using fMRI during real-time conversations, which helps to address the ecological validity issue in communication neuroscience.

Title: Schizophrenia influences responses of the theory of mind network to socially awkward events

Authors: *E. PRZYSINDA[1], B. SHOVESTUL[2], A. SAXENA[2], E. DUDEK[3], J. LAMBERTI[4], E. LALOR[5], D. DODELL-FEDER[2];

Abstract: Schizophrenia (SZ) is a debilitating and complex disorder. One often overlooked symptom is marked and persistent difficulties with social information processing. Increasing work has shown that these deficits can be attributed to abnormalities in the network of brain regions supporting mental state attribution, known as the theory of mind (ToM) network; namely, dorsal medial prefrontal cortex (dmPFC) and temporo-parietal junction (TPJ). The extant literature generally utilizes explicit tasks and non-naturalistic stimuli that only examine isolated aspects of social processing. However, social interactions are nuanced and context-dependent, so utilizing naturalistic stimuli more representative of daily social interactions could help us to better understand social difficulties in SZ. Here, we used an episode of the comedy TV show, *The Office*, as our stimulus because it contains a rich variety of social interactions, including some that may be violating social norms (i.e., awkward events). We modeled our analysis on a recent study (Pantelis et al. 2015) that examined the ToM network during awkward moments during the same episode of *The Office*. We focus on awkward moments because these scenes require complex social reasoning involving mentalizing about others' thoughts and feelings in addition to a thorough understanding of social norms. We aim to better understand the neural dynamics of the ToM network during scenes requiring mental state attribution, such as these socially awkward moments. We first replicated Pantelis et al's findings that across all participants, the ToM network was engaged during socially awkward moments. Preliminary comparison of 10 SZ patients with controls matched on age and sex showed group differences in the extent to which the ToM network is engaged during these awkward events; specifically the SZ group showed reduced recruitment of dorsal (d)mPFC compared to controls.

The dmPFC has been shown to be heavily involved in ToM assessment of others' evolving mental states, and these results indicate that these abilities might be impaired in patients with SZ. In summary, our preliminary results suggest that in those scenarios where mental state attribution is critical, patients with SZ failed to bring key regions of the ToM network online, possibly contributing to inappropriate social inferences and behaviors. Further analysis of behavioral data collected as part of this study will allow us to examine the behavioral consequences of functional abnormalities in the ToM network.

Title: Aberrant functional connectivity of brain networks for biological motion processing in Autism Spectrum Disorder

Authors: S. A. L. JARRELL[1], M. M. COLEMAN[1], S. Z. SALMASSI[1], P. J. WEBSTER[2], *J. W. LEWIS[1];
[2]Neurosci., [1]West Virginia Univ., Morgantown, WV

Abstract: Autism spectrum disorder (ASD) often manifests with difficulties in social interactions, which are behaviors that have been variably associated with aberrant cortical network organizations. A recent fMRI study by our group (Webster et al., 2020) revealed a hypoactivated corticobasal network during a simple motor task while participants observed a person (below the head) bouncing a basketball. Together with eight other brain regions of interest (ROIs) associated with processing human biological motion, we identified a global brain network that could be more broadly tested for functional connectivity pattern differences across groups using resting state functional connectivity MRI (rsfMRI). Using the Autism Brain Imaging Data Exchange (ABIDE) database, we processed neuroimaging data from 97 individuals with ASD and 97 typically developed (TD) matched for age, gender, and IQ using structural vector auto-regression (SVAR) modeling. This connectivity analysis modeled both contemporaneous and lagged interactions. The main finding was that the ASD group showed significantly fewer path effects across multiple hubs of this network, which was a finding opposite from most traditional autocorrelation analyses. Complementing conventional instantaneous effects rsfMRI analyses of ASD groups, these findings are newly suggestive of physiological differences in information flow across specific brain regions involved in biological motion processing.

Title: Investigating the neurocognitive processes of communicative language use in Autism Spectrum Disorder

Authors: *M. MANGNUS[1], S. KOCH[1], K. CAI[1], F. GOLTZ[1], P. HAGOORT[1], I. TONI[1], A. STOLK[2,1], J. BAŠNÁKOVÁ[1];

Abstract: Everyday communication often requires us to rapidly search for relevant context. Autism Spectrum Disorder (ASD) is defined by persistent communicative challenges (Wadge et al., 2019). Yet, language and communication research in ASD to date has largely focused on the processing of words absent of any communicative context. Accordingly, it remains largely unknown whether the communicative challenges experienced by autistic individuals are due to core issues with processing linguistic material or communicative context. The present study combines fMRI with eye-tracking to examine how autistic individuals disambiguate the meanings of words employed in a communicative context. Specifically, our experiment will reveal what parts of context autistic interlocutors use to disambiguate the meaning of these words.In the task, participants read chat conversations in which the meaning of a target word in the first sentence, indicated with bold text, is either literal (e.g. “bears” stands for an animal) or slang (“bears” stands for the police). Moreover, in half of the dialogs, the word’s meaning is known to the participant beforehand (control condition). The participants are instructed to determine the meaning of the target word. Tracking the participants’ eye movements while reading reveals in real time which portions of the dialog they analyze to resolve the target word’s meaning. To analyze which features of the context the participants focus on, the amount of semantic exploration in the context is calculated by measuring the semantic similarity of the target word and the words fixated on by the participant. We expect that autistic participants fail to fully benefit from contextual information in the dialog, such as references to unusual objects or idiosyncratic inferences derived on the fly from previous lines. Instead, we expect them to focus more on strong semantic relations between words and thus engage in semantic exploration more than neurotypical participants. fMRI data is acquired to measure whether the participants use brain regions typically involved in language processing (using data from a language localizer) or Theory of Mind (via non-verbal ToM localizer) when searching for meaning of the target word in the communicative context. We will present preliminary results of approximately half of the intended sample size. Our findings will provide new insights into the underlying processes of the differences in communication in autistic and neurotypical individuals.

Title: Communication in Context: a dual-fMRI study on social interaction in autism spectrum disorder

Authors: *S. KOCH[1], K. CAI[1], M. MANGNUS[1], I. TONI[1], J. BASNAKOVA[1], A. STOLK[2];
[1]Donders Inst. for Brain, Cognition and Behavior, Nijmegen, Netherlands; [2]Dartmouth Univ., Hanover, NH

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized with deficits in social interaction and communication (APA 2013). When investigating communicative abilities during live social interactions, a recent behavioral study found that individuals diagnosed with ASD struggled to align their contextual knowledge of the interaction with that of others, despite having otherwise indistinguishable performance from neurotypicals (Wadge et al., 2019). However, the neural mechanisms of this contextual misalignment hampering contextually appropriate communication in ASD remain largely unknown.
In this dual-fMRI study, we investigate the neural mechanisms underlying contextual communication difficulties in ASD. Contextual communication is investigated in a dual-fMRI setting, in which 26 pairs of ASD individuals, 26 pairs of neurotypical controls, and 26 pairs of socially anxious participants solve novel communicative problems in a live interactive setting. Pairs are asked to reproduce a goal configuration of two geometrical tokens, shown to one of the participants only, the 'Communicator'. Given that the other player, the 'Addressee', cannot see this configuration, the Communicator has to move her token in a way on a digital gameboard that conveys the Addressee's target to the Addressee. The pairs face communicative problems they have previously established joint solutions for ('Known' trials), and problems that require them to reach a shared solution still ('Novel' trials) (94 trials in total). At the behavioural level, we investigate group differences in communicative success and communicative alignment (i.e. correspondence in communicative signals across successive interactions). At the neural level, we investigate activity during accessing (Known trials) and building of (Novel trials) shared meaning, which is compared between groups. Preliminary fMRI results replicate previous findings of increased activity in the motor cortex, left cuneus, right angular gyrus, medial frontal cortex and right superior temporal gyrus during Known compared to Novel problems (Stolk et al., 2014) ($n = 39$, all $p_{FWE} < .05$), thus when pairs have access to shared contextual knowledge. To investigate cerebral synchronization between communicators, we investigate (group differences in) neural alignment, defined as shared BOLD fluctuations in the right superior temporal gyrus (rSTG), as well as stimulus-independent interpersonal cerebral coherence in the rSTG when pairs align their contextual knowledge of the interaction (Stolk et al., 2014). Preliminary behavioural and fMRI results will be presented.

Title: Engagement of the TPJ-pSTSRegion by Naturalistic Stimuli in Individuals at Clinical High Risk for Developing Schizophrenia

Authors: *J. K. LEE[1,2], N. CHOWDHURY[1,2], D. RUIZ-BETANCOURT[1], J. P. SANCHEZ-PEÑA[1,2], C. M. CORCORAN[3,4], D. C. JAVITT[1,2,5], G. H. PATEL[1,2];

Abstract: Individuals with schizophrenia show deficits in inferring sarcasm based on prosody detection and have reduced activation in the temporoparietal junction and posterior superior temporal sulcus (TPJ-pSTS) during speech reception. Previous studies have found evidence that auditory processing impairments precede the onset of schizophrenia. However it is unclear whether these deficits affect naturalistic speech comprehension which is critical for social functioning. To this end, the present study evaluates the functionality of the TPJ-pSTS associated with naturalistic language processing in individuals at clinical high-risk for developing schizophrenia.
We collected functional MRI images in 14 healthy controls (HC), 15 individuals at clinical high-risk for developing schizophrenia (CHR) and 20 schizophrenia patients (SzP) while they listened to a spoken story “Pie Man”. The level of brain activity evoked in response to this narrated story was measured by inter-subject correlation (ISC) using HC as the reference. We then compared the ISC scores to the performance on the attitudinal prosody task, which evaluates one’s ability to detect prosodic features of sarcasm in naturalistic speech.
The three groups significantly differed in the extent of brain activation and performance on the attitudinal prosody task, with the highest ISC scores and sarcasm detection rate in CHR and the lowest in SzP. More specifically, in comparison to HC and SzP, CHR showed significantly increased activation in areas within the posterior TPJ (TPJp; $F2,46 = 4.96$, $p=0.012$), along with prefrontal cortex, auditory cortex and visual/face-processing areas. In addition, the CHRs performed better on the attitudinal prosody task, compared to the other two groups ($F2,46=4.32$, $p=0.019$). Interestingly, greater activation of the TPJp significantly correlated with better auditory sarcasm detection in the attitudinal prosody task only in CHR (β CHR $=0.54$, $p<0.01$)
Overall, the juxtaposition of results from CHR and SzP suggest that increased activity within the TPJp node of the mentalization network may compensate for an otherwise compromised system. The current

findings in the CHRs point to a potential target for rehabilitation and neuromodulation-based treatments for social functioning deficits in schizophrenia.

Title: Redefining the posterior superior temporal sulcus: the functional organization of social interaction processing in the posterior superior temporal sulcus

Authors: *Q. LIANG, Y. LIANG, S.-G. KUAI;
East China Normal Univ., Shanghai, China

Abstract: Numerous studies recognized the posterior superior temporal sulcus (pSTS) as a key region for social information processing. However, looking into the details, some sharp incongruences come into view (e.g. whether the pSTS or extrastraite body area represents social interaction status). A major obstacle for understanding why these conflicts occurred is the lack of standard localizers for subregions in pSTS, mainly face area, biological motion area and social interaction area. A precise and well-controlled localizer is in urgent need. In this study, we conducted an fMRI study to examine the functional organization of social information processing in pSTS. We reviewed social perception and cognition studies in the past 10 years and adopted dynamic face perception task and biological motion perception task from the most cited studies. Since there was no standard task to locate social interaction area, we recruited four actors to perform dyadic social interactions and made videos and screenshots as stimuli. To make interactions varied, half of the stimuli were only with the face showed and the other half were face-masked full-body scenes. As for the comparative non-interacting conditions, we switched the positions of the two people and made them face away from each other. Then all the physical information was controlled and only the interaction status was altered. The social interaction area was defined by significantly higher activation in interacting conditions than non-interacting conditions. 20 healthy adults went through three fMRI sessions for functional localization. The results showed that the three areas were not overlapped with each other in individuals' brain. On the other hand, the areas that different kinds of social interaction activated were highly overlapped. Classifiers trained by neural activations in these areas succeeded in transfer decoding the interaction status (e.g., a classifier trained to decode whether a static

face-only scene was an interacting scene or not could also decode the interaction status in a dynamic body-only scene). These results showed that there was a region specialized for social interaction perception in pSTS and it represented abstract social interaction information. Moreover, our results suggested that these subregions should be defined individually since neither their coordinates were consistent among participants, nor the resting-state functional connectivity manifested these subareas. To sum up, our study indicates that there are functional subregions in pSTS specialized for different social information processing and they should be defined using well-controlled functional localizers individually.

Title: Transcultural differences of theory of mind among Chinese and Japanese cultures: an fMRI study

Authors: M. ZHANG[1], Z. LU[3,1], W. MA[2], *S. OTANI[4], Z. WANG[1];
[1]Inst. of Cognitive Neuroscienc, Sch. of Psychology and Cognitive Sci., [2]Sch. of Psychology and Cognitive Sci., East China Normal Univ., Shanghai, China; [3]Dept. of Psychology, The Ohio State Univ., Columbus, OH; [4]Aging in Vision and Action Lab, Inst. of Vision, CNRS-INSERM-Sorbonne Univ., Paris, France

Abstract: Theory of mind (ToM) is an ability of explaining one's own and others' actions. Further studies revealed that the neural mechanisms of TOM can be shaped by culture differences and differential activations between Asains and Westerners have been reported. Furthermore, some studies that focused on transcultural differences of ToM indicate that the medial prefrontal cortex (mPFC) shows differential activations between Asians and Westerners. However, Whether the same neural mechanisms underlying ToM in similar Asian cultures, such as Chinese and Japanese, is unclear. Hence, using representational similarity analysis (RSA), we explored the neural representation of ToM in the brain to study representational differences between Chinese and Japanese participants. We recorded the brain activities of Chinese (N=12) and Japanese (N=12) participants (recruited in Shanghai), using functional magnetic resonance imaging (fMRI) during a ToM video task. Behavioral data showed no significant group differences in the subjects' post-scan subjective evaluation of the movies. However, fMRI results showed differences of ToM representational patterns between the two groups. We calculated the similarities between the fMRI searchlight RDMs (representational dissimilarity matrix) with two coding model RDMs, video-style RDM, and ToM RDM, respectively. We found that left middle occipital gyrus (MOG) showed a strong correlation with the video-style processing in the task. The middle frontal gyrus (MFG), the superior temporal gyrus (STG), and the precentral gyrus (PreCG) were found involved in encoding ToM processing. However, Chinese participants' right middle temporal gyrus(MTG)and right STG

showed a stronger representation of encoding ToM than Japanese participants. In contrast, Japanese participants' left PreCG showed a stronger ToM representation than Chinese. These results suggest that Chinese show a rightward lateralization of ToM representation while Japanese are non-lateralized. In summary, our study presents a novel finding of the neural mechanism of ToM in our brains using RSA. Furthermore, the difference of encoding ToM between Chinese and Japanese participants demonstrates that the diversity within Asian culture can affect the neural representation of ToM.

Title: The road not taken: disconnection of a human-unique cortical pathway in schizophrenia and its effects on naturalistic social cognition

Authors: *G. H. PATEL[1], D. C. GRUSKIN[1], J. K. LEE[1], D. A. LEOPOLD[2], D. C. JAVITT[1];
[1]Columbia University/NYSPI, New York, NY; [2]NIMH, Bethesda, MD

Abstract: Background: Efficient processing of a complex dynamic social scene relies on intact connectivity of many underlying cortical areas and networks, but how structural deficits affect this functioning in social cognition remains unknown. Here we measure these relationships using functionally based localization of social cognition areas, resting-state functional connectivity, and movie-watching data.
Methods: In 42 schizophrenia participants (SzP) and 41 healthy controls (HC), we measured the functional connectivity of areas functionally localized by face-emotion processing, theory-of-mind, and attention tasks. We used weighted shortest path length between visual and medial prefrontal theory-of-mind areas in both populations to assess the impact of the functional connectivity deficits on the network structure. We then correlated connectivity along the shortest path in each group with movie-evoked activity in a key node of the theory-of-mind network (TPJp).
Results: SzP had pronounced connectivity deficits in temporoparietal junction/posterior superior temporal sulcus (TPJ-pSTS) areas involved in face-emotion processing ($t(81)=4.4$, $p=0.00002$). In HC the shortest path connecting visual and medial prefrontal theory-of-mind areas passed through TPJ-pSTS, whereas in SzP these deficits shifted the pathway to pass through prefrontal cortex (PFC). While movie-

evoked TPJp activity correlated with the connectivity along the TPJ-pSTS pathway in both groups ($r=0.43$, $p=0.002$), it additionally correlated with the connectivity along the PFC pathway only in SzP ($r_{SzP}=0.56$, $p=0.003$).
Conclusions: Connectivity along the human-unique TPJ-pSTS pathway affects both the structure and functioning of areas involved in processing complex dynamic social scenes. These results demonstrate how focal deficits can have widespread structural and functional impacts across cortex.

Title: Transformative neural representations across memory encoding, maintenance and retrieval

Authors: *J. LIU[1], N. AXMACHER[2], G. XUE[1];
[1]State Key Lab. of Cognitive Neurosci. and Learning, Beijing, China; [2]Ruhr Univ. Bochum, Bochum, Germany

Abstract: Emerging evidence has conceived memory as a dynamic process during which the mental representations are continuously transformed, yet the nature of this transformation and its functional significance have not been well understood. Combining intracranial EEG recordings, deep neural network models, representational similarity analysis, and a behavioral paradigm encompassing memory encoding, short-term maintenance, and long-term retrieval, we found that the cross-stage neural pattern similarity of the same item was significantly smaller than the within-stage pattern similarity. More importantly, neural representations during long-term memory retrieval were more similar to the representation during short-term maintenance than that during encoding. These results suggested that the memory representations went through continuous transformations from encoding, maintenance to retrieval. Critically, during encoding, items that experienced a greater neural transformation from visual processing to semantic processing were associated with better subsequent memory. These results provide novel insights regarding how human memory is formed and transformed.

Title: Insights into category learning through feature-level memory distortion

Authors: *M. C. TANDOC, C. V. DONG, A. C. SCHAPIRO;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Our semantic knowledge is rich and multi-faceted, encompassing both general patterns (most birds can fly) and unique details (herons have long legs). Our model of novel structured learning in the hippocampus (Schapiro et al., 2017, *Philos. Trans. R. Soc*) predicts that different forms of representation may best support these different kinds of knowledge, as shared structure benefits from pooling information across exemplars while idiosyncratic information benefits from keeping exemplars separate in memory. We leverage distortions in color memory (Chanales et al., 2021, *Psychol. Sci*) to behaviorally evaluate representational shifts in the learning of shared and unique features in a novel semantic domain. Participants learned two categories of novel "satellite" objects: Each satellite had parts that were shared with most members of the same category as well as a part that was unique to that exemplar. Each part had a specific color drawn from a 2D color space, with the parts for each category clustered in this space. As participants learned the features, we frequently tested their color memory to track representational change for each feature. Across learning, color memory resisted attraction to the category centre only for unique features. For shared features, attraction persisted throughout learning. Distortions in color memory across learning were thus systematically related to the category structure. This relative differentiation for unique relative to shared features should reduce interference in memory, and indeed, the unique features that most strongly resisted attraction were remembered best. Preliminary data in a separate sample appear to replicate these effects. These findings suggest that there are differences in the nature of the representations underlying shared and unique features in accordance with their different computational needs.

Title: Category representations after learning from both typical and atypical examples

Authors: *C. BOWMAN[1], T. IWASHITA[2], D. ZEITHAMOVA[3];
[1]Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Psychology, [3]Univ. of Oregon, Eugene, OR

Abstract: Whether concepts are represented by individual category members as posited by exemplar models or an abstracted central tendency as posited by prototype models has been debated for decades. To date, neuroimaging findings have been conflicting, with one study finding only prototype correlates, one finding only exemplar correlates, and one finding a mix of prototype and exemplar correlates. What drives this difference across studies? One factor may be the structure of the training examples, which can bias individuals toward either abstraction or memorization of individual items. In particular, including atypical training items close to the category boundary can reduce reliance on prototype representations. In the present study, we tested whether including atypical items in a paradigm that had previously produced only prototype correlates in the brain would shift individuals toward exemplar-based representations. Participants completed a category-training task that included both typical items close to category prototypes and atypical items close to the category boundary. Participants then completed a surprise old/new recognition test on training items and new items varying in distance from category prototypes, followed by a category generalization test during fMRI. Behavioral results revealed better categorization accuracy for items close to prototypes but better recognition accuracy for items near the category boundary, suggesting that participants may have relied on memorization of the atypical boundary items. In fitting formal categorization models to generalization behavior, we found a relatively even split between subjects who relied on prototype vs. exemplar representations. Neuroimaging results mirrored these behavioral findings by showing a mix of prototype and exemplar representations, sometimes within a single brain region. These results support the hypothesis that individuals flexibly form different types of category representations in response to demands at the time of learning and that multiple representations can form in parallel in the brain.

Abstract: Rationale and Aim(s) of the study: Mechanistic models of inhibitory motor control have identified cortical-sub cortical loops, involving the direct, indirect and hyper direct pathways. There are no such established pathways to explain how retrieval of episodic memories can be actively inhibited. Several previous studies have established that role of prefrontal regions in top-down memory control, but their functional interactions with sub-cortical and medial temporal lobe (MTL) structures, along with the mechanisms of action, are yet to be fully established.We sought to address this void, by looking at brain regions important for memory control, and mapping their mechanistic interactions. This project aims to investigate if the cortical and sub-cortical regions identified to be involved in motor control are also involved in memory control.**Materials and methods:** There are two studies in this project. Both studies sought to a) confirm if regions identified in motor inhibitory control are involved in memory control as well, b) explore the mechanisms of how memory retrieval is actively inhibited. Both studies used functional magnetic resonance imaging (fMRI) data, and dynamic causal modelling (DCM).***Study 1:*** 33 healthy young adults participated in the study. They performed two sessions inside the 3T scanner- an inhibitory Stop Signal motor task and a version of the Think No Think (TNT) memory inhibition task. ***Study 2:*** 10 previous TNT studies were pooled together, and key cortical and sub-cortical regions of interest (ROIs) taken from the motor inhibition literature, were investigated for engagement in the TNT memory control task. Preliminary functional connectivity analyses are currently underway to establish the mechanistic interactions between these structures. **Key results, and discussion:** For both the studies, we focussed on two key cortical areas: the right dorsolateral prefrontal cortex (rDLPFC), and the right ventrolateral prefrontal cortex (rVLPFC). The subcortical regions we focussed on includes the caudate nucleus, putamen, and sub-thalamic nucleus (STN). Both Study 1 and Study 2 revealed a novel discovery of the potential involvement of the STN in memory control. Both studies also revealed that akin to motor control, there are differential patterns of univariate activation seen for proactive versus reactive memory control. DCM efforts from Study 1 revealed that both the prefrontal regions, along with the basal ganglia, were causally involved in memory control. DCM analysis from Study 2 is expected to reveal the functional role of the STN in memory control, and also help us establish a mechanistic model of memory inhibition.

Title: Indirect downregulation of negative emotional memories

Authors: *S. KOZAK[1], N. HERZ[3], Y. BAR-HAIM[1,2], N. CENSOR[1,2];
[1]Sch. of Psychological Sci., [2]Sagol Sch. of Neurosci., Tel-Aviv Univ., Tel-Aviv, Israel; [3]Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Dysfunctional negative emotional memories remain at the core of psychopathological conditions such as posttraumatic stress disorder (PTSD), depression and addiction. This has inspired research geared towards memory modulation, by direct targeting of the negative emotional memory. However, reliable downregulation of maladaptive episodic memory in humans remains elusive as emotional memories show high resistance to direct modulation. Given the existing challenges associated with direct emotional memory modulation, here we asked whether negative emotional visual memory may be modulated indirectly. To address this question, we leveraged a paradigm previously shown to indirectly modulate neutral visual memories, through direct instructions to forget or remember embedded verbal information (Kozak et al., 2021). Participants studied two lists of neutral words embedded within negative emotional pictorial context and as in previous directed forgetting experiments, received a cue to forget or remember the words of the first list (Anderson et al., 2014). While the instructions were given only for the words, both word and emotional picture memory were tested at the end of the study session. Preliminary results indicate that consistent with previous studies, the instructions directly modified word memory strength. The remember instruction enhanced word recall and the forget instruction reduced it. Importantly, these instructions modulated indirectly and inversely the memory for the emotional pictures. Specifically, instructions to remember the words reduced picture recognition memory, and vice versa for instructions to forget the words. Moreover, these effects on emotional picture recognition memory carried over to the second list in which no differential instructions were provided. These data suggest that upregulation of temporally adjacent memory may indirectly downregulate negative emotional memory, opening a new avenue for treatment of memory related pathologies.

Title: Multiple codes of memory signals in parietal cortex

Authors: *N. YOUNG[1], M. PRICE[1], E. J. ALLEN[2], Y. WU[2], T. NASELARIS[2], K. KAY[2], J. B. HUTCHINSON[1];

Abstract: Memory recognition is a process that is strongly influenced by the passage of time—whether we recognize something from the past is thought to depend at least in part on a continuous signal that becomes weaker over time. This putative signal is a fundamental tenet of memory recognition, yet there remains substantial debate regarding where and how this signal is represented in the brain. Evidence from human neuroimaging suggests that parietal cortex possesses regions whose activity roughly tracks the degree to which someone believes they recognize a presented stimulus, as well as regions that represent

various continuous dimensions including egocentric space and the temporal distance of recalled memories. Building upon these studies, we conducted 7T fMRI during a continuous recognition memory task involving a very wide range of timescales spanning seconds to months. Specifically, eight participants viewed up to 10,000 unique images repeated 3 times each across 30 to 40 scanning sessions distributed over approximately 9 months. We examined how activity during correct recognition trials in each voxel varied as a function of the elapsed time from an item's prior presentation (i.e., lag). Preliminary results suggest that many regions in parietal cortex show response amplitudes that decline linearly as a function of the logarithm of the lag, consistent with a scalar signal that is used for recognition decisions. However, a significant proportion of voxels in medial parietal cortex exhibited maximal activity for windows of lag that were between relatively short and relatively long distances of time. There is also preliminary evidence that such voxels might be arranged in a topographic manner in which voxels tuned to longer lags are found more anterior and inferior relative to voxels tuned to intermediate and shorter lags. These results suggest that parietal cortex might support multiple codes of signals relevant to recognition memory in an organized, topographic fashion.

Title: Executive and mnemonic functions of the human posterior cingulate cortex revealed by single-unit recordings

Authors: *L. APONIK-GREMILLION[1], Y. Y. CHEN[3], E. BARTOLI[2], B. Y. HAYDEN[4], S. A. SHETH[2], B. L. FOSTER[3];
[1]Neurosci., [2]Neurosurg., Baylor Col. of Med., Houston, TX; [3]Neurosurg., Univ. of Pennsylvania, Philadelphia, PA; [4]Neurosci., Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Episodic memory supports the retrieval and construction of past events, facilitating experience-informed decision-making. In addition to the hippocampus, human neuroimaging has shown a consistent set of distributed neocortical regions are active during the retrieval of episodic memories, with the posterior cingulate cortex (PCC) serving as a core node of this retrieval network. In contrast to these findings, non-human primate single unit studies suggest a more executive role for the PCC, related to cognitive control and decision making. Consequentially, these divergent results have motivated radically different perspectives of PCC function across fields, leading to the question: *is the function of PCC mnemonic or executive in nature?* In order to reconcile these divergent perspectives and expand upon our understanding of PCC physiology, we utilized human intracranial stereo-electroencephalography (sEEG), including single-unit recordings, to allow for spatially and temporally precise investigation of PCC neural

activity during complex executive and mnemonic behavior. Additionally, hippocampal recordings were incorporated to provide a point of comparison for the selectivity and timing of task responses within PCC. Neurosurgical patients undergoing invasive monitoring performed an attention/memory switch task. On a given trial, subjects performed either an attention (search or arithmetic) or memory (past or future event) task, with a pre-trial cue indicating the trial type. Overall, PCC responses (unit and population measures) showed evidence for both attention and memory functions. A subset of PCC recordings exhibited sustained activation throughout the episodic memory conditions, similar to activity observed in the hippocampus, suggesting a role in the retrieval and construction of episodic memories. Other PCC recordings revealed activation of varying temporal profiles (i.e. transient and sustained) during the attention conditions. These results indicate that PCC populations are functionally heterogeneous and involved in both mnemonic and executive functions. These functionally divergent populations appear to be organized spatially across the dorsal-ventral axis of PCC, with more executive activity observed in the dorsal PCC, while mnemonic activity was predominately in the ventral PCC. Our findings help reconcile previously incongruous data across fields and suggest that PCC may serve as an important convergence zone of mnemonic and executive functions in order to support memory-based decision-making.

Title: Limited Evidence for a Triple Dissociation in the Medial Temporal Lobe: an fMRI Replication Study

Authors: *J. VAN[1], B. KIRWAN[2];
[2]Psychology, [1]Brigham Young Univ., Provo, UT

Abstract: What does the hippocampus do? A previous fMRI study demonstrated a triple dissociation within the medial temporal lobe, with different regions of the parahippocampal gyrus supporting subjective novelty and familiarity responses while the hippocampus supported subjective recollection regardless of the old/new status of stimuli (Daselaar SM, Fleck MS, Cabeza R [2006a] Triple dissociation in the medial temporal lobes: recollection, familiarity, and novelty. J Neurophysiol 96:1902–1911). However, a separate analysis of the same dataset demonstrated that the hippocampus responded to the objective old/new status of stimuli regardless of the subjective response as indicated by behavioral responses (Daselaar SM, Fleck MS, Prince SE, Cabeza R [2006b] The medial temporal lobe distinguishes old from new independently of consciousness. J Neurosci 26:5835–5839). To investigate this apparent conflict, we replicated the behavioral, fMRI scan acquisition, and data analysis procedures of the original studies as closely as possible. Fifty-three participants studied a list of words outside the MRI scanner and then were given a recognition memory test in the scanner in which they first indicated whether the word presented was repeated or novel and then indicated their confidence in their recognition memory decision.

Following the previous studies, two sets of analyses were conducted. In the first set of analyses, we contrasted objective old vs new stimuli (i.e., [hits + misses] > [correct rejections + false alarms]) and subjective old vs new responses (i.e., [hits + false alarms] > [misses + correct rejections]). We found evidence for objective old > new effects in the hippocampus (uncorrected $p < .01$, $k>40$ voxels) at coordinates similar to the original study (Daselaar et al., 2006b). In the second set of analyses, we modeled novelty, familiarity, and recollection. We found a robust recollection signal in the parahippocampal cortex but not in the hippocampus in contrast to the previous work (Daselaar et al., 2006a). Thus, the present work was able to partially replicate Daselaar et al. (2006a, 2006b) but found no evidence for a triple dissociation in the MTL. Title: Graded hippocampal activity during naturalistic recall is observable after multi-echo, but not single-echo, fMRI processing

Authors: *A. W. GILMORE, A. M. AGRON, E. I. GONZÁLEZ-ARAYA, S. J. GOTTS, A. MARTIN; Lab. of Brain and Cognition, NIMH/NIH, Bethesda, MD

Abstract: Recent years have seen an increase in the use of multi-echo fMRI designs by cognitive neuroscientists. Acquiring multiple echoes allows one to reduce thermal noise, identify nuisance signal components, and improve the overall quality of BOLD data. At the same time, acquiring multiple echoes incurs a cost to the temporal and spatial resolution of the acquired BOLD data and increases the overall complexity of data analysis. Here, we re-examine a multi-echo dataset (Gilmore et al., 2021) analyzed using multi-echo ICA (ME-ICA) and compare the results to a “traditional” single-echo analysis of the same data. Both processing streams utilized the same initial preprocessing steps (despiking, slice-time correction, and rigid-body motion correction) and both were rescaled, detrended, and analyzed using the same modeling parameters. The task involved 40 human participants overtly recalling recent and remote autobiographical events for periods of ~2 minutes and was intended to test competing theories of hippocampal involvement in remote recall. The goal of the current analysis was to determine if ME-ICA’s theoretical benefits might lead to a practical difference in the overall results of the experiment. Three results are notable. First, the temporal signal to noise (tSNR) was significantly improved following ME-ICA denoising, especially in signal-poor regions such as orbitofrontal cortex. Second, as a result of this improved tSNR, ME-ICA denoising revealed temporally graded activity in right lateral parietal and left frontal regions that was not detected by the single-echo analysis. Third, region of interest analyses focusing on hippocampal subregions produced qualitatively different results patterns between the two

analysis approaches. Whereas no significant differences in hippocampal activity were observed as a function of event recency in the single-echo analysis, a temporally graded pattern (recent < remote) was observed in posterior hippocampal regions in the ME-ICA processed data. Compared to the ME-ICA data, single-echo results rarely differed from baseline activity in the hippocampus bilaterally. Thus, whereas the outcome of the single-echo analysis did not clearly support any specific model of hippocampal function, ME-ICA results supported predictions of the Standard Model of Consolidation and a time-limited hippocampal involvement (e.g., Zola-Morgan & Squire, 1990). These data provide a practical example of the benefits multi-echo acquisitions and ME-ICA might offer to naturalistic paradigms and emphasize that effects may emerge in ways that are subtle yet important for informing theoretical debate.

Title: The neural basis for number processing and its relation to individual differences in adults' mathematical skills

Authors: *X. REN, M. N. COUTANCHE, J. A. FIEZ, M. E. LIBERTUS;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Number recognition is thought to be multi-constituent in nature. It relies on visual (e.g., written digits or number words), verbal (e.g., number names), semantic (e.g., dot arrays), and manual (e.g., fingers) formats to represent quantity. Here we will explore whether variations in brain activations associated with number processing of these different formats are predictive of adults' math achievements. To this end, we used functional magnetic resonance imaging (fMRI) to 1) broadly characterize visual, verbal, manual, and semantic neural constituents of adults' number processing that undergird number recognition and 2) investigate the relations between individual differences in the underlying brain activation and their math abilities. Specifically, we measured adult participants' brain activation while they completed a number comparison task (a semantic task) and a phonological comparison task (a verbal task) with two types of stimuli: Arabic numerals (visual code) and hand images (manual code). Participants' mathematical competence was measured using the math subtests of the Woodcock-Johnson Tests of Achievement in a separate behavioral session. Univariate contrasts of the fMRI tasks and stimuli revealed an extensive set of brain regions supporting each number format. We also applied a principal component analysis (PCA) to obtain two derived variables from the Woodcock-Johnson Tests. Correlational analyses revealed significant links between brain activation in regions such as left postcentral gyrus and left middle temporal gyrus, and participants' math abilities. In sum, our study

furthers our understanding of the neurocognitive architecture underlying number processing and its relation to individual differences in math achievement.

Title: Reactivation-induced learning in the numeric domain

Authors: *G. SCHRIFT[1], D. DOTAN[2], N. CENSOR[1];
[1]Sch. of Psychological Sciences, Sagol Sch. of Neurosci., [2]Sch. of Education, Sagol Sch. of Neurosci., Tel-Aviv Univ., Tel Aviv, Israel

Abstract: Learning of arithmetic facts such as the multiplication table often requires repeated time-consuming execution to achieve gains in performance. Motivated by recent studies successfully extending memory reactivation frameworks from fear-conditioning in rodents to skill learning in humans, we asked whether learning numeric facts can be induced by brief memory reactivations. To investigate this question, we had adult participants perform a novel task modeling number-fact learning. 101 naive healthy participants (14 males, 87 females; mean age 23.8±2.1 standard deviation) were asked to learn 8 arithmetic-like numeric facts (e.g., 4 & 6 = 79). The initial session included encoding of the facts and was followed by a free recall baseline test. Reactivation training was done by brief visual-auditory reactivations of only 40 seconds each, conducted on 3 separate days. Learning was evaluated in a final retest session performed 8 days following initial encoding. The *Reactivation* group showed significant learning gains (mean score change = 7.7%±3.1% standard error, p= 0.02), indicating that passive reactivations can facilitate learning in the numeric domain. This is in contrast to the *Control* group subjects, who performed test-retest without reactivations, and showed deteriorated performance (mean score change = -22.0%±4.5%, p< 0.00003). A *Standard Training* group completed active problem-solving sessions also conducted on 3 separate days and showed significant learning gains (mean score change = 26.3%±3.1%, p<2E-10). Interestingly, while these gains were higher than those of the *Reactivation* group, subjects showing reactivation-induced learning were characterized by superior efficiency relative to standard training subjects, with higher rate of improvement per training time. Overall, the results demonstrate the possibility of learning numeric skills with brief reactivations. Time-efficient learning in the numeric domain carries potential enhancement of learning strategies in daily life settings, including in neurological conditions such as attention deficit disorders.

Title: Rapid cognitive learning in the cerebellum

Authors: *L. LIKOVA, K. MINEFF;
Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Introduction: The main function of the cerebellum is generally understood to be in motor control and coordination, including a major role in motor learning; however recent neuroimaging studies have implicated it in many aspects of cognitive processing. Here we investigate the involvement of the cerebellum in two non-motor cognitive learning tasks - the memorization and mental visualization of visuo-spatial information. **Methods:** In a 3T Siemens Prisma scanner, participants performed a sequence of i) memorization of scientific or artistic visual images (30s) and ii) visualization-from-memory of these images (30s), interleaved with fixation periods (20s); this sequence was repeated three times for each image. Functional MRI, the SUIT cerebellar toolbox and Granger Causal connectivity analyses were used to establish and analyze the properties of the network structure and its rapid reorganization during these tasks. **Results:** Overall, the results revealed well-structured, task-specific bilateral activation at the lobule VI/Crus I border, and lobules VIIb, VIIIa/b and X, and suppression at the border of Crus I/Crus II, lobule IX, and at lobule VI of the vermis. At a cerebellar network level, both congruent and inverse Granger causal connectivity influences were identified for each task. The causal connectivity analysis also uncovered a characteristic dynamic of cross-coupling between key cerebellar regions of interest (ROIs) and large-scale brain networks such as the default mode network (DMN). In particular, DMN was shown to be the primary driver of the strong suppression in Crus I/Crus II during mental visualization. Remarkably rapid differentiation between the two tasks was observed in most cerebellar sites, in terms of different patterns of positive or negative changes of the BOLD responses over the repeats. Furthermore, the causal connectivity relationships between these local sites also underwent a rapid reorganization across the repeats. **Conclusions:** These multidimensional fMRI and connectivity findings provide a solid basis for a framework for the analysis of rapid cerebellar reorganization during non-motor cognitive tasks. To our knowledge, this is the first study to reveal this form of rapid non-motor/cognitive learning in the cerebellum - on the timescale of just a few minutes - as well as to do so at both the sub-lobular and the network causal connectivity levels. Collectively, the findings of this rapid cerebellar plasticity in the cognitive tasks of mental visualization and memorization offer novel insights into fundamental questions of cerebellar function.

Title: Defensive pessimists could promote the improvement of their ability and the brain structure in the competitive learning

Authors: *C. HOSODA[1,2], T. MATSUHASHI[2], K. OKANOYA[3];
[1]Univ. of Tokyo, Tokyo, Japan; [2]Advanced Comprehensive Res. Organization, Teikyo Univ., Tokyo, Japan; [3]Univ. od Tokyo, Tokyo, Japan

Abstract: The environment surrounding an individual has a significant impact on his/her behavior change. While people could improve their abilities by comparing with others, there was also a critical view of the competitive environment. This discrepancy might reflect individual differences in usage of the cognitive strategy in competitive environments. Some fMRI studies supported the comparison involved in the reward-related brain activity in estimating the advantages of yourself and others. Thus, the competitive-situation might evaluate in terms of reward processing, although an interaction between the competitive-situation and the behavior change (i.e. improvements of their ability) may occur independently of individual differences in the selection of their cognitive strategy. Here, we focus on the defensive pessimist (DP) that is the cognitive strategy making oneself think that a future performance will go poorly, so that one takes the necessary steps to make sure it does not go poorly. The purpose of this study is to elucidate the interaction between the degree of DP and the competitive-situation on the improvement of the ability.Fifty-one subjects were divided into two groups with no significant difference in DP score and English proficiency, gender, or age, and underwent a 12-week English listening (L2L) training. One group was in a competitive and the other was in a non-competitive-situations. Before and after training, we measured brain structure using magnetic resonance imaging scanning (3T-MRI, Siemens PRISMA,). To clarify the interaction between DP and the competitive-situations , we did a 2-by-2 ANOVA with a situations (competitive/non-competitive) and the degree of DP (high/low) as both of the between-subject variables. Consequently, we found two findings. Firstly, for the L2L improvement, the ANOVA revealed neither the main effect of the situations nor the degree of DP (ps >.50). An interaction of situations by the degree of DP was significant (p =.003). Post-hoc analysis revealed the improvement of L2L, in high DP, was greater in the competitive-situations than that in the non-competitive. (p =.009). Secondly, for gray matter volume of supramarginal gyrus involving in the phonology, neither circumstance effect nor trait (ps > .60) was obtained. Although an interaction was found (p = .047).We investigated the influence the individual difference in the cognitive strategy in the competition on the improvement of the ability. Suggesting that high DP strives to avoid the poor performance by making more pessimistic estimates of their future performance in a competition. Furthermore, it suggested that DP may also promote brain structural plasticity.

Title: Neural bases of event memory encoding: cortical alignment of neural state boundaries is associated with boundary strength and hippocampal response

Authors: *Y. LEE, J. CHEN;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Sensory inputs from the world dynamically change from moment to moment, yet people spontaneously summarize information in meaningful units (events). Recent research shows that brain regions in the default mode network (DMN) chunk information at timescales which match those of human event perception during naturalistic movie-viewing. Shifts in stable DMN neural states, i.e., neural state boundaries, are associated with human-labeled event boundaries - the beginning of a new movie event perceived by humans (Baldassano et al., 2017). Studies have consistently reported two findings: 1) hippocampal activity increases at DMN neural state boundaries that match event boundaries (Baldassano et al., 2017; Ben-Yakov & Henson, 2018), 2) some neural state boundaries in the DMN overlap with those identified from lower level brain regions such as early visual cortex ("cortical alignment" of neural state boundaries; Baldassano et al., 2017; Geerligs et al., 2021). These findings led us to the question: are neural state boundaries with more widespread cortical alignment associated with stronger hippocampal activity, in turn facilitating event memory? By applying the GSBS event segmentation method (Geerligs et al., 2021) to a naturalistic movie-viewing dataset collected in a prior study (Lee & Chen, 2021; $N = 20$), we identified neural state boundaries in three regions along the cortical processing hierarchy: early visual cortex, posterior medial cortex, and medial prefrontal cortex (mPFC). To examine whether hippocampal activity is modulated by alignment of neural state boundaries across different cortical regions, mPFC boundaries were divided into 1) those that overlapped across all three regions (*Aligned*), and 2) those that were limited to mPFC (*mPFC-alone*). Preliminary results show that, 7-8 seconds after boundary onset, hippocampal activity for *Aligned* boundaries was significantly greater ($p < .05$) than for *mPFC-alone*. Furthermore, human judgments of boundary strength were numerically higher for *Aligned* than for *mPFC-alone*. These preliminary data suggest that hippocampal activity increases when meaningful changes in movie events simultaneously occur at multiple levels (e.g., changes in luminance, location, dialogue topics, etc.), consistent with the role of hippocampus in associative binding during episodic memory encoding (Ranganath, 2010; Staresina & Davachi, 2009). In next steps, we will examine a wider range of regions across the cortical hierarchy, and test whether neural state alignment predicts individuals' subsequent event memory.

Title: The role of young adult-born neurons in pattern separation

Authors: *C. CASTILLON, M. BARRAZA, J. ARMSTRONG, A. CONTRACTOR;
Northwestern Univ., Chicago, IL

Abstract: The birth and incorporation of new neurons into the dentate gyrus of the hippocampus of adult mice has been determined to be important for many forms of hippocampal dependent behaviors and memory. Postmitotic adult-born dentate granule cells (abDGCs) mature over several weeks forming synapses with other components of the hippocampal network and eventually having similar properties to developmentally born neurons. During the postmitotic maturation process young abDGCs have unique functional properties with both differential intrinsic excitability and distinct excitatory and inhibitory synaptic input compared to mature granule cells. Therefore, how effectively these neurons are engaged by sensory and contextual information, and themselves contribute to relevant behaviors, remains largely unknown. In particular a role has been described for abDGCs in pattern separation, a memory function that enables discrimination of similar but distinct representations into non-overlapping memories. Yet many questions remain about when and how these neurons facilitate an animal's ability to discriminate between similar situations. In this study we proposed to directly determine when and how adult-born neurons are activated when mice perform a pattern separation task, and moreover to determine their maturation stage and functional characteristics. To do this we developed a custom automated touch screen pattern separation paradigm and determined which neurons were active during different phases of the learning using a mouse that allows Targeted Recombination in Active Populations (TRAP2). Combining this with birth-dating of neurons we are determining which cohorts of young abDGCs are active and using ex-vivo single-cell patch-clamp recording of synaptic and intrinsic properties to assess if they possess distinct functional properties. These studies will ultimately refine our understanding of how abDGCs are functionally incorporated into the hippocampal network and how they contribute to the ability of an animal to discriminate between distinct representations.

Title: The effects of chronic and transient ablation of adult born granule cells on neural flexibility in the Dentate Gyrus

Authors: *S. N. TUNCDEMIR[1], V. LUNA[1], H. CHUNG[2], A. GROSMARK[3], C. LACEFIELD[1], R. HEN[1];
[1]RFMH Columbia Univ., New York, NY; [2]NYSPI/ Columbia Univ., NY, NY; [3]Neurosci., Columbia Univ., New York, NY

Abstract: The dentate gyrus (DG) exhibits a unique form of neural plasticity that results from continuous integration of newborn excitatory granule cells. Recent studies have proposed that adult neurogenesis promotes cognitive flexibility, the ability to encode new memories without interference from previously stored memories that share similar features. However, the manner in which adult neurogenesis contributes to DG network activity and computations is incompletely understood. Here, we employed focal X-ray-irradiation (IR) of the hippocampus to suppress neurogenesis and examined population neural activity using *in vivo* 2-photon Ca^{2+} imaging. To assess the degree of remapping of neural representations of space, we compared the similarity between single-cell spatial tuning profiles by subjecting the mice to two sequential exposures of either identical or different environments. While spatial rate maps in Sham mice were less stable across than within environments (i.e., display remapping), IR mice exhibited significantly lower levels of remapping compared to controls. In addition, we found perseverance during reversal learning behavior and more stable spatial maps across days in IR mice compared to controls. To address the role of adult born granule cells specifically during their critical period of maturation we chemogenetically inhibited immature granule cells using an inducible AsclCreER; hM4Di transgenic mouse line. We confirmed that transiently silencing immature granule cells disinhibits mature granule cells' activity both *in vivo* and *in vitro*, consistent with the prevailing model. Our preliminary results also indicate that the transient and selective silencing of adult born granule cells resulted in significantly higher levels of stability in spatial rate maps across different environments compared to control mice, in line with the effects of chronically suppressing adult neurogenesis. Our ongoing work is aimed at untangling the mechanisms linking neuronal sparsity and flexibility in the DG. Our results highlight the long-hypothesized role of adult born granule cells in providing flexibility for DG to rapidly generate a context specific, distributed representation of important sensory stimuli such as spatial cues, which ultimately promotes cognitive flexibility.

Title: Changes in cellular activity of different dentate gyrus cell types during acquisition of trace eyeblink conditioning in mice

Authors: *L. N. MILLER, C. WEISS, J. F. DISTERHOFT;
Northwestern Univ., Chicago, IL

Abstract: The dentate gyrus (DG) serves as the first site for information processing in the classical hippocampal trisynaptic circuit. This position makes it an important structure for the formation of associative memories. The DG contains two types of excitatory neurons: granule cells and mossy cells. While prior research has demonstrated that granule cells are necessary for memory formation, the functional role of mossy cells in learning has not been thoroughly explored. Additionally, previous work from our laboratory had found populations of cells within DG of rabbits that may bridge the temporal gap between stimuli to support memory formation during an associative learning task, trace eyeblink conditioning. However, the identity of the cells showing this type of activity is still unknown. Therefore, we utilized *in vivo* single-neuron recording in conjunction with histological and physiological determination of cell types to investigate the functional role of mossy cells and granule cells during learning. To do this, male and female young-adult mice were implanted with Neuralynx Halo-10-Mini Microdrives prior to being trained on trace eyeblink conditioning, a hippocampal-dependent temporal associative memory task, for a total of ten days. The conditioned group received 50 trials per day of paired stimuli, while the pseudoconditioned group, serving as the control group, received 100 trials per day of randomly presented unpaired stimuli. Animals in the pseudoconditioned group never reached learning criterion, while conditioned mice were able to successfully learn the task (>60% adaptive CRs). Male mice learned at a significantly faster rate than female mice. In conditioned mice, granule cells tended to show an increase in firing rate during either the conditioned stimulus or the unconditioned stimulus. On the other hand, mossy cells from conditioned animals had a tendency to show a decrease in firing rate during the trace interval and the unconditioned stimulus. Given the connections between the two cell types, this decrease in mossy cell activity should act to enhance granule cell firing through disinhibition. These results indicate a novel role for mossy cells in bridging the temporal gap during an associative learning task, and indicates that the DG is involved in learning that does not involve pattern separation. This work builds and expands upon our knowledge of DG function, which then improves our ability to discern how aging and disease might disrupt this process.

Title: Distinct Rhythmic Profiles of Neurons in the Dentate Gyrus During Associative Memory Processing

Authors: *C. R. HEYMAN, M. BORZELLO, P. D. RIVIERE, L. M. RANGEL;
Cognitive Sci., Univ. of California San Diego, La Jolla, CA

Abstract: As a region important for associative memory, the hippocampus receives a variety of converging inputs. These inputs, which are thought to convey sensory and visuospatial information, target neurons along each hippocampal subregion, including the dentate gyrus (DG). This subregion is thus poised to play a crucial role in associative memory processing. To evaluate this hypothesis, we investigated the engagement of DG neurons in rhythmic circuit activity during an associative memory task. Specifically, we examined single neuron and local field potential activity from the DG as rats performed a task in which pairs of odors were associated with the contexts in which they were rewarded. We found that several DG rhythms exhibited abrupt shifts in amplitude during key intervals in which rats were presented with odor cues. For instance, theta (5-10Hz) and high gamma (75-115Hz) amplitude decreased significantly during odor cue intervals preceding correct trials only. Additionally, during odor cue intervals, cells became entrained to one or more local rhythms in a manner that was predictive of associative memory task performance. These results differed across putative principal cells (i.e. granule and/or mossy cells) and putative interneuron populations. Specifically, during correct performance, most putative principal cells exhibited rhythmic entrainment to only one rhythm, while most putative interneurons exhibited entrainment to multiple rhythms. Putative principal cell firing rates did not change across trial outcomes, suggesting that their engagement in specific rhythmic circuits was more predictive of successful associative memory processing than their gross activity levels. A subset of putative interneurons exhibited significant differences in firing rate across trial outcomes, with increases in firing rate preceding incorrect (unrewarded) trials. However, these cells exhibited higher rhythmic engagement during correct (rewarded) trials and *not* incorrect trials, suggesting that rhythmic engagement coincides with successful performance despite lower firing rates in these trials. Overall, these results suggest that DG neurons engage in exquisitely timed and rhythmically coordinated interactions during successful associative memory processing.

Title: Synchronous activity patterns in the dentate gyrus during immobility

Authors: *M. POFAHL[1], N. NIKBAKHT[1], A. N. HAUBRICH[1], T. NGUYEN[1], N. MASALA[1], F. DISTLER[1], O. BRAGANZA[1], J. H. MACKE[2], L. A. EWELL[1], K. GOLCUK[1], H. W. BECK[1];

Abstract: The hippocampal dentate gyrus is an important relay conveying sensory information from the entorhinal cortex to the hippocampus proper. During exploration, the dentate gyrus has been proposed to act as a pattern separator. However, the dentate gyrus also shows structured activity during immobility and sleep. The properties of these activity patterns at cellular resolution, and their role in hippocampal-dependent memory processes have remained unclear. Using dual-color in-vivo two-photon Ca^{2+} imaging, we show that in immobile mice dentate granule cells generate sparse, synchronized activity patterns associated with entorhinal cortex activation. These population events are structured and modified by changes in the environment; and they incorporate place- and speed cells. Importantly, they are more similar than expected by chance to population patterns evoked during self-motion. Using optogenetic inhibition, we show that granule cell activity is not only required during exploration, but also during immobility in order to form dentate gyrus-dependent spatial memories.

Title: Novelty enhances granule cell double-spikes by disinhibition of recurrent excitation.

Authors: *W.-C. SHU[1,2], M. B. JACKSON[1];
[1]Neurosci., [2]Biophysics PhD program, Univ. of Wisconsin-Madison, Madison, WI

Abstract: As the principal cells of the dentate gyrus (DG), granule cells (GCs) play key roles in the filtering and processing of information as it enters the hippocampus. GCs exhibit distinct spatial-temporal firing patterns to encode, store, and recall features in the environment. In order to investigate how GCs contribute to information processing, we used a hybrid voltage sensor (hVoS) to image their electrical activity, and Cre driver mice to target the probe to GCs. In mature GCs targeted by transient Prox1-Cre activation in neonates, voltage imaging revealed that electrical stimulation of the perforant path activated

GCs, some of which responded with doublets, two spikes separated by an interval of 2-10 ms. The incidence of doublets increased with stimulus current. GCs in the suprapyramidal and infrapyramidal blades produce doublets with a similar frequency, which fell within the range of 16-22%. We performed pharmacological studies to investigate the balance between inhibition and excitation in doublet generation. Blockade of GABAergic transmission increased the incidence of doublets to 28-35%, and this increase was reversed by DCG-IV and WIN II. The action of DCG-IV and WIN II indicated that the recurrent excitation loop formed by GCs and hilar mossy cells (MCs) can contribute to the second spike of a doublet. However, GCs still generate doublets when recurrent excitation has been blocked, suggesting that intrinsic GC excitability also plays a role in generating the second spike. Imaging optical signals from GC dendritic trees suggested that the second spike of a doublet can be evoked by synaptic inputs. To investigate the impact of experience on doublets, we targeted the probe to GCs with a conditional Cre-driver coupled to the immediate early gene, c-fos, and placed animals in a novel environment. GCs activated by novelty exhibited a higher doublet incidence, and the interval became longer when $GABA_A$ receptors were blocked. Unlike doublets with a shorter interval (<6 ms), the long-interval doublets can be completely inhibited with DCG-IV and WIN II. The longer intervals modulated by recurrent excitation and inhibition may reflect a circuitry modification resulting from prior experience. In GCs from Prox1-Cre::hVoS mice exposed to a novel environment, the incidence of long-interval doublets was higher than in control Prox1 labeled GCs, but lower than in c-fos-Cre novelty-labeled GCs. The increase in the incidence of doublets following exposure to a novel environment suggests that doublets play a role in information storage.

Title: Post-learning sleep loss may block engram cell reactivation in the hippocampal dentate gyrus

Authors: *L. WANG[1], L. PARK[1], A. VEGA MEDINA[1], F. RAVEN[1], A. ENSING[1], S. J. ATON[2]; [2]Molecular, Cellular, and Developmental Biol., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Over a century of research suggests that sleep plays an important role in learning and memory consolidation. Studies have shown that hippocampus-mediated contextual fear memory (CFM) consolidation requires post-learning sleep. One possibility is that post-learning sleep benefits CFM by selectively reactivating engram neurons activated during fear learning. To study the effects of post-learning sleep on engram cells, we first labeled the engram cell populations in the hippocampal dentate gyrus (DG) that encode specific contexts. Using cFos-CreER mice, we find that engram populations activated during exploration of a specific environmental context can be reactivated during subsequent contextual fear conditioning (CFC) in the same context. Our preliminary data also suggests that post-CFC

sleep deprivation, which disrupts consolidation of CFM, may block the reactivation of engram neurons engaged during CFC in DG.

Title: Hilar mossy cell dopamine D2 receptors modulate spatial memory and anxiety-like behavior in mice

Authors: *M. GULFO[1], P. E. CASTILLO[1,2];
[1]Dominick P. Purpura Dept. of Neurosci., [2]Dept. of Psychiatry and Behavioral Sci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Expression from the dopamine D2 receptor (D2R) promoter is a hallmark feature of dentate gyrus hilar mossy cells (MCs), but the physiologic function of the MC D2R is unknown. MCs are uniquely positioned to shape dentate gyrus function and have been implicated in learning and mood disorders, but the mechanisms underlying their involvement are not well-understood. D2R signaling could modulate key aspects of MC function. To address this possibility, we assessed potential behavioral impacts of genetic MC D2R removal. We injected 3- to 4-month-old male and female floxed-Drd2 mice with AAV5-CaMKII-mCherry-Cre or AAV5-CaMKII-mCherry to generate MC D2R conditional knockout (cKO) and control mice, respectively, for behavioral testing. Results thus far indicate that conditionally knocking out D2Rs from MCs increases anxiety-like behavior and impairs spatial and contextual fear memory, with trends clearest in male mice. Specifically, relative to control mice, cKO mice displayed decreased center duration in the open field test and decreased open arm time in the elevated plus maze. In addition, while neither control nor cKO mice exhibited a deficit in the novel object recognition task, cKO mice exhibited a deficit in the novel object location task relative to control mice. Finally, control but not cKO mice were able to discriminate between safe and aversive contexts in a contextual fear learning assay. We are currently assessing the cellular mechanisms underlying the observed behavioral effects. Better understanding the MC D2R can help clarify mechanisms of MC function in normal physiology and disease states.

Title: Cognitive dysfunction induced by chronic chemogenetic inhibition of somatostatin-positive interneurons in the dentate gyrus hilus

Authors: *J. LYU[1,2], R. NAGARAJAN[2], M. KAMBALI[2], M. WANG[1,2], U. RUDOLPH[2,1];
[1]Neurosci., [2]Comparative Biosci., Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: The cellular mechanisms leading to cognitive dysfunction in the elderly are not completely understood. In aged rodents, hyperactivity of DG granule cells and CA3 pyramidal cells and hypoactivity of CA1 pyramidal cells have been reported, and a reduction of somatostatin positive (Sst+) interneurons in the dentate gyrus (DG) hilus correlates with cognitive dysfunction. We wanted to test the hypothesis that chronic but not acute suppression of the activity of hilar Sst+ interneuron causes defined learning and memory deficits. An AAV vector expressing hM4D(Gi) was stereotaxically injected bilaterally into the DG hilus of Sst-Cre mice. The control groups were injected with an AAV vector lacking hM4D(Gi). Clozapine was administered to the mice to activate hM4D(Gi) and thus inhibit hilar Sst+ interneurons. The chronic treatment group received clozapine (0.1mg/kg/day) in the drinking water for 21 days before the first behavioral experiment and throughout testing and the acute treatment group was administered clozapine (0.1mg/kg i.p.) 30 minutes before behavioral experiments. We found that both chronic and acute chemogenetic inhibition (CCI and ACI, respectively) of Sst+ DG hilar interneurons increased the number of c-Fos+ neurons only in the DG hilus, but neither in the DG granule cell layer nor in CA3 or CA1. In contrast, SST expression was decreased after CCI but not after ACI. Likewise, compared to ACI, CCI resulted in a decreased recognition index in the novel object recognition test, and an increased path length and increased latency to find the hidden platform in the water maze, both for learning and reversal learning. Our data suggest a causal relationship between a chronic loss of activity of Sst+ interneurons in the DG hilus region and cognitive dysfunction. Furthermore, our results indicate that chronic suppression of the activity of hilar Sst+ interneurons leads to a reduction of SST expression, which has been observed in aging cognitive dysfunctional rodents. CCI but not ACI thus mimics at least some molecular and behavioral features of aging, which itself is a long-lasting process. CCI of DG hilar Sst+ interneurons may thus be further evaluated as an experimental model of aging-related processes in the hippocampus.

Title: Selective loss of early growth response-3 expression in adult dentate gyrus attenuates learning performance in male and female mice

Authors: *U. SASAKI[1], H. HAGIWARA[2], M. FURUTA[2], Y. OGURA[2], T. FUNABASHI[2];
[2]Physiol., [1]St. Marianna Univ. Sch. of Med., Kawasaki, Japan

Abstract: Early growth response-3 (EGR3) is a transcription factor and is a member of a family of immediate-early growth response genes. It is suggested to be involved not only for regulation of genes associated with autoimmunity (Morita et al, 2016) but also for learning process (Gallitano et al, 2007; Meyers et al, 2018). In fact, the expression of EGR3 is found to be in the brain area related to memory such as the hippocampus (Crosby et al, 1992; Yamagata et al, 1994). Since EGR3 may affect brain development process, we tried to knockdown EGR3 during adult age as a site specific manner. To this end, we used Cre-Lox P system: hippocampus-specific EGR3 inactivation by adeno-associated virus (AAV) delivery of Cre recombinase. Male and female EGR3 floxed mice were injected AAV Cre-GFP into the dentate gyrus. Control mice received the injection of AAV GFP without Cre. Three weeks after the injection, mice were subjected to open field test and Y maze task. After the behavioral examinations, all mice were examined the immunocytochemistry using antibody to EGR3. AAV expression was examined by fluorescence microscopy. We revealed that Cre expression by AAV completely eliminated EGR3-immunoreactivity in the injected site. We confirmed that this was not because of cell loss since immunohistochemical staining of neuron-specific enolase was evident in AAV injected site. When mice confirmed AAV injection by fluorescence, we counted the number of EGR3-immunoreactive cells in the dentate gyrus. AAV-mediated Cre-GFP transfer into the dentate gyrus significantly decreased the number of EGR3-expressed cells in EGR3-floxed mice (approximately 50% reduction) compared to AAV-GFP injected mice, regardless of sex. In the open field test, the total distance and the spent time in the center in AAV Cre-GFP injected mice were not significantly different from those in AAV GFP injected mice, regardless of sex. However, in the Y maze test, the alternation score in AAV Cre-GFP injected EGR3 floxed mice was significantly decreased compared with AAV GFP injected mice, regardless of sex. In AAV Cre-GFP injected mice, however, the number of EGR3-immunoreactive cells loss was not clearly correlated with the degree of the impairment Y maze ability. We conclude that the attenuation of EGR3 expression in the dentate gyrus during adult is associated with learning disability but the number of EGR3 cells in the hippocampus is not simply correlated with memory function.

Title: Sparse versus dense coding of very large environments in hippocampal subregions CA3 and CA1

Authors: *S. R. MAIMON, T. ELIAV, L. LAS, N. ULANOVSKY;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: The hippocampus is differentiated into distinct subregions, including areas CA1 and CA3, which differ markedly in their extrinsic and intrinsic anatomical connectivity. CA1 is largely a feedforward network with almost no intrinsic excitatory connections, whereas CA3 is a recurrent network of densely interconnected pyramidal neurons - which also projects to CA1. While the anatomical connectivity differs substantially between these two subregions, the basic firing properties of spatially-modulated place cells in CA1 and CA3 were found by previous studies to be surprisingly similar, consisting mainly of single place-fields with similar field-sizes and spatial information. We hypothesized here that perhaps the similar coding properties reported for CA1 and CA3 neurons stem from the small laboratory environment sizes that were used - and that perhaps under more naturalistic spatial scales of hundreds of meters or kilometers the coding schemes of these two areas might differ. Recently (Eliav*, Maimon* *et al*., *Science* 2021) we showed that CA1 place cells recorded in bats flying in a 200-meter long tunnel, exhibit multiple place fields with very different field-sizes for different fields. This multifield multiscale spatial code is fundamentally different from the single fields observed in small laboratory boxes. Here we compared these findings from CA1 to place cells in CA3 that we recorded in bats flying in the same long tunnel. Preliminary analyses showed a dramatic difference between these two subregions: Unlike CA1 place-cells, CA3 place-cells mostly had only single place-fields; however, the sizes of individual place-fields were similar between the two areas. Consequently, the spatial information was significantly higher for place-cells in CA3 versus CA1. These preliminary results suggest a fundamental functional difference in neural-coding between these two anatomical subregions of the hippocampus: Sparse coding in CA3 versus dense coding in CA1.

Title: Natural switches in behavior rapidly modulate hippocampal position × distance coding

Authors: A. SAREL[1], ***S. PALGI**[1], D. BLUM[1], J. ALJADEFF[2], L. LAS[1], N. ULANOVSKY[1];
[1]Dept. of Neurobio., Weizmann Inst. of Sci., Rehovot, Israel; [2]Section of Neurobiology, Div. of Biol. Sci., Univ. of California, San Diego, CA

Abstract: In the real world, both humans and animals dynamically and rapidly switch between different behaviors. However, neuroscience research typically studies the brain while the animal is performing *one* behavioral task at a time - and little is known about how brain circuits rapidly switch between different

natural behaviors. Navigation is a complex dynamic behavior that enables testing these kinds of behavioral switches: It requires the animal to know its own location within the environment, while also paying attention to incoming sudden events such as obstacles, predators or conspecifics. Here we set out to test how brief attentional switches to 'things out there' affect the representation of space in the hippocampus. To this end, pairs of bats flew in a 135-meter flight tunnel, alternating between flying alone and flying towards each other ('cross-over' events). During cross-overs, bats had to be attentive to the other bat in order to avoid collision. Indeed, bats increased their echolocation call rate and amplitude ~20 meters before the moment of cross-over, indicating that the bats were attentive during these events. We recorded the neural activity in hippocampal area CA1 and tracked the positions of the bats using wireless-electrophysiology and custom tracking devices. We found that during cross-overs, many CA1 neurons encoded the distance to the other bat: The neurons switched from allocentric coding (place tuning) to a conjunctive egocentric × allocentric coding (inter-bat distance × place tuning) - and then switched back to allocentric coding after the bats passed each other. These neuronal switches were very rapid, as fast as 100 ms. This switching was correlated on a trial-by-trial basis with the attention signal, as indexed by the bat's echolocation calls - suggesting that spatial attention and active-sensing are controlling these major switches in neural coding. Interestingly, we found that in place-cells, the different place-fields of the same neuron often exhibited very different tuning to inter-bat distance - creating a non-separable coding of allocentric position × egocentric distance. Theoretical analysis demonstrated that such a non-separable code leads to better decoding of distance. Together, our results suggest that attentional switches during navigation - which in bats can be measured directly by their echolocation signals - elicit very rapid dynamics of hippocampal spatial coding. More broadly, this study demonstrates that during natural behavior, neural circuits can rapidly and flexibly multiplex several computations, representing the relevant behavioral variables - to support behavioral flexibility.

Title: Object × position coding in the deep layers of the MEC in flying bats

Authors: *G. GINOSAR, L. LAS, N. ULANOVSKY;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: A spatial environment is composed of its geometric layout, and the objects within it. These two classes of information - spatial geometric information on one hand, and information about objects on the other hand - have been shown to be coded in the medial entorhinal cortex (MEC) and lateral entorhinal cortex (LEC). Some neurons, like grid cells in MEC, encode positional information about the environment. Other neurons, like object-vector cells in the superficial layers of MEC and object-cells and trace-cells in the LEC, encode the presence of objects in the environment regardless of their location.

However, while the position of specific objects is important for navigation, little is known on how this intersection is encoded in the brain. Here we recorded from the medial entorhinal cortex of flying bats as they foraged for food in a 6×5×3 meter room, in which 6-11 landing-objects were placed at various heights. We found that a substantial fraction of cells in deep layers of the MEC fired at the vicinity of specific landing-objects at specific locations. These cells fired near the landing-object when the bat flew from or to the object, but not when it flew through the same location without engaging with the object. While most of these neurons coded for a single object in a single position, some coded for 2 or more objects. We speculate that these cells in the deep layers of the MEC combine object-vector information from the superficial layers of the MEC, which is then being spatially-modulated by hippocampal position-coding via the MEC-hippocampus-MEC loop that anatomically projects to the deep layers of MEC - and possibly together with object information coming from the LEC - to create a unique object × position coding in the deep layers of MEC.

Abstract: Astrocytic calcium dynamics are involved in encoding of sensory information, and modulating them has been shown to impact behavior. Recent studies have implicated hippocampal astrocytes in memory processes, but their real-time calcium activity in awake mice has never been investigated. To this end, we chronically calcium imaged CA1 astrocytes using 2-photon microscopy when mice performed a spatial task. Specifically, we trained mice to run on a linear treadmill in order to proceed in a virtual environment and obtain water rewards. We find that astrocytic activity persistently ramps towards the reward location in a familiar environment, but not in a novel one. Using linear decoders, we accurately reconstructed mice location trajectories in a familiar environment from astrocyte activity alone. We could not do the same in the novel environment, suggesting that the spatial modulation of astrocytic activity is experience dependent. This is the first indication that astrocytes can encode location in spatial contexts, thus broadening their known computational abilities, and their role in cognitive functions.

Title: In search of neuronal replay sequences in the hippocampus of bats in a very large environment (200 meters)

Authors: *T. ELIAV, S. R. MAIMON, L. LAS, N. ULANOVSKY;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: In rodents, ensembles of hippocampal place-cells exhibit offline reactivations of neuronal sequences (termed replay) during rest and sleep - depicting sequences of experienced trajectories that occurred during movement. Recently, we found a multifield multiscale representation in the hippocampus of bats flying in a very large 200-meter tunnel (Eliav et al., Science 2021): Individual neurons exhibited multiple place-fields of diverse sizes, ranging from less than 1 meter to more than 30 meters, and the fields of the same neuron could differ up to 20-fold in size. This unexpected coding scheme opened intriguing questions regarding replay sequences in large naturalistic environments: Are there ultra-long compressed replay sequences during rest and sleep, as observed in rodents - but extending over dozens or hundreds of meters? Do individual replay sequences cover the entire environment or just parts of it, and in particular important locations? And how is the multifield multiscale representation manifested in such replay sequences - where each neuron could participate multiple times in each sequence, each time at a different location and with a different spatial scale? To investigate this, we applied here a clusterless state-space model (Denovellis et al., bioRxiv 2021) to decode sequential reactivations when bats were resting or sleeping in the 200-meter long tunnel. We then tested the spiking activity of single place-cells with respect to the decoded sequences. Here, we will present preliminary results from our analysis.

Title: Hippocampal representations during natural social behaviors in a bat colony

Authors: *S. RAY, I. YONA, L. LAS, N. ULANOVSKY;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Highly-social animals, like humans, live in complex communities and interact with different individuals at times, locations and manner of their choosing. However, neurophysiological investigation of social responses is rarely conducted in rich settings that allows such affordances. To determine how the brain represents social information in a naturalistic setting, we constructed a bat cave for a colony of 5-10 Egyptian fruit bats of both sexes. The bats lived there 24x7, free to engage in any behaviors. Every day we conducted a ~3 hour recording session, which included tracking the bat's identities, their 3D positions and their social interactions using cameras and an RF-based positioning system, while performing wireless single-unit neural recordings from their hippocampus. Behavioral data analysis indicated that the session could be deconstructed into three distinct and interleaved phases: (1) Flight phase - bats were flying in the room, (2) Interaction phase - bats were engaged in social interactions, and (3) Observation phase - bats were in their roosts, observing other bats. Here we investigated how hippocampal CA1 neurons represent information when the animals' behavior is not experimentally constrained to a particular task. Preliminary results indicate that in the flight phase, the place-tuning of a subset of neurons was modulated by the presence or absence of conspecifics at take-off or landing locations. In the interaction phase, we identified and delineated several types of social interactions and found - (i) neurons responsive to a specific interaction type regardless of the identity of the conspecific, and (ii) neurons selective for both interaction type and individual identity. In the observation phase, while the bats were in the roost observing each other, we reasoned that the neurons could potentially represent multiple factors, which can be broadly categorized into three groups: (a) self-position or head direction, (b) allocentric locations of other bats, or (c) egocentric information about other bats. To glean a systematic understanding of the contribution of these factors to the neural representation, we utilized generalized additive models (GAM). Preliminary findings indicate that single neurons merge several streams of information, and simultaneously represent multiple factors - often combining factors related to self and others. Taken together, these findings suggests that dorsal CA1 neurons represent complex social and spatial information across multiple behavioral phases.

Title: Representation of 3D space in the hippocampus of freely moving marmosets

Authors: *D. B. PIZA[1], B. W. CORRIGAN[2], R. A. GULLI[3], L. E. MULLER[1], J. C. MARTINEZ-TRUJILLO[4];

[3]Zuckerman Inst., Columbia Univ., New York, NY; [4]Dept. of Physiol. and Pharmacol. and Psychiatry, Brain and Mind Institute, Univ. of Western On, London, ON, Canada

Abstract: The role of the hippocampus in representing space is widely supported. Neurons that increase their firing rate when an animal occupies a certain region, 'Place Cells,' have been thoroughly identified and studied in multiple species. This unique population of neurons has been thought to support a cognitive-map like representation of space in the brain; however, little is known about how these representations are formed in the common marmoset during free navigation in a 3D environment. Moreover, whether these representations are modulated by spatial view or movement kinematic has yet to be determined. In this work, we sought to identify the firing properties of neurons in the CA fields of the hippocampus while we register spatial and view information of freely navigating marmosets as they engage in a variety of foraging behaviors in 3D space. For this purpose, we habituated the experimental subjects to freely move inside a plexiglass recording chamber with four vertical levels while wearing affixed infrared reflective markers on top of skull implants that allowed for 6 degrees of freedom position and head direction camera tracking (Optitrack, Natural Point Inc, USA). Using MRI-guided neuro-navigation techniques, we chronically implanted 32ch microwire arrays in the hippocampus, and we were able to record single-unit activity during the aforementioned behaviors wirelessly. We analyzed data from 2 animals; spatial view and occupancy rate maps were constructed using 20cm3 bins. Spatial Information Content (SIC) was calculated independently for place and view for 200 total cells. SIC was higher for the spatial view than body position. We also found cells whose firing rate was highly correlated for both body velocity and head angular velocity.

Title: Independent influences of place and view in the hippocampus of the non-human primate

Authors: H. TAN[1], T. P. Y. NG[1], C. OWENS[1], C. LIBEDINSKY[1,2], S.-C. YEN[1,3];
[1]The N.1 Inst. for Hlth., [2]Dept. of Psychology, [3]Innovation and Design Programme, Fac. of Engin., Natl. Univ. of Singapore, Singapore, Singapore

Abstract: The hippocampus and surrounding regions of the hippocampal formation are critical for spatial memory in multiple mammalian species. On a single-cell level in the rodent, pure selectivity for location (place cells) is most prevalent in the hippocampus proper, with some mixed selectivity for two or more spatial variables (e.g. conjunctive grid and head direction cells) in the surrounding areas. In the non-

human primate (NHP) hippocampus, however, evidence for pure place selectivity is scarce (Courellis et al., 2019; but see Rolls et al., 1999) with some studies finding greater proportions of mixed selectivity with spatial variables like location of gaze in space (Wirth et al., 2017; Mao et al., 2020). This may be true of the primate hippocampus, or be due to artifacts arising from linear track experiments where location and heading were confounded. To rule out the latter, we recorded hippocampal activity from a male NHP in a virtual navigation task where the directions of motion and view were not constrained by location, and employed a maximum likelihood approach (Burgess et al., 2005) to dissociate the independent contributions of spatial variables to cell firing rates. We recorded from 364 putative hippocampal neurons. Prior to accounting for independent influences of place and view, 68 cells emerged as selective, made up of 38 cells jointly selective for place and view, 20 selective exclusively for place, and 10 exclusively selective for view. After correcting for the influence of place on view and vice versa, the number of selective cells increased to 88, with 44 jointly selective for place and view, 12 exclusively selective for place, and 32 exclusively selective for view. Mixed selectivity remained the most prevalent mode of selectivity after isolating independent contributions of either spatial variable, suggesting that it could be a true property of the primate hippocampus.

Title: Sensory Conflicts Induce Graded Remapping in Hippocampal Ensembles

Authors: *D. FETTERHOFF, A. SOBOLEV, C. LEIBOLD;
Dept. Biol. II, Ludwig-Maximilians-Universitat Munchen, Munchen, Germany

Abstract: An animal's spatial location in an environment can be inferred from multiple simultaneously available sources including allothetic (e.g. visual landmarks) and idiothetic (multisensory self-motion) cues. Which cues an animal preferentially utilizes to estimate its location may depend on task demands, experience, and idiosyncrasies and should be reflected in the hippocampal population activity. We recorded from CA1 place cells while Mongolian gerbils were navigating one-dimensional mazes in virtual reality, in which we introduced conflicts between task-irrelevant visual cues and reward-related movement patterns (turning direction). By introducing this conflict, we found that self-motion (turn type) was strongly over-represented, but responsiveness to visual cues, although task-irrelevant, elicited both rate and global remapping in both single cells and the recorded hippocampal ensemble. We propose that these types of remapping can be reconciled by considering global, partial, and rate remapping on a continuous scale on which the graded change of activity in the entire CA1 population can be interpreted as the expectancy of the animal about its spatial environment. This hypothesis is further supported by successful decoding of maze type in situations with identical sensory input.

Title: The macroevolution of the mammalian hippocampus

Authors: *D. VANIER[1], P. MANGER[3], J. SMAERS[2];
[2]Anthrop., [1]Stony Brook Univ., Stony Brook, NY; [3]Anat., Univ. of the Witwatersrand, Johannesburg, South Africa

Abstract: Intro The evolution of map-like neural representations constituted a sea change in cognition which greatly enhanced navigation in early vertebrates. Over deep evolutionary time, the brain region supporting navigational representations, the hippocampus (HP), became pivotal to a host of cognitive processes ranging from declarative memory to divergent creativity. Characterizing the macroevolution of HP could reveal neuroanatomical changes that enable high-level HP-dependent abilities, including those possibly unique to humans. Here we model the evolution of the mammalian HP relative to brain and neocortex size across 435 species from 21 orders.
Methods A bivariate Bayesian evolutionary model was used to estimate where shifts in slope (covariance) and intercept (mean) of HP/brain occurred in the mammalian tree. Volumetric data from the literature and the genetic relatedness of species were used as input for the model. To confirm whether certain groups of species statistically differed in mean HP/brain (as predicted by the model), a phylogenetic least squares ANOVA was used. To determine if changes in mean HP/brain were driven by changes in HP or brain size, phylogenetic means for both traits were calculated using least-squares procedures to generate an ancestral to descendent ratio of change in mean size.
Results 12 shifts in the HP/brain scaling relationship resulted in 13 groups of species with distinct slopes or intercepts ($F=20.26$, $p<0.001$). Monkeys and apes ($b=0.70$), ferungulates ($b=0.66$), and fruit bats ($b=0.79$) indicate a decrease in slope of HP/brain as compared to their ancestral conditions ($b=0.90$, $b=0.89$, $b=0.93$, respectively). Other groups indicate negative (cetaceans, seals, manatees, elephants, other primates, other bats) or, rarely, positive (plains zebras, tapirs, elephant shrews) shifts in intercept alone.
Discussion Mammals with large brains, including those thought to possess exceptional memories such as great apes, exhibit decreases in HP relative to the brain which were driven by large changes in mean brain (neocortex). These evolutionary shifts imply fundamental changes to the developmental, genetic, and functional interactions of HP and the neocortex. In large-brained mammals, it thus seems likely that the emergence and expansion of neocortical association areas, and their interactions with HP, led to higher-level HP-dependent cognition. Different association areas, however, evolved via accretion in different lineages, and many human association areas only emerged in monkeys and apes. This suggests that, despite the conserved cytoarchitecture of HP, different mammals possess qualitatively different types of memory.

Title: Long-range frontal theta phase modulation during cognitive planning

Authors: *M. DOMIC[1], M. IRANI[2], V. MEDEL[2], T. OSSANDÓN[2], *M. PERRONE-BERTOLOTTI[3]; [1]Univ. Católica del Norte, Antofagasta, Chile; [2]Pontificia Univ. Católica de Chile, Santiago, Chile; [3]Univ. Grenoble Alpes, Grenoble, France

Abstract: Cognitive planning (CP), the ability to develop a sequenced plan to achieve a goal, plays a crucial role in human goal-directed behavior. It has been suggested that cognitive control might result from frequency-specific interactions of specialized and widely distributed cortical regions due to the enriched rhythmic structure nature of the brain. We have previously demonstrated that CP induces a significant increase in the frontal midline theta (FMθ) power. It is suggested that the FMθ could interact with distant brain regions by modifying their local power amplitude in specific alpha and beta bands. Here, we specifically evaluated this using a phase to phase (weighted Phase Lag Index, wPLI) and phase-amplitude coupling approach. Our results show a robust increase in theta phase (4-8 Hz) connectivity during planning between frontal and widely distributed electrode sites. Additionally, we found that this frontal theta phase modulates frontal alpha amplitude (9-12 Hz) and frontal, central, and parietal low beta amplitude (13-20 Hz). These results support the idea that cognitive control implementation in the brain is performed via theta phase connectivity, which coordinates information processing (such as visuospatial analysis and motor control preparation). The prefrontal cortex performs this long-range coordination over disparate brain regions, modulating local alpha and beta amplitude.

Title: Distinct, adjacent networks for place memory and scene perception in the human brain

Authors: *A. STEEL, B. D. GARCIA, A. MYNICK, Y. B. CHOI, C. E. ROBERTSON;
Psychology and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: How do visual and spatio-mnemonic systems interface during naturalistic scene perception? The reinstatement account posits that the same areas that perceive a stimulus are recruited during memory retrieval. Alternatively, in the context of scenes, recent studies suggest a transition from perception to memory moving anteriorly from the brain's scene perception areas. Here, we explicitly tested the reinstatement vs. anterior shift accounts of place memory using a combination of VR and fMRI. In Experiment 1 (N=14), we independently localized the three scene perception areas (parahippocampal place area, occipital place area, and medial place area/RSC) by comparing activation when participants saw images of scenes and faces. Then, in the same individuals, we localized areas that preferentially activated when participants recalled personally familiar real-world places (e.g., their house) versus faces (e.g., their mother). Remarkably, recall activity for personally familiar places was shifted anterior from, rather than co-localized with, category-selective scene perception areas in the brain (all $p<0.001$; Steel et al., 2021). To determine whether this anterior shift reflected the spatial aspects of memory and not episodic or semantic features, in Experiment 2 participants (N=11) studied 20 real-world places using head-mounted VR. VR affords exquisite stimulus control, enabling us to isolate the spatial component of memories. After training, we scanned participants during an explicit recall task and a passive perception task of the studied places. Here again, recall-related activity of learned VR environments was shifted anterior from the scene perception areas on all cortical surfaces. Moreover, the place memory areas were strongly recruited during recall and perception of VR environments, while the scene perception areas were not (all $p>0.001$). Finally, multivariate decoding analyses revealed robust representations of individual places in the place memory areas (all $p>0.01$). These findings validate the anterior shift account of place memory in contrast to reinstatement accounts. Moreover, they provide insight into the neural basis of visuospatial memory for naturalistic environments and, more broadly, the mechanisms by which stored knowledge about the world influences ongoing perception during naturalistic visual experience.

Title: Discrete scene snapshots prime perception of 360° space in immersive real-world scenes

Authors: *A. MYNICK, C. E. ROBERTSON, T. L. BOTCH, A. L. BURROWS, B. D. GARCIA; Dartmouth Col., Hanover, NH

Abstract: We experience our visual environment in discrete glances. How do we build a unified representation of a 360º visual environment? One possibility is that neighboring scene views become associated through concurrent activation during learning, enabling a single view to prompt reactivation of the surrounding environment. In this two-part study, we used Virtual Reality (VR) to ask whether a single view in an immersive panorama primes perceptual judgements of adjacent views in 360º space, and whether that priming is yoked to the spatial structure of a scene.
To examine whether a single view primes perceptual judgements of adjacent views in 360º space, subjects in Experiment 1 (N=21) learned 18 real-world panoramas using head-mounted VR. In a subsequent Priming Test, on each trial, subjects turned their head left or right to view a target image taken from a studied panorama (110º field-of-view), and made a perceptual (open/closed) judgement. Before target onset, a brief (300ms) prime image was presented directly ahead, either depicting: 1) an adjacent snapshot from the same panorama (Valid prime), 2) a snapshot from a different panorama (Different Scene prime), or 3) a grey box (Neutral prime).
We found an effect of priming condition on reaction time ($p<.001$): subjects made faster open/closed judgements when primed with an image from the same panorama (Valid prime condition) compared to Neutral ($p<.05$) and Different Scene primes ($p<.001$).
To examine whether perceptual priming is yoked to the 360º structure of a scene, subjects in Experiment 2 (N=21) performed a Priming Test with Valid, Neutral, and Spatially Incoherent primes. Spatially Incoherent primes were taken from the same panorama as the target, but targets were presented opposite their true location relative to the prime.
We found an effect of priming condition on reaction time ($p<.001$): subjects made faster open/closed judgements when primed with an image from the same panorama (Valid prime condition) compared to Neutral ($p<.001$) and Spatially Incoherent primes ($p<.001$).
To ensure spatial knowledge of the panoramas, all subjects completed an Explicit Memory Test, where on each trial they reported whether a snapshot had appeared on the left/right/front of a studied panorama. Performance was above chance ($p<.001$ in Experiments 1 and 2), indicating accurate spatial knowledge.
Taken together, we show that discrete views of a panorama prime each other in 360º space, and that priming is yoked to the spatial structure of a scene. These results suggest that reinstatement of unseen, adjacent views may play an important role in facilitating ongoing perception and maintaining a seamless sense of our 360º visual environment.

Title: A cortical network representing visuospatial context in posterior cerebral cortex

Authors: *B. D. GARCIA, A. STEEL, K. GOYAL, A. MYNICK, Y. B. CHOI, C. E. ROBERTSON; Psychological & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: How does the brain represent knowledge of the local visuospatial environment during naturalistic scene perception? Here, using controlled, naturalistic stimuli learned in head-mounted VR, we investigated where in the brain surrounding visuospatial context associated with a real-world scene is represented. We hypothesized that the place memory network, a set of cortical brain areas adjacent and anterior to the scene perception areas, would play a preferential role in representing visuospatial context. Participants (N=11) studied 20 real-world scenes using VR with varying spatial context. The Image Condition consisted of 45° of a panoramic environment (315° occluded). The Panorama Condition consisted of 270° of a panorama. Finally, the Street Condition consisted of a navigable environment made up of contiguous panoramas. Using fMRI, we examined neural responses when participants recalled (Exp. 1) and perceived discrete fields of view from each scene (Exp. 2). We first isolated neural regions that were selective for place memory and scene perception as described in Steel et al., 2021, and we assessed the relative sensitivity of these "place memory areas" and "scene perception areas" to the degree of spatial context associated with a scene during recall and perception. As predicted, all three of the place memory areas showed significant modulation by spatial context during both recall and perception (all $p>0.001$), with greater spatial context eliciting more activity in these areas. In contrast, spatial context did not modulate activity in the scene perception areas during recall (all $p>0.6$) or perception (all $p>0.4$). Intriguingly, spatial context did not impact hippocampal activity. Importantly, activity in control areas (V1 and FFA) was not impacted by spatial context (all $p>0.05$). Together, these results show that a specific cortical network represents spatial context in the brain and suggest that hippocampal responses may not reflect the spatial scale of an environment. This finding provides an important step towards articulating the neural structures underlying memory of navigable space.

Title: Representational changes in the ventromedial prefrontal cortex during memory integration

Authors: *W. KANG[1], S.-H. LEE[1,2];
[1]Dept. of Bio and Brain Engineering, Col. of Engin., [2]Program of Brain and Cognitive Engineering, Col. of Engin., Korea Advanced Inst. of Sci. and Technol. (KAIST), Daejeon, Korea, Republic of

Abstract: Memory integration, a process of interconnecting related memories, is a basis of our adaptive behaviors. Prior memory studies have shown that the ventromedial prefrontal cortex (vmPFC) is engaged

in memory integration. However, it remains unclear how original memory traces change during the integration of new information into previous memory. Here we performed an event-related functional magnetic resonance imaging (fMRI) experiment to investigate the neural mechanism underlying memory integration. In the experiment, participants were asked to conduct two-phase learning and retrieval sessions. During the first phase of the learning session, they learned the first set of object pairs. After the first phase, they learned the second set of object pairs (second phase), which partially overlapped with the first set of object pairs. Using trial-by-trial similarity analyses, we found that the degree of shared representations for the first set of pairs in the vmPFC gradually decreased while that for the second set of pairs gradually increased during the second learning phase. Moreover, there was also a gradual increase in the degree of shared representations for the indirect association in the vmPFC. These results suggest that memory integration involves reorganizing related memory traces, including both existing and new memory traces in the vmPFC.

Title: The Dual Mechanisms of Cognitive Control (DMCC) Project: A neuroimaging study of individual variation in cognitive control function

Authors: *T. S. BRAVER[1], A. KIZHNER[2], R. TANG[2], M. C. FREUND[2], M. F. SINGH[2], J. A. ETZEL[3]; [1]Washington Univ. in St. Louis, Saint Louis, MO; [2]Psychological and Brain Sci., Washington Univ., St. Louis, MO; [3]Psychological and Brain Sci., Washington Univ., St.Louis, MO

Abstract: The Dual Mechanisms of Cognitive Control (DMCC) project provides a rigorous experimental test of a theoretical framework positing two key modes of control - proactive and reactive - that may reflect domain-general dimensions of individual variation). This framework is currently being evaluated through an on-going, larger-scale fMRI neuroimaging study (target N=200), that features a multi-session imaging protocol, composed of a novel cognitive control task fMRI battery, plus a comprehensive, out-of-scanner individual differences assessment. Study participants include both healthy young adults recruited from the Human Connectome Project, as well as monozygotic twin pairs. Participants are tested in a longitudinal design; each assessment wave includes 3 fMRI scanning sessions. In each fMRI session, 4 theoretically-optimized variants of well-established cognitive control paradigms are performed (plus resting-state scans): AX-CPT, Stroop, Cued Task-Switching, and Sternberg Working Memory. In the first session, tasks are performed under low-control Baseline conditions; the other two sessions task conditions encourage Proactive or Reactive control (counter-balanced order). Task fMRI scans follow a mixed blocked/event-related design, enabling estimates of both sustained and transient neural activity dynamics. A whole-brain ROI approach was used for analyses, relying upon well-established cortical parcellation

schemes. Additional analytic approaches, reported elsewhere, examined whole-brain neural modeling as a preprocessing step to filter intrinsic brain activity dynamics, multivariate pattern analyses to identify cognitive control neural coding, and neural fingerprinting approaches to assess twin similarity and test-retest reliability. Initial results based on 80 participants identified a neural signature of cognitive control involving parcels, involving the fronto-parietal and cingulo-opercular networks, that was domain-general (consistent across all four tasks), and also modulated in distinct fashion by the reactive and proactive conditions. A clear brain-behavior relationship was also observed, particularly in the reactive condition, such that individuals showing more efficient neural activity patterns also exhibited the strongest reactive-related enhancement of cognitive control function. The DMCC project is being conducted according to Open Science principles, so that data will be of maximal value to the scientific community. A subset of DMCC data is currently available at OpenNeuro (https://openneuro.org/datasets/ds003465); the full dataset will be made publicly available at project completion.

Title: Predictors and mechanisms of neurostimulation effects on cognitive control in aging.

Authors: *K. JONES[1], E. L. JOHNSON[2], A. GAZZALEY[3], T. ZANTO[1];
[1]Neurol., Univ. of California, San Francisco, San Francisco, CA; [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [3]Neurol & Physiol, Adam Gazzaley, San Francisco, CA

Abstract: Background: Noninvasive transcranial electrical stimulation (tES) research is plagued with inconsistencies. Recent work suggests that neuroanatomical and neurophysiological variability alter tES efficacy. However, direct evidence is limited. Furthermore, the structural and functional mechanisms underpinning how tES affects learning remain poorly understood. **Objective**: We previously replicated effects of theta transcranial alternating current stimulation (tACS) on improving cognitive control in young adults. Here, we assess whether the same stimulation parameters have comparable effects in older adults (aged 60-80 years), a population known to have greater variability in neuroanatomy and neurophysiology. We hypothesized that variability in neuroanatomy and neurophysiology would predict tACS efficacy. We further sought to identify underlying mechanisms of behavioral gains through measuring EEG connectivity changes and the structural integrity of specific white matter tracts. **Methods**: tACS was applied to prefrontal cortex (F3-F4) while participants engaged in a gamified multitasking

intervention. Participants received either 6-Hz (theta) or 1-Hz (delta) tACS on three consecutive days (Tuesday-Thursday). To account for neuroanatomy, MRI data were used to form individualized models of the tACS-induced electric field (EF) in the brain. To account for neurophysiology, EEG data were used to identify individual peak theta frequency. Functional connectivity was assessed by measuring changes in phase-locking values (PLV) from the tACS-free baseline (Monday) at each tACS session and the one-day follow-up (Friday). Structural connectivity was measured used diffusion tensor imaging (DTI) collected at baseline. **Results**: In the theta tACS group, performance gains correlated with modeled EF and peak theta frequency. Together, these measures accounted for 54-65% of variance in performance gains, which were sustained for a month. Furthermore, performance gains were associated with a double dissociation in daily PLV changes, with theta tACS driving broadband (theta-beta) increases in PLV and delta tACS leading to reductions in PLV. The structural integrity of white matter tracks further predicted daily PLV changes, with maximal effects in inferior longitudinal and fronto-occipital fasciculi. **Conclusion**: These results demonstrate the importance of considering individual neuroanatomy and neurophysiology in tES research and begin to resolve inconsistencies across studies. Interventions should account for these differences and target underlying neural mechanisms of behavioral gains to reliably improve cognition in aging.

Title: A ubiquitous laminar motif of local field potential power across cortical areas, individual subjects and studies

Authors: *A. BASTOS[1], D. MENDOZA-HALLIDAY[2], N. LEE[2], M. LICHTENFELD[1], A. J. MAJOR[2], R. DESIMONE[3], E. K. MILLER[4];
[1]Vanderbilt Univ., Nashville, TN; [2]MIT, Cambridge, MA; [3]MIT, McGovern Inst. Brain Res., Cambridge, MA; [4]Picower Inst. Learning Memory, Massachusetts Inst. Technol., Cambridge, MA

Abstract: The cerebral cortex is anatomically organized as a six-layered motif. This motif is preserved across all cortical areas and is thought to form the underlying architecture for a canonical cortical microcircuit that, with some variations, can be used by different areas to execute a diversity of functions. While this motif has been well described as a pattern of cytoarchitectonic differences across layers, little

is known about whether it can also be ubiquitously observed across cortex as a pattern of physiological differences across layers. Here, we report the discovery of such a physiological pattern in the power of neuronal oscillations. We analyzed electrophysiological recordings obtained using laminar probes implanted across layers in a variety of cortical areas (MT, V4, MST, LIP, 7A, right and left LPFC) in four macaque monkeys from two studies performed in different labs. We show that the relative power of local field potentials (LFP) oscillations across layers follows a characteristic pattern: Putative superficial layers (layers 2/3) have stronger power in the gamma (40-150 Hz) and delta/theta (1-6 Hz) bands than deeper layers. Putative deep layers (layers 5/6) have stronger alpha/beta (8-30 Hz) band power than superficial layers. We represented each laminar probe's relative power as a two-dimensional layer by frequency map. We then quantified the similarity between maps using image similarity analysis. We found that the relative power maps generalize across monkeys, areas, and studies. This suggests the presence of a ubiquitous physiological motif across cortex that represents a putative physiological signature of the canonical cortical microcircuit. Taking advantage of this motif, we propose a method for cortical layer identification in laminar electrophysiological recordings, and demonstrate its advantages compared to the current source density method.

Title: Effects of cardiovascular risk factors on prefrontal cortical activation during trail walking task: A dual task fNIRS study.

Authors: *A. BISHNOI, M. HERNANDEZ;
Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Cardiovascular measures such as heart rate (HR) and blood pressure are expected to change with age. However, the underlying mechanism by which impaired HR affects mobility and cognitive impairment remains unclear. HR reserve (HRR) is the difference between individual's maximum HR and resting HR, which has been shown to decrease with increased age. Impaired HRR in some older adults may result in reduced motor and cognitive abilities that may predispose them to an increased fall risk. Dual task (DT) paradigms have shown to measure this cognitive impairment while walking in older adults. Based on which, we designed the Instrumented trail walking task (TWT) to find this cognitive decline in older adults who are affected due to unknown cardiovascular impairments. This is the first study examining the effects of an instrumented TWT on prefrontal cortical (PFC) activation patterns evaluated by functional near infrared spectroscopy (fNIRS) among older adults with and without lower HRR (LHRR). We hypothesized that there would be an increase in activation going from an easier to a

more difficult task among older adults, particularly in those with LHRR, relative to those without LHRR. In this cross-sectional study, we examined 24 older adults with (LHRR: n=10; 70.2±4.71yrs; 1.02±0.23m/s) and without LHRR (HHRR: n=14; 60±8.14yrs; 1.17±0.17m/s). Participants completed baseline cognitive and motor testing before starting the paradigm on an instrumented treadmill. The DT paradigms consisted of four tasks: comfortable walking tasks (CW1 and CW2) and trail walking tasks (TWT-A with only sequential numbers and distractors and TWT-B with both sequential letters and numbers and distractors). The order of the tasks was CW1, TWT-A, CW2, TWT-B. Participants completed the TWTs under their comfortable walking speed with easier task first (TWT-A) and difficult task later (TWT-B). We found significant differences in age and gait speed between LHRR and HHRR ($p<0.05$). The results of the linear mixed model analysis with age as a covariate revealed trial (TR) ($p<0.01$) effects, and 2-way interaction among Cohort and TR ($p<0.0001$). Post hoc analysis confirmed these interactions between Cohort and Trial. We found significantly higher PFC activation i.e., higher oxyhemoglobin levels among both cohorts while going from TWT-A to TWT-B i.e., easier to difficult task. However, we found the use of higher activation in HHRR group, relative to LHRR, in TWT-B. This study confirms that the older adults had to use more attentional resources to do the difficult task, but that LHRR may be facing limitations in PFC recruitment, which merits further exploration.

Title: Nansen - an ecosystem of tools to provide a complete pipeline for analyzing two-photon microscopy data

Authors: *E. HENNESTAD, K. VERVAEKE, A. WITOELAR;
Univ. of Oslo, Oslo, Norway

Abstract: Two-photon microscopy is widely used to investigate brain functions. This technique produces vast amounts of images that require advanced and labour-intensive processing steps to extract neuronal signals. The complete analysis pipeline typically includes many steps such as brain motion correction (image registration), delineating neural structures of interest (image segmentation), and methods to infer neuronal spiking from the extracted signals. An increasing number of toolboxes have appeared that deal with these individual steps, but few of these provide a complete analysis pipeline. This often leaves the users with a significant amount of programming to incorporate a diverse set of toolboxes into their data analysis pipeline. Furthermore, these toolboxes often provide limited functionality for visualization and quality control. To tackle this problem, we have developed the “Neuroscience ANalysis Software ENsemble” (NANSEN). This package contains modules for building a complete processing pipeline and

exploring data using interactive graphical user interfaces. Currently available modules include existing toolboxes widely used by the neuroscience community, such as NoRMCorre, CaImAn and Suite2P. Because each toolbox has strengths and weaknesses for a specific step in the analysis pipeline, the user can choose what works best for their data. All these toolboxes are implemented as plugins, and as new toolboxes appear, they can be easily added. Importantly, to facilitate sharing and re-use data, we aim to make the data format compatible with the Neural Data without Borders (NWB) standard. The aim is to streamline the process for new users and provide powerful visualization tools for existing and advanced users. We further hope that this package can provide a common framework for further development of tools and analysis methods that can be shared widely within the neuroscience community.

Abstract: The common marmoset (Callithrix jacchus) is quickly gaining traction as a premier neuroscientific model. However, considerable progress is still needed in understanding the functional and structural organization of the marmoset brain to rival that documented in long-standing preclinical model species, like mice, rats, and Old World primates. To accelerate such progress, we present the Marmoset Functional Connectivity Resource (marmosetbrainconnectome.org), consisting of over 70 hours of resting-state fMRI (RS-fMRI) data acquired at 500 µm isotropic resolution from 31 fully awake marmosets in a common stereotactic space. Three-dimensional functional connectivity (FC) maps for every cortical and subcortical gray matter voxel are stored in an online repository. Users can instantaneously view, manipulate, and download any whole-brain functional connectivity (FC) topology along with the raw datasets and preprocessing code. We expect that this resource will be of broad value, supporting novel hypotheses about the functional organization of the marmoset brain.

Title: The Brain Image Library: A Brain Data Archive for Microscopy

Authors: *A. ROPELEWSKI[1], A. WETZEL[1], G. HOOD[1], M. BRUCHEZ[2], A. WATSON[3], S. WATKINS[3];
[1]Pittsburgh Supercomputing Ctr., [2]Mol. Biosensor and Imaging Ctr., Carnegie Mellon Univ., Pittsburgh, PA; [3]Ctr. for Biologic Imaging, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The Brain Image Library (BIL) is a public resource serving the neuroscience community by providing a persistent centralized repository for microscopy data generated by brain researchers. BIL contains thousands of brain datasets including high-resolution data from the BRAIN Initiative Cell

Census Network. Data in BIL includes: whole brain datasets and their accompanying neuron tracings; whole brain datasets from cell counting experiments; datasets from spatial transcriptomics; datasets arising from multimodal experiments such as patch-seq; and data from other experimental modalities. BIL provides critical infrastructure that enables investigators to meet data sharing requirements such as those of the NIH BRAIN Initiative which requires data sharing for funding applications submitted after March 1, 2020 as well as the more broad National Institutes of Health data sharing policy effective in 2023. Deposited data in BIL does not need to have NIH funding, but does need to be relevant to the BRAIN Initiative.
BIL services include data transfer testing and network analysis assistance, LTO-7/8 tape processing and a visualization/computational enclave to allow researchers to process datasets in-place and share restricted and pre-release datasets. In addition, the BIL data is available on the Pittsburgh Supercomputing Center's Bridges2 supercomputer, which provides significant computational ability to process data in-place.

Title: Brain platform: validating and sharing neurodata analysis pipelines

Authors: G. MAGNUSSON[1], ***Z. BOWEN**[1], M. DIEP[1], W. LOSERT[2];
[1]Fraunhofer Inst., College Park, MD; [2]Col. of Computer Mathematical and Natural Sci., Univ. of Maryland, College Park, MD

Abstract: Two-photon calcium imaging is one of the most powerful tools in modern neuroscience, however going from two-photon images to interpretable data requires pre-processing of images and post-processing of extracted signals. As a result, many algorithms and pipelines have been developed for the analysis of two-photon imaging data. While some algorithms and pipelines are published and publicly available, others are often home brewed and tweaked to fit the needs of individual researchers. Furthermore, the metadata associated with two-photon imaging data varies between different experimental setups. The vast differences in algorithm choices, pipeline parameter settings, and data sources combine to create an immense challenge of data reproducibility and collaboration. The BRAIN Platform is a tool that aims to reduce the friction of collaboration between researchers working on two-photon calcium imaging. The BRAIN Platform helps researchers share their algorithms as reusable modules, and then to combine and configure these modules as shareable workflows/pipelines. The BRAIN Platform implements an approach to evaluate the sensitivity and robustness of the configured pipelines; which can help guide researchers in selecting the appropriate parameter settings for the pipeline for their own specific data. The BRAIN platform has been developed as part of the BRAIN Initiative in

collaboration with 11 research labs, and as such comes with a set of validated modules and workflows. However, over time we hope to crowdsource more with help from the community. By making modules and workflows sharing easier, researchers can focus on developing and maturing their unique contribution while leveraging other parts of the analysis pipeline from the community. Furthermore, researchers can disseminate their analysis pipeline and results in a way that promotes repeatable, reproducible, and trustworthy analysis process.

Title: Community Accessible Augmented Reality Data Layering for Neuroscientific Communication

Authors: *T. ARD, A. W. TOGA;
USC Stevens Neuroimaging and Informatics Inst., Los Angeles, CA

Abstract: Neuroscientific research has become heavily intertwined with digital information, however neuroscientific communication remains largely based on journal articles and other static communications that struggle to effectively portray modern data. This widening gap between neuroscientific research and neuroscientific communication can be bridged through augmented reality (AR) technologies. Specifically, AR facilitates the inclusion of digital media with journal articles and other communications through data layering. Here we demonstrate these capabilities through a framework termed 'Schol-AR,' which includes tools for viewing scientific augmentations as well as an automated pipeline to create augmentations from common forms of neuroscientific data. This approach facilitates thorough reporting by enabling entire datasets to be viewed in place of representative images for formats such as volumetric MRI scans and image z-stacks. Furthermore, augmentation dramatically improves the comprehensibility of 3D data as well as overall dataset viewing and availability. Ultimately, augmenting scientific articles, posters, and other formats modernizes neuroscientific publication by merging the data and information that form the basis of neuroscientific research with the media we use to communicate.

Title: Template and atlas-based processing pipeline for macaque MRI

Authors: *A. MESSINGER[1], P. PERKINS[1], B. JUNG[2], J. SEIDLITZ[3], C. SPONHEIM[4], D. GLEN[1], P. A. TAYLOR[1];
[1]NIH, Bethesda, MD; [2]Dept. of Neurosci., Brown Univ., Providence, RI; [3]Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [4]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Non-human primate (NHP) functional neuroimaging research has been accelerated by recent advances and a greater availability of shared data. Consequently, there is a need for robust analysis tools designed for NHP neuroimaging with accompanying template spaces to standardize the localization of neuroimaging results. To this end, we have introduced a pipeline for processing structural and functional MRI data from the rhesus macaque (Jung et al., 2021). The pipeline includes the NMT v2, anatomical atlases, and software tools for aligning, processing, and analyzing structural and functional MRI data. The NMT v2 is a high-resolution population average brain template, with a stereotaxic orientation and coordinate system to facilitate surgical planning and standardized localization. Both the symmetric and asymmetric versions of the template include custom maps delineating the brain, each hemisphere, the cerebellum, and five different tissue types (cortical gray matter, subcortical gray matter, white matter, CSF, and blood vessels). Hierarchical atlases describing the anatomy of the cortex (CHARM, Jung et al., 2021) and subcortex (SARM, Hartig et al., 2021) at multiple levels of detail have been defined on the template for surgical planning, source localization, and volumetric and region of interest based analyses.The template and atlases have been integrated into the AFNI neuroimaging analysis software (Cox et al, 1996) to provide a comprehensive and robust pipeline for fMRI processing, visualization and analysis of NHP data. AFNI's new @animal_warper program can be used to efficiently align anatomical scans to the NMT v2 for (group) analysis in a standardized anatomy or for creating brain masks, atlases, and surfaces customized to an individual subject. AFNI's afni_proc.py program then integrates these alignment results with full fMRI processing using macaque-specific parameters: from motion correction through regression modeling. Both the @animal_warper and afni_proc.py programs generate reports and quality control images to facilitate assessment of their structural and functional outputs. Taken together, the NMT v2 and AFNI represent an all-in-one package for macaque functional neuroimaging analysis, as demonstrated with available demos for both task and resting state fMRI.

Sch. of Med., Baltimore, MD

Abstract: The desire to understand how the brain generates and patterns behavior has driven rapid methodological innovation in tools to quantify natural animal behavior. While recent advances in deep learning and computer vision have enabled markerless pose estimation in individual animals, extending these to multiple animals presents unique challenges for studies of social behaviors or animals in their natural environments. Here we present SLEAP (Social LEAP Estimates Animal Poses), a machine learning system for multi-animal pose tracking. This system employs modern software engineering approaches to enable highly versatile and performant workflows for data labeling, model training and inference on new data. SLEAP features an accessible graphical interface, standardized data model, reproducible configuration system, over 30 model architectures, two approaches to part grouping, and two approaches to tracking. We applied SLEAP to 7 datasets across 4 species to systematically evaluate each approach and architecture, and we compare with other existing approaches. SLEAP achieves higher accuracy and speeds of more than 800 FPS, with latencies of less than 3.5 ms at full image resolution. This makes SLEAP usable for real-time applications, which we demonstrate directly by controlling social behaviors of one animal based on the tracking and detection of behaviors of its social partner.

Abstract: Spatial transcriptomics techniques such as STARmap enable the subcellular detection of RNA transcripts within complex tissue sections. The data from these techniques are impacted by optical microscopy limitations, such as shading or vignetting effects from uneven illumination during image capture. Downstream analysis of these sparse spatially resolved transcripts is dependent upon the correction of these artefacts. We introduce a novel non-parametric vignetting correction tool for spatial transcriptomic images, which estimates the illumination field and background using an efficient iterative sliced histogram normalization routine. We show that our method outperforms the state-of-the-art shading correction techniques both in terms of illumination and background field estimation and requires fewer input images to perform the estimation adequately. As demonstration of the efficacy of our approach, we show that spatial transcriptomic volumes corrected by our method yield higher and more uniform gene expression spot-calling in a 20um section of dorsal rodent hippocampus. For example, RGS10, an enriched hippocampal gene, had over a five-fold increase in the number of gene-expression spots called with substantially more spots visualized in the periphery of the imaging FOV. Average gene expression spot-calling was increased by over three-fold from our method compared to the uncorrected image. Furthermore, many cell type specific genes such as CCK for interneurons and PLP1 for microglia that were undetectable in the uncorrected image were abundantly identified after application of our method enabling profiling the diversity of neural populations. Our method effectively corrects optical artefacts for downstream analysis of differential gene expression analysis, gene set enrichment, and other comparative genetic approaches. Python code and a demo file to reproduce our results are provided in the supplementary material and at this github page: https://github.com/BoveyRao/Non-parametric-vc-for-sparse-st

Title: Cd-1 outbred mice produce less variable ultrasonic vocalizations than fvb inbred mice, while displaying a similar developmental trajectory

Authors: *M. BINDER, H. SHI, A. BORDEY;
Neurosurg., Yale Med. Sch., New Haven, CT

Abstract: The production of ultrasonic vocalizations (USVs) in neonatal mice is a critical means of communication that is used to elicit maternal care. Alterations in neonatal USV production is also an indicator of neurological deficits. However, USVs have been predominately assessed in inbred animals and are significantly understudied in outbred mice, even though outbred animals better represent the genetic diversity of humans and are used in several neurological disorder models. To determine the reproducibility of USVs across models, we compared male and female CD-1 (outbred) and FVB (inbred) mice on postnatal days (PD) 4,8,12,16, and 20. We found that CD-1 and FVB mice displayed a similar developmental trajectory of USVs. However, CD1 mice emitted more USVs on PD 12 than FVB mice. In addition, FVB mice emitted a longer duration of calls on PD 4 and 8 and a higher overall maximum and minimum frequency of USVs than CD-1 mice. No differences in mean amplitude were found between groups. We also detected numerous significant differences between outbred and inbred mice when comparing each groups' respective call type utilization. We next assessed the relative variability of mouse vocalizations between groups, finding that outbred mice were less variable than inbred mice. For the spectral and temporal characteristics of the USVs, variability was similar between groups. Altogether, we found that CD-1 outbred mice display a similar, if not lower, degree of variability than FVB inbred mice when assessing neonatal USVs.

Title: 4E-BP1 expression reverses aberrant HCN4 channel acquisition in mTOR hyperactive neurons

Authors: *L. H. NGUYEN, Y. XU, A. BORDEY;
Yale Univ. Sch. of Med., New Haven, CT

Abstract: Hyperactivation of mTOR signaling due to mutations in the mTOR pathway alters neuron structure and function, leading to intractable epilepsy. We previously found that mTOR hyperactive pyramidal neurons in layer (L) 2/3 medial prefrontal cortex have aberrant expression of functional HCN4 channels that are normally absent in L2/3 pyramidal neurons. The abnormal presence of these channels confers a unique mode of excitability in mTOR hyperactive neurons that is dependent on intracellular cyclic AMP levels and contributes to seizures. To identify the mTOR downstream processes leading to increased HCN4 levels, we investigated whether expressing 4E-BP1, a downstream regulator of cap-dependent translation that is inhibited by mTOR, would reduce HCN4 expression. We used *in utero* electroporation to co-express a constitutive active (CA) mTOR activator, $Rheb^{CA}$, with a tamoxifen-inducible, conditional 4E-$BP1^{CA}$ (c4E-$BP1^{CA}$) plasmid. Tamoxifen was administered in postnatal day (P) 12-16 mice to induce 4E-$BP1^{CA}$ expression. Whole-cell patch clamp recordings were obtained from L2/3 pyramidal neurons expressing control (BFP), $Rheb^{CA}$, or $Rheb^{CA}$+c4E-$BP1^{CA}$ in acute brain slices from P23-32 mice. $Rheb^{CA}$ neurons displayed increased membrane capacitance and conductance, as well as more depolarized resting membrane potentials (RMPs). c4E-$BP1^{CA}$ expression normalized the RMP and partially rescued membrane capacitance but not conductance. $Rheb^{CA}$ neurons displayed significantly larger hyperpolarization-induced inward currents, including HCN-mediated currents (termed I_h). Consistent with the function of I_h in maintaining the RMP at depolarized levels, larger I_h amplitudes were significantly correlated with more depolarized RMPs. No I_h was detected in either control or $Rheb^{CA}$+c4E-$BP1^{CA}$ neurons, suggesting that c4E-$BP1^{CA}$ expression abolished the abnormal I_h. Additionally, injections of hyperpolarizing current steps evoked a prominent I_h-mediated voltage sag in $Rheb^{CA}$ neurons, which was absent or minimal in control and $Rheb^{CA}$+c4E-$BP1^{CA}$ neurons. Immunostaining for HCN1-4 isoforms verified increased HCN4 levels in the $Rheb^{CA}$ condition which was eliminated by c4E-$BP1^{CA}$ expression, while no changes in HCN1-3 were detected across all groups. Overall, our findings demonstrate that aberrant acquisition of HCN4 channels in mTOR hyperactive cortical neurons is regulated downstream of mTOR by 4E-BP1-mediated cap-dependent translation.

Title: Water deprivation amplifies hyperpolarization-activated inward current in vasopressinergic supraoptic neurons of rats.

Authors: E. F. SILVA[1], Z. S. THIROUIN[2], ***E. COLOMBARI**[1], C. BOURQUE[2];
[1]Physiol. & Pathology, Sch. of Dent. of Araraquara - UNESP, Araraquara, Brazil; [2]Brain Repair and Integrative Neurosci. Program, Res. Inst. of the McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Neurons of supraoptic nucleus (SON) express members of the cyclic nucleotide-gated family of ion channels like the hyperpolarization-activated and nucleotide-gated cation (HCN) channel that contribute to their electrical excitability and VP release. Here, we evaluated the role of hyperpolarization-activated inward current (I_H) in the control of electrical activity of vasopressinergic neurons of SON after water deprivation (WD). Electrophysiological recordings were performed through the patch-clamp technique using transgenic rats expressing enhanced green fluorescent protein (eGFP) under the control of VP promoter (VP-eGFP rats). Control (euhydrated) rats had continuous access to water and food, whereas WD rats had the water but not food removed for 48 h before initiating the experiments. The I_H was evaluated by bath application of ZD 7288 (a blocker of HCN channels). Under voltage-clamp, subtraction of current responses to hyperpolarizing steps was recorded in the absence and presence of ZD 7288 to investigate the properties of I_H, whereas voltage responses to depolarizing currents were recorded by current-clamp mode. The results showed that vasopressinergic neurons of SON from WD rats presented an amplified I_H (-0.836 ± 0.08 pA/pF, at -110 mV; $p<0.05$) compared with controls (-0.523 ± 0.09 pF/pA, at -110 mV). In addition, WD increased the number of spikes in vasopressinergic cells of SON at baseline (33 ± 5 total of spikes, *vs.* control: 10 ± 3 total of spikes; $p<0.05$), which was normalized after the selective block with ZD 7288 (20 ± 5 total of spikes, *vs.* baseline; $p<0.05$). Therefore, WD amplifies I_H in vasopressinergic SON neurons that contributes to their electrical excitability.

Title: Role of HCN Currents in Epileptiform Activity in Subicular Neurons

Authors: *M. ALFRED, S. K. SIKDAR;
Mol. Biophysics Unit, Indian Inst. of Sci., Bangalore, India

Abstract: Role of HCN Currents in Epileptiform Activity in Subicular Neurons
Monica Alfred and Sujit Kumar Sikdar
SKS Lab, MBU, Indian Institute of Science, Bangalore, India
Subicular neurons play a critical role in Temporal Lobe Epilepsy. While studies have shed light on how

synaptic conductances contribute to epileptiform activity in these neurons, it is still unclear how intrinsic conductances influence epileptic discharges. HCN channels play crucial role in pathophysiology by modulating the electrophysiological properties of neurons. To investigate the ability of intrinsic properties in a subicular neuron to generate epileptiform activity, we studied the effects of HCN currents (I_h) in 4-Aminopyridine magnesium-free epileptic model in various classes of subicular neurons. To study the modulation of epileptiform activity due to I_h in these neurons, we modeled subicular HCN currents in dynamic clamp that mimicked the effects of blocker and overexpression. We observed similar changes in input resistances with the subtraction and addition of currents in burst firing, regular firing and interneurons. However, the firing rate characteristics during epileptiform activity with the addition and subtraction of HCN channels in burst firing and regular firing differed from those observed in interneurons. The results indicate that burster cells majorly contribute to the epileptic firing characteristics due to HCN in subiculum. During the epileptiform activity, these bursters showed progressive loss of homeostatic compensation characterized by initial increase in sag followed by its decrease. The loss of homeostatic compensation incurred was found to be irreversible.These irreversible changes are also characterized by altered HCN channel kinetics. To study how these post-epileptic alterations govern neuronal excitability, we studied the electrophysiological profiles of subicular neurons with altered HCN current kinetics introduced through dynamic clamp in the presence of ZD7288. It was observed that the theta selectivity was modulated, and post-inhibitory rebound firing was evoked making the cell hyperexcitable. It is known that the stable neuronal network is homeostatically regulated by intrinsic excitability and synaptic currents. Attempts are being made to study the interaction between I_h and synaptic currents before and during the epileptiform activity in neurons with epilepsy-induced hyperexcitability.

Title: The persistent sodium channel blocker GS967 reduces hyperexcitability in Kcnq2 pyramidal neuron null neonatal mice ex vivo.

Authors: *B. HOU[1], S. SANTANIELLO[2], A. TZINGOUNIS[1];
[1]Physiol. and Neurobio., [2]BIOMEDICAL ENGINEERING, Univ. of Connecticut, Storrs, CT

Abstract: KCNQ2 loss-of-function pathogenic variants could lead to a spectrum of neurological and neuropsychiatric disorders including Developmental and Epileptic Encephalopathy as well as Autism Spectrum Disorders. KCNQ2 channels are expressed early in development being critical regulators of

neonatal network excitability. Indeed, using mesoscale calcium imaging in acute slices from neonatal Kcnq2 conditional mice, we recently showed that Kcnq2 deletion from forebrain pyramidal neurons in the presence of elevated extracellular potassium led to multifocal activity across the neocortex and hippocampus. Surprisingly, the aberrant activity persisted in slices treated with synaptic glutamatergic and gabaergic blockers, but it was eliminated by the pan-sodium channel blocker TTX. In this study, we tested whether sodium channels with differing mechanisms of action could also dampen neuronal excitability of Kcnq2 null slices. To image calcium activity we used Emx1-cre::PCG5-tdT::Kcnq2$^{-/-}$ mice, mice that express GCamp5 in the presence of cre-recombinase. Similar to our earlier work, deletion of Kcnq2 from forebrain pyramidal neurons led to increased excitability across the forebrain in slice bathed with 8mM potassium. This activity was multifocal and, on many occasions, propagated across multiple forebrain subregions. Application of carbamazepine (60-100uM), a use-dependent sodium channel blocker, significantly dampened excitability across the whole forebrain with its greatest impact in the neocortex and lowest in the entorhinal cortex. Although carbamazepine decreased overall excitability it did not fully prevent propagation of activity across subregions. In contrast to carbamazepine, GS967 (2μM), a blocker of persistent sodium currents, was able to not only reduced excitability in Kcnq2 null mice, but also prevent signal propagation across regions. Thus, we propose that targeting the persistent sodium current might be beneficial in neurons and networks with Kcnq2 loss-of-function.

Title: Changing roles of BK potassium channels in ictal activity and hippocampal parvalbumin neurons during early development in mice

Authors: *M. HUNSBERGER, B. MCDERMIT, M. MYNLIEFF;
Biol. Sci., Marquette Univ., Milwaukee, WI

Abstract: The BK potassium channel is a key regulator of neuronal firing and is implicated in neurological dysfunctions such as epilepsy. The BK antagonists, paxilline, has been shown to prevent seizure induction in adult animals with a history of seizures, but not in animals naïve to seizures. Comparison of our prior data to existing literature suggests that neurons from neonatal animals share hallmarks of BK channel function with neurons from more mature animals with a history of seizure induction. We tested the hypothesis that BK channel antagonists more effectively inhibit 0 Mg^{2+} induced seizure-like activity in hippocampal slices from immature mice than from more mature mice. We also characterized the developmental patterns of BK channel activity in CA1 excitatory pyramidal cells and CA1 region parvalbumin interneurons (PVIns), known to be major inhibitors of seizures.

We recorded local field activity in the CA1 region of hippocampal slices from mice aged P4 (postnatal day 4) to P15 days during perfusion with 0 Mg^{2+} aCSF with/without 1 µM paxilline. 0 Mg^{2+} aCSF evoked seizure-like discharges (SLDs) in 50% of P4-5 slices, 67% of P9-10 slices, and 14% of P14-15 slices. Paxilline decreased SLD rates to 17% and 33% in the P4-5 and P9-10 cohorts respectively, but increased SLD rates to 33% in P14-15 cohort. Paxilline delayed the onset of SLDs at all ages (two way ANOVA, Holm-Sidak multiple comparisons, P=0.04), and decreased SLD duration in P9-10 slices, from 13.1±2.2 to 5.0± 2.0 seconds, while not affecting SLD duration in P4-5 or P14-15 slices (two-way ANOVA, Holm-Sidak multiple comparisons, P=0.01).
Whole cell patch clamp in current clamp mode was used to record from hippocampal slices from mice with PV::TDtomato reporter for identification of PVIns. Preliminary data showed that PVIns in immature slices have fast firing rates, with firing rates in excess of 30 (P4-5), 70 (P9-10), and 100 (P14-15) Hz (1 s depolarization). A portion of PVIns in P5 slices fire no action potentials or fire a single slow action potential; this may be a quality issue of P4-5 slices or represent delayed maturation of PVIns. BK channel blockade with paxilline revealed that immature PVIns are more reliant on BK channels to maintain firing rates than pyramidal neurons. 1 µM paxilline induced more spike frequency adaptation in P10 PVIns than P10 pyramidal cells over the first 20 action potential pairs during a 1 s depolarization (two way ANOVA, P<0.001).
We found that blockade of BK channels decreased seizure-like activity in immature mice. Immature BK channel and PVIns may partly underlie heightened seizure susceptibility in neonates raising the possibility of targeting BK channels as in treating neonatal seizures.

Title: A novel in vitro modeling system for SCN1A- Dravet Syndrome disease

Authors: *J. A. SIERRA DELGADO, C. N. DENNYS, A. HARTLAUB, F. ROUSSEL, X. ZHANG, S. SINHA RAY, K. C. MEYER;
Ctr. for Gene Therapy, Nationwide Children's Hosp., Columbus, OH

Abstract: SCN1A mutations lead to a heterogenous disease spectrum of epileptic disorders, with incomplete penetrance and variable expressivity. This spectrum encompasses familiar hemiplegic migraines, febrile seizures, and other infantile epilepsies, with Dravet Syndrome (DS) being the most severe manifestation. DS is characterized by prolonged myoclonic, hemi-clonic or generalized tonic-clonic seizures with early onset (1 -18 months) that are refractive to anti-epileptic drugs (AED). The disease manifestation depends on the type of mutation as well as other poorly understood disease modifiers. To date, most research focuses on the function and expression of the Nav1.1 sodium channel

on neurons, while little is known about the role of other cell types of the nervous system in disease progression, modulation of the disease phenotype and response to AEDs. To address this, we used a direct reprogramming method to generate neural progenitor cells (iNPCs) from primary fibroblasts derived from SCN1A-DS patients. We then differentiated the iNPCs into induced Astrocytes (iAs) to evaluate cellular pathways known to be affected by neurological disease. In addition to markers of cellular stress, we evaluated the metabolic profile of SCN1A-DS iAs as well as analyzed the impact of iAs on neuronal morphology and viability . We found cell-type and mutation specific metabolic profile of SCN1A-DS patient cells that were significantly different from controls. Co-culturing healthy mouse GFP+ neurons and patient iAs demonstrated that SCN1A-DS iAS induced a high degree of neuronal death. Pretreatment of select patient iAs with specific therapeutics prevented iAs mediated neurotoxicity. Interestingly, iAs that responded favorable to these therapeutics showed a specific mitochondrial energetic profile that upon treatment, was restored to healthy levels. Here we show for the first time that human SCN1A-DS iAs have aberrant mitochondrial activity, are toxic to neurons and can be implicated in disease pathology for SCN1A. Our results indicate that patient specific mutations may have a differential effect on the mitochondria and on the mitochondrial response to AEDs. We have developed two screen assays to evaluate both the impact of specific SCN1A mutations on disease pathologies as well as subgroup the patient population based on therapeutic response to a compound. This system allows detailed evaluation of the impacts of SCN1A-DS mutations on patients with diverse genetic backgrounds.

Title: Sur1-trpm4 upregulation in epilepsy pathogenesis

Authors: *M. MOYER, R. SERRA, M. BACHANI, S. IVANOVA, V. GERZANICH, A. KSENDZOVSKY, M. SIMARD;
Neurosurg., Univ. of Maryland, Baltimore, MD

Abstract: Rationale: Current treatment for chronic epilepsy are inadequate. SUR1-TRPM4 is a depolarizing monovalent cation channel that is minimally expressed in the healthy human brain but is upregulated by hypoxia in traumatic brain injury and stroke. Furthermore, we recently described hypoxia-associated neuronal metabolic changes in chronic epilepsy. As such, we hypothesize that chronic seizures lead to neuronal Sur1-TRPM4 upregulation, which may facilitate seizures by increasing resting depolarizing sodium current. **Methods:** We used pentylenetetrazol (PTZ) kindling in mice as a model of chronic epilepsy. Mice were injected intraperitoneally with a sub-convulsive dose (35 mg/kg) of PTZ

every other day for 20 days, then monitored behaviorally (Racine scores) and with intracranial video electroencephalogram (EEG) for seizure activity. After kindling, immunohistochemistry was used to assess SUR1-TRPM4 expression in cerebral cortex and hippocampus of PTZ and control mice. SUR1-TRPM4 quantification was performed by counting cells that demonstrated a specific immunohistochemical signal, defined by an intensity greater than a threshold of 1.5x background intensity, within three 20x magnified fields per region. **Results:** PTZ-kindled mice had progressively worsening seizure severity over the course of induction, as evidenced by elevated Racine scores (Dose 1 average: 2.5; Dose 10 average: 4.75) and increased seizure frequency (Dose 1 average: 0 seizures/injection day; Dose 10 average: 1.25 seizures/injection day). SUR1-TRPM4 positive cell counts were increased in cortex (PTZ:49.9±11.3; Control:3.3±2.8; p=0.01) and hippocampus (PTZ=43.3±5.0; Control=2.2±0.7; p=0.002) of PTZ-kindled mice compared to controls. **Conclusions:** SUR1-TRPM4 is upregulated in chronic seizures. Future experiments will focus on evaluating HIF1α and NF-κB as upstream regulators, and assessing whether upregulation of SUR1-TRPM4 promotes seizures through its depolarizing effect on neuronal resting membrane potential. ![endif]>

Title: Effects of Interneuron-Selective HCN Channel Knockdown on Working Memory Performance in Female Sprague-Dawley Rats

Authors: *B. HUGHES[1], T. K. O'BUCKLEY[2], A. L. MORROW[3];
[1]Dept. of Psychiatry, [2]Bowles Ctr. for Alcohol Studies, [3]Psychiatry, Pharmacology, & Bowles Ctr. for Alcohol Studies, Univ. of North Carolina Sch. of Med., Chapel Hill, NC

Abstract: Chronic alcohol use elicits deficits in cognition and behavioral control that are associated with prefrontal cortical (PFC) dysfunction. Recently, we observed reduced excitability of inhibitory Martinotti cells in female rats after chronic ethanol exposure that correlated with reduced HCN channel-mediated current in these cells. In contrast, excitatory pyramidal neurons, also known to robustly express HCN currents, did not exhibit any change in excitability or HCN-mediated current after alcohol exposure. Previous studies have reported that cell-indiscriminant inhibition of PFC HCN activity facilitated working memory performance, indicating these channels act as potent regulators of cognitive function. On this basis, we hypothesized that the effects of alcohol exposure on Martinotti cell HCNs specifically contribute to the observed enhancements in working memory performance in female rats. To test this, we employed a multiplexed viral approach using a double-floxed miR-adapted shRNA targeting HCN channels that is co-infected with a Somatostatin-Cre virus. This system permits selective knock down of

HCN channels in somatostatin-positive interneurons, which include Martinotti cells, and preliminary electrophysiological characterization has demonstrated near-total knockout of HCN-mediated current in infected neurons. Based on these data, we conducted preliminary behavioral experiments using this approach, in which rats undergo training and testing on a delayed non-match-to-sample T-maze task 2-3 weeks post-infection. Initial observations demonstrate a strong trend toward enhanced working memory performance on this task in HCN-shRNA infected animals relative to scrambled control rats. After initial testing, we then exposed rats to water or ethanol (5 g/kg; intragastric gavage) for 15 days, and conducted a second test 24 hours after the last exposure. We again report a robust facilitation of working memory performance in both scram-shRNA and HCN-shRNA groups exposed to ethanol, although we presently lack sufficient n to determine an effect of HCN-shRNA infection on this enhancement. Additional experiments are currently underway to both increase animal numbers as well as further characterize the selectivity and penetrance of this viral knockdown system. Observations from these experiments will offer insight into whether alcohol effects on interneuron-expressed HCN channels mediate concomitant effects on cognitive function, and further demonstrate the suitability of this novel approach for interneuron-selective protein knockdown.

Title: Sex-specific regulation of neuropathic pain by microglial Orai1 channels

Authors: *K. DEMEULENAERE[1], S. TSUJIKAWA[1], M. CENTENO[1], M. M. MANESHI[1], M. TAPIES[1], M. YAMASHITA[1], K. STAUDERMAN[2], M. SALTER[3], V. APKARIAN[1], M. PRAKRIYA[1]; [1]Northwestern Univ. - Chicago, Chicago, IL; [2]CalciMedica, In., La Jolla, CA; [3]Hosp. for Sick Children Res. Inst., Toronto, ON, Canada

Abstract: Store-operated Orai1 channels are implicated in initiating inflammatory responses in many immune cells, yet much less is known about their role in regulating neuroinflammation that causes neuropathic pain. Spinal cord microglia play central role in directing inflammatory responses that underlie neuropathic pain. Here, we determine that Orai1 channels regulate microglia-mediated neuroinflammation and chronic pain in a sex-specific manner. Microglia deficient in Orai1 show reductions in ATP-evoked Ca^{2+} signaling and synthesis of pro-inflammatory cytokines including IL-6 and TNFa. Following nerve injury, male, but not female microglial Orai1 KO mice show mitigation of inflammatory cytokines and the pathological potentiation of glutamatergic neurotransmission in the spinal cord. Consistent with these cellular measures of neuroinflammation, male but not female microglial Orai1 KO mice are protected against pain hypersensitivity. A small-molecule Orai1 antagonist, CM4620, also mitigates

hypersensitivity in male but not female Orai1 KO mice. These findings identify Orai1 channels as a critical checkpoint for the sex-specific regulation of microglial neuroinflammation underlying neuropathic pain.

Title: Cue-induced recall for cocaine or morphine self-administration increases ryanodine 2 (RyR2) phosphorylation in the prefrontal cortex

Authors: *K. R. BARBER[1], B. M. LOPEZ[1], P. CULVER[2], V. S. VIZCARRA[1], L. MAJUTA[1], C. DIEZEL[1], R. PARMAR[1], A. C. RIEGEL[1];
[1]Pharmacol., Univ. of Arizona, Tucson, AZ; [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: Ryanodine receptors (RyRs) are intracellular calcium (Ca2+) release channels important for long-term potentiation, dendritic spine remodeling, and learning/memory formation. In the CNS, the type-2 RyR channel (RyR2) localized to the endoplasmic reticulum is subject to activity-dependent phosphorylation and transcriptional regulation. In the hippocampus, chronic overactivation/hyperphosphorylation of RyR2 (RyR2*P*) at a serine residue 2808 also produces a pathological posttranslational modification associated with the persistent leak of Ca2+ from intracellular stores, alterations in synaptic plasticity, and cognitive disease. In the prefrontal cortex (PFC) area 32V (A32V; formerly prelimbic) a region important for relapse/drug-seeking, the relevance of RyR2*P* is not yet defined. However, addictive drugs, including stimulants and opiates, are known to result in hyperphosphorylation. Prior PFC studies suggest that the contextual memory formation associated with non-contingent drug-induced plasticity increases unphosphorylated RyR2 content. In the present study, we evaluated if drug-seeking in rats with a history of contingent drug self-administration impacted RyR2*P* in A32. We trained male Sprague Dawley rats to chronically (14d) self-administer either drug cocaine (0.5 mg/kg i.v.) or morphine (1mg/kg i.v.) or natural (sucrose; 45 mg) rewards and then performed a single 'recall' test to engage reward-seeking PFC neuron ensembles, without the confounding ingestion of the reward itself. At 90 minutes of 'recall,' the rats underwent cardiac perfusion for later brain sectioning and immunohistochemical analysis. The phospho-antibody directed against the serine residue 2808 of RyR2*P* showed robust expression in the cytosol and specifically apical dendrites of a heterogeneous population of A32 Layer 5 pyramidal cells. A subpopulation of these A32 cells

expressing RyR2*P* was also colocalized with the intermediate early gene product c-fos (RyR2*P*+/Fos+). Manual quantification of A32V indicated a similar RyR2*P*+/Fos+ expression with recall for cocaine or morphine, which was ~twice that of sucrose. This difference in the colocalization expression was not evident in more dorsal regions. Ongoing studies using RNAscope are visualizing the parallel changes in gene expression. Taken together, these data indicate that the neuronal activation in the PFC during drug-seeking is not randomly distributed and is associated with greater RyR2*P* expression for drug-seeking behaviors, rather than natural rewards. Consequently, overactivation of RyR2*P* at serine 2808 may contribute to the ensemble activity of PFC neurons during relapse to drug-seeking.

Title: Voltage-gated calcium channel inactivation determines the extent of channel inhibition by small RGK GTPases

Authors: *Z. BURAEI[1], R. LEVENSON-PALMER[2], S. ALLAM[1], B. CERNUDA[3], G. SUPPA[4], S. DOBBINS[5], Z. CHIA CHANG[1], S. KAUR[1], J. YANG[6];
[1]Pace Univ., New York, NY; [2]NYU Sch. of Med., New York, NY; [3]UConn Hlth., Farmington, CT; [4]SUNY Donstate Hlth. Sci. Univ., New York, NY; [5]Stanford Univ., Stanford, CA; [6]Columbia Univ., New York, NY

Abstract: Voltage-gated Ca2+ channels (VGCC) directly control muscle contraction and neurotransmitter release, and slower processes such as cell differentiation, migration, and death. They are potently inhibited by RGK GTP-ases (Rem1, Rem2, Rad and Gem/Kir), which decrease Ca2+ channel membrane expression, as well as directly inhibit membrane-resident channels. The mechanisms of membrane-resident channel inhibition are difficult to study because RGK-overexpression causes complete or near complete channel inhibition. Using titrated levels of Gem expression in Xenopus oocytes to inhibit WT P/Q-type calcium channels by ~50%, we show that inhibition is dependent on channel inactivation. Interestingly, fast-inactivating channels, including Familial Hemiplegic Migraine mutants, are more potently inhibited than WT channels, while slow-inactivating channels, such as those expressed with the β2a auxiliary subunit, are spared. We found similar results in L-type channels, and, remarkably, Timothy Syndrome mutant channels were insensitive to Gem inhibition. Further results suggest that RGKs slow channel recovery from inactivation and identify RGKs as likely modulating factors in channelopathies.

Title: Ion-channel degeneracy and plasticity manifolds govern the emergence of circadian oscillations of neuronal intrinsic properties in the suprachiasmatic nucleus

Authors: *H. NAGARAJ, R. NARAYANAN;
Indian Inst. of Sci., Bangalore, India

Abstract: Organismal adaptation to the day-night cycle is achieved by circadian oscillators in most organs, which are synchronized by the suprachiasmatic nucleus (SCN). Neurons in the SCN undergo autonomous oscillations in their intrinsic physiological properties through changes in a subset of ion channels they express. However, it is not known if characteristic physiology of SCN neurons could be achieved through multiple ion-channel combinations or if there are several routes to achieve the circadian transitions in their physiological properties. In this study, we first employed an unbiased stochastic search (spanning 13 parameters involving 11 SCN neuronal ion channels) to construct a biophysically realistic population of SCN neurons with day-like phenotypes. We generated 30,000 models and found a subset of 128 valid models that manifested 9 different characteristic signatures of day-like SCN neurons. We found these valid models to manifest ion-channel degeneracy, whereby disparate ion-channel combinations were able to elicit similar characteristic functional outcomes, also expressing weak pairwise dependencies across model parameters. We next chose 20 day-like neuron models and subjected a specific subset of 6 ion channels to physiologically established directions of transitions, with transition magnitudes defined by an unbiased stochastic search algorithm. We validated these transitions employing 9 night-like physiological features, and found 719 valid night-like SCN models that manifested ion-channel degeneracy. We performed nonlinear dimensionality reduction analyses on these transitions and found the manifestation of *plasticity manifolds*, structured low-dimensional manifolds in the space of all permitted changes, underlying day-to-night transitions. Finally, towards completing the circadian cycle, we picked 26 night-like neurons and performed an unbiased stochastic search on the magnitude of changes in the same subset of 6 ion-channel conductances, with directions of changes opposite to those for day-to-night transitions. Validation against day-like phenotypes yielded 1184 valid transitions, with the emergent day-like neurons showing ion-channel degeneracy but with a notable absence of structured plasticity manifolds in the associated transitions. These results pointed to the possibility that night-to-day transitions might have greater flexibility relative to their day-to-night counterparts. Together, our analyses demonstrate the expression of ion channel degeneracy in SCN neurons and points to the existence of structured plasticity manifolds in defining ion-channel transitions during circadian oscillations.

Title: Heterogeneous Populations of Synapses Contribute to Globally Stable Output of the Drosophila Larval Neuromuscular Junction

Authors: *K. AGHI[1], R. LI[2], R. SCHULTZ[1], Z. L. NEWMAN[2], E. Y. ISACOFF[1,2];

Abstract: Glutamate-releasing motor neuron connections to the fruit fly larval muscle are diverse in their synaptic communication properties. Two distinct motor neurons types (Ib and Is) form the neuromuscular junction (NMJ), each containing hundreds of sites of neurotransmitter release. There is great heterogeneity between synapses in the probability (Pr) that an action potential will evoke release of neurotransmitter under low frequency stimulation (0.2 Hz) that reflects basal transmission (ranging from $\leq$0.005 to 0.5). A portion of the variance in Pr can be explained by synapse-to-synapse differences in the quantity of three elements of the presynaptic release machinery: the scaffolding protein, ELKS/CASK homolog, Bruchpilot, the voltage-gated Ca^{2+} channel, Cacophony, and the SNARE protein interacting protein Complexin. Our central hypothesis is to ask if the relative locations of synapses is a critical factor in setting basal Pr, We used a k-Nearest Neighbor (k-NN) framework of analysis to relate distances between synapses to release behavior. Our finding is that Pr is randomly distributed in space across synapses: there is neither a relationship between synapse spacing and Pr, nor the Pr of a synapse and that of its neighbor. We asked how Pr changes with elevated stimulation frequency. While we observed the expected behavior that synapses with low basal Pr tended to facilitate or and synapses with high basal Pr tended to depress, we observed many relatively high Pr synapses that were stable or facilitated and many low Pr synapses that were stable or depressed. Remarkably, despite the great diversity in the balance between facilitation and depression across synapses, transmission the distribution of Pr in the population of synapses was globally stable, providing a constant safety factor for transmission. We are now asking whether fast feedback contributes to the diversity of frequency-dependent changes in Pr and are focusing on the presynaptic metabotropic glutamate receptor (DmGluRA).

Title: Characterization of Molecular Mechanisms that Contribute to Functional Synaptic Diversity Between Tonic and Phasic Motoneurons

Authors: *S. K. JETTI[1], A. B. CRANE[1], Y. AKBERGENOVA[1], C. A. WHITTAKER[2], N. A. APONTE-SANTIAGO[1], *J. T. LITTLETON[1];

Abstract: Synapses exhibit striking diversity in morphology, synaptic strength, response kinetics, and short-term plasticity. Although extensive progress has been made in characterizing mechanisms of synaptic transmission, the molecular logic that specifies functional synapse diversity remains poorly understood. Synaptic transmission differences between neuronal classes is likely secondary to differences in gene expression programs as well as changes in the nanoscale organization of key synaptic proteins. Larval *Drosophila* Tonic and phasic motoneurons show multiple distinctions in synaptic connectivity and synaptic release properties, providing an attractive neuronal subpopulation to examine molecular and structural differences that contribute to these features. To further examine how their unique synaptic differences arise, we used GAL4 drivers for tonic Ib and phasic Is motoneuron subtypes. We combined single neuron isoform Patch-Seq, STED nanoscopy, synaptic GCaMP imaging, optogenetics, and electrophysiology to characterize a subset of Ib and Is motoneurons innervating a common postsynaptic muscle target. We confirmed physiological differences in synaptic physiology at these two distinct synapses using synaptic GCaMP imaging, optogenetics, and electrophysiological analyses. In addition, STED nanoscopy revealed differential active zone organization of key proteins between Ib and Is motoneurons that also likely contribute to their unique differences in synaptic transmission. A collection of several hundred differentially expressed loci were identified by isoform Patch-Seq. RNAi knockdown was coupled with morphological analysis and cell-type specific optogenetics to screen these candidates for roles in establishing diversity in tonic and phasic synaptic transmission. Although the screen is ongoing, multiple differentially expressed loci that contribute to differences in tonic versus phasic synaptic properties have already been identified. These include the AZ proteins RIM and Rbp, the extracellular matrix components Ana, synaptic cleft protein Hig, the cyclic nucleotide gated-channels, and the calcium-binding protein Cbp53E. In addition, tonic and phasic motoneurons differentially express a large repertoire of cell adhesion and axonal pathfinding proteins, as well as G-protein coupled neuromodulatory receptors. These findings indicate the unique nanoscale organization of AZs, together with differences in molecular programs that regulate several synaptic properties, contribute to functional differences between phasic and tonic motoneurons.

Title: Structural and functional analysis of TRAPP complexes in the Drosophila larval central nervous system and neuromuscular junction

Authors: *L. LIANG, R. THAKUR, K. M. O'CONNOR-GILES;
Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Communication in the nervous system is the basis for behaviors such as movement and cognitive functions including learning and memory. Synapses are the sites of this communication between neurons. In presynaptic neurons, neurotransmitter filled synaptic vesicles are docked near calcium channels for efficient neurotransmission upon arrival of an action potential. Yet, little is known about how synaptic vesicles are recruited and positioned at the presynaptic membrane to achieve this organization. Ultrastructural analysis of synapses across species shows the presence of protein tethers linking synaptic vesicles to other vesicles and to active zone membranes. However, the composition of these tethers remains unknown.
The Transport Protein Particle (TRAPP) is a multi-subunit protein complex that has been identified to tether endoplasmic reticulum-derived vesicles to vesicular tubular clusters. Mutations in TRAPP subunits have been implicated in motor dysfunction, intellectual disability, and developmental delay. However, a potential role for TRAPP in tethering synaptic vesicles at synapses remains unexplored. We find that core TRAPP subunits are expressed in the *Drosophila* larval ventral nerve cord and at the neuromuscular junction, where we observe co-localization with synaptic vesicles. Functionally, we find that knocking down some, but not all, TRAPP subunits leads to decreased levels of synaptic vesicle proteins as well as components of the active zone cytomatrix, a conserved complex of proteins implicated in the organization of synaptic vesicles at synapses. We propose that TRAPP complexes play an important role in synaptic vesicle recruitment and neurotransmission, and that studying their function will provide new insights into long-standing questions about synaptic vesicle trafficking.

Title: Calcium channel localization and function are altered in worms carrying patient CACNA1A mutations

Authors: *M. ZULUAGA-FORERO[1,2], Y. DONG[3], J. BAI[3], P. T. KURSHAN[1];
[1]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., New York city, NY; [2]Dept. de Biología, Univ. Nacional de Colombia, Bogota, Colombia; [3]Fred Hutchinson Cancer Inst., Seattle, WA

Abstract: Mutations in the P/Q-type voltage-gated calcium channel (CACNA1a) in humans are associated with diseases ranging from motor disorders such as episodic ataxia type 2 (EA2) to familiar hemiplegic migraine type 1 (FHM1) to cognitive dysfunction including attention deficit hyperactivity disorder (ADHD) and autism spectrum disorder (ASD). These channels are expressed in both the somatodendritic compartment and at presynaptic terminals, however, the mechanistic links between different mutations and their roles in *neuronal excitability* versus *synaptic transmission* are not well understood. We use the nematode *C.elegans* due to its lack of gene redundancy, genetical tractability, and simplified nervous system, to elucidate changes in presynaptic calcium channel localization and functional defects produced by these mutations. The worm has only one ortholog of the channel (UNC-2) expressed in its nervous system that shares high homology with the human protein. We have found that worms carrying several patient-derived mutations show various defects in channel localization at pre-synapses as well as altered synaptic function, assessed using both electrophysiological and behavioral readouts. Interestingly, some channel mutations lead to decreased synaptic localization yet have increased acetylcholine release (as assessed by aldicarb sensitivity), miniature EPSC frequency, and behavioral hyperactivity. Single-molecule localization, additional mutations, and interactions with other presynaptic proteins are being evaluated to assess the impact of mutations associated with a range of disorders on presynaptic morphology and synaptic function.

Hlth., Würzburg, Germany; [5]Ctr. for Computat. and Theoretical Biology, Univ. of Würzburg, Würzburg, Germany

Abstract: Hippocampal mossy fiber (MF) synapses play a key role in information processing and express unique presynaptic plasticity (Salin et al., PNAS 1996, 93:13304-09). The cytomatrix of proteins at active zones (AZs), specialized presynaptic sites for vesicle release, precisely facilitate temporal and spatial interaction to transform action potentials into chemical synaptic transmission. While morphological complexity of MF boutons (MFBs) has been well documented with classical transmission and scanning electron microscopy (EM), functional EM techniques only recently allowed to further investigate how presynaptic architectural complexity may be coupled with functional properties of synaptic transmission at MFBs (Borges-Merjane et al., Neuron 2020, 105:1-15; Imig et al., Neuron 2020, 108:843-60). Therefore, several aspects of the three-dimensional AZ architecture in MFBs, its alteration in plasticity and the contribution of single AZ proteins to it, remain to be elucidated. The Rab3a-interacting molecule (RIM) protein family contributes to vesicle exocytosis at presynaptic membranes. In electrophysiological experiments, hippocampal MFBs lacking the RIM1 isoform RIM1α express impaired presynaptic plasticity (Castillo et al., Nature 2002, 415: 327-30). Ultrastructural studies have emphasized a morphological involvement of RIM1α and equivalent protein homologues to AZ architecture in artificial synaptic preparations, e.g. synaptosomes (Fernanández-Busnadiego et al., J Cell Biol 2013, 201:725-40), and in synapses of other organisms, e.g. *C. elegans* (Stigloher et al., J Neurosci 2011, 31:4388-96).
We carried out rapid cryo-immobilisation of acute brain slices from adult RIM1α$^{-/-}$ mice and performed electron tomography of synapses in giant MFBs to spine head CA3b pyramidal neurons, standardized in brain level and hemisphere. 3D stereogeometric analyses of 60 reconstructed electron tomograms of AZs in RIM1α$^{-/-}$ and wild type RIM1α$^{+/+}$ mice facilitated novel ultrastructural contributions of RIM1α on synaptic nano-architecture. Beside structural complexity, our approach uncovers an immense structural heterogeneity within AZs of hippocampal MFBs in both phenotypes. In addition, three-dimensional nano-architecture of RIM1α deficient AZs shows significant differences to wildtype AZs in AZ area expansion, SV pool organization and differentiation of docking states within less than 5 nm to the presynaptic membrane.

Title: Two mechanisms of synaptic vesicle clustering by synapsins: roles of liquid-liquid phase separation and oligomerization

Authors: *S.-H. SONG, G. J. AUGUSTINE;
Lee Kong Chian Sch. of Medicine, NTU, Singapore, Singapore

Abstract: Synapsins are synaptic vesicle (SV) proteins that participate in SV trafficking by making a cluster of SVs that constitutes a SV reserve pool (RP). We compared two molecular mechanisms that are proposed to allow synapsins to cluster SVs: liquid-liquid phase separation (LLPS), which could cluster SVs by creating synapsin condensates within the presynaptic terminal (Science 361: 604); and oligomerization, which could cluster SVs because synapsins can bind both to SVs and to other synapsin molecules (Science 259: 780). *In vitro*, all synapsin isoforms can create LLPS, with the size of their condensates well-correlated with the length of their intrinsically disordered regions. This process is inhibited by ATP, with half-maximal inhibition occurring at 1.7 mM. In the presence of 5 mM ATP, synapsin can still create macromolecular structures; these are caused by oligomerization, because they get smaller with synapsins harboring point mutations that impair oligomerization. Although both mechanisms can cluster SVs *in vitro*, synapsin oligomerization is more effective than LLPS: in 5 mM ATP, which favors oligomerization, SV clusters are larger and SVs better co-localize with synapsin. We also examined the roles of these two mechanisms at synapses from cultured neurons from synapsin triple-knockout mice. At GABAergic synapses, expression of synapsin 2a mutants that prevent oligomerization still clusters SVs and supports normal GABA release. However, at glutamatergic synapses, these synapsin 2a mutants accelerate the rate of synaptic depression, indicating a defect in mobilization of SV from the RP. This contrasts with expression of wild-type synapsin 2a, which rescues synaptic depression and SV mobilization from the RP (J. Neurosci. 28: 10835). In summary, both LLPS and oligomerization contribute to synapsin-dependent trafficking of SV. Remarkably, the relative roles of these two processes differ at excitatory and inhibitory synapses.

Title: Proximity Labeling Reveals NMDA Receptors Localized on the Presynaptic Terminal of Parvalbumin Interneurons in the Mouse Cortex

Authors: *A. S. BATTISON[1], J. L. BALSBAUGH[2], J. C. LIDDLE[2], C. B. O'CONNELL[3], J. J. LOTURCO[1];
[1]Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT; [2]Univ. of Connecticut Proteomics and Metabolomics Facility, Storrs, CT; [3]Univ. of Connecticut Advanced Light Microscopy Facility, Storrs, CT

Abstract: We present a method for obtaining cell-type specific local proteomes in fixed mouse tissue using an antibody based proximity labeling method. We focus our analysis on the three major GABAergic

cell types in the cortex, Parvalbumin (PV), Somatostatin (SST) and Vasoactive Intestinal Peptide (VIP). To achieve cell type specificity in our proximity labeling we cross a PV, SST, or VIP-Cre mouse line to a TdTomato-Synaptophysin reporter mouse, resulting in offspring that have a novel TdTomato antigen in the presynaptic terminal exclusively in our cell type of interest. We use the TdTomato antigen as the basis for proximity labeling which results in biotinylation of proteins that are in the vicinity of our target cell. These proteins are isolated with a streptavidin pull-down, and prepped for mass spectrometry (LC-MSMS). Results show that we are able to detect local presynaptic proteomes of the three major GABAergic interneuron subtypes, and further analysis of the parvalbumin (PV) presynaptic terminal suggests the presence of presynaptic NMDA receptors on that cell type alone. Through superresolution microscopy and electrophysiology we investigate the presence and function of these presynaptic NMDA receptors on parvalbumin cortical interneurons.

Title: A tale of two NTs: structure and function of dual glutamatergic-GABAergic neurons in major depressive disorder

Authors: *D. WHITE, M. STOWELL;
MCDB, Univ. of Colorado Boulder, Boulder, CO

Abstract: Dissecting the Regulation of Disparate Synaptic Vesicle Pools in the LHb. The equilibrium of excitatory and inhibitory neurotransmission is critical for normal brain function and disruptions in this balance can result in several devastating neurological disorders. While most neurons in the brain release a single primary neurotransmitter, certain populations are capable of releasing two neurotransmitters. These “dual-release” neurons often transmit ostensibly competitive molecules but manage to regulate vital neurological processes. In particular, GABA and GLUT dual-release neurons in the lateral habenula (LHb) are involved in mood regulation. Aberrant release at the LHb is associated with major depressive disorder (MDD), but the mechanism underlying this relationship is unknown. To investigate the role of LHb dual-release neurons in the pathology of MDD, we have combined optical imaging, CyTOF and EM to investigate the murine LHb. Characterizing the spatial arrangement of GLUT and GABA is critical for understanding how dual-release is regulated at the molecular level. Super-resolution STORM imaging allows nanoscale visualization of the pre-synaptic terminal. This resolution is sufficient to distinguish between populations of GLUT and GABA vesicles, as well as vesicles that contain both transporters.

Additionally, both isolated synaptosomes and pre-synaptic vesicles are used with CyTOF to investigate the proportional load of GABA vs GLUT in the LHb. Here we present preliminary data that suggests there is complex molecular regulation and distribution of GABA and GLUT synaptic vesicles in the LHb and points towards potential targets for the treatment of MDD.

Title: Ketogenic diet effects at short-, medium and long-term on cortical synaptic proteome in aging mice

Authors: *D. ACUNA[1], A. ACEVEDO[2], C. OLMOS[1], C. WEHRFRITZ[3], S. SHAH[3], B. SCHILLING[3], J. C. NEWMAN[3], C. GONZÁLEZ-BILLAULT[1,3,2];
[1]Biol., Univ. de Chile, Santiago, Chile; [2]Inst. of Nutr. and Food Technology, (INTA), Santiago, Chile; [3]Buck Inst. for Res. on Aging, Novato, CA

Abstract: Aging is a complex process affecting brain function progressively over time with increased risk of cognitive decline and neurodegenerative diseases. Cerebral cortex is particularly vulnerable to age due to significant molecular changes in neurons such as energy metabolism decline, loss of proteostasis and synaptic dysfunction. Recent studies found that long-term treatments with ketogenic diet (KD) preserve memory and motor function in old mice, however the precise molecular mechanisms involved and duration of treatment that is required remain to be elucidated. Therefore, we investigated how KD administration at short- (1 week), medium- (6 weeks) and long- term (12 months) affects the cortical synaptic proteome in C57BL/6 mice. We performed mass spectrometric analysis using a label-free, data-independent acquisition (DIA) approach to analyze pre-synaptic and post-synaptic preparations from animals at the end of the treatment period (24-26 months old). Bioinformatic analysis revealed increased expression of presynaptic proteins involved in actin cytoskeleton, mitochondria, synaptic vesicle cycle and cAMP pathways in old mice treated with KD at long and medium-term, whereas modest changes in the postsynaptic proteome were identified at short-term administration. Additionally, these findings were corroborated by dendritic spine morphology analysis and synaptic contacts counting in cortical brain slices. Overall, we show that KD predominantly modulates the presynaptic proteome of cortical synapses through the activation of key specific molecular pathways involved in energy supply and synaptic organization, preserving their function in aging mice.

Title: Distinct molecular pathways govern presynaptic homeostatic plasticity

Authors: *A. NAIR, P. MUTTATHUKUNNEL, M. MUELLER;
Univ. of Zurich, Zurich, Switzerland

Abstract: Presynaptic homeostatic plasticity (PHP) stabilizes synaptic transmission by counteracting impaired neurotransmitter receptor function through increased presynaptic release. PHP is thought to be triggered by impaired receptor function, and to involve a stereotypic signaling pathway. However, here we demonstrate that different receptor perturbations that similarly reduce synaptic activity result in vastly different responses at the Drosophila neuromuscular junction. While receptor inhibition by the glutamate receptor (GluR) antagonist γ-DGG is not compensated by PHP, the GluR inhibitors PhTx-433 and Gyki induce compensatory PHP. Intriguingly, PHP triggered by PhTx and Gyki involve separable signaling pathways, including inhibition of distinct GluR subtypes, differential modulation of the active-zone scaffold Bruchpilot, and short-term plasticity. Moreover, while PHP upon Gyki treatment does not require genes promoting PhTx-induced PHP, it involves presynaptic Protein Kinase D. Thus, synapses not only respond differentially to similar activity impairments, but achieve homeostatic compensation via distinct mechanisms, highlighting the diversity of homeostatic signaling.

Title: Dynamic regulation of calcium channels and their auxiliary subunits at the Drosophila neuromuscular junction

Authors: A. T. MEDEIROS[1], S. J. GRATZ[1], A. DELGADO[1], K. M. O'CONNOR-GILES[2];
[1]Dept. of Neurosci., [2]Neurosci., Brown Univ., Providence, RI

Abstract: Nervous systems must be plastic to maintain effective communication within dynamic environments. Communication between neurons relies on calcium-dependent neurotransmitter release at specialized areas of synapses called active zones. Calcium channels are critical mediators of neurotransmitter release, but how they modulate synaptic activity to keep communication within established parameters is incompletely understood. We have investigated calcium channel dynamics during homeostatic plasticity, a conserved mechanism for stabilizing the activity of a neuron around an established set-point. In *Drosophila* the application of Philanthotoxin, a wasp toxin that blocks postsynaptic glutamate receptors, induces presynaptic homeostatic potentiation (PHP) within minutes. During PHP, neurotransmitter release is increased to compensate for glutamate channel impairment and maintain effective communication. PHP is achieved through an increase in the probability of release thought to involve both an increase readily-releasable synaptic vesicles and calcium influx. We have found that the sole *Drosophila* CaV2 calcium channel Cacophony (Cac) is rapidly recruited to active zones within 10 minutes of Philanthotoxin challenge, indicating that synaptic calcium channel levels can be dynamically regulated on rapid time scales to influence synaptic probability of release. However, calcium influx depends not only on the pore forming α_1 subunit, but also auxiliary subunits that impact the trafficking, organization, and function of the channel. CaV2 channels are composed of an α_1 subunit, a β subunit, and an $\alpha_2\delta$ subunit, each of which is encoded by multiple genes and/or alternative isoforms. While we know that the α_1 subunit, Cac, is rapidly trafficked to the synapse to aid in potentiation, it is unknown how these auxiliary subunits are modulated to influence channel trafficking and membrane insertion at active zones. To address this question, we used CRISPR gene editing to create endogenously tagged lines of the *Drosophila* β and $\alpha_2\delta$ subunits. We have confirmed normal channel function in our tagged lines. We find that subunits localize to synapses with both overlapping and unique cellular patterns. In ongoing studies, we are investigating the dynamic regulation of channel composition during PHP. Using our genetic toolset to characterize calcium channel complex dynamics will enable us to understand how channel levels, sub-synaptic localization, and subunit composition are modulated to tune synaptic probability of release.

Title: Mechanisms of Presynaptic Homeostatic Plasticity at a Central Cholinergic Synapse in Drosophila

Authors: *F. J. BERNARDO-GARCIA, G. W. DAVIS;
Univ. of California San Francisco, San Francisco, CA

Abstract: Synaptic homeostasis refers to a set of adaptive physiological mechanisms that ensure robust, reliable information transfer at synaptic connections. Presynaptic homeostasis (PHP) is the process by which neurons adjust the release of neurotransmitter to offset disruptions that impair synapse integrity and function, including the effects of synapse degeneration. Large-scale forward genetic screens in *Drosophila* have revealed highly conserved molecular mechanisms of PHP, operating at neuromuscular junctions in fly and mouse. By contrast, little is known about the expression or molecular mechanisms of PHP at central synapses in any organism. Here, we establish for the first time that PHP occurs at a cholinergic synapse in the *Drosophila* adult central nervous system. This system is amenable to forward genetic screens. We demonstrate that PHP can be rapidly induced within minutes, and is persistently expressed, paralleling observations at the *Drosophila*, mouse and human NMJ. However, emerging molecular mechanisms appear to be distinct from those observed in the peripheral nervous system. Furthermore, distinct molecular mechanisms appear to govern the rapid induction (minutes) versus sustained expression (days) of PHP. These data highlight the relevance of PHP to the maintenance of robust information transfer at central synaptic connections. Novel mechanisms and a model for PHP at a cholinergic central synapse will be presented.

Title: The mTOR protein interaction network responds to homeostatic scaling and is disrupted in Shank3 knockout mice

Authors: *D. WEHLE[1], W. E. HEAVNER[2], S. E. P. SMITH[1];
[1]Univ. of Washington Grad. Program In Neurosci., Seattle, WA; [2]Natl. Inst. of Neurolog. Disorders and Stroke, Washington D.C, DC

Abstract: While Autism spectrum disorder (ASD) is a heterogenous disorder with a wide array of causative mutations implicated, animal modeling studies of many implicated genes have identified shared mechanisms and deficits. One such common disfunction lies in a form of synaptic plasticity called homeostatic scaling, a non-Hebbian form of plasticity that allows a neuron to maintain its firing rate within a useful dynamic range despite changes in overall network excitability. Another common

dysfunction in ASD involves disruption in the PI3K-AKT-mTOR signal transduction pathway, which itself is implicated in homeostatic scaling. Here, to relate disruptions in mTOR signaling with disruptions in homeostatic plasticity, we investigated the activity of an mTOR protein interaction network (PIN) during homeostatic scaling in wildtype and ASD-model mice. We treated p16 to p20 cultured cortical neurons with tetrodotoxin (TTX) to induce upscaling and bicuculine (BIC) to induce downscaling. We then observed the response of a PIN composed of proteins involved in mTOR signal transduction using a novel Qualitative Multiplex Immunoprecipitation (QMI) antibody panel. We found extensive re-arrangement of protein complexes containing PI3K, mTORC1/2, TSC, FMRP and EIF4E/G, among others. The protein complexes altered by up- vs. down-scaling partially overlapped; both up- and down-scaling induced similar changes in interactions involving the EIF4 complex, while down scaling produced unique protein network changes involving TSC and mTORC1/2 complexes and up scaling induced a small set of unique interactions involving EIF4, AKT, p70S6K, and TSC. Next, we compared frontal cortical tissue from unmanipulated Shank3B KO and wildtype adult mice using QMI. We identified genotype-dependent differences in the mTOR PIN, including downregulation of a complex containing EIF4E and EIF4G, which suggested downregulated protein synthesis in Shank3 animals. Using Puromycin labeling of newly synthesized proteins, we confirmed downregulation of basal levels of protein synthesis in Shank3 cortex. Finally, we induced homeostatic scaling in Shank3B wildtype and mutant cortical cultures to compare genotype-dependent responses to scaling in the mTOR PIN. Overall, our results indicate that homeostatic scaling induces changes in mTOR and EIF4-related protein complexes, implying that mTOR signaling may mediate homeostatic scaling. The mTOR PIN, specifically EIF4 interactions, are dysregulated in the Shank3 knockout model, which may link molecular mTOR signaling deficits to the altered synaptic plasticity observed in this model of ASD.

Title: A phosphorylation switch in Shank3 bidirectionally regulates homeostatic synaptic scaling

Authors: *C.-H. WU[1], V. TATAVARTY[1], P. M. JEAN BELTRAN[2], A. A. GUERRERO[1], H. KESHISHIAN[2], K. KRUG[2], S. A. CARR[2], J. R. COTTRELL[3], G. TURRIGIANO[1];

Abstract: Synaptic scaling is an important form of homeostatic plasticity that bidirectionally adjusts postsynaptic weights in response to perturbation of neuronal activities. It maintains stable neuronal firing by globally changing the synaptic accumulation of GluA2-containing AMPA receptors. Up to date, how

synaptic GluA2 is regulated during scaling remains incompletely understood. Phosphorylation is a posttranslational modification that regulates many forms of synaptic plasticity and likely mediates the molecules crucial for synaptic scaling. Src homology 3 (SH3) and multiple ankyrin repeat domains 3 (Shank3) is a postsynaptic scaffold protein enriched in excitatory synapses. It interacts with various cellular factors within the postsynaptic density (PSD) and engages in local signaling pathways important for synaptic transmission. Mutations and deletion of the *SHANK3* gene have been associated with neurodevelopmental disorders, including intellectual disability autism spectrum disorders (ASD). Our lab previously demonstrated that Shank3 is indispensable for the expression of synaptic scaling.Nonetheless, it is unknown how Shank3 facilitates synaptic scaling and whether phosphorylation is involved in the process. Here we aim to investigate changes in the phosphoproteome after pharmacologically inducing bidirectional synaptic scaling in cultured rodent cortical neurons. Our quantitative mass spectrometry analysis revealed widespread and temporally complex changes at many phosphosites, with strong enrichment for synapse-associated proteins. We further identified Shank3 among the molecules that showed opposite changes in phosphorylation during scaling up and down. We found that Shank3 was stably hypophosphorylated during activity blockade, which was maintained by increased activity of protein phosphatase 2A (PP2A). Using pharmacological and genetic approaches, we then showed that the hypophosphorylated state of Shank3 supported the synaptic abundance of both Shank3 and GluA2 through the PP2A-dependent process. Lastly, we conducted imaging and electrophysiological experiments and demonstrated that overexpressing Shank3 phospho-mutants ablated scaling-induced changes in postsynaptic strength in a direction-specific manner. This work demonstrates that PP2A-dependent hypophosphorylation of Shank3 is essential for scaling up, and suggests that widespread changes in the phosphoproteome are instrumental in reconfiguring postsynaptic sites during homeostatic synaptic plasticity.

Title: Widespread remodeling of synaptic protein interaction networks following homeostatic plasticity requires Homer1 and Shank3

Authors: W. E. HEAVNER, J. D. LAUTZ, H. E. SPEED, E. P. GNIFFKE, J. P. WELSH, N. A. BAERTSCH, ***S. SMITH**;
Univ. of Washington, Seattle, WA

Abstract: Neurons maintain constant levels of excitability using homeostatic scaling, which adjusts relative synaptic strength in response to large changes in overall activity. While previous studies have

catalogued the transcriptomic and proteomic changes associated with scaling, the resulting alterations in synaptic protein interaction networks (PINs) are less well understood. We monitored a glutamatergic synapse PIN composed of 380 binary interactions among 21 protein members to identify protein complexes altered by synaptic scaling. In cultured cortical neurons, we observe widespread bidirectional PIN alterations with up- versus downscaling. In the barrel cortex, the PIN response to 48 hours of sensory deprivation exhibits characteristics of both upscaling and downscaling, consistent with emerging models of excitatory/inhibitory balance in cortical plasticity. Mice lacking *Homer1* or *Shank3* do not undergo normal PIN rearrangements, suggesting that they serve as structural hubs for synaptic homeostasis, which may be disrupted in Autism Spectrum Disorders (ASDs). Our approach demonstrates how previously identified RNA and protein-level changes induced during homeostatic scaling translate into functional PIN alterations that mediate changes in neuronal excitability.

Title: Electrophysiological analysis of conserved sleep factors reveals that calcineurin signaling regulates homeostatic synaptic plasticity

Authors: *N. ARMSTRONG, C. FRANK;
Anat. and Cell Biol., Univ. of Iowa, Iowa City, IA

Abstract: The ability of synapses to maintain physiological levels of evoked neurotransmission is essential for neuronal stability. Defective neurotransmission can result in a plethora of chronic disorders like forms of epilepsy and migraine or disturbed routine behaviors, like sleep. A variety of perturbations can disrupt neurotransmission, but synapses often compensate for disruptions to stabilize activity levels, using forms of homeostatic synaptic plasticity. Presynaptic homeostatic potentiation (PHP) is one such mechanism. In PHP, neurotransmitter release increases in response to challenges to the synapse, resulting in the maintenance of evoked neurotransmission. We hypothesized that conserved proteins known to control sleep (a homeostatic process) might have conserved roles in functional synapse stability. Using the *Drosophila melanogaster* neuromuscular junction (NMJ) as a model synapse that expresses PHP, we tested the ability for the synapse to express PHP when it lost conserved sleep factors. One core finding of this approach was that multiple calcineurin components are necessary either for the rapid induction or chronic maintenance of PHP in neuron, muscle, or glia. Overexpression of a calcineurin regulator, *sarah* (*sra*), in either neuron or muscle results in chronic PHP deficits. Interestingly, the PHP deficit observed in animals with a muscle-specific overexpression of *sra* can be partially rescued using the calcineurin inhibitor, FK506. Additional data suggest that tissue-specific expression of genes encoding either the

regulatory subunit of calcineurin or encoding the catalytic subunit are necessary for PHP.Prior work suggests that intracellular calcium signaling mediated by IP_3 receptors and Ryanodine receptors is required for the maintenance of PHP, but it is unclear what the mechanism is by which IP_3R and RyR – or downstream intracellular calcium signaling – function to maintain PHP. Our current findings suggest that calcineurin signaling could be driving this function across multiple tissue types and over different temporal phases of PHP expression.

Title: The E3 ligase Thin controls homeostatic plasticity through neurotransmitter release repression

Authors: *M. BACCINO-CALACE, K. SCHMIDT, M. MÜLLER;
Univ. of Zurich, Zurich, Switzerland

Abstract: Synaptic proteins and synaptic transmission are under homeostatic control, but the relationship between these two processes remains enigmatic. Here, we systematically investigated the role of E3 ligases, key regulators of protein degradation-mediated proteostasis, in presynaptic homeostatic plasticity (PHP). An electrophysiology-based genetic screen of 157 E3 ligase-encoding genes at the *Drosophila* neuromuscular junction identified *thin*, an ortholog of human *tripartite motif-containing 32 (TRIM32)*, a gene implicated in several neural disorders, including Autism Spectrum Disorder and schizophrenia. We demonstrate that *thin* functions presynaptically during rapid and sustained PHP. Presynaptic *thin* negatively regulates neurotransmitter release under baseline conditions by limiting the number of release-ready vesicles, independent of gross morphological defects. We provide genetic evidence that *thin* controls release through *dysbindin*, a schizophrenia-susceptibility gene required for PHP. Thin and Dysbindin localize in close proximity within presynaptic boutons, and Thin degrades Dysbindin in vitro. Thus, the E3 ligase Thin links protein degradation-dependent proteostasis of Dysbindin to homeostatic regulation of neurotransmitter release.

Title: Chaperones HSP26 and 27 promote the induction of homeostatic synaptic plasticity by regulating protein aggregates

Authors: *C. FRANK, **B. MALLIK**;
Univ. of Iowa, Iowa City, IA

Abstract: Accumulation of toxic proteins in muscle has been linked with the onset of pathophysiological conditions, which in many cases, are characterized by altered muscle function and synapse loss. Heat shock proteins (HSPs) help protein folding and resolution of unfolded proteins, thereby reducing stress caused by protein aggregation. While most heat shock proteins are expressed in neurons, their functional relevance in muscle is largely unknown. Here we describe a role for muscle heat shock proteins in inducing the expression of a form of homeostatic synaptic plasticity. At the *Drosophila melanogaster* neuromuscular junction, perturbation of postsynaptic glutamate receptors activates retrograde signaling which precisely increases neurotransmitter release to restore baseline synaptic strength. This signaling can be induced in as little as 10 minutes with the drug Philanthotoxin-433 (PhTx). Moreover, increased transmitter release is associated with molecular signatures, like increased active zone protein material. We performed a reverse genetic screen to identify factors in the postsynaptic compartment necessary to generate retrograde homeostatic signaling. This approach helped us to identify heat shock proteins 26 and 27 (HSP26 and 27) . When these factors are genetically depleted, there is a failure in the acute, 10-minute induction of synaptic homeostasis. By contrast, after chronic genetic perturbation of glutamate receptors or extended incubation of PhTx in an open NMJ preparation (~ 45 minutes) the synapse is able to express and maintain homeostatic signaling, even in the absence of *hsp26* or *27* function. Interestingly, transgenic expression of human disease PolyQ repeat proteins in the muscle (such as human Huntington *HTT46Q* or *HTT72Q*) phenocopies the homeostatic induction timing defects of *hsp26* and *27* gene loss. Moreover, muscle overexpression of *hsp26* and *27* in the genetic background of these PolyQ-expressing flies restores the successful 10-minute induction of synaptic homeostasis. This restoration includes NMJ function, and it includes restoration of molecular signatures, like increased presynaptic active zone material after homeostatic induction. Together our findings support the model that protein aggregation in muscle slows the induction of homeostatic signaling. In the context of modeling human disease, our data could shed light on the consequences that protein aggregation may have on neuroplasticity and downstream neurophysiological function.

Title: Activity-dependent Regulation of the PARbZIP transcription factor family in mouse cortical neurons.

Authors: *E. A. BARRIOS[1], V. VALAKH[1,4], M. SHA[2], S. B. NELSON[3];
[1]Biol., [3]Dept Biol MS#008, [2]Brandeis Univ., Waltham, MA; [4]Stanley Ctr. for Psychiatric Res., Broad Inst. of Harvard and MIT, Cambridge, MA

Abstract: Homeostatic plasticity requires gene transcription. However, little is known about how gene expression regulates this form of plasticity. We found that in organotypic slice cultures following prolonged activity deprivation, expression of the members of the PARbZIP transcription factor family (TEF, HLF, DBP) are robustly increased. Knockout of these PARbZIP TFs causes seizures in mice. In the absence of these TFs homeostatic response to activity deprivation is increased in cortical slice cultures. Together, these findings suggest that PARbZIP TFs normally constrain homeostatic plasticity. These TFs are regulated by circadian clock genes, and since components of the molecular clock have also been implicated in epilepsy, we tested the role of the clock genes in activity-dependent PARbZIP regulation. Knockout of the obligate clock gene Bmal1 reduced PARbZIP expression and impaired their elevation during activity deprivation. We also tested whether translation of other TFs are required for the elevation of PARbZIPs following activity deprivation. Blocking translation with cyclohexamide did not prevent the elevation of PARbZIP expression during activity deprivation. This implies that PARbZIPs function as immediate early genes that recognize a fall rather than an elevation in activity.
